Tetanus severity scores provide prognostic information. Extremes of heart rate, high blood pressure, advanced age, short duration of symptoms, and presence of underlying diseases are associated with worse outcome.

Complications of tetanus include pneumonia, venous thrombosis, pulmonary embolism, and long bone and spine fractures from severe sustained muscle contractures. The mortality rate from tetanus ranges from 21–31% in the United States and may be as high as 52% in patients over 60 years of age. Poor outcome is associated with autonomic disturbances such as blood pressure lability, with cardiac arrhythmias and rate disturbances, and with hyperglycemia, hyperthermia, and anticoagulation therapy.

Some studies have suggested a poor prognosis when patients present with short incubation periods and heavily contaminated wounds. A better prognosis is suggested if there is no demonstrable focus of infection.

C. Laboratory Findings—The wound in a patient suspected of having tetanus should be cultured anaerobically for *C. tetani*. However, the etiologic confirmation is infrequently made in this manner, and the diagnosis usually is based on the absence of detectable tetanus toxoid antibody and the exclusion of other diseases.

Differential Diagnosis

The differential diagnosis of tetanus includes a list of rather unusual diseases not commonly encountered in the ICU (Table 15–9).

Treatment

A. Tetanus Immune Globulin—Patients who present with tetanus should receive tetanus immune globulin as early as possible to neutralize unbound toxin. Delay in treatment may result in a poorer prognosis. The optimal dose of tetanus immune globulin has not been established, but a single dose of 3000–6000 units intramuscularly can be given.

Table 15-9. Differential diagnosis of tetanus.

Meningoencephalitis (viral, bacterial)
Phenothiazine overdose
Peritonsillar abscess
Hypercalcemic tetany
Retropharyngeal abscess
Retroperitoneal hemorrhage
Dental abscess
Epilepsy
Mandibular fracture
Opioid withdrawal
Tonsillitis
Strychnine poisoning
Diphtheria
Rabies
Mumps
Neuroleptic-malignant syndrome
Trichinosis
Septicemic spondylitis
Mandibular osteomyelitis

It is advised that some of the dose be injected into the area of the presumed injury.

B. Supportive Care—Metronidazole is accepted as the drug of choice. Far more important, wounds should be debrided properly. In patients with wounds that continue to be infected, it may be necessary to repeat passive immunization with tetanus immune globulin after 3–4 weeks because toxin production may continue, and antibiotic therapy will not eradicate the spores.

Tracheostomy should be performed in all but very mild cases to allow for prolonged respiratory assistance with a ventilator. Problems arising from cardiovascular instability should be treated appropriately.

Analgesics should be used to relieve pain from muscle contractions. Benzodiazepines—particularly diazepam—may be effective in reducing muscle spasms. Inadequate muscle relaxation or inadequate control of seizure activity can lead to complications such as long bone and vertebral fractures. Benzodiazepines may not prevent reflex spasms, however, and effective respiration may require neuromuscular blockade.

Patients require nutritional support and meticulous attention to the prevention of decubiti and flexion contractures. Consideration should be given to subcutaneous

heparin therapy, particularly in illicit injection drug users and elderly patients, who appear to be at highest risk for pulmonary embolism. Constipation is common, and an initial cleansing enema is helpful. A rectal tube helps to control abdominal distention. Nosocomial infections may develop and should be considered if a patient with tetanus develops more than a moderate elevation in temperature.

C. Immunization—Patients who develop tetanus are not subsequently immune to the infection. Tetanospasmin is toxic in such minute quantities that it appears to escape reaction by the immune system, and protective antibody is not produced. Therefore, active immunization with a primary immunization series with tetanus toxoid should be administered to all patients during the convalescent phase of illness—usually a period of several weeks.

Current Controversies and Unresolved Issues

Many controversies remain in the management of patients with tetanus, particularly with respect to cardiovascular complications. Suggested therapeutic modalities occasionally are based on single case reports.

Clonidine has been reported to control sympathetic overactivity in severe tetanus. More recently, the beta-blocker esmolol was reported to be effective in controlling autonomic instability. Patients with severe tetanus who failed to respond to beta blockade and low doses of ganglionic blocking agents had dramatic suppression of cardiovascular instability when given continuous spinal anesthesia with bupivacaine, which provided complete blockade of sympathetic and parasympathetic portions of the autonomic nervous system.

Another area of interest in the treatment of tetanus is the control of the severe spasms without sedation and artificial ventilation. Intrathecal baclofen and intravenous magnesium sulfate have both been used for control of spasms owing to tetanus. In patients treated with these modalities, it appears that less autonomic instability is encountered, and spasms are controlled while preserving spontaneous ventilation. Propofol has been used similarly.

Surgical Infections

16

Timothy L. Van Natta, MD*

General Considerations

Persistent fever in the postoperative patient is always concerning. Potential causes include infection, atelectasis, deep venous thrombosis, and drug reactions. The surgical wound and urinary tract are common infection sites. While management of these problems is relatively straightforward, diagnosis and treatment of other inflammatory and infectious processes can be problematic. It is often difficult to differentiate between systemic inflammatory response syndrome (SIRS) and sepsis. Documentation of a discrete infection is required for diagnosis of the latter. Infection types and sites not thought of are unlikely to be identified. An organized diagnostic approach pays dividends, particularly when based on analysis by body region and through monitoring the presence and duration of indwelling devices. Early diagnosis of infection portends optimal outcomes, preempting sepsis and its attendant complications—*provided antimicrobial agents and adjunctive measures are used rationally.*

Sepsis may be the reason for ICU admission, or it may complicate another critical illness. A surgical patient can present anywhere along a spectrum from *SIRS* to *sepsis* to *severe sepsis* (ie, sepsis associated with organ dysfunction) to *septic shock* to *multiple organ dysfunction syndrome* (MODS). A patient's course often devolves along these stages despite the physician's best efforts. However, prompt application of goal-directed therapy raises the likelihood of course reversal before irrevocable organ damage occurs.

Prevention of Surgical Infections in the ICU

Surgical infections can be prevented through proper use of prophylactic antibiotics. To be effective, the appropriate antibiotic must be administered within 1 hour before the operation so that tissue levels are high at incision time. Antibiotics with 24-hour dosing are attractive in this regard because no postoperative doses are necessary. Prophylactic antibiotics have no value beyond the first 24 hours following surgery. Their continued use puts patients at risk for antibiotic-associated *Clostridium difficile* colitis, infection by multidrug-resistant bacteria (eg, methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant *Enterococcus*, and *Acinetobacter* species), and fungal infections. No less important, this practice adversely affects the bacterial ecology in the ICU. Continuing “prophylactic” antibiotics for the duration of drain and chest tube presence cannot be condoned. Furthermore, antibiotics cannot compensate for suboptimal surgical conduct.

Invasive procedures in the ICU require strict sterile technique. This demands that one don a cap, mask, sterile gloves and gown; generously prepare the area with chlorhexidine; and meticulously drape the field. Once percutaneous catheters are in place, making connections and sampling must be done fastidiously. Chlorhexidine-laden catheter-site dressings are effective in preventing infections and should be used routinely. Of course, clinical crises can demand expeditious, nonsterile placement of intravenous and other catheters. These should be removed as soon as feasible and never beyond 24 hours from time of placement. When central venous access is necessary but central pressure monitoring is not, conversion from a central line to a percutaneously inserted central catheter (PICC line) lessens infection risk. When central access is no longer required, a change from central to peripheral access should be accomplished as soon as practical. Other devices, such as ventriculostomy drains, chest tubes, epidural catheters, arterial lines, and urinary catheters, should be removed as soon as their utility wanes. The ICU team should take daily stock of all such devices and think critically about the continued value of each.

Other preventive measures are noteworthy. It has been established that postoperative hyperglycemia is directly associated with increased infection rates. The goal should be to strive for glucose levels of 80–110 mg/dL and certainly to prevent levels from exceeding 150 mg/dL. In the ICU, hourly glucose monitoring and aggressive insulin use are commonly required to achieve this goal. Insulin drips are frequently necessary, and there should be no reluctance to use them on a protocol-driven basis. Judicious use of steroids and other immunosuppressive medications is an important adjunct as well. For patients with diseases requiring these agents, the intensivist must balance their use with the need to prevent and/or treat infections. The same can be said for transfusion of blood and blood products. As the immunosuppressive nature of blood transfusion has become increasingly recognized, the elevated risk of surgical infection must be weighed against the desire to optimize oxygen delivery.

Malnutrition clearly puts patients at risk for infections, and nutritional support is a signal feature of intensive care. For many reasons, including lower infection rates, enteral feeding is preferred over the intravenous route. However, the latter has the advantage of prompt delivery of full nutritional support. There should be no hesitation to initiate parenteral nutrition should tube feedings be unsuccessful or impractical. Currently, numerous immune-enhanced formulas are available. Some of the purported benefits are simply due to their increased protein content, but additionally, there may be clinically significant benefits to increased provision of certain amino acids (eg, glutamine, arginine, and glycine), nucleic acids, and omega-3 fatty acids. This is an area of particularly intense research activity, and critical care physicians should follow this work closely.

Diagnosis of Surgical Infection in the ICU

Despite the highly technical atmosphere of the ICU, assiduous physical examination remains the cornerstone for timely diagnosis of surgical infections. The presence of complex devices and dressings, along with the patient's relative immobility, can inhibit thorough physical assessment. Diagnostic delays are commonly attributable to an intubated patient's inability to communicate. Fever and leukocytosis often prompt early evaluation by CT scan. Negative or equivocal imaging studies are not uncommonly followed by a revealing physical evaluation that could have obviated the trip to radiology.

Clues to presence of infection can be subtle. Examples include unexplained hyperglycemia and gradual worsening of hepatic, pulmonary, and/or renal functional indices.

Additionally, stagnant or falling nutritional markers such as prealbumin may signify infection rather than inadequate provision of calories and nutrients. Immunosuppressed individuals may not manifest the usual signs of infection, and index of suspicion should be high if the clinical course is not proceeding smoothly. For these and other critically ill patients, both overt and subtle indicators of infection warrant blood, sputum, and urinary cultures. More sophisticated evaluations also generally will be necessary. It can be quite difficult to differentiate true infection from bacterial or fungal colonization. It takes experience and discipline to react appropriately when confronted with culture results in critically ill patients.

Fortunately, there are many tools for diagnosing infections even when their existence is not forthcoming from physical examination or culture data. Critical care specialists are increasingly using bedside ultrasound and echocardiography. Pleural, pericardial, peritoneal, and soft tissue fluid collections can be identified and sampled safely. Diagnostic peritoneal lavage, though largely supplanted by emergency department ultrasonography for trauma, still has an occasional role in determining the presence of peritonitis in patients too unstable for travel to the radiology suite. Intensivists routinely perform fiberoptic endoscopy of all sorts. This allows accurate and timely diagnosis of pneumonia and infectious esophagitis and colitis. Diagnostic laparoscopy and pleuroscopy now can be done at bedside.

Imaging studies play a crucial role in the diagnosis of infection in the critically ill. Ultrasound, CT, and MRI are sometimes complementary and sometimes competing. It is often productive to discuss clinical scenarios in depth with radiology colleagues *before* sending the patient for one type of scan or another. This avoids unnecessary excursions from the ICU and limits suboptimal studies, redundancy, expense, and patient risk. Of the three, MRI probably is the least useful in evaluation of the unstable ICU patient. In some cases, though, particularly when CNS infection is a concern, MRI may be superior. CT scanning and ultrasound, besides providing high-quality images, allow therapeutic abscess drainage. To a large extent, this has replaced surgical exploration for management of abdominal and pelvic infections. Nuclear medicine studies, when selected appropriately, also serve an important purpose. For example, indium-labeled white blood cell scans, though of limited utility early in the postoperative period, can pinpoint the site of infection later in a patient's course when other methods have failed.

Treatment of Surgical Infection in the ICU

Significant progress has been made over the past decade relative to treatment. Advances are attributable to two major areas: improvement in use of antimicrobial agents and

advancement in interventional radiology techniques. A handful of new antibacterial and antifungal agents have been introduced recently. While these agents have broadened therapeutic options, multidrug-resistant pathogenic strains continually threaten the ICU patient. By employing newer agents rationally and using older agents more effectively, the clinician stands a better chance against problematic organisms. The change to once-daily dosing of aminoglycosides, for instance, addresses several issues. Higher doses given over broader time intervals provide greater peak blood levels. This enhances bacterial killing, whereas low or undetectable trough levels limit renal and other toxicity. Renal toxicity is a largely saturable process. Despite high peak levels, only so much aminoglycoside can be taken up by renal cells per unit time. Later in the interval, when renal cells could absorb more antibiotic, there is little available to produce toxic effects. Other antibiotics work much better when some continuous minimum level is maintained. Since there appears to be no augmentation of bacterial killing by pushing levels higher, lower doses given more frequently (or even by continuous infusion) provide a persistent satisfactory level to achieve optimal bactericidal effect. Penicillins and cephalosporins exemplify this strategy. As newer agents are introduced, these principles should be borne in mind.

Newer antibiotics have improved options for treating surgical infections caused by multidrug-resistant strains. Examples include linezolid to treat methicillin-resistant *S. aureus* (MRSA) and tigecycline to combat difficult gram-negative rods such as *Acinetobacter baumannii*. To retain their efficacy, they must be used with discretion. While broad agents are often necessary at the onset of infection, there should be a rapid taper to narrower agents once culture data are available. Again, it is particularly important to differentiate between bacterial colonization and true infection so as not to overuse new agents and diminish their capabilities.

It is worthwhile at times to also consider alternative routes of antibiotic administration. These include intrathecal, inhalational, enteral, and intracavitary drug delivery. Several antimicrobial classes have bioavailability via the enteral route that rivals that of parenteral delivery. Examples include quinolones and fluconazole. Once tube feedings are well tolerated, a switch from parenteral to enteral delivery can be made confidently, limiting administrative costs and allowing removal of intravenous catheters that may, in turn, become infected. Finally, a broader array of antifungal and antiviral agents has become available in recent years, enhancing treatment options while in many cases reducing renal and other toxicity. On occasion, a critically ill patient whose infection is not responding to multiple antibiotics must be started presumptively on a systemic antifungal agent despite lack of supportive culture data. Close collaboration with infectious disease consultants is necessary in these cases.

Duration of antimicrobial coverage is continually debated. While there is a trend toward limiting treatment

duration, some infections are particularly hard to treat given the difficulty of antibiotic penetration into the tissues involved. Examples include endocarditis, osteomyelitis, sinusitis, and otitis media. When presence of one of these infections is certain, prolonged antibiotic courses generally are necessary and accepted. For most other surgical infections, however, shorter durations are preferable. It has been well established that peritonitis following perforated diverticulitis or appendicitis (after surgical source control) should be discontinued once fever, leukocytosis, and ileus have resolved. If these occur even as early as postoperative day 3, it is reasonable to stop antibiotics then. Failure to meet these criteria by days 5, 6, or 7 usually means an abscess has formed. Continued or additional antibiotics likely will be ineffective, and one should proceed with an abdominopelvic CT scan searching for a drainable abscess. In most cases, abscesses thus identified can be treated definitively by CT- or ultrasound-guided aspiration via percutaneous, transrectal, or transvaginal routes. This obviates a return to the operating room and its attendant morbidity. Occasionally, multiple abscesses are identified, not all of which are amenable to image-guided drainage. Options then are limited to continuing conservative (ie, broad antibiotic) treatment versus reoperation. This decision hinges on the patient's status. If substantial leukocytosis or left shift persists, but the patient is eating well and lacks marked constitutional symptoms, prolonged antibiotic therapy may be successful. This is unusual, though, and most patients with multiple postoperative abscesses must be taken back to the operating room.

These concepts involving intraabdominal infection are not new. Limiting duration of treatment and earlier pursuit of imaging studies have been applied recently to other infections, however, such as pneumonia. The common goal is to get the most out of available agents by preserving their efficacy, limiting toxicity and microbial resistance during therapy, and slowing emergence of resistant strains that might affect future patients. Every institution and its individual ICUs have their own unique bacterial ecology. This limits somewhat the broad applicability of treatment guidelines. Review of institutional antibiograms on a quarterly basis can positively influence empirical coverage of apparent pneumonias and bloodstream infections while spotlighting emerging resistance patterns. Antibiotic "crop rotation" has been employed as a means to stem development of resistant strains within ICUs, although this concept remains controversial. What is probably more important is for the intensivist to employ all means at his or her disposal to rapidly identify the site of infection and its causative organism(s), allowing the most rapid application of the narrowest effective agent(s). An organized approach to patient assessment by body region is helpful.

Bennett KM et al: Implementation of antibiotic rotation protocol improves antibiotic susceptibility profile in a surgical intensive care unit. *J Trauma* 2007;63:307–11. [PMID: 17693828]

► Evaluation and Management of Infection by Body Site

Head and Neck

CNS infections, including meningitis, ventriculitis, and intracerebral abscess, must be considered in patients who have sustained head injury or have undergone neurosurgical procedures. Patients with skull base and paranasal fractures are included in this group. Use of intraparenchymal cerebral pressure (ICP) monitors and ventriculostomy catheters, while applied appropriately along guidelines for severe head injury management, is associated with serious infection risk. Previously, antibiotic prophylaxis was used for the duration of ICP monitor presence and for 5–7 days following diagnosis of skull base or paranasal sinus fractures. It is now recognized that this exerts pressure toward infection by multidrug-resistant organisms. Controlled data are lacking as to appropriate antibiotic use in these patients, but it is clear that the indiscriminant use of antibiotics in these settings is associated with difficult-to-treat secondary infections. With regard to transcranial pressure monitors, it is hoped that with sterile technique at placement, fastidious fluid sampling, prudent antibiotic use, and device removal as early as feasible, occurrence of serious infections will diminish.

Another important consideration is infection in and around the eye. As mentioned earlier, ocular inflammation often goes unnoticed in the complex ICU patient. Problems not considered go undiagnosed, and any abnormal ocular finding should prompt early ophthalmologic consultation as appropriate. Periorbital cellulitis is of particular concern because therapeutic delay can result in the catastrophic complication of cavernous sinus thrombosis.

Given the ubiquitous use of nasogastric tubes, paranasal sinusitis remains a risk. There may or may not be associated purulent nasal drainage. It is important to remember this not infrequent but often undiagnosed infection in the febrile critically ill patient. CT scan is far superior to plain films for making this diagnosis. Surgical drainage sometimes must augment antibiotics to clear this infection. It is best to avoid this condition altogether by choosing the oral over the nasal route for enteral decompression and feeding in orotracheally intubated patients. Dental abscess, simple or complicated, should be considered in the febrile, critically ill patient, particularly when dentition is poor. These and pharyngeal infections can evolve into life-threatening necrotizing infections that can descend transcervically into the chest (ie, acute necrotizing mediastinitis). The cervical component of this process is not difficult to recognize given neck edema, induration, and erythema, but the thoracic component can have protean manifestations. New and unexplained pleural fluid noted on chest x-ray is an important early finding.

Central line infections contribute significantly to morbidity and mortality in surgical patients. In the United States, about 200,000 nosocomial bloodstream infections occur annually, the majority of which are associated with the presence of

intravascular catheters. Internal jugular and femoral venous catheters previously carried higher infection rates than those in the subclavian position, but recent preventive strategies have perhaps neutralized this difference. Such measures include perfect sterile technique at placement, chlorhexidine site preparation, selection of catheters with antibacterial coatings, use of antiseptic site dressings, and device removal as early as possible. Application of catheter-site antibiotic ointments should be avoided because they encourage development of infection by resistant bacteria and fungi. Rotation of catheter sites on a scheduled basis is not helpful, and catheter changes over a guidewire should be kept to a minimum. In certain situations, vascular access may be exceedingly difficult. Despite development of fever or leukocytosis, risk-benefit analysis may favor guidewire exchange over attempting placement at a new site. However, the removed catheter tip should be sent for culture. A positive culture mandates immediate removal of the catheter that replaced the original one. Infection also can be introduced via the catheter hub, and those accessing the catheter must maintain strict sterile technique.

Treatment of head and neck infections is summarized in [Table 16–1](#).

Chest

Ventilator-associated pneumonia (VAP) is the most common infection in the surgical ICU. VAP is defined as pneumonia occurring at least 48–72 hours following endotracheal intubation. There is debate as to whether or not VAP independently increases mortality, but it clearly lengthens ICU stay, increases patient days on the ventilator, and adds tremendously to health care expenditures. Antibiotic therapy for VAP is often complex and prolonged, adversely affecting an ICU's bacterial ecology. Over recent years, much effort has been expended to better characterize the pathophysiology, diagnosis, and proper treatment of VAP. There is no diagnostic “gold standard,” and treatment is complicated by undisciplined antibiotic administration with vague treatment endpoints. The Centers for Disease Control and Prevention original criteria for pneumonia (ie, fever, leukocytosis, positive sputum Gram stain, and new or changing pulmonary infiltrate) have proven insufficient for diagnosis of VAP in the complicated, critically ill patient. In patients with a markedly abnormal chest x-ray because of acute respiratory distress syndrome (ARDS), it is often impossible to identify a new infiltrate superimposed on the background of noncardiogenic pulmonary edema. Although VAP diagnosis and treatment remain problematic,

Table 16-1. Summary of head and neck infections in adult surgical patients.

Diagnosis	Organisms	Initial Antibiotics	Adjunctive Therapy
Meningitis and ventriculitis	<i>S. pneumoniae</i> , <i>S. aureus</i> , coliforms, <i>P. aeruginosa</i> , <i>Acinetobacter</i> sp.	Vancomycin 500–750 mg IV q6h + cefepime or ceftazidime 2 g IV q8h <i>or</i> meropenem 2 g IV q8h + vancomycin 1 g IV q6–12h	Removal of intracerebral device, intrathecal antibiotic administration
Periorbital cellulitis	<i>S. pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i> , <i>S. aureus</i> , group A <i>Streptococcus</i> sp.	Nafcillin-oxacillin 2 g IV q4h (if MRSA, vancomycin 1 g IV q12h) + ceftriaxone 2 g IV q24h + metronidazole 1 g IV q12h	IV heparin for cavernous sinus thrombosis if present
Paranasal sinusitis	Gram-negative bacilli, <i>S. aureus</i>	Imipenem 500 mg IV q6h <i>or</i> meropenem 1 g IV q8h <i>or</i> ceftazidime 2 g IV q8h <i>or</i> cefepime 2 g IV q12h (for possible MRSA, add vancomycin 1 g IV q12h)	Removal of nasoenteric tube, aspiration of fluid from sinus
Central line infection	<i>S. aureus</i> (MSSA, MRSA), <i>S. epidermidis</i> , enterococci	Vancomycin 1 g IV <i>or</i> linezolid 600 mg IV q12h	Removal of catheter, vein resection if suppurative thrombophlebitis

Data from Gilbert DN et al (eds): *The Sanford Guide to Antimicrobial Therapy*, 37th ed. Sperryville, VA: Antimicrobial Therapy, Inc., 2007.

its causes have become better understood. Presence of an endotracheal tube (ETT) allows contaminated oropharyngeal secretions to circumvent natural protective barriers. The endotracheal tube, impaired host immunity, and lurking environmental pathogens conspire to produce VAP in the critically ill surgical patient. Negative effects of blood transfusion, hyperglycemia, and malnutrition, so commonly seen in the ICU, elevate risks further.

There has been a strong push lately to improve the prevention and management of VAP. Influential multidisciplinary societies (eg, the American Thoracic Society and the Infectious Disease Society of America) have promulgated clinical guidelines. These ICU “bundles” promote consistency in approach within and across institutions. Prevention strategies include head-of-bed elevation 30–45 degrees (or reverse Trendelenburg position when thoracic spine stability is in question) and avoidance of gastric distention to minimize aspiration of gastric contents, use of ETTs with suction ports to remove secretions pooling above the ETT cuff, use of sleeved suction catheters, and improved oral hygiene. Selective gut decontamination has been advocated, but its value is questionable because enteric organisms generally are not responsible for VAP. The most common offending organisms are MRSA and species of the genera *Pseudomonas*, *Acinetobacter*, and *Stenotrophomonas*. Minimizing transfer of these pathogens from one patient to another is another key to prevention. Finally, since the incidence of VAP correlates with a patient’s duration of intubation,

any prevention program should include an aggressive strategy for liberation from the ventilator.

Diagnosis of pneumonia is usually not difficult in the emergency department. History, physical findings, and chest x-ray generally suffice. For the intubated ICU patient, development of fever, leukocytosis, and apparent purulent sputum raise the question of pneumonia, but establishing a confident diagnosis may be difficult. Both chest x-ray and tracheal sputum aspirate analysis lack specificity in these patients. A normal chest x-ray excludes the diagnosis. When the chest x-ray is abnormal, the next step is to obtain a reliable sputum sample for performance of quantitative analysis. Preferred methods are use of a protected-specimen brush (PSB) and bronchoalveolar lavage (BAL). Commonly used thresholds for confirming pneumonia are 10^3 colony-forming units (cfu)/mL for PSB and 10^4 cfu/mL for BAL. These techniques, which require bronchoscopy, are expensive and time-consuming. However, they more firmly establish the correct diagnosis and direct appropriate antibiotic therapy. More recently, catheters have been developed that allow reliable sampling by the respiratory therapist, eliminating need for bronchoscopy. Both PSBs and mini-BAL sets are available and are enjoying wider use. The goals are to distinguish between infection and colonization and, if infection is present, to determine the offending organism(s) as soon as possible so that treatment can be tailored specifically.

Aggressive treatment should immediately follow acquisition of a good sputum sample. Antibiotic selection depends on the prevailing organisms within an individual ICU. Offending bacteria change over time, justifying quarterly analysis of cultures and resistance patterns. In general, initial therapy should cover MRSA and the difficult gram-negative rods. It is important to start broadly because delays in appropriate coverage may lead to increased mortality. Once reliable microbiologic data are available, antibiotic coverage should be tailored immediately to the narrowest bactericidal agent to which the organism is sensitive. Previously, it was recommended that two antibiotics with different mechanisms of action should be used to treat the multidrug-resistant gram-negative rods. This was extrapolated from the neutropenic cancer patient population and applied to other groups. Supportive data are lacking for the surgical ICU population, and single-agent therapy appears to be satisfactory. When final microbiologic data do not support the diagnosis of VAP, and the patient is not deteriorating, it is reasonable to stop antibiotics altogether. If culture results are equivocal and/or the patient's condition is worsening, it is appropriate to continue broad antibiotic coverage, but a firm endpoint of about 7 days should be selected early. In the majority of cases, culture and sensitivity results will guide selection of the narrowest appropriate antibiotic, and duration of therapy can be determined by the patient's response.

Antibiotics with high enteral bioavailability often can be converted safely from intravenous to enteral administration early in the treatment process. Inhaled administration of antimicrobials should be considered in some instances. Pneumonia can be difficult to treat, even with the correctly chosen and delivered agent, and courses of 10–14 days are often necessary. Patients with blood and respiratory cultures growing the same organism have a more serious infection and generally will need a longer antibiotic course. However, improvement should be seen within 1 week, and if this has not occurred, a prolonged antibiotic course is not likely to be effective. Failure of a timely response should prompt a search for complications of pneumonia such as pulmonary abscess or empyema or consideration of an alternative infection diagnosis. CT scanning is important in this assessment.

Another important surgical infection is empyema, or pus in the pleural space. Indicative findings on pleural fluid analysis are pH less than 7.20, organisms present on Gram stain, and a positive culture. Ultrasound is helpful to guide safe aspiration of pleural fluid. Surgical patients at risk are those who have had VAP, blunt or penetrating trauma, thoracostomy tube placement, or thoracotomy. CT scan defines the empyema's extent. Treatment options include thoracostomy tube placement, instillation of tissue plasminogen activator (tPA), video-assisted thoracoscopic surgery (VATS) or open thoracotomy with lung decortication, and open drainage. Choice of treatment is influenced by the duration of the process, the pleural fluid distribution, and the patient's condition. The three stages of empyema are the early *exudative stage*, the intermediate *fibrinopurulent stage*, and the late

organization stage. A simple empyema in its early stage often can be well managed with a chest tube and antibiotics. Beyond antibiotics, the goals are to drain all the infected fluid and eliminate all free intrapleural space. Generally, the admonition of “no space, no problem” applies. The chest tube does not always have to be of large caliber. A single loculated collection not draining adequately via a well-placed thoracostomy tube may respond to dissolution by a thrombolytic agent. This can be effective, but it is best done in collaboration with the surgeon who would operate if thrombolytics fail because subsequent operative intervention can be rendered much more difficult.

Multiple loculated fluid collections and more advanced empyema stages are best dealt with surgically (VATS or thoracotomy). For the critically ill or severely debilitated patient, rib resection and drainage may be the best approach, allowing the space to heal from the inside out as the thoracostomy tube is slowly withdrawn over weeks to months. A special empyema subset is that occurring early after pneumonectomy. The majority of these are due to a breakdown of the bronchial stump. The problem is manifested by a productive cough, dyspnea, and sepsis. The first maneuver is to place a thoracostomy tube to drain the infected fluid that will diminish the septic focus and prevent spread of infection to the remaining lung. Open thoracostomy with bronchial repair and muscle or omental flap coverage are required then to correct the process. Eventually, the chest can be closed over a pleural space filled with antibiotic solution, with expectation of success in most cases.

Two other major chest infectious processes are mediastinitis and endocarditis. Mediastinitis can occur as a postoperative infection following median sternotomy, as a result of spontaneous or iatrogenic esophageal perforation, or as a descending necrotizing process originating from oropharyngeal or odontogenic infection. Sternal wound infection after cardiac surgery can be superficial, responding to antibiotics and local wound care. Associated life-threatening mediastinitis occurs in just over 1% of cardiac surgery patients, with the incidence in children approximating that in adults. One adult group at higher risk is diabetic women undergoing bilateral internal thoracic artery harvest. Fever, leukocytosis, sternal instability, and wound erythema and drainage warn of this problem, and a new pleural effusion adds to the probability. Treatment includes administration of intravenous antibiotics, surgically evacuating all purulent fluid and necrotic soft tissue and bone, and either reclosing the sternum over an inflow-outflow antibiotic delivery system or filling the defect with pedicled muscle or omental flaps. Esophageal perforation occurs most commonly now as a complication of endoscopy. Small tears occasionally can be managed with antibiotics with or without stent placement, provided that there is no free flow of diagnostic contrast agent into the mediastinum or pleural space. Most esophageal perforations require thoracoscopic or open pleural drainage, mediastinal debridement, and esophageal repair over a bougie when feasible. Generally, tears in the upper two-thirds of the esophagus are approached via

right posterolateral thoracotomy and those in the distal third by way of left posterolateral thoracotomy.

Acute necrotizing mediastinitis (ANM) is third major form of mediastinitis. It is a destructive, life-threatening process usually originating in the oropharyngeal region and extending transcervically into the mediastinum along continuous fascial planes. While the cervical component is easy to recognize, mediastinal involvement is less obvious, causing significant diagnostic delays. Management includes prompt institution of broad-spectrum intravenous antimicrobials to cover oropharyngeal aerobes and anaerobes, immediate contrast-enhanced cervicothoracic CT scanning, and urgent surgical therapy directed at the oropharyngeal, cervical, and thoracic components. Tracheostomy should be applied selectively. Occasionally, mediastinal involvement confined to the upper anterior mediastinal aspect *may* be amenable to drainage via the transcervical approach, but the potential for rapid, diffuse spread deeper into the mediastinum must be anticipated and dealt with accordingly. Minimally invasive approaches have been reported, but generally they are inadequate to treat this process. A team of surgeons including otolaryngologists and thoracic surgeons (and maxillofacial surgeons in the presence of odontogenic infection) serves the patient best. At the outset, surgeons should acknowledge the likely need for multiple operations.

Endocarditis can be seen in surgical patients. This diagnosis is particularly likely in the febrile patient with a positive blood culture and new murmur. Other classic signs of endocarditis (eg, splinter hemorrhages, Osler's nodes, and Janeway's lesions) are often absent in acute endocarditis. Risk factors include intravenous drug abuse (IVDA), poor dental hygiene, long-term hemodialysis, diabetes mellitus, mitral valve prolapse, and rheumatic heart disease. In the ICU, endocarditis can occur in patients admitted for other reasons but who require multiple intravascular catheters. Enterococci, though overwhelmingly associated with bacteremia rather than endocarditis, can be a cause of endocarditis in this patient group, and the organisms are commonly resistant to many antibiotics. Previously, *viridans* streptococci led the list of causative bacteria. In most recent series, *S. aureus* predominates. Polymicrobial endocarditis is unusual and generally associated with IVDA. Blood cultures positive for *Streptococcus bovis* suggest a colon lesion in older patients, warranting colonoscopy. Endocarditis involves native valves 75–93% of the time, with prosthetic valve infection comprising the remainder. As for the latter, infections occurring within 2 months of surgery are thought to be hospital-acquired. If onset exceeds 12 months from time of surgery, the endocarditis is considered community-acquired. Between 2 and 12 months, valve infection can be either origin.

Echocardiography is the primary diagnostic modality for endocarditis. Transthoracic echocardiography (TTE) has sensitivity as low as 70% but a specificity approaching 98% for identification of the characteristic vegetations. When suspicion remains high despite a negative TTE, or

additional detail is required for operative planning, transesophageal echocardiography (TEE) is indicated. TEE sensitivity for endocarditis is around 95%, with a negative predictive value around 92%. Despite its more invasive nature, TEE offers a much better view of the cardiac interior. TEE is particularly valuable for assessment of prosthetic valves and evaluation for myocardial abscess. The latter is associated with conduction system disturbances. Surgery is indicated urgently to address acute valvular incompetence, myocardial abscess, or continued septic embolization despite apparently adequate antibiotic coverage. Sometimes multiple cultures are negative in the febrile patient with a positive echocardiogram. If the laboratory is alerted to this situation, special culture techniques can be employed to capture fastidious organisms. For patients undergoing surgery, the polymerase chain reaction (PCR) can be run to identify otherwise unculturable organisms obtained from valve tissue or peripheral emboli.

Treatment of thoracic infections is summarized in Table 16-2.

Abdomen and Pelvis

This broad class includes infections of the GI mucosa or full bowel thickness, visceral infarction, abscesses, and diffuse peritonitis. Infections also occur secondary to mechanical blockage of the biliary tract (eg, ascending cholangitis and cholecystitis), urinary tract (eg, pyelonephritis and cystitis), and female internal genitalia (eg, tubo-ovarian abscess and pelvic inflammatory disease). Peritonitis occurs in primary, secondary, and tertiary forms. Primary (spontaneous) bacterial peritonitis truly can be spontaneous (eg, *Pneumococcal* peritonitis seen in young girls) or more commonly a complication in cirrhotic patients with ascites or in those receiving

Table 16-2. Summary of thoracic infections in adult surgical patients.

Diagnosis	Organisms	Initial Antibiotics	Adjunctive Therapy
Ventilator-associated pneumonia (VAP)	<i>S. pneumoniae</i> , <i>S. aureus</i> , <i>P. aeruginosa</i> , <i>Acinetobacter</i> sp., <i>Stenotrophomonas maltophilia</i> , coliforms, anaerobes	Imipenem 500 mg IV q6h or meropenem 1 g IV q8h (+ vancomycin 1 g IV q12h if ICU MRSA pneumonia rate high) or cefepime 2 g IV q8h or high-dose piperacillin-tazobactam + vancomycin	Prevention, quantitative sputum cultures, ICU antibiogram
Empyema	<i>S. pneumoniae</i> , <i>S. aureus</i> (consider MRSA), <i>S. pyogenes</i> , <i>S. milleri</i> , <i>H. influenzae</i> , <i>Bacteroides</i> sp., Enterobacteriaceae	Cefotaxime 1–2 g IV q4–12h or ceftriaxone 1–2 g IV q24h (+ clindamycin 450–900 mg IV q8h for possible anaerobes) or nafcillin-oxacillin 2 g IV q4h (MSSA) or vancomycin 1 g IV q12h (MRSA)	Thoracostomy tube, intrapleural thrombolytics, VATS, thoracotomy
Mediastinitis after sternotomy	<i>S. aureus</i> , possible MRSA	Vancomycin 1 g IV q12h	Surgical debridement, mediastinal inflow-outflow catheters
Other mediastinitis	MRSA/MSSA, coliforms, <i>Bacteroides</i> sp., and other anaerobes	Piperacillin-tazobactam 3.375 g IV q6h (or ceftazidime 2 g IV q8h + metronidazole 15 mg/kg IV q12h or a carbapenem IV) + vancomycin 1 g IV q12h	Surgical debridement
Endocarditis	<i>S. aureus</i> , <i>S. epidermidis</i> (prosthetic valve), <i>viridans</i> strep, <i>S. bovis</i> , enterococci	Vancomycin 1 g IV q12h + gentamicin 1–1.5 mg/kg IV q8h × 14 days or (for penicillin-sensitive organisms) penicillin G 18–30 million units in divided doses IV q4h + gentamicin	Valve repair or replacement, myocardial debridement

Data from Gilbert DN et al (eds): *The Sanford Guide to Antimicrobial Therapy*, 37th ed. Sperryville, VA: Antimicrobial Therapy, Inc., 2007.

peritoneal dialysis. Tuberculous and other granulomatous forms of peritonitis also are included in this group. In these instances, there is no leak of organisms from the GI tract. Secondary peritonitis occurs when there is perforation of a hollow viscus, such as in duodenal ulcer, anastomotic leak, appendicitis, or diverticulitis. The further along the GI tract a perforation occurs, the higher is the bacterial density. Whereas gastroduodenal perforations are best described as causing chemical peritonitis complicated by the presence of bacteria, colonic perforation delivers an enormous load of bacteria into a peritoneal space that secondarily becomes an altered, low-pH environment. Sometimes perforations are contained by surrounding structures such as omentum or adjacent bowel loops. This produces focal rather than diffuse peritonitis that is often amenable to antibiotic therapy with or without percutaneous drainage. Surgical therapy can be postponed or even avoided altogether. Patients often can be spared the two-stage emergency procedure with its associated temporary colostomy. Examples include perforated

appendicitis and diverticulitis with abscess. Diffuse secondary peritonitis, on the other hand, requires urgent operative intervention.

Two phases of secondary peritoneal infections have been described. Initially, hundreds of bacterial species exit into the peritoneum on colonic perforation, but within short order these numbers are reduced to two or three pathogenic species (*simplification*). These organisms are predictable because only a few species can survive in the unusual environment of peritonitis: obligate anaerobes such as *Bacteroides fragilis* and endotoxin-producing members of the family Enterobacteriaceae that includes facultative anaerobes such as *Escherichia coli*. These bacteria work together (*synergism*) to produce both abscess formation and systemic sepsis. Included in this synergistic relationship are *Enterococcus* species, at least with regard to abscess formation and wound infection. However, *Enterococcus* is of questionable importance when the other two groups are surgically reduced and then eliminated by appropriate antibiotics and host defenses.

Wound infection is largely eliminated by the practice of leaving the cutaneous portion of the surgical wound open to allow healing by secondary intention. Addition of ampicillin or other antienterococcal antibiotics (part of the old mainstay of “triple antibiotic coverage”) is now considered anachronistic. Since the mid-1990s, appropriate antibiotic treatment of secondary peritonitis has included metronidazole to cover most strains of *B. fragilis* and a non-antipseudomonal third-generation cephalosporin to cover the important Enterobacteriaceae organisms. This remains a reasonable combination today, although some single-agent strategies have shown equivalent efficacy. Intraoperative peritoneal cultures are of little value because the important pathogens are predictable from the pathophysiology.

Overall, the management goals for secondary peritonitis as outlined by Wittmann, Schein, and Condon in the mid-1990s remain true today. Supportive treatment includes provision of appropriate antibiotics, treatment of hypovolemia and shock, optimizing tissue oxygenation, nutritional support, and support of failing organ systems. Surgical measures include early source control, mechanical cleansing of the peritoneal cavity, recognition and avoidance of abdominal compartment syndrome, and identification and drainage of persistent or recurrent infection. As discussed earlier, antibiotic treatment is necessary only until there is absence of fever, normalization of leukocytosis, and resolution of ileus. Presence of any of these beyond 5–7 days prompts a search for undrained infection, not addition of extra antibiotics. Culture of fluid collected with image-guided drainage may be of value to direct adjunctive antibiotic therapy at this stage.

Tertiary peritonitis is an entity occurring late in the course of treatment for secondary peritonitis. In patients with persistent multiple-organ dysfunction after seemingly appropriate treatment of intestinal perforation, diligent searches for undrained infection are usually undertaken. Abdominal or pelvic collections revealed by CT scan are tapped, only to demonstrate organisms of low pathogenicity. Unfortunately, the finding of organisms like *S. epidermidis*, *Candida albicans*, and even *A. baumannii* only confirms the existence of tertiary peritonitis rather than suggesting definitive antimicrobial treatment. This really only identifies one more organ that is failing, the peritoneum. Drainage of such collections and intensifying antibiotic coverage probably provide little benefit. Optimization of nutritional support and oxygen delivery are at least as effective as seemingly more direct measures.

There are a number of other life-threatening intraabdominal infections besides peritonitis. Examples include ascending cholangitis, gangrenous cholecystitis, and necrotizing pancreatitis. Acute biliary obstruction in and of itself does not require urgent intervention. However, when coupled with fever, leukocytosis, and hemodynamic changes, biliary tract decompression is needed emergently. Causative bacteria are predictably enteric organisms, primarily anaerobes and gram-negative rods, and antibiotic selection is straightforward in most cases. High blood levels of appropriate antimicrobials

are more helpful than high biliary concentrations. More important than antibiotic therapy is prompt biliary drainage via endoscopic retrograde cholangiopancreatography (ERCP). When ERCP is either unavailable or unsuccessful, percutaneous or surgical drainage is required. Gangrenous cholecystitis, identified by the presence of air in the gallbladder wall noted on imaging studies, requires urgent cholecystectomy. Other forms of cholecystitis, including the acalculous form complicating critical illness, can be treated by percutaneous transhepatic cholecystostomy tube placement. The transhepatic route prevents spillage of any purulent fluid into the peritoneal cavity. Interval cholecystectomy can be performed when the patient's condition has improved.

Pancreatic infections can be particularly difficult to sort out. Severe pancreatitis without sepsis can produce fulminate SIRS and ARDS that can be confused with sepsis. Presence of air bubbles within an edematous or necrotic pancreas indicates infection requiring an aggressive surgical approach. In the absence of this finding, the deteriorating patient with necrotizing pancreatitis should undergo CT-guided fine-needle aspiration for Gram stain and culture of the most prominently involved area. Although this risks introducing infection to sterile pancreatic necrosis, high mortality can be expected if true infection is missed and surgery is withheld. Recently, a number of minimally invasive approaches have been reported for the surgical management of this problem. As for other necrotizing infections, however, the need for multiple surgical interventions should be anticipated. When infection is not present, the value of pancreatic necrosectomy in the critically ill is controversial. The value of prophylactic systemic antibiotics (eg, carbapenems), widely employed previously, has been debated recently. Other pancreatic infections, such as infected pseudocyst, often are amenable to percutaneous drainage. Creative combinations of endoscopic and transcutaneous drainage can eliminate the need for complex open surgery in many cases.

Other important surgical infections of the abdomen and pelvis include a variety of abscesses (eg, subdiaphragmatic, hepatic, splenic, and perinephric), and complications of blunt and penetrating trauma, gastroenteritis, bowel ischemia, inflammatory bowel disease (ie, Crohn's and ulcerative colitis), vasculitis, antibiotic-associated colitis, and sexually transmitted diseases in women. Appropriate treatment includes attention to the primary causes.

Whether owing to hemorrhage, SIRS, or septic shock, visceral and peritoneal edema can produce a dangerous rise in intraabdominal pressure. Physical findings include abdominal distention, respiratory distress, and measured urinary bladder pressures exceeding 30 mm Hg. Patients on mechanical ventilation manifest progressive elevation of peak inspiratory pressures and an increasing PCO_2 . Urine output falls, probably owing to compression of renal veins. Decompressive laparotomy is indicated to prevent a downhill spiral toward irreversible organ dysfunction and death.

Treatment of abdominal and pelvic infections is summarized in [Table 16-3](#).

Table 16-3. Summary of abdominal and pelvic infections in adult surgical patients.

Diagnosis	Organisms	Initial Antibiotics	Adjunctive Therapy
Primary peritonitis	Enterobacteriaceae, <i>S. pneumoniae</i> , enterococci, anaerobes, <i>S. aureus</i> ,* <i>S. epidermidis</i> ,* <i>P. aeruginosa</i> *	Cefotaxime 2 g IV q4-8h <i>or</i> ticarcillin-clavulanate 3.1 g IV q6h <i>or</i> piperacillin-tazobactam 3.375 g IV q6h <i>or</i> ampicillin-sulbactam 3 g IV q6h <i>or</i> ceftriaxone 2 g IV q24h <i>or</i> ertapenem 1 g IV q24h	Removal of PD catheter as indicated
Secondary peritonitis	Enterobacteriaceae, <i>Bacteroides</i> sp., enterococci, <i>P. aeruginosa</i>	Ceftriaxone 1-2 g IV q24h + metronidazole 1 g IV q12h <i>or</i> imipenem 500 mg IV q6h <i>or</i> meropenem 1 g IV q8h	Surgical source control, peritoneal washout, prevention and treatment of abdominal compartment syndrome
Tertiary peritonitis	<i>S. epidermidis</i> , <i>Candida</i> sp., vancomycin-resistant enterococci (VRE), <i>Acinetobacter</i> sp.	Antimicrobial agents of questionable benefit	Supportive care, optimization of O ₂ delivery, nutritional therapy, percutaneous or surgical drainage
Biliary tract infection, including ascending cholangitis (AC)	Enterobacteriaceae, enterococci, <i>Bacteroides</i> sp., <i>Clostridium</i> sp.	Ceftriaxone 1-2 g IV q24h + metronidazole 1 g IV q12h <i>or</i> piperacillin-tazobactam 3.375-4.5 g IV q6-8h <i>or</i> ampicillin-sulbactam 3 g IV q6h <i>or</i> ticarcillin-clavulanate 3.1 g IV q6h <i>or</i> carbapenems IV	ERCP with sphincterotomy ± stent placement, percutaneous transhepatic biliary drainage, or surgical common bile duct decompression for AC
Pancreatic infections	Enterobacteriaceae, enterococci, <i>S. aureus</i> , <i>S. epidermidis</i> , anaerobes, <i>Candida</i> sp.	Same as for biliary tract infection, guided by fine-needle aspiration results	Prophylactic antimicrobials controversial for sterile pancreatic necrosis, surgical drainage/debridement, ERCP with stent PD stent placement, nutritional support
Pelvic inflammatory disease	<i>Neisseria gonorrhoeae</i> , <i>Chlamydia trachomatis</i> , <i>Bacteroides</i> sp., Enterobacteriaceae, <i>Streptococcus</i> sp.	(Cefotetan 2 g IV q12h <i>or</i> cefoxitin 2 g IV q6h + doxycycline 100 mg IV/PO q12h) <i>or</i> (clindamycin 900 mg IV q6h + gentamicin 4.5 mg/kg IV q24h, then doxycycline 100 mg PO bid × 14 days)	Several alternative antibiotic regimens available

Soft Tissues of the Extremities and Torso

Serious soft tissue infection is another common reason for surgical ICU admission. Cellulitis and soft tissue abscesses can occur in patients admitted to the ICU for other conditions.

ICU clinicians commonly care for patients with complicated diabetic foot infections either because of the complexity of the infection or for acute management of advanced cardiovascular disease so frequently seen in these patients. Necrotizing fasciitis affecting the extremities and Fournier's gangrene are two life-threatening infectious processes often faced by intensivists. Less commonly seen but equally lethal is suppurative thrombophlebitis. Most of these infections are caused by multiple organisms working synergistically to produce tissue destruction, bacteremia,

and sepsis. Suppurative thrombophlebitis and type 2 necrotizing fasciitis are generally monomicrobial. For the most part, antibiotic treatment is important but secondary to aggressive surgical debridement.

Cellulitis is an infection of soft tissues that retain their blood supply and viability. There is edema and erythema, but appropriate antibiotic therapy will resolve the infection in most cases. Abscesses and fasciitis are associated with loss of blood supply, tissue necrosis, and collections of bacteria, leukocytes, and cellular debris. Surrounding tissues contain an abscess, whereas fasciitis involves and spreads along fascial planes. Necrotizing fasciitis is a virulent process frequently associated with septic shock and carries a high mortality.

Diabetic foot infections can present anywhere along this range from cellulitis to fasciitis, with associated dry or wet gangrene. Limited infection often responds to antibiotics, but surgical debridement or amputation is required in the face of abscesses, wet gangrene, osteomyelitis, or fasciitis. These infections are associated with the neuropathy and vasculopathy of diabetes. In these patients, a distinction should be made between macrovascular and microvascular disease. Peripheral pulse assessment and documentation of ankle-arm indices are essential to the evaluation of these patients, although the latter can be inaccurate if the arteries are calcified and noncompressible. At any rate, stenoses and occlusions of named arteries may be amenable to percutaneous and/or surgical amelioration, allowing salvage of tissue and resolution of infection. Presence of wet gangrene, radiographic evidence of soft tissue emphysema or osteomyelitis, and signs of sepsis influence urgency of surgical management of these infections. Surgeons must strike a balance between being too radical with tissue resection and avoiding serial operations that only postpone amputation.

Ultrasound and CT scanning define the character and extent of soft tissue abscesses. Most abscesses will not resolve with antimicrobial therapy alone; a combined approach with image-guided or surgical drainage is usually required. It can be difficult to distinguish between cellulitis and abscess on the one hand and life-threatening necrotizing fasciitis on the other. Classic "hard signs" of fasciitis include skin necrosis and bulla formation, palpable crepitation and soft tissue gas on radiography, and hypotension. However, some or all of these may be absent. Pain out of proportion to clinical findings is also an important clue to the diagnosis. CT scanning, with its greater sensitivity than plain films, is currently used widely to help with the diagnosis of these difficult cases. When available, frozen-section analysis of a musculofascial biopsy obtained at bedside under local anesthesia can establish the diagnosis in difficult cases.

There are two major categories of necrotizing fasciitis. Type 1 is polymicrobial with involvement of at least one anaerobic species such as *C. perfringens*. Facultative anaerobes from the Enterobacteriaceae family and nontypable streptococci generally are involved as well. A subclass of type 1 necrotizing fasciitis is Fournier's gangrene. This fulminate

infection involves the skin and soft tissues of the scrotum, perineum, and penis. It spreads along the fascial planes and can involve the thighs and wall of the torso. The majority of patients with Fournier's have diabetes mellitus. Type 2 is monomicrobial, most commonly owing to group A β -hemolytic streptococci (ie, GAS or *Streptococcus pyogenes*), the so-called flesh-eating bacteria. Increasingly, community-acquired MRSA is producing necrotizing fasciitis, including the pediatric population. Antecedent varicella infection is a risk factor in about half these patients.

Necrotizing fasciitis has a mortality ranging from 20–60% in developed countries. Risk of death is elevated in association with immunosuppression, IVDA, streptococcal toxic shock syndrome, advanced patient age, and presence of significant comorbidities. Delays in medical and surgical therapy are deleterious to patient survival. Initial antibiotic therapy includes high-dose intravenous penicillin, semisynthetic β -lactam antibiotics, and clindamycin. The latter should cover most strains of community-acquired MRSA, but vancomycin should be considered pending final culture and sensitivity results. Whether the fasciitis is type 1 or type 2 cannot be determined confidently at the outset. Hemodynamically unstable patients require early, aggressive crystalloid replacement of intravascular volume. In general, central venous pressure monitoring guides this volume resuscitation and directs rational addition and titration of vasoactive medications such as norepinephrine and vasopressin.

The mainstay of treatment for necrotizing fasciitis is prompt radical debridement of all involved skin, subcutaneous tissue, muscle, and fascia. Defining the limits of this resection is difficult and requires experience, but insufficient initial debridement can compromise patient survival. Immediate amputation, even hip disarticulation, may be necessary to effect survival in advanced cases. It is important, when possible, to have a compassionate but frank discussion with the patient and family as to the possible extent of surgery before embarking on an operation for necrotizing fasciitis. General comprehension of this illness's severity should not be assumed. Just as in ANM and necrotizing pancreatitis discussed earlier, the need for multiple operations should be anticipated. Adjunctive measures such as hyperbaric oxygen therapy and intravenous immunoglobulin administration have been advised for treatment of necrotizing fasciitis, but their use has not been rigorously verified in controlled studies.

An uncommon but similarly life-threatening infection seen in burn and other surgical ICUs is suppurative thrombophlebitis. Inflammatory superficial thrombophlebitis occurs quite often after placement of peripheral vein catheters. Fortunately, its infectious counterpart is unusual. It should be suspected, though, in the febrile ICU patient whose site of infection is elusive. All former sites of intravenous access should be examined carefully for induration, erythema, tenderness, centrally projecting red streaks, and purulent drainage. The latter cinches the diagnosis, whereas the other signs may indicate vein exploration under local anesthesia.

Table 16-4. Summary of soft tissue infections in adult surgical patients.

Diagnosis	Organisms	Initial Antibiotics	Adjunctive Therapy
Diabetic foot infection	<i>S. aureus</i> (assume MRSA), group A strep (<i>S. pyogenes</i>), group B strep (<i>S. agalactiae</i>), coliforms, anaerobes	Vancomycin 1 g IV q12h + β -lactam with β -lactamase inhibitor <i>or</i> carbapenem IV	Surgical debridement, vascular surgical evaluation as indicated
Cellulitis and soft tissue abscess	<i>S. pyogenes</i> , group B, C, and G strep, <i>S. aureus</i> , Enterobacteriaceae	Penicillin G 1-2 million units IV q6h <i>or</i> nafcillin-oxacillin 2 g IV q4h; vancomycin 1 g IV q12h for facial cellulitis; for diabetics, linezolid 600 mg IV q12h <i>or</i> vancomycin 1 g IV q12h + carbapenem IV	Consider necrotizing fasciitis
Type 1 necrotizing fasciitis	Aerobes, anaerobes including <i>Clostridium sp.</i>	Penicillin G 24 million units/24 h in divided IV doses q4-6h + clindamycin 900 mg IV q8h + vancomycin 1 g IV q12h + ceftriaxone 2 g IV q24h	Goal-directed therapy for sepsis, prompt and aggressive surgical debridement
Type 2 necrotizing fasciitis	<i>S. pyogenes</i> (GAS), <i>S. aureus</i> (community-acquired MRSA)	Penicillin G 24 million units/24 h in divided IV doses q4-6h + clindamycin 900 mg IV q8h	Goal-directed therapy for sepsis, prompt and aggressive surgical debridement
Suppurative thrombophlebitis	<i>S. aureus</i> , <i>S. pyogenes</i> , Enterobacteriaceae	Vancomycin 1 g IV q12h (MRSA), nafcillin-oxacillin 2 g IV q4h (MSSA), carbapenem IV <i>or</i> extended-spectrum penicillin (Enterobacteriaceae)	Removal of intravascular device, excision of entire involved vein

Data from Gilbert DN et al (eds): *The Sanford Guide to Antimicrobial Therapy*, 37th ed. Sperryville, VA: Antimicrobial Therapy, Inc., 2007.

If the vein is infected, it must be excised urgently in a distal-to-proximal direction, stopping only when normal, patent vein is encountered or all infected vein clearly has been removed. On occasion, infection extends from peripheral veins into central ones, and thoracotomy with central vein resection may be a necessary lifesaving measure.

Treatment of soft tissue infections is summarized in Table 16-4.

Bleeding & Hemostasis

17

Elizabeth D. Simmons, MD

Bleeding is a common problem in critically ill patients in the ICU. A rational approach to diagnosis and treatment of bleeding requires an understanding of the major elements of the hemostatic system, currently available laboratory tests of hemostatic function, and specific disorders of hemostasis. Bleeding disorders generally are categorized into defects of coagulation and fibrinolysis, defects of platelets, and defects of vascular integrity, but critically ill patients who are bleeding may have defects in multiple arms of the hemostatic system. Furthermore, defective hemostasis may result in thrombosis as well as bleeding.

Normal Hemostasis and Laboratory Evaluation

A. Normal Hemostasis—The major elements of hemostasis are outlined in [Table 17–1](#). A complex interaction of vascular endothelium, platelets, red blood cells, coagulation factors, naturally occurring anticoagulants, and fibrinolytic enzymes results in formation of blood clot at the site of vascular injury and activation of repair mechanisms to promote healing of the injured blood vessel. Vascular injury results in platelet adhesion and aggregation, activation of coagulation factors ultimately resulting in cleavage of fibrinogen to fibrin, and formation of a stable blood clot consisting of cross-linked fibrin polymers, platelets, and red blood cells. Simultaneously, naturally occurring anticoagulants and fibrinolytic enzymes are activated, a process that limits the amount of clot formed and degrades clot once the vessel is repaired. The latter aspects of hemostasis serve to confine clot formation to the site of vascular injury while permitting continued blood flow through the affected blood vessel. The precise factors that regulate the balance between clot formation and breakdown are not fully understood.

B. Laboratory Tests of Hemostasis (See [Table 17–2](#))—

There are several generally available laboratory tests for evaluation of the function of the hemostatic system. Currently available screening laboratory tests detect clinically significant defects (quantitative and qualitative) of most but not all

of the important elements of hemostasis. The history should dictate the choice of tests to determine the adequacy of hemostatic function. A highly suggestive history for a bleeding disorder calls for sophisticated or specialized laboratory testing, whereas abnormal test results may not be predictive of future risk of bleeding in the absence of a significant bleeding history.

1. TESTS OF COAGULATION—Calcium and phospholipid are required for normal coagulation to occur. In the laboratory, measurement of coagulation times (eg, prothrombin time and partial thromboplastin time) involves mixing decalcified plasma (collected in citrate) and a phospholipid substitute (thromboplastin), adding calcium, and determining the time for visible clot formation using an automated system. Different phospholipid reagents activate different parts of the coagulation cascade, and an activating agent is added for performance of the activated partial thromboplastin time (aPTT). Prothrombin time (PT) generally is reported as the international normalized ratio (INR), which compares observed results against a reference thromboplastin to minimize interlaboratory variability owing to differing sensitivities of thromboplastin reagents. The thrombin time (TT) is performed by adding excess thrombin to decalcified plasma (phospholipid is not required).

Standard coagulation times are not prolonged until factor activities drop to less than 20–50% of normal (depending on the specific factor deficiency). Therefore, a mixture of patient plasma with normal plasma in equal quantities (1:1 dilution) should normalize a prolonged coagulation time if due solely to one or more factor deficiencies. Failure of a prolonged coagulation time to correct after 1:1 dilution with normal plasma implies the presence of a circulating inhibitor of coagulation, including heparin. Detection of some factor inhibitors may require incubation of the mixture prior to performing the assay.

In vitro assessment of coagulation depends on the action of factor XII, high-molecular-weight kininogen, and prekallikrein (the contact factors), whereas in vivo hemostasis

Table 17-1. Normal hemostasis.

Element	Participation in Hemostasis
Endothelium	
Procoagulant	Release of von Willebrand factor (vWF), factor VIII, tissue factor, plasminogen activator inhibitor, and platelet activating factor in response to injury; maintains tight interendothelial junctions to prevent blood extravasation.
Anticoagulant	Negative charge repels platelets and coagulation factors; produces prostacyclin; releases tissue plasminogen activator in response to vessel injury; provides thrombomodulin for thrombin-mediated activation of protein C; provides heparin-like molecules which interact with antithrombin III and accelerate its inactivation of thrombin and other serine proteases.
Platelets	Adhere to exposed subendothelium via vWF and aggregate in response to activation (via fibrinogen-glycoprotein IIb/IIIa interaction); secrete agonists which stimulate further platelet aggregation; provide phospholipid for production of thromboxane A ₂ and for coagulation reactions; provide surface on which coagulation reactions are localized; secrete coagulation factors (V, vWF), which increase local concentration; provide contractile machinery for clot retraction; perhaps maintain interendothelial tight junctions by secretion of metabolically active substances.
Coagulation factors	
Proenzymes	In response to vascular injury, sequential activation (VII, IX, X, II) results in generation of thrombin and cleavage of fibrinogen to fibrin.
Thrombin	In addition to cleavage of fibrinogen, activates platelets, factors V, VIII, and XIII, and protein C.
Fibrinogen	Cleaved by thrombin to fibrin, which polymerizes to insoluble fibrin clot.
Factor XIII	After activation by thrombin, cross-links fibrin polymers to stabilize clot.
Cofactors	Factors V and VIII, both activated by thrombin, act as cofactors for X and IX, respectively.
Tissue factor	Integral membrane constituent of vascular endothelial cells and stimulated monocytes; acts as receptor for factor VII; initiates blood coagulation.
Calcium, phospholipid	Necessary for several steps in coagulation.
Contact factors	Factor XII, HMW kininogen, and prekallikrein are important for in vitro hemostasis only.
Anticoagulants*	
Protein C	Vitamin K-dependent anticoagulant, inactivates factors V and VIII after activation by thrombin bound to thrombomodulin on endothelial surfaces.
Protein S	Vitamin K-dependent cofactor for protein C.
Thrombomodulin	Receptor for thrombin, initiates activation of protein C pathway.
Antithrombin (AT)	Inactivates thrombin and other serine proteases of the coagulation cascade.
Tissue factor pathway inhibitor (TFPI)	Inhibits tissue factor/factor VIIa complex.
Fibrinolytic system	
Tissue plasminogen activator	Cleaves fibrin-bound plasminogen to plasmin.
Urokinase	Plasminogen activator found in urine and in plasma when fibrinolysis is stimulated.
Plasminogen	Once activated to plasmin, lyses fibrin and fibrinogen.
Plasminogen activator inhibitor-1 (PAI-1)	Prevents activation of plasminogen by tissue plasminogen activator.
Alpha ₂ -antiplasmin	Inactivates circulating plasmin and prevents lysis of fibrin and fibrinogen.
Blood elements and rheology	Laminar flow prevents contact of cellular elements with endothelium; free flow prevents accumulation of factors at uninjured sites and dilutes concentration of activated factors; dislodges platelet plugs if not firmly attached to subendothelium; provides inhibitory plasma proteins other than antithrombin to inactivated coagulation factors.

*Precise physiologic role in hemostasis not well defined: Other serine proteinase inhibitors (Serpin): alpha₂-macroglobulin, alpha₁-proteinase inhibitor, C1 esterase inhibitor, protein C inhibitor, heparin cofactor II.

Table 17-2. Tests of hemostatic function (average normal values given).

Test (normal range)	Significance of Abnormal Test
Coagulation	
Prothrombin time (PT) (10–13 seconds) expressed as the international normalized ratio (INR) (1.0)	Deficiencies of or inhibitors to extrinsic and common pathway factors: VII, X, V (<50%), II (<30%), fibrinogen (<100 mg/dL).
Activated partial thromboplastin time (aPTT) (25–40 seconds)	Deficiencies of or inhibitors of contact factors, intrinsic and common pathway factors: XII, HMW kinogen, prekallikrein, XI (<50%), VIII, IX (<20%), X, V, II (<30–50%), fibrinogen (<100 mg/dL). Decreased value may indicate increased concentration of factor (especially VIII) or hypercoagulable condition.
Thrombin time (TT) (10 seconds)	Deficiency or defect of fibrinogen, inhibitors of thrombin action (heparin), or inhibitors of fibrin polymerization (FDP, myeloma proteins).
Reptilase time	Deficiency or defect of fibrinogen. Similar to thrombin time but unaffected by heparin.
Stypven time (Russell viper venom time)	Differentiate factor X from factor VII deficiency (abnormal in factor X deficiency).
Dilute Russell viper venom time	Detect lupus anticoagulant; affected by heparin.
1:1 dilution test (corrects to normal)	Failure to correct consistent with inhibitors to specific factors or to phospholipid; heparin effect. Correction to normal consistent with factor deficiency (some inhibitors may require incubation).
Factors assays (60% to >100%)	Deficiencies of one or more coagulation factors.
5 M urea clot stability	Deficiency of factor XIII.
Platelets	
Platelet count (150,000–400,000/ μ L)	Quantitative abnormalities of platelets.
Bleeding time (3–10 minutes)	Impaired platelet function, thrombocytopenia, severe anemia, improper technique.
Aggregation (qualitative)	Impaired platelet aggregation in response to platelet agonists; can localize defect based on pattern of abnormal aggregation.
Ristocetin cofactor assay	Decreased quantity or function of vWF in patient plasma.
Fibrinolysis	
Fibrin(ogen) degradation products (FDP) (<10 μ g/mL)	Accelerated fibrinolysis.
Fibrinogen (150–400 mg/dL)	Deficiency of fibrinogen.
Euglobulin lysis time (>2 hours)	Accelerated fibrinolysis.
Protamine sulfate test	Positive test indicates presence of circulating fibrin monomers.
D-dimer test	Positive test indicates presence of cross-linked FDP, formed only if activation of factor XIII has resulted in cross-linkage of fibrin polymers. Elevated in DIC, fibrinolysis, deep vein thrombosis, and pulmonary embolism.

appears to occur normally even with complete deficiency of any of these proteins. Factor XI likewise is essential for *in vitro* coagulation, but factor XI deficiency generally is associated with a very mild bleeding tendency. Specific coagulation factor deficiencies can be identified using known deficient plasma in a modification of the 1:1 dilution test when clinically indicated.

Standard screening coagulation tests (ie, PT, aPTT, and TT) do not detect mild coagulation factor deficiencies, factor XIII deficiency, defects in fibrinolysis, or abnormalities of platelets, blood vessels, or supporting connective tissue. They are not useful for determining deficiencies of the naturally occurring anticoagulants or for evaluating patients with thrombotic disorders (except for patients with lupus

anticoagulants and contact factor deficiencies). Coagulation times shorter than normal occur frequently, particularly if there are higher than normal levels of any of the factors measured by the test (especially factor VIII), which may mask deficiencies of other factors.

2. PLATELETS—The platelet count can be determined by automated cell counter or by estimation on a peripheral blood smear (normal, 10–20 platelets/high-power field [hpf]). The bleeding time is an *in vivo* test of platelet function. Bleeding time is affected by platelet number, platelet function, position and depth of the incision, maintenance of constant pressure above the site of the incision, medications, hemoglobin concentration, and renal function. In thrombocytopenic patients, the bleeding time varies as a function of the cause as well as the degree of thrombocytopenia. Although the bleeding time is useful in diagnosis of disorders of platelet function, it may not be reliable as a predictor of clinical bleeding. Other tests of platelet function include *in vitro* platelet aggregation in response to various agonists (eg, thrombin, epinephrine, adenosine diphosphate, and ristocetin) for evaluation of patients suspected of having significant disorders of platelet function rather than number.

3. FIBRINOLYSIS—Elevated fibrin and fibrinogen degradation products and decreased fibrinogen concentration may reflect excessive intravascular fibrinolysis, but these measurements are not specific. The protamine sulfate test and the D-dimer test may be useful to confirm the presence of disseminated intravascular coagulation (DIC) as the cause of elevated fibrin degradation products. The euglobulin lysis time, which measures the action of plasminogen activators and plasmin in blood, may be useful for confirming the presence of excessive fibrinolysis. Specific assays for elements of the fibrinolytic system are available if clinically indicated.

► Inherited Coagulation Disorders

ESSENTIALS OF DIAGNOSIS

- Personal and family history of bleeding disorder.
- Abnormal screening coagulation tests.
- Abnormal specific factor assays.

General Considerations

Inherited coagulation disorders result from a decrease in quantity or function of a single coagulation factor, although there are some cases of familial multiple coagulation factor deficiencies. The inheritance pattern may be autosomal or X-linked, dominant or recessive, or may be the result of a new mutation, so a negative family history does not preclude the presence of an inherited disorder of coagulation. A personal history of bleeding may be absent if the defect is mild or if there has been no prior challenge to the hemostatic system (eg, major surgery or trauma). In addition, some coagulation

defects are variable over time, with fluctuations both in bleeding manifestations and in laboratory abnormalities. Nevertheless, most of the inherited disorders of blood coagulation result in a typical clinical bleeding history accompanied by characteristic reproducible laboratory abnormalities (Table 17–3).

von Willebrand disease (vWD) is the most common inherited bleeding defect in humans, but prevalence figures vary widely because of variable expression and penetrance of the genetic abnormality. The disease results from inheritance of an autosomal dominant (rarely, autosomal recessive) decrease in the quantity or function of von Willebrand factor (vWF). vWF is essential in platelet adhesion and serves as a carrier for the procoagulant factor VIII protein. Clinical manifestations typically reflect impaired platelet function, with epistaxis, easy bruising, menorrhagia, and excessive bleeding after surgery, trauma, or dental procedures. Severe deficiencies (<1% activity) are rare and may result in bleeding similar to that seen in hemophilia A. vWD is heterogeneous in severity and is subject to variability over time and within families. During pregnancy, vWF levels increase, often sufficiently to permit adequate hemostasis at childbirth.

Hemophilia A, which accounts for 80% of all hemophilias, results from inheritance of an X-linked recessive mutation in the factor VIII gene, giving rise to severe (<1% activity), moderate (1–5% activity), or mild (>5% activity) factor VIII deficiency. The incidence of hemophilia A is approximately 1 in 5000 men. Hemophilia A does occur in women, owing either to early X chromosome inactivation of the normal X in a heterozygous female or to inheritance of two abnormal X chromosomes (one from an affected father and one from a carrier mother).

Clinical manifestations depend on the severity of the deficiency (70% of patients have severe deficiency) but typically include lifelong spontaneous hemarthroses and soft tissue hematomas, hematuria, and if severe, increased epistaxis, gum bleeding, and ecchymoses. Postoperative or dental bleeding is severe and prolonged. CNS hemorrhage occurs in about 3% of patients and may be fatal. The severity of the deficiency is generally constant within a family and over time in an individual, but it varies between families.

Hemophilia B results from inheritance of an X-linked recessive mutation in the factor IX gene. The pathophysiology and clinical manifestations are virtually identical with those of hemophilia A, although severe deficiency is present in only 50%. Hemophilia B is much less common than hemophilia A, with an estimated incidence of 1 in 50,000 men.

Inherited deficiencies of all the other coagulation factors have been reported (see Table 17–3), but these are rare. All are autosomally inherited, usually recessive, and often result from consanguineous parentage. Clinical severity correlates with the degree of factor deficiency but is typically milder and more variable than in hemophilias A and B. Combined deficiencies of multiple coagulation factors are rare. Deficiencies of factor XII, prekallikrein, and high-molecular-weight kininogen cause prolongation of the aPTT but are not associated with excessive bleeding or thrombosis.

 Frequency of clinical manifestations: + common; (+) occasional; · rare

Clinical Features

A. Symptoms and Signs—Bleeding may occur spontaneously, but patients sometimes will give a history of bleeding only after surgery, trauma, or dental extractions. In those with vWD, platelet function is affected, so easy bruising and menorrhagia may be prominent complaints. On the other hand, patients with hemophilia often have spontaneous hemarthroses, soft tissue hematomas, and hematuria. Physical findings may reflect recent bleeding or may show evidence of chronic bleeding such as decreased range of joint motion.

B. History—A detailed personal and family history of bleeding often will uncover the nature of the coagulation disorder and suggest its inheritance pattern. A family history of consanguinity is pertinent for the rare autosomal recessive disorders, and Ashkenazic Jewish ancestry may suggest the possibility of factor XI deficiency.

C. Laboratory Findings—Laboratory abnormalities may suggest an underlying hereditary bleeding disorder, but it is important to remember that not all prolonged coagulation tests indicate a bleeding diathesis, and some inherited bleeding disorders are associated with normal coagulation tests. There may be variability over time in some disorders, such as vWD. The extent of laboratory evaluation for an inherited coagulation disorder should be determined by the clinical history. Table 17–3 outlines the typical laboratory features of the inherited coagulation disorders. Functional assays for factors II, V, VII, VIII, IX, X, XI, and XII using known deficient plasma in a modification of the 1:1 dilution test confirm specific factor deficiencies. Clot stability in 5 M urea with and without the addition of normal plasma is the screening test of choice for diagnosis of factor XIII deficiency and can be confirmed with a specific factor assay. The diagnosis of vWD is based on finding low vWF antigen, abnormal ristocetin cofactor activity, and low factor VIII activity (usually <10%). Quantitative deficiency of vWF can be differentiated from qualitative defects by electrophoretic analysis of vWF multimers. Determining the subtype of vWD by multimer analysis is important for proper management of bleeding episodes.

Differential Diagnosis

Bleeding associated with abnormal coagulation tests also may result from acquired coagulation disturbances, including liver disease, vitamin K deficiency, DIC, inhibitors of specific factors, or therapeutic anticoagulation. Abnormal coagulation tests may result from a deficiency of one of the contact factors or from the presence of antiphospholipid antibodies (lupus anticoagulant), neither of which causes bleeding but may be associated with thrombosis. Mild coagulation factor deficiencies may be associated with normal or minimally prolonged clotting times and may result in bleeding only if major vascular injury occurs. Bleeding in the presence of normal coagulation times suggests the presence

of an underlying vascular defect, abnormal supporting connective tissue, thrombocytopenia or platelet dysfunction, excessive fibrinolysis, or factor XIII deficiency. Acquired inhibitors to coagulation factors may be found in patients with inherited factor deficiencies as a consequence of replacement therapy and may be suspected in those who do not respond adequately to factor replacement. An inhibitor of coagulation can be confirmed by performing a 1:1 dilution test with normal plasma (preincubation may be necessary to demonstrate the inhibitor).

Treatment

Factor replacement is appropriate for patients with inherited coagulation disorders who have active bleeding or who require surgical or dental procedures. The activity level necessary for adequate hemostasis varies for each factor and with the type of bleeding or planned procedure. General guidelines for factor replacement are outlined in Table 17–4. Aspirin and intramuscular injections should be avoided. Surgical procedures should be performed only in centers with adequate blood bank, coagulation laboratory, and hematology consultation services. Treatment strategies for patients with inhibitors complicating factor deficiencies include desmopressin (for minor bleeding), high-dose factor replacement, use of products that bypass the factor inhibitor (eg, activated prothrombin complex concentrate with factor VIII inhibitor bypassing activity, recombinant factor VIIa, and porcine factor VIII), and techniques to lower the titer of the inhibitor (eg, plasmapheresis, intravenous immune globulin, immunosuppression, and induction of immune tolerance).

Adjuncts to factor replacement include desmopressin acetate, antifibrinolytic agents such as aminocaproic acid and tranexamic acid, and topical hemostatic agents such as fibrin glue and fibrillar collagen preparations applied directly to local areas of mucosal bleeding, such as epistaxis. Desmopressin by intravenous (0.3 µg/kg over 15–30 minutes) or intranasal (1.5 mg/mL in each nostril) administration increases circulating levels of vWF and factor VIII by 2 to 5 times baseline within 15–30 minutes by releasing these factors from endothelial storage sites. Desmopressin is useful for most patients with vWD and in patients with mild to moderate hemophilia A. Repeated infusions within 1–2 days may be less effective, however, limiting the usefulness of desmopressin in patients requiring sustained increases in vWF, factor VIII, or both. On the other hand, use of desmopressin may completely eliminate the need for blood products in mild bleeding episodes or during minor dental or surgical procedures and may decrease the amount of blood products required for major bleeds or surgical procedures. A test dose of desmopressin should be administered about 1 week before a planned surgical procedure to determine if a patient with vWD or hemophilia A is responsive. Severe hemophiliacs and those with qualitative abnormalities of vWF are rarely responsive to desmopressin. Some subtypes of vWD (eg, type 2B)

Table 17-4. General principles of factor replacement for inherited coagulation disorders.

Factor Deficiency	$t_{1/2}$	Hemostatic Level ¹	Preferred Sources ²	Dose	Interval Between Doses
vWF	12 hours	25-50%	a. Desmopressin ³ b. Humate-P c. Cryoprecipitate ⁴	a. 0.3 µg/kg IV/30 minutes or 1.5 mg/mL nasal spray b. 30 units/kg	a. 24-48 hours b. 12 hours for 2 days, then 24 hours
VIII	9-18 hours	25-30%	a. Purified factor VIII b. Recombinant factor VIII c. Desmopressin ⁵	a. 10-15 units/kg (minor), 30-40 units/kg (major) b. 10 units/kg (minor); 15-25 units/kg (moderate); 40-50 units/kg, then 20-25 units/kg (major); 50 units/kg (surgery)	12 hours (6-12 hours following major surgery)
IX	20-25 hours	15-30%	a. Purified factor IX b. Recombinant factor IX c. Purified prothrombin complex concentrates (PCC)	a. 10-20 units/kg b. 100 units/kg, then 7.5 units/kg/h c. 20-30 units/kg, then 15 units/kg (minor); 40-60 units/kg, then 20-25 units/kg (major bleeding or surgery)	24 hours
II	3 days	20-40%	a. Plasma b. Purified PCC	a. 15 mL/kg, then 5-10 mL/kg b. 20 units/kg, then 10 units/kg	24 hours
V	36 hours	25-30%	FFP, PCC	15-20 mL/kg, then 10 mL/kg	12-24 hours
VII	4-7 hours	15-20%	a. Plasma b. Purified PCC c. Recombinant factor VII d. Factor VII concentrate	a. 20 mL/kg, then 5 mL/kg b. 30 units/kg, then 10-20 units/kg c. 15-30 µg/kg d. 30-40 units/kg	a/b. 4-6 hours c/d. 12 hours
X	40 hours	10-20%	a. Plasma b. Purified PCC	a. 15-20 mL/kg, then 10 mL/kg b. 20-30 units/kg	24 hours
XI	80 hours	10-20%	Plasma	15-20 mL/kg, then 5 mg/kg	48 hours
XIII	9-12 days	3-5%	a. Plasma b. Cryoprecipitate c. Factor XIII concentrate	a. 15-20 mL/kg b. 1 bag/10 kg c. 10-20 units/kg	20-30 days
Fibrinogen	3-4 days		a. Plasma b. Cryoprecipitate c. Fibrinogen concentrate	a. 15-20 mL/kg b. 1 bag/10 kg c. 20-30 mg/kg	48 hours
Combined factors V/VIII	36 hours (V) 9-18 (VIII)	25-30%	a. Plasma b. Desmopressin (as in VIII)	a. 15-20 mL/kg	12 hours
Multiple Vitamin K-dependent factors	Varies by factor (II, VII, IX, X)	Varies by factor	a. Plasma b. PCC c. Oral Vitamin K	a. 15-20 mL/kg b. 10-30 units/kg c. chronic, high dose	Monitor levels

¹Estimated level required for normal hemostasis. Higher levels required for major bleeding or surgery (factors VIII and IX: 100%, factor XIII: 25-50%).

²Plasma, fresh frozen (FFP) or fresh (FP), may be used interchangeably except for replacement of factors V and VIII.

³Desmopressin is thrombogenic; use with caution in older patients with vascular disease; may induce fibrinolysis, often used in combination with antifibrinolytic agents. Must give a test dose to determine efficacy; not effective for vWD type 2b, platelet-type vWD.

⁴Use only if factor concentrate is unavailable.

⁵In mild hemophilia A, may reduce or eliminate need for factor VIII replacement for minor surgery, dental work, or acute bleeding episodes. Same dose as in vWD.

have been associated with thrombocytopenia following desmopressin therapy because of increased binding of aberrant vWF to platelets. If the response to desmopressin is unknown and a patient is actively bleeding, factor replacement with blood products is preferable. Desmopressin also stimulates release of tissue plasminogen activator, so antifibrinolytic therapy is often administered simultaneously.

Aminocaproic acid and tranexamic acid are two commercially available antifibrinolytic agents that may be useful for managing bleeding in patients with a wide variety of bleeding disorders. The use of antifibrinolytics in combination with desmopressin often eliminates the need for any blood product administration for patients with vWD or mild hemophilia A with minor bleeding or after dental procedures. Antifibrinolytic therapy also may be useful as an adjunct to factor replacement in any inherited coagulation disorder unless there are contraindications such as hematuria, uncontrolled DIC, or use of prothrombin complex concentrates. For acute bleeding, aminocaproic acid usually is given as an intravenous infusion at a rate of 1 g/h until bleeding is controlled (maximum 24 g in 24 hours), followed by a maintenance dose of 6 g intravenously or orally every 6 hours for 7–10 days. The suggested dose of tranexamic acid is 10 mg/kg intravenously or 25 mg/kg orally three or four times a day beginning 1 day before surgery or at the onset of acute bleeding and to be continued for 2–8 days.

Current Controversies and Unresolved Issues

Current recommendations regarding factor replacement for inherited coagulation disorders stem primarily from anecdotal experience rather than from carefully designed clinical trials comparing one regimen with another. The optimal level of factor activity, the precise interval between doses, and the duration of therapy are somewhat arbitrary and for most of the rare disorders reflect a lack of clinical experience. Genetic heterogeneity contributes further to the lack of firm data to support current recommendations.

Because of the risks of bleeding, infections, and other transfusion-related complications, elective surgery should be avoided when possible. There is a body of literature demonstrating the success of surgery in hemophiliacs and others with inherited coagulation defects, but clearly, surgery in such patients poses significant risks and increases the demand for scarce resources, including blood products.

Current screening for infectious diseases and processing of factor concentrates to eliminate many (but not all) infectious agents has significantly decreased the risk of transmission of infectious diseases from plasma-derived products. All patients with hemophilia and related coagulation disorders should be vaccinated against hepatitis B. The development of recombinant factors VIII and IX has contributed to a marked decrease in virus-associated illnesses in these patients (no documented cases of HIV and hepatitis B or C since 1985 and 1990, respectively), and human albumin-free products have been developed to reduce further the possible transmission

of Creutzfeldt-Jakob disease. However, recombinant factors are two to three times more expensive than plasma-derived factors, are not always available owing to limited production capacity, and may be associated with a higher rate of inhibitor development compared with plasma concentrates. Hemophilia patients who acquired HIV infection prior to the widespread availability of screening and purified factors have been treated successfully with antiretroviral therapy, but there appears to be an increased risk of spontaneous bleeding in these patients.

The development of inhibitors to factors continues to be a problem for patients with severe hemophilia; recombinant factors do not eliminate this risk (estimated at 10–15%). Recombinant factor VIIa and activated prothrombin complex concentrates (aPCCs) can be used to control hemorrhage by bypassing factors VIII and IX in patients with inhibitors, but both may be associated with thromboembolism. Porcine factor VIII is no longer used owing to contamination with porcine parvovirus. Protein A sepharose immunoabsorption may transiently lower factor VIII inhibitors, allowing time for other immunosuppressive therapies to work. Optimal management of inhibitors remains a challenge in management of severe hemophilia.

Factor IX replacement (recombinant or purified plasma-derived) can cause anaphylaxis in 5% of patients with severe hemophilia B. Further replacement therapy in these patients is risky. Recombinant factor VIIa is the only available therapeutic option for these patients.

Research in gene therapy is ongoing for patients with severe hemophilia A and B. Results from preliminary trials are promising, but this approach remains experimental. Gene therapy may not prevent inhibitor development, however, and patients who are undergoing treatment for HIV infection or who have hepatitis may not respond to this approach.

▶ Acquired Coagulation Disorders

ESSENTIALS OF DIAGNOSIS

- ▶ Absence of a personal (if newly acquired) or family history of bleeding disorder.
- ▶ Abnormal screening coagulation tests.
- ▶ Clinical situation leading to decreased production or increased destruction of coagulation factors or presence of an anticoagulant.

General Considerations

Acquired coagulation disorders result from four basic mechanisms: vitamin K deficiency, liver disease, consumption of factors, or inhibition of factor activity or fibrin polymerization. Unlike inherited disorders, acquired coagulation disorders are often characterized by multiple factor deficiencies as

well as platelet defects (quantitative and qualitative). In addition, many of the clinical symptoms and signs result from the underlying disease process; the coagulopathy is just one of many processes contributing to the overall clinical picture.

A. Vitamin K Deficiency—Vitamin K is a cofactor necessary for the synthesis of functional factors II (ie, prothrombin), VII, IX, and X and proteins C and S. Vitamin K is found in dietary sources (green vegetables) and is synthesized by bacteria in the intestinal lumen. It is fat-soluble, requiring bile salts for absorption in the intestine. Vitamin K deficiency is most likely to occur in patients who have disruption of both dietary and bacterial sources of vitamin K (eg, patients who are receiving broad-spectrum antibiotics who are not eating), who have biliary obstruction or fat malabsorption, or who are taking warfarin derivatives that inhibit metabolism of vitamin K in the liver and induce a vitamin K–depleted state. Vitamin K stores also may be depleted in patients with acute or chronic liver disease. By unclear mechanisms, certain antibiotics—particularly certain cephalosporins—and high doses of aspirin are known to induce a deficiency of vitamin K–dependent coagulation factors that is reversible with administration of vitamin K. Cholestyramine, mineral oil, and other cathartics may interfere with vitamin K absorption when taken for a prolonged period. Normal newborns have low levels of vitamin K–dependent factors that fall further during the first few days of life. Deficiency of vitamin K results in progressive depletion of all the vitamin K–dependent factors as they are metabolized. Factor VII has the shortest biologic half-life and is depleted first, followed by proteins C and S and then factors IX, X, and II. Bleeding owing to vitamin K deficiency is uncommon unless the deficiency is severe (PT >25–30 seconds) or vascular injury is present.

B. Liver Disease—Coagulation disorders associated with liver disease are complex. With the exception of vWF and factor VIII, all the coagulation factors and other regulatory proteins (eg, α_2 -antiplasmin, proteins C and S, and antithrombin) are synthesized in hepatocytes. The liver is also the site of clearance of activated coagulation factors and degradation products of fibrin and fibrinogen and is responsible for regeneration of vitamin K after it participates in synthesis of the vitamin K–dependent coagulation factors. Liver disease from any cause may result in multiple abnormalities, including decreased synthesis of all the coagulation factors (with the exception of factor VIII), abnormal synthesis of factors and proteins (eg, dysfibrinogenemia), abnormal vitamin K metabolism resulting in functional vitamin K deficiency, impaired fibrin polymerization owing to increased fibrin degradation products, and accelerated fibrinolysis. In addition, thrombocytopenia (owing to multiple mechanisms, including inadequate synthesis of thrombopoietin in the liver and hypersplenism, among others), defective platelet function, or both may complicate severe liver disease. Advanced cirrhosis is often associated with abnormalities of blood vessels (eg, esophageal and gastric varices) and other defects (eg, gastritis, ulcer disease, and esophageal tears),

which are the major sites of bleeding in patients with liver disease. Hemostatic abnormalities exacerbate bleeding from these sites and contribute to epistaxis, ecchymoses, and increased bleeding with invasive procedures. In general, the presence of a coagulopathy is a sign of advanced liver disease, although passive congestion of the liver owing to right-sided heart failure may be associated with coagulation disturbances without irreversible liver dysfunction.

C. Consumption of Coagulation Factors—Consumption of coagulation factors may result from massive internal or external blood loss or from DIC. Occasional patients who have massive blood loss will develop a clinically significant deficiency of multiple hemostatic factors, but DIC is the most typical condition associated with consumption of coagulation factors.

DIC occurs as a result of abnormal activation of coagulation because of vascular injury, direct release of procoagulant materials into the circulation, or both. There also may be decreased quantity or function of naturally occurring anticoagulants (ie, thrombomodulin–protein C pathway) in patients with sepsis-associated DIC or in patients following resuscitation for cardiac arrest. Consumption of coagulation factors and platelets is accompanied by secondarily accelerated fibrinolysis and results in a generalized bleeding tendency associated with mucosal bleeding, ecchymoses, and oozing from sites of vascular trauma, including venipuncture and surgical sites. Fibrin deposition in the microcirculation may contribute to some of the clinical sequelae of DIC, such as tissue hypoxia. Rarely, purpura fulminans complicates DIC. As a result of widespread arterial and venous thrombosis, patients with purpura fulminans may have skin necrosis and gangrene of the distal extremities and digits. The conditions in which DIC occurs are complex (Table 17–5), with multiple pathophysiologic mechanisms contributing to the overall outcome of patients. DIC itself contributes to multiple-organ-system failure and death in patients with severe systemic disorders, particularly sepsis. Localized consumption of coagulation factors and platelets owing to massive internal bleeding may mimic DIC but is not associated with intravascular fibrin generation or generalized fibrinolysis. In this situation, depletion of coagulation factors and platelets may be accompanied by elevated circulating fibrin degradation products and may result in a serious bleeding tendency, but it is not associated with microvascular thrombus formation. Primary systemic fibrinolysis is extremely rare and results in rapid destruction of fibrin clots, destruction of circulating fibrinogen, and consumption of plasminogen and its inactivators. Systemic fibrinolysis accompanies DIC and may contribute significantly to clinical bleeding. Primary fibrinolysis can be confused with DIC but usually is not associated with thrombocytopenia and generalized consumption of coagulation factors.

D. Inhibitors of Coagulation—Infrequently, inhibitors of coagulation develop and may result in a serious bleeding diathesis. Inhibitors directed against factor VIII are encountered

Table 17-5. Causes of disseminated intravascular coagulation (DIC).

Cause	Examples
Infections	Bacterial sepsis (gram-negative and gram-positive), viremia, rickettsiae, malaria, tuberculosis
Trauma	Massive tissue injury, head trauma, fat embolism, burns
Malignancy	Adenocarcinomas, acute leukemia
Obstetrical complications	Abruptio placentae, amniotic fluid embolism, retained dead fetus, septic abortion, placenta previa, eclampsia
Vascular disorders and prosthetic devices	Giant hemangioma (Kasabach-Merritt syndrome), aortic aneurysm
Toxins	Snake venoms, drugs
Immunologic disorders	Severe allergic reaction, hemolytic transfusion reaction, transplant rejection
Metabolic disorders	Hypotension, hypoxia, hyperthermia, hypothermia, cardiac arrest

most frequently as a complication of treatment for severe hemophilia A and also may be associated with pregnancy, collagen vascular diseases, malignancy, or certain drug reactions. Inhibitors may occur as an isolated condition. The abrupt development of factor V inhibitors following surgical procedures has been reported and may cause unexpected severe postoperative bleeding. These inhibitors appear to be related to the use of topical bovine thrombin preparations containing bovine factor V intraoperatively that may crossreact with human factor V. Inhibitors to other coagulation factors, including vWF and factor XIII, have been described. These inhibitors are immunoglobulins with neutralizing activity directed against specific factors and result in a clinical picture consistent with a factor deficiency state. Other types of inhibitors include substances that inhibit fibrin polymerization without immunologic specificity for the fibrin molecule (eg, fibrin degradation products or myeloma proteins). The lupus anticoagulant typically prolongs the aPTT and therefore may be confused with factor deficiencies or other inhibitors, but it is not associated with bleeding. Heparin is a therapeutic inhibitor of coagulation, accelerating the rate of antithrombin-mediated inactivation of thrombin and other coagulation factors that act as serine proteases (ie, factors VII, IX, and X).

Clinical Features

The clinical history, physical examination, and screening laboratory abnormalities are usually sufficient to determine the nature of the coagulation defect.

A. Symptoms and Signs—Patients with acquired coagulation disorders occasionally may have spontaneous bleeding but more commonly have excessive bleeding with surgical or other invasive procedures or exacerbations of bleeding from GI or other sites. Other clinical features reflect the underlying disorder. Patients with liver disease may have bleeding from esophageal varices as well as signs of hepatic dysfunction. In DIC, bleeding is a common finding, but ongoing coagulation may be manifested as intravascular thrombosis with skin necrosis and gangrene (ie, purpura fulminans). Features of the disease causing DIC—particularly sepsis—may predominate.

B. Laboratory Findings (See Table 17-6)—The PT and the aPTT may be prolonged in all the acquired coagulation defects as a result of multiple factor deficiencies. A 1:1 dilution test that fails to correct the abnormal PT or aPTT indicates the presence of an inhibitor (including heparin and lupus anticoagulants). Complete correction of the prolonged PT and aPTT within 24 hours of administration of intravenous vitamin K confirms the presence of vitamin K deficiency; vitamin K administration therefore is both diagnostic and therapeutic. The diagnosis of DIC is based on the presence of prolonged PT and aPTT, thrombocytopenia, and elevated fibrin degradation products or D-dimer in the presence of an appropriate underlying condition. Hypofibrinogenemia may be present in very severe cases, but—because fibrinogen is an acute-phase reactant—fibrinogen levels are often normal. None of these tests is sensitive or specific enough to determine conclusively whether DIC is present. Circulating fibrin monomers (protamine sulfate test) and degradation products of cross-linked fibrin (D-dimer test) confirm the presence of increased thrombin or plasmin generation, and both are usually present in DIC; they also may be positive occasionally in patients with liver disease. Laboratory findings also vary as the condition of the patient changes. Despite numerous attempts to standardize the diagnostic criteria for DIC, DIC remains a clinical diagnosis, and assessment of the consequences of DIC is the most critical aspect of management.

Coagulation defects owing to liver disease may be confused with DIC because of the presence of accelerated fibrinolysis, decreased clearance of fibrin and fibrinogen degradation products, thrombocytopenia, and prolongation of both the PT and the aPTT. Therefore, differentiating DIC from the coagulopathy of severe liver disease may be difficult, and clinical experience is required to interpret the often complex laboratory abnormalities. Schistocytes may be found on peripheral blood smear; when present, DIC must be distinguished from microangiopathic hemolytic anemia. This disorder, which can be due to thrombotic thrombocytopenic purpura—hemolytic uremic syndrome, chemotherapy, malignant hypertension, and the HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome, results from endothelial injury with subsequent platelet activation, thrombin generation, and fibrinolysis. Thrombocytopenia,

Table 17-6. Laboratory diagnosis of acquired coagulopathies.

Laboratory Abnormality	Vitamin K Deficiency	Liver Disease	DIC	Specific Factor Inhibitors	Lupus Inhibitors	Primary Fibrinolysis
PT prolonged	+	+	+	+*	(+)

*Pattern of clotting time prolongation depends on specific factor to which inhibitor is directed.

†May require incubation.

Key: + common; (+) occasional

hemolytic anemia, and fragmented red blood cells are the hallmarks of microangiopathic hemolytic anemia, without prolongation of coagulation times in most cases.

Differential Diagnosis

Inherited coagulation defects, thrombocytopenia, platelet dysfunction, and accelerated fibrinolysis all may result in bleeding at sites of vascular injury. Prolonged screening coagulation tests may be abnormal owing to technical error (including obtaining blood samples through heparinized lines or inadequate quantity of blood in the tube) because of inhibitors that do not cause bleeding (eg, lupus anticoagulant) and deficiencies of factors that are not important for in vivo hemostasis (eg, the contact factors, factor XII, high-molecular-weight kininogen, and prekallikrein). Finally, impaired surgical hemostasis, mucosal abnormalities, and primary vascular abnormalities may result in clinical bleeding regardless of coagulation status.

Treatment

Treatment of the underlying disease state, avoidance of invasive procedures, and replacement of deficient factors during acute bleeding episodes are the mainstays of treatment. Vitamin K₁ (phytonadione), 1–10 mg orally or subcutaneously (*not* intramuscularly), should be administered to

patients at risk for vitamin K deficiency as both a diagnostic and therapeutic strategy. The American College of Chest Physicians recommends different dosing ranges of vitamin K depending on the elevation of the PT and the bleeding status or risk of the patient. Weekly administration (10 mg) reduces the risk of vitamin K deficiency in patients who are poorly nourished, receiving antibiotics, or who have malabsorption. Intravenous vitamin K administration works more rapidly but rarely may cause severe allergic reactions. Larger doses may be required to reverse massive overdoses of warfarin. Fresh-frozen plasma administration is necessary to correct multiple factor deficiencies, but this treatment may be complicated by the large volume required to achieve adequate hemostatic levels, especially if factors are being consumed rapidly. The quantity of fresh-frozen plasma administered must be individualized, but in general, 30–40% of plasma volume (eg, 1000–1200 mL) is required to achieve adequate levels of all the deficient factors; this amount must be readministered every 6–8 hours to maintain adequate levels of factor VII. Many patients will not tolerate such a high volume of fresh-frozen plasma replacement, so only partial correction may be possible—yet, if increased consumption of factors is present, even more frequent administration may be needed.

A. Liver Disease—Management of liver disease complicated by bleeding is difficult owing to the presence of multiple

pathologic processes. Factor replacement with fresh-frozen plasma, platelet concentrates for thrombocytopenia, and cryoprecipitate for severe hypofibrinogenemia is a reasonable intervention for serious bleeding but must be accompanied by attempts to correct vascular and mucosal defects that often are the main reasons for bleeding. The volume of fresh-frozen plasma required to completely reverse prolonged clotting times is substantial (>1000 mL), which limits its efficacy. Prothrombin complex concentrate provides essential coagulation factors in a much smaller volume, but because it is associated with increased thromboembolic complications and DIC (particularly with severe liver disease owing to decreased clearance of activated clotting factors present in the complex), it should be used only in life-threatening bleeding. Vitamin K₁ administration (10–20 mg) may improve the PT and aPTT in some patients and should be tried. Desmopressin may shorten the bleeding time in some patients with platelet dysfunction complicating cirrhosis, but its efficacy has not been determined for control of bleeding in liver disease. Treatment with desmopressin may exacerbate hyponatremia and hypotension and should be used with caution. Antifibrinolytic agents have been advocated for patients with evidence of accelerated fibrinolysis, but their safety and efficacy in patients with advanced liver disease have not been proved.

B. Disseminated Intravascular Coagulation—Patients with DIC have diverse underlying conditions (see Table 17–5) and heterogeneous complications (both hemorrhagic and thrombotic). Management should be directed primarily at the underlying disorder. If serious bleeding is present, or if an invasive procedure is required, factor replacement with fresh frozen plasma to shorten the PT to within 2–3 seconds of normal, cryoprecipitate to maintain fibrinogen levels greater than 100 mg/dL, and platelet concentrates to raise the platelets to greater than 50,000/μL should be attempted, but these efforts may be compromised by short survival of the hemostatic factors. Prophylactic administration of factors and platelets in the absence of bleeding is not effective, and coagulation factor concentrates should be avoided because activated factors present in the concentrate may increase intravascular coagulation.

Interruption of the primary pathologic coagulation of DIC with heparin is controversial. DIC complicating acute leukemia may be associated with marked bleeding owing to impaired platelet production and may necessitate the use of low-dose heparin (eg, 5–10 units/kg per hour) to achieve adequate platelet counts with platelet concentrates, although controlled studies have demonstrated that heparin administration increases platelet transfusion requirements without decreasing complications associated with DIC. Patients with solid tumors and chronic DIC are more likely to experience thrombotic complications than bleeding and may benefit from long-term administration of heparin. Patients with overt thromboembolism or purpura fulminans should be treated with heparin, but because of an increased risk of

adrenal hemorrhage, the initial dose should be relatively low and adjusted based on clinical response. Although secondary fibrinolysis often contributes to the bleeding diathesis, antifibrinolytic agents generally are contraindicated in the presence of DIC because of the potential for unopposed intravascular coagulation, which may result in significant thrombotic complications. If marked symptomatic fibrinolysis is present and there is no evidence of thrombotic complications, however, antifibrinolytic therapy may be attempted in combination with low-dose heparin to control bleeding.

C. Circulating Inhibitors—Circulating inhibitors pose substantial difficulties in management of the bleeding patient. As in patients with hemophilia A with factor VIII inhibitors, strategies include high-dose factor replacement, decreasing the titer of the inhibitor by immunosuppression or plasmapheresis, or using factors that bypass the need for the factor being inhibited (eg, use of activated prothrombin complex concentrates or recombinant factor VIIa). When high concentrations of fibrin and fibrinogen degradation products are present, treatment of the underlying process (eg, sepsis-induced DIC) is more useful than specific hemostatic therapy. Myeloma proteins that inhibit fibrin polymerization should be definitively treated with chemotherapy, but plasmapheresis may be used as a temporizing measure.

Current Controversies and Unresolved Issues

Despite our understanding of the multiple processes that contribute to bleeding in patients with liver disease, management of bleeding has not been subject to careful clinical study to determine optimal treatment strategies. Recombinant factor VIIa (rFVIIa) has been shown to improve outcome from acute variceal bleeding in a small preliminary trial, but its precise role in the management of bleeding in liver disease has not been defined by clinical studies. The use of thrombopoietin to improve thrombocytopenia is under investigation.

DIC is a syndrome that occurs in diverse clinical conditions and is usually diagnosed on the basis of a combination of laboratory abnormalities in the appropriate situation. Several confirmatory laboratory tests have been proposed as essential for the diagnosis, but the lack of a “gold standard” combined with lack of standardization for the newer tests has resulted in conflicting data on their usefulness. Management of DIC is directed primarily against the underlying condition, but interventions to interrupt the state of pathologic coagulation and fibrinolysis seem to be logical because these processes may contribute significantly to the pathologic state. Nevertheless, it has been difficult to demonstrate a clear benefit of anticoagulation or antifibrinolytic therapy in any situation complicated by DIC above and beyond that of aggressive supportive care and treatment of the underlying disease, with the possible exceptions of purpura fulminans and thromboses associated with solid tumors. The use of rFVIIa to treat bleeding associated with DIC may increase

thrombotic sequelae and is not recommended by the manufacturer. However, control of refractory bleeding with rFVIIa without thrombotic complications has been reported in several patients with DIC. The use of activated protein C has been shown to reduce hospital mortality in patients with severe sepsis; however, this benefit was seen in patients both with and without DIC. It is not known whether this benefit is due to its anti-inflammatory properties, profibrinolytic properties, or antithrombotic properties. Other strategies aimed at interrupting important steps in the pathogenesis of DIC such as the use of antithrombin concentrate and inhibitors of the tissue factor pathway are under investigation for treatment of DIC. Antifibrinolytic therapy has proven to be useful in the management of some of the inherited coagulation disorders as an adjunct to factor replacement. Because the acquired coagulation disorders are often more complex, disruption of fibrinolysis has been attempted infrequently. Potential complications of such therapy, such as unmasking an underlying thrombotic diathesis, have limited its role in the management of acquired coagulation disorders. There is some evidence, however, that patients with severe liver disease may have excessive fibrinolysis as a major contributor to bleeding. Future studies to determine the efficacy and safety of antifibrinolytic therapy are necessary before it can be recommended.

▶ Inherited Platelet Dysfunction

ESSENTIALS OF DIAGNOSIS

- ▶ Lifelong history of easy bleeding.
- ▶ Prolonged bleeding time out of proportion to platelet count.
- ▶ Normal platelet count or mild thrombocytopenia.
- ▶ Normal coagulation times.

General Considerations

Platelets are involved in multiple aspects of normal hemostasis. Defects in platelet membrane constituents, granules, metabolism, or coagulant function give rise to defective adhesion, aggregation, secretion, or procoagulant activity (Table 17-7). These disorders are generally rare, usually follow autosomal recessive inheritance patterns, and result in varying degrees of bleeding associated with prolongation of the bleeding time or defective or absent platelet aggregation in response to platelet agonists. The most severe defects have onset in the neonatal period or in early childhood with ecchymoses, epistaxis, and other mucosal bleeding, but milder defects may be manifest only after surgery or trauma. Thrombocytopenia is present in some platelet disorders and may contribute to the bleeding tendency. Other congenital abnormalities (eg, albinism) also may be present.

Table 17-7. Inherited disorders of platelet function.

Function	Disorder
Adhesion	Bernard-Soulier syndrome (GP Ib deficiency) von Willebrand disease.
Aggregation	Glanzmann's thrombasthenia (GP IIb/IIIa deficiency) Afibrinogenemia*
Secretion/ signal transduction	Gray platelet syndrome (alpha granule deficiency) Storage pool deficiency (delta granule defects) Arachidonic acid pathway abnormalities Defective calcium mobilization Wiskott-Aldrich syndrome (defective cytoskeletal regulation)
Procoagulant activity	Decreased platelet factor III activity Scott syndrome (asymmetry of platelet phospholipids)

*Defect is extrinsic to platelet but affects platelet function, with exception of platelet-type von Willebrand disease.

Clinical Features

A clinical history of lifelong bleeding, accompanied by a prolonged bleeding time in the presence of normal platelet count (or mild thrombocytopenia), PT, and aPTT, should suggest the possibility of an inherited platelet disorder. A peripheral smear made from fresh non-anticoagulated blood may uncover morphologic platelet abnormalities or absence of platelet aggregation. Platelet aggregation studies using a wide variety of platelet agonists (including ristocetin) are helpful for identifying the specific defect. Confirmation of the specific diagnosis may require specialized studies available only in research laboratories.

Differential Diagnosis

A prolonged bleeding time in the absence of a history of clinical bleeding is unreliable as an indicator of platelet dysfunction or as a predictor of future bleeding. In the presence of bleeding, a prolonged bleeding time may suggest the diagnosis of vWD or an acquired disorder of platelet function (eg, uremia, drug therapy, cardiopulmonary bypass, or myeloproliferative disorders) rather than an inherited defect. Mucosal bleeding, ecchymoses, and posttraumatic bleeding may result from severe coagulation disorders, accelerated fibrinolysis, thrombocytopenia, or vascular injury or from multiple hemostatic defects. Adult onset of a severe bleeding tendency makes the diagnosis of an inherited disorder of platelet function very unlikely.

Treatment

Serious bleeding usually requires transfusion of normal platelets. Alloimmunization to HLA antigens and to platelet-specific antigens may result in refractoriness to platelet transfusions, so efforts to decrease alloimmunization are

recommended (eg, limiting transfusions to life-threatening situations, use of leukocyte-poor platelet preparations, or administration of HLA-matched platelets). For unclear reasons, some defects respond to therapy with desmopressin. Antifibrinolytic agents (eg, aminocaproic acid or tranexamic acid) may be useful for control of minor mucosal bleeding or as adjuncts to platelet transfusions. Hormonal suppression of menses is indicated for control of menorrhagia. Antiplatelet agents are contraindicated, and surgical procedures should be avoided whenever possible. Antifibrinolytic agents (eg, epsilon-amino caproic acid and tranexamic acid) may be helpful for controlling bleeding, as they do in inherited coagulation disorders.

Current Controversies and Unresolved Issues

Optimal therapy of inherited platelet disorders is hampered by the infectious risk of platelet concentrates and by the risk of alloimmunization to HLA antigens and platelet-specific antigens that renders further transfusions ineffective. The risk of antibody formation is highest in patients with membrane protein defects because of the presence of these proteins on normal platelets. Bone marrow transplantation can completely correct the bleeding tendency in patients with inherited platelet disorders but remains experimental because of potential lethal toxicity. Desmopressin releases vWF and factor VIII from the endothelium, but it also may shorten the bleeding time in some patients with a wide variety of platelet disorders independent of vWF and factor VIII levels; its mechanism of action in these intrinsic platelet disorders has not been established. Corticosteroid therapy prior to surgery may improve hemostasis via an effect on vascular integrity and may be indicated for control of bleeding in patients with inherited platelet disorders who have no contraindications to steroid use.

► Acquired Platelet Dysfunction

ESSENTIALS OF DIAGNOSIS

- ▶ Mucosal bleeding, ecchymoses, or excessive surgical bleeding in the absence of thrombocytopenia.
- ▶ Abnormal bleeding time.
- ▶ Normal coagulation times.
- ▶ Clinical condition or medication associated with platelet dysfunction.

General Considerations

Acquired platelet dysfunction may result from defects in platelet adhesion, aggregation, secretion, or procoagulant function. Drugs, liver or renal disease, cardiopulmonary bypass, antiplatelet antibodies, acquired vWD, dysproteinemias, and myeloproliferative or lymphoproliferative disorders

(acute and chronic) may be associated with impairment of platelet function, as measured by the bleeding time or by abnormal tests of platelet aggregation. The clinical importance of the laboratory abnormalities in these diverse clinical conditions is not always clear. Bleeding depends not only on the severity of the defect but also on the presence of vascular injury and other hemostatic defects. Typical manifestations reflect impaired platelet function with mucocutaneous bleeding and excessive posttraumatic bleeding. Petechiae are rare unless thrombocytopenia is also present. Spontaneous soft tissue hematomas and joint bleeding are rare.

Thromboxane A_2 is an important mediator of platelet secretion and aggregation. Aspirin irreversibly acetylates and inactivates cyclooxygenase, thus preventing the production of prostaglandins, including thromboxane A_2 . Most individuals who take aspirin will have a slight prolongation of baseline bleeding time that may persist for several days, but marked prolongation or clinical bleeding owing to platelet dysfunction is rare at doses used in most clinical situations, although chronic use may be accompanied by easy bruising and mucosal bleeding. Patients with other hemostatic defects, however, may experience marked prolongation of bleeding time and clinical bleeding if they take aspirin. Increased GI tract bleeding is common in patients chronically taking high doses of aspirin, but this is due to its irritant effect on the mucosa rather than its effect on platelet function. The effect of aspirin on bleeding following major surgery or invasive procedures is controversial. While other nonsteroidal anti-inflammatory agents reversibly inhibit cyclooxygenase, these rarely prolong the bleeding time or induce clinical bleeding even in patients with severe coagulation defects.

Dextran is used occasionally for its antiplatelet effect in preventing postoperative deep vein thrombosis without increasing postoperative blood loss. Ticlopidine and clopidogrel are newer antiplatelet agents that inhibit ADP-induced platelet aggregation and prolong the bleeding time, and these occasionally may cause increased mucosal bleeding or bruising. Both agents appear to have irreversible effects on platelet function, requiring 7 days for normal platelet function to appear after withdrawal of the drugs (see Table 39–2). Platelet glycoprotein IIb/IIIa inhibitors are used for treatment of acute coronary ischemia, usually in combination with anticoagulants or fibrinolytic agents, and work by preventing fibrinogen-mediated platelet aggregation. β -lactam antibiotics given at high doses for a prolonged period of time may affect platelet function and can cause bleeding. However, most patients with overt bleeding have multiple contributing problems and can be managed without discontinuing the antibiotic. Many other drugs have been linked to prolongation of the bleeding time but rarely result in clinical bleeding.

Renal failure is frequently associated with abnormal platelet function, as measured by the bleeding time and by platelet aggregation tests. Impaired platelet function appears to result from biochemical alteration of intrinsically normal platelets, although the precise mechanisms have not been

elucidated. Severe anemia seen with renal failure can contribute to prolongation of the bleeding time. Bleeding manifestations attributed to uremia include purpura, epistaxis, and menorrhagia, but the risk of bleeding does not correlate well with laboratory assessment of platelet function. With adequate dialysis and generally improved care of uremic patients in the past 25 years, bleeding may not be increased significantly compared with those without renal failure.

Cardiopulmonary bypass induces both thrombocytopenia and transient platelet dysfunction. Platelet activation while the platelets circulate through the bypass circuit results in a state of functional “refractoriness” that usually reverses within the first few postoperative hours. Multiple mechanisms appear to be responsible for the observed changes in platelet membranes, granule content, and functional activity following bypass. Modest transient coagulation factor deficiencies—owing mainly to hemodilution coupled with heparin and protamine use—may result in prolongation of coagulation times. Bleeding following cardiopulmonary bypass therefore may result from multiple defects in hemostasis, including inadequate surgical hemostasis.

Acquired hematologic disorders cause platelet dysfunction through production of intrinsically abnormal platelets (eg, myeloproliferative disorders, myelodysplastic syndromes, acute leukemias, or hairy cell leukemia), or through production of abnormal substances that interfere with platelet function (eg, immunoglobulins in myeloma or Waldenström’s macroglobulinemia; rarely, immune-mediated thrombocytopenia), or from abnormalities in vWF (acquired vWD, seen in aortic stenosis, myeloproliferative and lymphoproliferative disorders, collagen vascular diseases, and angiodysplasia). Clinical bleeding is more often the result of associated hemostatic defects or other hematologic abnormalities, such as severe anemia, thrombocytopenia, marked leukocytosis, or hyperviscosity. Thrombotic sequelae also may result from abnormal platelet function, particularly in the myeloproliferative disorders.

Clinical Features

A. Symptoms and Signs—Mucosal bleeding, ecchymoses, or excessive posttraumatic or surgical bleeding in the absence of thrombocytopenia or abnormal coagulation times should suggest the possibility of an acquired defect of platelet function.

B. Laboratory Findings—In most cases, the underlying condition of the patient and medication use are obvious, and minimal laboratory evaluation is needed to confirm the presence of platelet dysfunction. The bleeding time is a readily available *in vivo* test of platelet function that will identify most patients with significantly abnormal platelet function. *In vitro* platelet aggregation studies require significant technical experience for reliable results and should be reserved for patients with bleeding suggestive of platelet dysfunction and an unexplained prolongation of the bleeding time—or a very suggestive history of bleeding without prolongation of the bleeding time. Bleeding time and platelet aggregation

studies are influenced by multiple factors, and while they are useful for diagnosis in patients with significant bleeding, they are not reliable indicators of the risk of future bleeding.

Differential Diagnosis

Inherited disorders of platelet function usually are readily differentiated from acquired disorders by the presence of a long history of bleeding and the absence of underlying conditions associated with acquired platelet dysfunction. Mucosal bleeding, ecchymoses, or excessive posttraumatic and surgical bleeding may result from severe coagulation disorders, thrombocytopenia, excessive fibrinolysis, vascular injury, or multiple hemostatic defects. Prolongation of the bleeding time may result from severe anemia, thrombocytopenia, improper technique, or insignificant platelet dysfunction, and in the absence of bleeding suggestive of platelet dysfunction, it is not a reliable indicator of future risk of bleeding.

Treatment

Impaired platelet function in the absence of clinical bleeding usually requires no specific therapy even when invasive procedures are performed. If bleeding is present, or if the nature of an invasive procedure is such that any increased risk of bleeding is unacceptable, a number of therapeutic options are available depending on the underlying cause of the platelet dysfunction. Withdrawal of aspirin or other suspect drugs is usually adequate for management of drug-induced platelet dysfunction. Desmopressin may be useful for management of bleeding in patients with a wide variety of disorders of platelet function, including uremia, cardiopulmonary bypass, and liver disease. Cryoprecipitate infusions and correction of severe anemia with red blood cell transfusions or epoetin alfa (ie, erythropoietin), aggressive dialysis, and conjugated estrogens are other strategies for controlling bleeding in uremic patients with platelet dysfunction. Aprotinin is a plasmin inhibitor that reduces significant postoperative bleeding following cardiopulmonary bypass and also may decrease bleeding after liver transplantation.

Platelet transfusions are indicated in the treatment of severe bleeding when platelet dysfunction is due to drugs, cardiopulmonary bypass, or acquired intrinsic abnormalities of platelets (eg, leukemias, myelodysplasias, and myeloproliferative disorders) but are not helpful for management of bleeding in uremia. Avoidance of aspirin and other antiplatelet agents, correction of vascular defects, and treatment of the underlying disease process are the most important strategies for prevention and treatment of bleeding associated with platelet dysfunction.

Current Controversies and Unresolved Issues

The bleeding time has enjoyed widespread use as a screening test for patients requiring surgical procedures and as a diagnostic test in bleeding patients. The bleeding time may be affected by technique, the site and depth of the incision, the

presence of anemia, and characteristics of the supporting connective tissues regardless of the functional status of the platelets. A recent review of hundreds of studies of bleeding time produced no convincing evidence that the bleeding time is a useful predictor of bleeding in any clinical situation. Its main value is in diagnosing conditions associated with impaired platelet function, but even when platelet dysfunction is present, the bleeding time does not correlate well with clinical bleeding.

Desmopressin acetate has proved to be useful in shortening the bleeding time in a wide variety of platelet disorders, and it may decrease clinical bleeding as well. Conflicting reports on its efficacy and a lack of understanding of its mechanism of action in diverse diseases have limited its widespread use. In addition, a few case reports have suggested that desmopressin may contribute to thrombotic complications, particularly in elderly patients with cardiovascular disease. Antifibrinolytic agents may prove to have a role as adjuncts to other therapies for treatment of acquired platelet disorders, but the potential for thrombotic complications must be appreciated when considering their use.

▶ Thrombocytopenia

ESSENTIALS OF DIAGNOSIS

- ▶ Mucocutaneous bleeding; petechiae in severe cases.
- ▶ Decreased platelet count.
- ▶ Absence of other hemostatic defects.
- ▶ Associated condition leading to thrombocytopenia.

General Considerations

Thrombocytopenia may result from decreased production, increased destruction or utilization, or sequestration of platelets in the spleen (Table 17–8). Decreased production usually affects all hematopoietic cells and rarely results in isolated thrombocytopenia. Mechanical destruction of platelets is often accompanied by evidence of hemolysis with anemia, reticulocytosis, and red blood cell fragmentation on peripheral blood smear, as well as clinical manifestations of the underlying disease process. Immunologic destruction of platelets may occur as an isolated problem (eg, autoimmune thrombocytopenic purpura) or may result from drugs, transfusions, or disease states associated with the production of autoantibodies (eg, chronic lymphocytic leukemia, systemic lupus erythematosus, or HIV infection). Splenomegaly from any cause may result in thrombocytopenia and is often accompanied by anemia and leukopenia.

Clinical Features

The history and physical examination with attention to bleeding symptoms, medication usage, splenomegaly, and

symptoms and signs of underlying disorders often will reveal clues to the diagnosis.

A. Symptoms and Signs—Mucocutaneous bleeding is the most common bleeding manifestation of thrombocytopenia. Petechiae usually occur only with severe thrombocytopenia and may reflect the platelet's essential role in the maintenance of endothelial tight junctions. Spontaneous soft tissue hematomas and hemarthroses are distinctly unusual. The risk of serious bleeding depends on the cause and severity of the thrombocytopenia, the presence of other hemostatic defects or vascular injury, and the condition of the patient. In general, patients with thrombocytopenia owing to consumption, destruction, or splenic sequestration are at less risk for serious bleeding than patients with decreased production of platelets because decreased platelet survival results in production of a younger, more functional population of platelets. The most feared complication of severe thrombocytopenia is CNS hemorrhage, which is rare unless the platelet count is less than 10,000/ μ L and there are other predisposing factors, such as leukemic infiltration, marked leukocytosis, or other vascular injury. Bleeding manifestations associated with various degrees of thrombocytopenia are shown in Table 17–9.

B. Laboratory Findings—Review of the complete blood count and peripheral blood smear is essential to evaluate associated abnormalities in other blood cell lines and to exclude the possibility of pseudothrombocytopenia owing to in vitro platelet clumping in the presence of EDTA anticoagulant. Other instances of artifactual thrombocytopenia may be due to platelet satellitism around neutrophils or may occur when many giant platelets are present that may not be counted as platelets by automated cell counters. Isolated thrombocytopenia is most often the result of immunologic destruction of platelets but may be found in some patients with mild hypersplenism, acute alcohol intoxication, or early acute leukemia and in the rare patient with isolated amegakaryocytic thrombocytopenia. The presence of fragmented red blood cells suggests the possibility of intravascular mechanical trauma to cells, as seen with DIC, thrombotic thrombocytopenic purpura–hemolytic uremic syndrome, eclampsia (ie, HELLP syndrome), or mechanical prosthetic heart valves. Abnormal white blood cells may indicate the presence of leukemia or lymphoma. The combination of nucleated red blood cells and immature white blood cells in the peripheral smear, a *leukoerythroblastic* picture, suggests the possibility of bone marrow infiltration from myelofibrosis or metastatic carcinoma. Macrocytosis and pancytopenia should suggest the possibility of vitamin B₁₂ or folate deficiency.

The PT and aPTT should be determined to detect conditions such as DIC or thrombocytopenia associated with liver failure. Bone marrow biopsy and aspiration are useful for evaluation of platelet production and should be performed when the diagnosis is not certain or if confirmation of a specific diagnosis (eg, leukemia, aplastic anemia, or metastatic carcinoma) is essential to proper management.

50,000–100,000	Minimal bleeding even with surgery unless platelet dysfunction is present
30,000–50,000	Increased bleeding with surgery or trauma*
20,000–30,000	Occasionally associated with easy bruising or other minor spontaneous bleeding*
10,000–20,000	Epistaxis, petechiae, menorrhagia, gum bleeding
<10,000	Increased gastrointestinal blood loss, spontaneous life-threatening bleeding [†] (eg, intracranial hemorrhage, hematuria, melena, hematemesis)

*Minimal in patients with immune thrombocytopenia or other consumptive disorders.

[†]Life-threatening hemorrhage usually occurs only with underlying vascular defect or if a second hemostatic defect is present (including aspirin ingestion).

Differential Diagnosis

The finding of a normal platelet count in the presence of palpable or nonpalpable purpuric skin lesions (eg, ecchymoses or petechiae) should suggest the possibility of increased intravascular pressure, abnormalities or injury to blood vessels (eg, vasculitis), thromboembolic events (including septic thromboemboli), decreased integrity of the microcirculation and its supporting structures, or primary cutaneous diseases. Severe coagulation disorders may result in mucocutaneous bleeding but are easily distinguished from thrombocytopenia by the presence of markedly prolonged coagulation times and quantitatively normal platelets. Impaired platelet function and vWD should be considered when easy bruising and mucosal bleeding are present and can be identified in most cases by prolongation of the bleeding time in the absence of thrombocytopenia. Abnormalities of coagulation or platelet function rarely result in petechial skin lesions.

Treatment

The most important aspect of treatment is to reverse the underlying disease process. Platelet transfusions should be given only when the risk of bleeding and the probability of efficacy are sufficient to warrant the potential risks of blood component therapy. Prophylactic platelet transfusions are indicated for patients with decreased production of platelets with counts under 10,000/ μL to prevent fatal CNS hemorrhage. When life-threatening bleeding is present or invasive procedures are required, platelet transfusions may be useful if the platelet count is less than 50,000/ μL and no alternative therapies are available. When decreased platelet survival is present, platelet transfusions are not likely to effect a sustained rise in platelet count and should only be given if life-threatening bleeding is present or if an urgent invasive procedure is required. Platelet transfusions may be harmful in patients with thrombotic thrombocytopenic purpura–hemolytic uremic syndrome and heparin-associated thrombocytopenia and should be avoided unless active, life-threatening hemorrhage is present.

Medications such as aspirin that impair platelet function should be avoided when thrombocytopenia is present—with the exception of thrombotic thrombocytopenic purpura, in which antiplatelet agents may be indicated as part of therapy. Correction of severe anemia may decrease clinical bleeding in thrombocytopenic patients. Antifibrinolytic agents such as aminocaproic acid or tranexamic acid may decrease mucosal bleeding in chronically thrombocytopenic patients but should not be used if there is evidence of thrombosis (eg, in DIC) or hematuria. Alternatives to platelet transfusion for patients with bleeding owing to thrombocytopenia are outlined in Table 3–2.

Current Controversies and Unresolved Issues

Intravenous administration of human immunoglobulin (IVIG) may rapidly increase the platelet count in patients with immune-mediated thrombocytopenia. Its effect is postulated to be due to competitive blockade of macrophage receptors

for immunoglobulin, although other mechanisms may be important. Although it may rapidly increase the platelet count, its usefulness as therapy for immune thrombocytopenia is limited by only transient efficacy combined with its high cost in the face of a low risk of life-threatening bleeding in patients with autoimmune idiopathic thrombocytopenia. It is appropriate for use in patients with serious bleeding with this disorder as a temporizing measure while other therapies are being administered. Anti-D antibodies (Rh₀D immune globulin) also may be useful in the management of immune-mediated thrombocytopenia in patients who are Rh-positive, presumably by a similar mechanism (antibody-coated red blood cells block macrophage receptors). IVIG has not been proven to be useful in treatment of thrombocytopenia owing to platelet alloimmunization.

Alloimmunization to platelet-specific antigen or HLA antigens is a common sequela of repeated platelet transfusions and limits the response to subsequent platelet transfusions. For patients requiring long-term platelet support, prevention of alloimmunization is desirable in order to preserve the efficacy of transfusion therapy. Methods to minimize platelet alloimmunization include reducing the total number of all blood product transfusions, adhering to strict criteria for transfusing platelets, removing the source of the HLA sensitization (ie, white blood cells) before transfusion of any blood product (by filtration or irradiation), and using HLA-identical donors.

The optimal management of several conditions associated with thrombocytopenia is under active study. Treatment of these conditions should be undertaken in consultation with a hematologist to ensure accurate diagnosis and up-to-date treatment.

APPROACH TO THE BLEEDING PATIENT

When approaching a patient with a suspected bleeding disorder, it is important to assess quickly the prior personal and family history of bleeding, the pattern of bleeding, and the pattern of laboratory abnormalities. If the personal or family history is suggestive of an inherited bleeding disorder, the apparent inheritance pattern, bleeding manifestations, and laboratory abnormalities should suggest the most likely diagnoses. If the personal and family histories are negative, defective hemostasis is most likely acquired, although some of the milder inherited disorders of hemostasis may not be manifested until significant trauma or surgery occurs later in life. The pattern of bleeding may suggest the nature of the hemostatic defect (Table 17–10), and the pattern of laboratory abnormalities (Table 17–11) will help to localize defects in the hemostatic system.

CURRENT CONTROVERSIES & UNRESOLVED ISSUES

Gastrointestinal Hemorrhage

For more than a century, critically ill patients have been observed to have a high rate of GI hemorrhage. Preventive strategies emerged to decrease this complication, including

Table 17-10. Approach to the bleeding patient by pattern of bleeding.

Pattern of Bleeding	Possible Disorders
Ecchymoses and mucosal bleeding; petechiae	Thrombocytopenia or platelet dysfunction von Willebrand disease Severe coagulopathies
Spontaneous hemarthroses, soft tissue hematomas	Hemophilia A and B, other severe coagulopathies
Posttraumatic or surgical bleeding	Thrombocytopenia or platelet dysfunction von Willebrand disease Coagulopathies Impaired vascular integrity Inadequate surgical hemostasis Massive injuries
Generalized oozing from mucosal, venipuncture, surgical sites	Consumptive coagulopathies, DIC Excessive fibrinolysis Severe thrombocytopenia or platelet dysfunction

the use of antacids, histamine-2(H₂) receptor blockade, proton pump inhibitors (PPIs), and mucosal protective agents. However, trials of these therapeutics have yielded conflicting results, with some studies showing a benefit in selected high-risk patients (eg, patients with mechanical ventilation, hemostatic defects, or prior GI hemorrhage), others

showing an increase in hospital-acquired pneumonia and complications related to drug interactions, and others demonstrating no difference in any clinical outcome. Until this issue is resolved, preventive therapy with mucosal protectant agents (eg, sucralfate), H₂ blockade, or PPIs can be considered for patients identified to be at high risk for bleeding. Underlying hemostatic defects should be treated according to the general principles discussed earlier. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) and low-dose aspirin increases the risk of GI bleeding independent of their effects on platelet function. When *Helicobacter pylori*-associated ulcer is identified, long-term treatment with omeprazole or eradication with antibiotics can decrease the risk of recurrent bleeding associated with aspirin or NSAIDs.

Gastroesophageal variceal hemorrhage is the most serious form of GI hemorrhage, with 30% mortality observed with first episodes. Varices occur in the setting of severe liver disease so that—in addition to mechanical problems—coagulation abnormalities, quantitative and qualitative platelet defects, and excessive fibrinolysis contribute to bleeding. Management of acute variceal bleeding requires GI specialists who can diagnose and treat varices endoscopically (eg, ligation, sclerosis, or balloon tamponade) but also includes medical therapy with vasoactive agents such as beta-blockers, nitrates, vasopressin, and somatostatin analogues (eg, octreotide and vaptotide). When these approaches fail, transjugular or surgical shunting may be required to control bleeding.

Perioperative Bleeding

Preoperative evaluation of hemostasis should include medical history with attention to adequacy of hemostasis—spontaneous bleeding or bruising or unexpected bleeding

Table 17-11. Approach to the bleeding patient by pattern of screening laboratory abnormalities.

Abnormal Test	Possible Defects
PT only	Factor VII deficiency (inherited, vitamin K deficiency, warfarin effect) or inhibitor
aPTT only*	Factor XII, HMW kininogen, prekallikrein, XI, IX, or VIII deficiency or inhibitors to these factors; lupus anticoagulant
PT and aPTT	Deficiency or inhibitor of factor X, V, II (prothrombin), fibrinogen Multiple factor deficiencies (liver disease, DIC, consumptive coagulopathies, vitamin K deficiency, high dose warfarin effect)
Bleeding time prolonged	Platelet dysfunction or thrombocytopenia, improper technique
All screening tests normal	Other coagulation abnormalities: Factor XIII deficiency Excessive fibrinolysis Paraproteinemia Vascular defect (including inadequate surgical hemostasis) Supporting tissue abnormality

*Deficiencies of factor XII, HMW kininogen, prekallikrein, and lupus-type inhibitors prolong the aPTT but do not cause bleeding.

Table 17-12. Preoperative laboratory screening.

Bleeding History	Type of Surgery	Recommended Laboratory Tests
No suggestive history	Minor (dental, skin biopsy)	None
No suggestive history	Major	Platelet count, aPTT
Possible bleeding history	Major, bypass pump	PT, aPTT, platelet count, bleeding time; if normal, factor XIII assay, euglobulin clot lysis time
Positive bleeding history	Minor or major	Same as above; if negative: thrombin time, factor assays for VIII, IX, XI, alpha ₂ -antiplasmin assay, post-aspirin bleeding time

after dental extractions or prior surgical procedures suggests the presence of an underlying hemostatic defect. Medical illnesses such as liver or renal disease, myeloproliferative disorders, and paraproteinemias predispose patients to excessive postoperative bleeding. In the absence of symptoms of a bleeding disorder or such medical illnesses, the value of routine laboratory screening has been questioned. Most postoperative bleeding results from surgical or technical problems and not from hemostatic defects. The PT and aPTT are not sensitive enough to detect mild defects and, when abnormal in a patient with no previous bleeding history, may not accurately predict the risk of bleeding. Whether any laboratory screening should be done depends also on the type of planned procedure (ie, minor versus major, use of cardiopulmonary bypass, neurosurgical procedures, etc.). [Table 17-12](#) outlines suggested laboratory screening prior to surgery. If abnormalities in screening tests are detected, further evaluation should be done to define the precise abnormality.

Intraoperative hemostasis with ligature, cautery, and topical thrombogenic substances (eg, fibrin glue or topical bovine thrombin) is essential to prevent postoperative bleeding. In the postoperative period, excessive bleeding may be due to a hemostatic defect that was not detected by the screening tests. Mild coagulation factor deficiencies may not prolong the aPTT, particularly if other factors are elevated (eg, factor VIII increases in acute inflammatory states and may mask mild deficiency of other factors). Preoperative use of aspirin or other antiplatelet drugs may increase postoperative bleeding; if bleeding is severe and the bleeding time is prolonged, desmopressin or platelet transfusions may be required for control of bleeding. Surgery on the prostate gland or uterus may be associated with localized hyperfibrinolysis with excessive bleeding. Antifibrinolytic therapy with aminocaproic acid can be considered for control of bleeding (5-g loading dose followed by 1 g/h intravenously or orally until bleeding has stopped), although there is some risk of thrombi developing in the ureters (following prostate surgery) that are resistant to lysis. Acute DIC may occur for many reasons following surgery, or decompensation of previously

compensated DIC may develop as a result of tissue factor release during surgery ([Table 17-13](#)).

Acute renal failure owing to hypotension, massive blood loss, or medications can result in platelet dysfunction, which is exacerbated by anemia. Posttransfusion purpura with thrombocytopenia may occur in previously sensitized individuals. The use of intraoperative bovine thrombin as a hemostatic agent may precipitate the development of antibodies to thrombin and factor V. There does not appear to be any significance

Table 17-13. Causes of postoperative DIC.

Sepsis
Hypotension
Acute hepatic necrosis
Release of bone marrow thromboplastins
Liver injury (drugs, hypotension, blunt or penetrating trauma)
Tissue factor release during surgery
Peritoneovenous shunting
Use of cell saver device with excessive suction
Release of tissue factor from placenta
Abruptio placentae
Amniotic fluid embolism
Septic abortion
Placenta previa
Retained dead fetus
Trauma
Fat embolism
Brain injury
Extensive soft tissue injury
Burns
Decompensation of chronic (compensated) DIC
Dissecting aortic aneurysm
Kasabach-Merritt syndrome
Cancer
Infusion of activated clotting factors
Prothrombin complex concentrates
Recombinant activated factor VII

to the antithrombin inhibitor; however, factor V inhibitors may cause bleeding. Factor VIII inhibitors also may develop postoperatively; the mechanism for this has not been defined. Hetastarch, a plasma volume expander, may cause persistent coagulation abnormalities, particularly in elderly patients, those with preexisting hemostatic defects, or with prolonged use. If bleeding is severe, plasmapheresis to remove these large molecules may be required to control bleeding.

When postoperative bleeding is encountered, immediate evaluation with history (to uncover preexisting risks and medication use) and laboratory testing (ie, PT, aPTT, and platelet count) should be done. Medical treatment of hemostatic defects will depend on the specific abnormalities identified. If history and screening laboratory tests are unrevealing, consideration should be given to reexploration of the surgical site to identify adequacy of surgical hemostasis.

Perioperative management of patients with inherited bleeding disorders requires preoperative collaboration among the surgeon, anesthesiologist, hematologist, and blood bank to ensure that optimal hemostasis is achieved during and after surgery. The details of therapy will depend on the nature of the specific disorder, the type of surgical procedure, and whether any additional medical complications are present.

Posttraumatic Bleeding

In the setting of massive trauma, multiple pathophysiologic processes contribute to severe bleeding, including multiple vascular defects, massive transfusion with dilution of coagulation factors and platelets, DIC with acceleration of fibrinolysis, and hypotension. The presence of coagulopathy following trauma increases the risk of mortality. Severe coagulation disturbances associated with trauma may result in adrenal hemorrhage, which can further exacerbate hypotension. Certain types of injuries are particularly associated with DIC: fat embolism, brain injury, extensive soft tissue injury, and extensive burns. Pelvic ring fractures are associated with massive blood loss, often hidden owing to tracking of bleeding up into the retroperitoneal space. Control of bleeding in such circumstances may be difficult, even with aggressive blood product support—with fresh-frozen plasma, platelets, red blood cells, and cryoprecipitate. rFVIIa has been used to treat massive hemorrhage in trauma patients with some success, but evidence supporting its use is primarily anecdotal. Further studies are necessary to determine which patients are most likely to benefit from rFVIIa and at what dose it should be administered.

Psychiatric Problems

18

Stuart J. Eisendrath, MD
John R. Chamberlain, MD

ICUs provide the most advanced technology available to patients with the most serious medical and surgical illnesses. Perhaps as a consequence, these facilities are often associated with some of the most stressful psychiatric conditions within the hospital. Indeed, some physicians have jokingly referred to the ICU as the “intensive scare unit.” These conditions in ICUs may affect both patient and staff. This chapter will describe some of the significant problems.

Most patients entering the ICU will attempt to manage the stress of their stay with their characteristic coping mechanisms. Some regression generally occurs, however, as most patients experience stressors such as fear of death, enforced dependency, and potential permanent loss of function. Separation from family and the loss of autonomy that accompanies medical treatment in the ICU frequently lead to further psychological regression. They may try to cope with stress by suppressing their feelings, using humor to laugh at stressful aspects of their situation, or trying to anticipate a return to good health. If these techniques fail, the individual may turn to more primitive mechanisms such as projection, passive-aggressive maneuvers, acting-out behavior, and gross denial of illness. All this takes place during a time when the patient must deal with serious and usually multiple medical problems.

A number of clinical syndromes may develop as a result of the stressors inherently associated with occupancy of a bed in the ICU. This discussion will focus on several that may adversely influence recovery. *Delirium*, the so-called ICU psychosis, generally is not due to psychological stress alone but develops in association with altered brain function. *Anxiety* may occur at any time during the patient’s stay in the ICU—entry, midpoint, or discharge. *Depression* also may occur at any point during the patient’s stay but most often occurs after the immediate threat to life has been dealt with and the patient must contemplate the subacute prognosis and ultimate outcome of the disease. Finally, we will discuss how the ICU environment affects the staff working there.

▶ Delirium

ESSENTIALS OF DIAGNOSIS

- ▶ Waxing and waning of consciousness.
- ▶ Disorganized thinking.
- ▶ Perceptual disturbances such as visual hallucinations.
- ▶ Disorientation.

General Considerations

Early reports from ICUs gave rise to the diagnosis of an *ICU syndrome* characterized essentially as a delirious state with psychotic features such as hallucinations. It was believed to be due to the stress an ill individual felt in a foreboding environment with little privacy, lack of sleep, and sensory overload. Whether or not this syndrome actually existed as a specific entity, current research indicates that delirium occurring in the ICU is most likely due to factors similar to those patients experience on general medical and surgical wards—with the difference that ICU patients may have more severe reactions because of their more severe illnesses.

Stress may play some role in producing delirium, but it is typically only a contributing one. Other factors that alter brain function are usually the primary etiologic agents. The critical care physician should not automatically attribute delirium to stress. Remembering that delirium is an organic dysfunction of the CNS will facilitate the search for likely causes and the provision of appropriate treatment. This aggressive approach is justified given the serious impact of delirium on morbidity and mortality in hospitalized patients. Studies have shown that patients suffering an episode of delirium have an increased risk of death, a longer hospital stay, and a greater need for subsequent nursing home placement. There are at least three broad hypotheses

relating to the production of delirium. Any one or any combination of these factors may cause delirium in a particular patient.

A. Increased Central Noradrenergic Production—Drug or alcohol withdrawal states are the most common condition producing delirium in the hospital and probably also the most common condition responsible for increased noradrenergic discharge. Locus ceruleus–controlled production of brain catecholamines is believed to play a central role in this type of delirium.

B. Dopamine and Cholinergic Systems—Imbalance of brain dopamine and cholinergic systems can be recognized in central anticholinergic syndromes produced by atropinic agents. These may produce a relative excess of dopaminergic activity, giving rise to an agitated delirium. This hypothesis also provides a framework for understanding how dopamine-blocking agents such as haloperidol may act by restoring the relative balance between dopaminergic and cholinergic systems that is disturbed in delirium. Delirium-producing agents such as the amphetamines, which cause a shifting of the balance toward the dopaminergic side, also can be better understood in this framework.

C. Toxic Causes of Delirium—A third framework for understanding delirium involves the environment brain cells operate in. Side effects of medications or endotoxins associated with bacterial infections can affect neuronal functioning. Similarly, conditions such as hyperthermia or hypoxia can disturb functioning throughout the CNS. Many of the preceding abnormalities are believed to affect the midbrain particularly; this may, in turn, lead to fluctuations in the reticular activating system with alterations in level of consciousness and the ability to attend to stimuli in the environment—a key feature of many cases of delirium.

D. Multifactorial Features—In the ICU there are typically numerous factors that play a role in producing delirium. A patient with asthma and pneumonia provides an example—with fever and hypoxia as well as high levels of circulating corticosteroids and catecholamines. Although single causes should be sought diligently, it is unusual to be able to identify and correct just one causative factor of delirium.

Clinical Features

The clinical criteria for delirium in the ICU setting consists of a number of signs and symptoms. Typically, the patient has a waxing and waning of consciousness—may be somnolent at one moment and highly alert and agitated a short time later. The patient's ability to attend to external stimuli fluctuates over time. Delirious patients usually have disorganized thinking manifested by rambling or incoherent speech. Patients frequently have perceptual disturbances such as misperceptions of real objects (illusions) or frank hallucinations. Patients usually have disorders in normal sleep-wake cycles and altered psychomotor behavior (either agitation or retardation).

Patients also typically have disorientation to time, place, and situation. Memory impairment, when present, is generally global for both recent and remote events. Delirium usually develops within hours to days. The presence of delirium signifies primarily organic brain dysfunction and is not a manifestation of psychological distress alone.

The signs and symptoms listed in the preceding paragraph are useful in making a clear-cut diagnosis. Unfortunately for that purpose, however, many ICU patients present only some of the criteria and may require ongoing vigilance. Indeed, one of the keys to diagnosis in these patients is repeated observations over time. The waxing and waning of consciousness so common in delirious patients requires serial monitoring because a patient may appear quite lucid at one moment and quite confused a half hour later. Nursing staff often have the best data on mental status because of their continuing contact with the patients.

The physician should examine specifically for the presence of delirium. This involves performing some type of specific cognitive assessment such as the Folstein Mini Mental Status Exam. However, intubated patients can be difficult to assess with this instrument. Newer diagnostic instruments such as the Cognitive Test for Delirium (CTD) can be very useful in this setting. This instrument was developed for use in critical care settings and reliably distinguishes patients with delirium, dementia, and acute psychiatric illness. This type of examination tests the patient's ability to attend to stimuli, concentrate on a task, comply with simple memory requests, demonstrate language capabilities through auditory comprehension, and show orientation to time and situation. More important, this type of test allows the examiner to detect cognitive deficits that otherwise would go unrecognized. For example, psychiatric consultation may be sought for a patient who is poorly compliant with the medical regimen. Many of these patients prove to be suffering from delirium and have significant memory deficits that make compliance impossible—they cannot remember instructions for 30 seconds.

The patient may appear quietly confused and in a daze. This type of delirium may be easily missed because the patient presents no behavioral problem. Some delirious patients, on the other hand, present behavioral problems ranging from pulling out catheters and lines to biting or striking members of the staff. These patients appear agitated, fearful, and restless. They may be hallucinating and intensely involved in their psychotic states. One physician described his state of mind during his stay in the ICU as follows: "I saw a vulture flying over me. I worried about any drop of blood spilling onto the sheets because I knew that would bring the vulture down for the attack." This physician had been fearfully watching the ceiling for several days but never told the doctors or nurses because "they couldn't do anything, and they'd think I was crazy."

Many delirious patients resort to primitive psychological coping mechanisms. They may exhibit massive denial of any medical problem or externalize their problem as being the fault of somebody else rather than of their illness. Delirious patients often project anger about their helplessness onto

their caregivers. This gives rise to paranoid ideation about caregivers trying to poison or otherwise harm them. Other delirious patients—like the doctor in the preceding example—experience hallucinations that are often threatening. These hallucinations usually are visual and occur without any external stimulus. Many patients will have visual illusions that involve a misperception of actual external stimuli. For example, one patient was convinced that the intravenous standard in his room was actually a person poised to attack him.

Differential Diagnosis

In the critically ill patient—especially an intubated patient, for whom communication is most difficult—delirium may appear to be similar to other conditions.

A. Anxiety—Anxiety occurs quite frequently in the ICU. In some instances, anxiety may occur in patients who have delirium. Individuals with cognitive processing impairment may be quite difficult to reassure. Thus many patients may be anxious in the ICU, but only some will also have delirium—although the majority of delirious patients will experience anxiety and fear. Patients without delirium do not have the significant cognitive impairment and deficits in reality testing (such as hallucinations) so common in delirium.

B. Underlying Psychosis—ICU patients may have an underlying psychosis (eg, schizophrenia) that can be confused with delirium. Schizophrenic patients rarely have visual hallucinations. Visual hallucinations usually are present owing to an organic cause that requires investigation. Schizophrenic patients who have paranoid delusions generally have well-formed ones that are fixed over months and years. Delirious patients, on the other hand, have rapidly developing delusional beliefs that shift over hours to days. Most schizophrenic patients have a history of psychiatric treatment and neuroleptic medications. Delirious patients generally do not have such a history. Furthermore, schizophrenic patients typically have onset of illness by the early to middle twenties, characterized by a progressive decline in function. In contrast, delirium often affects older patients and causes a precipitous decline in mental status and functioning.

C. Neuroleptic Malignant Syndrome—Schizophrenic patients—or any patient who has received a neuroleptic medication—are at risk for development of *neuroleptic malignant syndrome*, characterized by altered mental status, autonomic instability, and extrapyramidal symptoms that are often severe (eg, lead-pipe rigidity). This syndrome can develop particularly with high-potency neuroleptic medications when the individual also suffers from complicating conditions such as fever and dehydration. Diagnosis in these patients is often assisted by elevated creatine phosphokinase (CPK) levels, myoglobinuria, and decreased serum iron levels.

D. Depression—The subdued, quiet delirious patient may be mistaken for a depressed one. The depressed patient, however, usually has the depressive view of the world associated with

that disorder along with symptoms such as a sense of worthlessness, guilt, and global pessimism. In some instances, small test doses of dextroamphetamine (eg, 2.5 mg twice daily) may allow the clinician to differentiate depressive and delirious patients. The depressed patient may become less depressed after medication, whereas the delirious patient usually becomes more agitated. A past psychiatric history of depressive disorder also may help to differentiate the disorders.

E. Personality Disorder—It is not unusual for staff to apply the pejorative label *personality disorder* to a patient who fails to comply with their requests. Whenever such a diagnosis is contemplated, one should seek confirmation from family or friends. Personality disorders represent longstanding patterns of maladaptive behavior. They do not develop acutely, although they may be exacerbated by the stress of illness. They may emerge in patients after the immediate threat to life has passed. Psychiatric consultation is often helpful in confirming this diagnosis.

F. Dementia—One way of conceptualizing the difference between dementia and delirium is by applying the analogy of acute and chronic renal failure. Delirium represents acute cerebral insufficiency, whereas dementia is typically a chronic condition. Dementia syndromes may represent a variety of conditions (eg, multi-infarct dementia or Alzheimer's disease) characterized by generalized diminution of intellectual functioning. Most dementias—except for the subcortical ones, such as in Parkinson's disease—show some evidence of cortical dysfunction such as aphasia or apraxia. Dementia syndromes develop over months or years rather than hours or days. The patient's family should be consulted to clarify baseline mental functioning.

A key finding is that delirious patients typically have a waxing and waning of consciousness and the ability to attend to stimuli; deficits in demented patients generally are fixed throughout the day until nightfall, when “sundowning” may occur. It is quite common to see dementia patients who have preserved remote memory, whereas in delirium, all forms of memory may be impaired. It is unusual for dementia patients to suffer hallucinations, whereas delirious patients frequently have hallucinations.

Electroencephalograms may aid in the differentiation of delirium and dementia. The former often show generalized slowing, whereas the latter do not.

Treatment

A. Establish the Cause—The key to treatment of delirium is identification of its cause or causes whenever possible. Since delirium is usually an acute process, a vigorous investigation of reversible causes should be undertaken, much as one would investigate the cause of acute renal failure and attempt to correct it as rapidly as possible. Delirium should be regarded as an example of acute cerebral failure that is associated with significantly increased morbidity and mortality. There are studies in which patients with delirium had a

Table 18-1. Common causes of delirium in the ICU.

Drug or alcohol withdrawal or intoxication
Medication effects (eg, corticosteroids, cimetidine, lidocaine)
Hypoxia
Hypoperfusion
Infections (eg, systemic or central nervous system, HIV)
Structural lesions (eg, subdural hematomas)
Metabolic disorders (eg, electrolyte abnormalities, hypercalcemia, hyperglycemia)
Ictal or postictal states
Postoperative states
Fat emboli
Dehydration
Sleep deprivation
Environmental stress
Pulmonary embolism

markedly higher mortality rate than other patients (8% versus 1%; likelihood ratio = 2.3), a higher rate of admission, and a higher rate of institutionalization. Hospital stays often are prolonged by an average of 7 days in delirious patients.

There are many causes of delirium. The most common causes in the ICU are listed in Table 18-1. *Withdrawal states* are among the most common causes of delirium in the general hospital and always should be considered in assessing the patient. In some instances, the patient may conceal or be unable to provide information about drug or alcohol use. Family and friends will be able to help to establish this history. In some instances, considerable probing may be necessary. For example, one postoperative vascular surgery patient denied the use of alcohol or drugs; persistent questioning, however, revealed that she had increased her usual daily 0.5-mg alprazolam dosage fourfold in the month prior to surgery because of anxiety. When she entered the hospital, this medication had been discontinued. Two days later, she had a florid delirium that responded rapidly to alprazolam. The benzodiazepines are the prototypical agents for the treatment of alcohol and sedative withdrawal. They are safe in large doses, prevent seizures, and are well tolerated. An important feature for ICU use is that they are available in oral, parenteral, and sublingual formulations.

Medications given in the ICU frequently can produce significant psychoactive effects. Table 18-2 lists a number of drugs that have been established as having these effects. Switching medications certainly is one of the easiest changes to make in trying to manage a delirious patient.

Other causes such as *hypoxia* and *hypoperfusion* need to be reversed before improvement from delirium can occur. Delirium may be the first sign of an *infectious process* and should suggest that possibility when no other cause is discovered. For example, a postoperative patient who develops delirium without any identifiable cause may be suffering from a wound abscess that only becomes apparent several days later.

Table 18-2. Drugs that may cause delirium in the ICU.

Acyclovir	Fluoroquinolone antibiotics
Amiodarone	Ganciclovir
Amphetamines	Histamine H ₂ blockers
Amphotericin B	Interferon alfa
Anticonvulsants	Isoniazid
Antidepressants	Ketamine
Antihistamines	Ketonazole
Atropine and other anticholinergics	Levodopa
Barbiturates	Lidocaine
Benzodiazepines	Methylphenidate
Beta-adrenergic blockers	Metoclopramide
Cimetidine	Metronidazole
Corticosteroids	Nonsteroidal anti-inflammatory drugs
Cycloserine	Opioids
Cyclosporine	Procaine derivatives
Digitalis glycosides	Propafenone
Dronabinol	Quinidine
Epoetin alfa (erythropoietin)	Trimethoprim-sulfamethoxazole

Modified from: Drugs that cause psychiatric symptoms. *Med Lett Drugs Ther* 1988;40:21-24.

B. Nonpharmacologic Management—Once one or more causes are identified, the primary goal of treatment is to reverse the disorder. In a significant number of cases of delirium, no specific cause can be identified; in others, the identified cause cannot be reversed easily (eg, an asthmatic on high-dose corticosteroids). In these instances, symptomatic treatment may be required. Family may be enlisted to spend time at the bedside to provide an orienting stimulus. Other environmental measures may include providing a clock, calendar, and soft music. Staff should attempt to provide adequate day-night orientation and allow the patient to sleep at night as much as possible. Four-hour periods that allow for all stages of sleep may be the most beneficial.

C. Pharmacologic Management—For many patients with delirium, the aforementioned measures will not be enough. Medications become indicated when behavioral control is necessary or when distress is severe. For example, a quietly delirious patient suffering from frightening hallucinations is a candidate for pharmacotherapy.

1. MANAGEMENT OF WITHDRAWAL SYNDROMES—A number of principles must be considered in initiating therapy. If a withdrawal state is present, the appropriate agent to cover the withdrawal should be given as soon as possible. Sufficient medication must be given to abort the withdrawal process and keep it from reemerging. Alcohol withdrawal is the most common of these conditions. A frequent mistake is to underdose with a benzodiazepine early in the withdrawal process and then try to catch up with a full-blown delirium later. Early substantial doses of long-acting agents such as

diazepam may provide timely control. However, lorazepam may be preferred in patients with liver disease because its metabolism (via glucuronide conjugation) is less affected in such individuals.

2. MANAGEMENT OF DELIRIUM OF UNKNOWN CAUSE—

a. Benzodiazepines—When the cause of delirium is not known but withdrawal from sedatives or alcohol is suspected, one might consider a pharmacologic probe by giving a benzodiazepine such as 1–4 mg lorazepam. If the patient's condition worsens, that essentially rules out alcohol and most benzodiazepine withdrawals. A different course of pharmacotherapy then must be pursued. In addition, these agents are preferred for the agitation present with anticholinergic overdose or when there is a need to raise the seizure threshold. Relatively short-acting agents with no active metabolites, such as lorazepam, are preferred for this application.

b. Haloperidol alone or with lorazepam—Haloperidol is often administered intravenously even though the intravenous form is not approved by the Food and Drug Administration (FDA). Before initiating haloperidol, some cardiovascular considerations must be addressed (discussed below). Initial dosage depends on the age and size of the patient. A small elderly woman may benefit from 0.2 to 0.5 mg haloperidol every 4 hours. A younger 70-kg man may start with 1–2 mg every 2 hours or even higher doses. A more agitated patient should receive larger doses, and some studies have advocated an initial infusion of 5–10 mg followed by a continuous infusion at a rate of 5–10 mg/h. This medication has a mean distribution time of 11 minutes and a half-life of 14–17 hours. If the first dose fails to produce significant improvement, the dose should be repeated at 30-minute intervals to allow time for distribution to occur. The second dose is usually twice the first dose. If monotherapy fails to produce the desired effect, one may add 0.5–1 mg lorazepam. This combination has been found to improve symptom control while decreasing the side effects of treatment. If the patient remains agitated 30 minutes following the addition of lorazepam, one may give doses of haloperidol up to 5 mg and lorazepam 0.5–2 mg at 30-minute intervals until control is established. In many instances, control of delirium can be achieved with 5–30 mg haloperidol and 2–4 mg lorazepam. Some patients may require amounts substantially above these levels. Doses up to 975 mg haloperidol in a 24-hour period have been reported.

Once control is established, approximately half the first 24-hour total dosage can be given on the following day in equally divided doses. Each subsequent day's dosing is reduced by half until further dosing is no longer necessary. The goal, once symptom control is achieved, is to taper the patient to the minimally required dose. Many cases of delirium will clear within a few days, particularly when the cause has been reversed.

When giving intravenous haloperidol, several points need to be considered. Generally speaking, intravenous haloperidol imposes a much lower risk of extrapyramidal side effects than oral or intramuscular forms. The reason is

not completely clear. It may be that the intravenous route allows brain receptors to bind with different forms of the drug. It is possible also that most patients who receive intravenous haloperidol have some form of central anticholinergic process by virtue of their delirium that provides a protective effect against extrapyramidal reactions. Nonetheless, when giving haloperidol, the clinician should continue to monitor the patient for adverse reactions, which include dystonias, akathisia, and neuroleptic malignant syndrome.

The incidence of cardiovascular side effects from haloperidol is very low. Haloperidol has been found to prolong the QT interval and has been linked with rare episodes of torsade de pointes, ventricular fibrillation, and sudden death. These effects generally seem to occur with high doses of the medication and have led to recommendations for establishing a baseline ECG and subsequent monitoring of the QT interval. Additional recommendations are to monitor serum magnesium and potassium. Most cases of hypotension with haloperidol have been in association with hypovolemia. Administering the medication in a slow infusion over 5–10 minutes may be helpful in preventing hypotension, so intravenous pushes should be avoided.

c. Newer agents—Newer agents such as the atypical antipsychotics (including risperidone, quetiapine, and olanzapine) are receiving increased attention in the treatment of delirium. They have fewer neurologic side effects (eg, extrapyramidal symptoms) than the typical antipsychotics (eg, haloperidol), particularly in elderly and seriously medically ill individuals who are most at risk for delirium. In one prospective, double-blind trial, haloperidol and risperidone were equally efficacious in the treatment of delirious patients. In a small open-label trial, low doses of risperidone (average maintenance dose of 0.75 mg/day) improved cognitive and behavioral symptoms of delirium. Olanzapine was compared with haloperidol in a randomized, prospective trial. While both groups demonstrated similar clinical improvement and a lessened need for benzodiazepine sedation, 6 of 45 patients treated with haloperidol were found to have extrapyramidal symptoms, whereas no patients treated with olanzapine developed extrapyramidal or other side effects. Quetiapine has been found, in small studies, to be effective for the treatment of delirium and well tolerated when used at low doses. One drawback to atypical neuroleptic use is that only olanzapine and ziprasidone are currently available in immediate-release parenteral formulations.

d. Other pharmacologic interventions—When the combination of haloperidol (or another antipsychotic) and lorazepam fails to achieve control, additional interventions may be necessary, including sedation (with opioids, propofol, barbiturates, or benzodiazepines), pharmacologic paralysis, and mechanical ventilation. These measures, however, do not enhance the patient's sense of control, and if sedation is inadequate, they can be quite terrifying to the patient. A newer agent for sedation and analgesia in the critical care patient is dexmedetomidine, an α_2 -agonist. Reported advantages of this medication are minimal interference with

respiration and the ability for patients to be aroused easily. It is currently approved for infusions up to 24 hours in adults.

D. Social and Psychologic Management—A key consideration in managing delirium involves the psychological aspects. The patient's family often has major concerns about the prognosis for mental recovery. The physician should reassure both the family and the patient that the condition is usually reversible and that return to baseline mental functioning can be expected. Empathically telling the patient that the physician understands the confusion the patient feels may convey a real sense of hope. Encouraging the patient to report any strange phenomena such as hallucinations may make the patient feel more at ease. Similarly, informing the family that accusations and delusional ideas brought forth during an episode of delirium have no real meaning is obviously useful.

Current Controversies and Unresolved Issues

Delirium is such a heterogeneous entity that many issues remain to be delineated by prospective studies. Molecular mechanisms for delirium and the role of neurotransmitters need to be established. We still do not know what the optimal medications are for controlling delirium, the maximum daily dosage of haloperidol and other agents, and whether patients really benefit from large doses of medications or if the practice helps the staff more than the patient. The use of atypical antipsychotic medications in the elderly also requires further study because the available information suggests that use of at least some of these agents in elderly patients with dementia may be associated with an increased risk of cerebrovascular adverse events. Other questions relate to possible preventive measures, whether psychological factors alone can cause delirium in the absence of organic factors, and a possible final common pathway for all cases of delirium.

► Depression

ESSENTIALS OF DIAGNOSIS

- Depressed mood.
- Feelings of worthlessness and inappropriate guilt.
- Negative thinking.
- Recurrent thoughts or wishes for death or suicide.

General Considerations

Depression occurs in 20–42% of the medically ill. Any patient with a medical illness severe enough to require admission to the ICU faces a number of psychological issues, including real and potential losses. For example, the patient with myocardial infarction must deal with the threat to life as well as the potential loss of future health and normal function. These losses are enough to produce depressive symptoms in

many patients and sad feelings in most patients. An individual undergoing major surgery must deal with the loss of bodily integrity and the threat of death. These actual and potential losses may produce a sense of helplessness in many patients.

Patients are usually placed in unfamiliar surroundings with little sense of autonomy. These conditions may generate a depressive view of the world. Cognitive distortions can develop so that the individual begins to make mistakes in judgment such as forecasting catastrophe or interpreting innocuous events negatively. Patients may begin to think of themselves as worthless and feel they are a burden to family and friends. Motivation to participate in medical care may be impaired. In an interesting study, healthy volunteers were admitted to an ICU to investigate the psychological changes associated with that environment. Subjects developed decreased vigor as well as increased confusion and fatigue that were attributed solely to the ICU environment. The subjects also were found to engage in introspection and to have a negative view of the hospital environment. In another study of patients undergoing coronary artery bypass grafting, those with longer stays in the ICU were at risk for greater levels of depressive symptoms postoperatively.

This depressive picture is often associated with biologic changes. Neurotransmitter levels and receptor function change significantly. Serotonin and noradrenergic systems have substantial alterations. Endocrine dysfunction in both the pituitary-adrenal and thyroid axes may become disturbed. Even immune function may be altered.

Clinical Features

Patients in the ICU who have clinically significant depression can be assessed by general criteria for depression. These criteria, however, have only limited usefulness in the ICU patient because of the context. For example, neurovegetative symptoms are of limited value; many ICU patients have appetite and sleep disturbances, but that does not mean they are depressed.

Nonetheless, some signs and symptoms of depression in ICU patients can be used to make a diagnosis of depression. The presence of a depressed or lowered mood is a hallmark. Irritability, particularly when out of character for an individual, is another marker of depression. Diminished interest in activities such as interacting with family or viewing television often indicates depression. Pronounced thoughts about death or wishes for it in the form of suicidal ideation also indicate depression.

Additional criteria can be used in assessing a patient for depression. One group of factors involves the depressive view of the world a depressed patient develops. For example, seeing oneself, one's doctor, and one's future in negative terms correlates positively with a diagnosis of depression. Feelings of guilt, worthlessness, and hopelessness are also common in depression. Feeling helpless means the individual feels unable to help himself or herself get better; feeling hopeless means the individual does not believe anyone else can help

either. The physician always should ask a depressed patient about any suicidal ideation. As a practical matter, very few ICU patients have the means to commit suicide in the unit, but knowing the patient's feelings about suicide may help the physician to gauge the level of depression.

In addition to these cognitive factors, assessing the patient's self-esteem often serves as a clue to depression. The patient who is grieving normally usually feels sad in reaction to losses sustained or anticipated. The grieving individual may appear sad but still maintain a proper sense of self-esteem: "I'm okay, really—I'm still a good person despite my medical problem." The depressed individual, on the other hand, feels worthless and useless: "I'm washed up—a burden to my family."

Another way of identifying the depressed individual engages the physician in using his or her own feelings as an assessment tool. Depressed patients often generate a feeling of depression in their physicians; they also may produce a sense of aversion so that the physician is eager to get away from the bedside. An appropriately grieving patient, on the other hand, usually generates a sense of sympathy and sadness in the physician. Thus the physician who is sensitive to his or her own responses to a patient may be able to confirm a diagnosis of depression quite readily.

Differential Diagnosis

The key differential diagnosis in a patient who is being considered for a diagnosis of depression is appropriate grief or organic mood disturbances. A number of conditions may produce depressive symptoms. It is completely normal for an individual to experience sadness and some emotional withdrawal in response to a loss. Disease often produces a sense of loss for many individuals, and it may be difficult for the physician to differentiate appropriate grieving from a clinical depression. One should consider the degree of dysfunction as an indicator of depression. Thus, when a patient's emotional state is seriously interfering with medical recovery or compliance with medical care, some form of treatment should be offered. Depression becomes a likely diagnosis when the patient makes a decision to terminate treatment for a disease whose prognosis is favorable.

Certain medical conditions frequently produce depressive symptoms. Examples are Cushing's disease, hypothyroidism, and pancreatic carcinoma. Virtually all the organic causes described in the section on delirium also can produce depressive states. In fact, a smoldering delirium may be mistaken for depression unless cognitive function is assessed. Some hypoxic individuals, for example, will appear lethargic and depressed. Medications such as β -blockers, corticosteroids, digoxin, cimetidine, levodopa, diazepam, and antihypertensives may produce a depressive picture. Some dopamine antagonists such as prochlorperazine or metoclopramide produce psychomotor retardation or akathisia that may mimic depression. A recent study indicated that the presence of depression at baseline in patients with acute

coronary syndromes predicted failure to return to work and not feeling better at 1 year. This study provided support for the assessment of depression in identifying individuals at risk for poorer outcomes.

Treatment

A key point in the treatment of depression is for the physician to recognize that depression is a painful and serious condition that should not be considered "normal." Just because a knifing victim might be expected to exsanguinate and experience a fall in blood pressure, medical treatment is not withheld; similarly, the identification of depression warrants appropriate interventions. In serious cases of depression, there may be a substantial risk of failing to provide treatment. A depressed patient is poorly compliant and poorly motivated to participate in recovery—or may fail to take adequate nutrition and participate in other aspects of recovery such as being weaned from a ventilator.

The initial treatment of depression in the ICU should emphasize psychosocial measures. To the extent possible, the patient should be permitted to feel some control over what is happening. Nurses should offer the patient a choice whenever possible. For example, the patient can be asked whether or not pain medication is needed, whether it is time to be moved, etc. Asking the patient to help plan the day's bath and hygiene schedule is very helpful. Encouraging the family to visit as much as possible also may help to counter depression. The physician can help to reduce depression by providing realistic encouragement and support.

If these measures fail to reduce the depression, psychiatric consultation is indicated followed by pharmacologic treatment. The consultant will inquire about the patient's psychiatric history, particularly to see if some specific antidepressant medication has been successful in the past. If so, that drug should be used. If the patient has not had a prior trial of antidepressant, a psychostimulant such as dextroamphetamine or methylphenidate should be considered unless there is a medical contraindication such as tachyarrhythmia. With the usual starting dextroamphetamine dosage of 2.5 mg at 7 a.m. and 1 p.m., there is little risk of side effects. In an occasional patient, there may be some increase in blood pressure or pulse, but these are usually minimal and do not require stopping the trial. If the patient fails to respond to the preceding dosage, on the next day one can double the dosage to 5 mg given twice. The maximum dosage is 15 mg twice daily, but this level is rarely necessary. The medication is given early in the day so as not to interfere with sleep. Many people have the misconception that dextroamphetamine may worsen appetite because it has been used in the past for dieting; in depressed patients, however, it generally improves appetite.

Dextroamphetamine has the advantage of being essentially free of side effects in most patients; some may have slight tremor or anxiety. A rare patient may develop persecutory feelings with this drug, but typically only at much higher doses. The tremendous advantage of dextroamphetamine is

the rapidity of response when it is successful. The physician often can observe a beneficial effect 1–2 hours after the first or second dose. Many patients report improved mood, energy, appetite, and will to live. The response rate varies in different studies from 48 to 80% improvement in depressive symptoms.

A number of other agents are effective and well tolerated for the treatment of depression. An example is fluoxetine, which was the first serotonin reuptake inhibitor released in the United States. Although fluoxetine has essentially no anticholinergic or blood pressure effects, it elevates many other drug plasma levels by displacing them from their plasma protein binding sites. This makes fluoxetine an undesirable medication for most ICU patients. Other newer agents have been developed that appear well suited for use in ICU patients. Citalopram, sertraline, and venlafaxine are effective antidepressants that share fluoxetine's lack of blood pressure and anticholinergic effects but are associated with fewer drug interactions. Bupropion has little blood pressure or anticholinergic effect, but in its immediate-release form it has been associated with a higher incidence of seizures than other antidepressants. All these agents have the limitations of being available only in oral formulations and taking 1–4 weeks to have an effect.

Tricyclic antidepressants can be considered for ICU patients, but like the newer agents mentioned briefly earlier, they take 1–4 weeks to show an effect. Their anticholinergic and quinidine-like side effects also can cause problems. Tricyclic antidepressants also have the disadvantage of producing marked α -adrenergic blockade, which can have troublesome effects on blood pressure. If treatment with a tricyclic is elected, nortriptyline is the best choice because it has the least effect on postural hypotension and only modest anticholinergic effects. It also has a clear therapeutic window of maximum effectiveness of 50–150 ng/mL.

Current Controversies and Unresolved Issues

Depression may be hard to differentiate at times from normal grief and sadness, so it would be useful to have a biologic marker for the condition. Several years ago there was excitement about using the dexamethasone suppression test as a marker for major depression. Although this was of important research significance, it has not been useful clinically because 50% of patients will suppress but still have the disorder. Therefore, the test is of very little significance in trying to decide on a diagnosis. It will be important for further research in depression to develop biologic markers the clinician can use.

Another important area for further research involves the identification of subtypes of depression so that specific pharmacotherapy can be tailored appropriately. There have been attempts to differentiate depression by global measures of neurotransmitter levels. Cerebrospinal fluid and urinary levels of methoxyhydroxyphenylglycol (MHPG) and serotonin have been used to predict response to serotonergic and noreadrenergic antidepressants. These efforts have not yet produced clinically useful applications.

► Anxiety & Fear

ESSENTIALS OF DIAGNOSIS

- Overt terror and panic.
- Hypervigilance.
- Fear of being alone.
- Autonomic arousal.

General Considerations

Anxiety is the unpleasant feeling associated with an unknown internal stimulus and is out of proportion to the threat from the environment. Fear, on the other hand, is the same feeling state but derived from a known external stimulus and proportionate to the threat. Obviously, in the ICU these two feelings are hard to distinguish, and they will be discussed here under the term *fear*, which refers to both entities.

Fear is often prominent when the patient first enters the ICU because of awareness of a substantial threat to his or her continued existence resulting from the medical or surgical problem that necessitated the admission. The ICU patient may be reacting not only to the fear of death but to other unspoken fears as well. The patient may be anxious about how the family is responding to the illness and may have concerns about ability to return to work or may harbor unrealistic ideas about the nature of the problem and the treatment required. For example, some patients jump to the conclusion that they will need open-heart surgery for any type of cardiac problem. The patient also may associate the illness with a loved one who had a similar problem. For example, one 59-year-old man admitted to the coronary care unit feared he would not survive his heart attack because his father had died of one at the same age. Asking the patient about whom he or she knows who had the same medical problem or treatment may reveal a significant factor contributing to the patient's fear. A recent study indicated that the risk of developing posttraumatic stress disorder was linked with anxiety during the time in the ICU. The study further found that perceived social support was negatively correlated with symptoms of posttraumatic stress disorder.

Fear and anxiety may produce significant physiologic changes. Catecholamine and corticosteroid levels may fluctuate along with anxiety levels. It has been demonstrated that the perception of physical or emotional stress results in the activation of several brain regions—serotonergic, catecholaminergic, and perhaps cholinergic nuclei. These pathways are apparently then integrated by unknown mechanisms into the hypothalamus. The end result of this complex response is the secretion of glucocorticoids. Evidence also has accumulated for a variety of links between the serotonergic region and the hypothalamic-pituitary axis that may underlie the connection between stress and mood. A recent study found that the risk of cardiocirculatory complications was

decreased by a factor of 2 in periods of unrestrictive visiting policies in an ICU. This also was correlated with a greater reduction in anxiety score and less of an increase in thyroid-stimulating hormone during the course of admission. A restrictive visiting policy was associated with a nonsignificant increase in mortality rate. The authors concluded the unrestrictive visiting policy might decrease cardiovascular complications through lessened anxiety and a more desirable hormonal profile.

Clinical Features

The physician can observe fear in many guises in the ICU. Patients with a past history of generalized anxiety, panic, or “nervous” disorders should be expected to have increased fearfulness in the ICU. Some patients will demonstrate their terror and panic overtly. Others may appear hypervigilant, constantly scanning the environment. Others will talk excessively or seek the presence of the nurse so as not to be left alone. Some patients will fight going to sleep because of fear of dying while asleep. Blood pressure and heart rate may be elevated as the autonomic accompaniments of fear ensue.

Some patients may exhibit their fear by major denial of illness. These individuals may attempt to demonstrate their good health by exercising in the coronary care unit. Others will try to sign out of the hospital against medical advice. Fear is perhaps recognized most easily in the patient being weaned from the ventilator “before I’m ready.” These patients often show stark terror as the ventilator settings are reduced. In such cases, anxiety may grossly interfere with medical treatment.

Furthermore, anxiety related to experiences in the ICU does not dissipate at the door on departure from the unit. Patients may continue to have nightmares and experience episodes of hypervigilance and panic even after returning to home care, thus suggesting the diagnosis of posttraumatic stress disorder (PTSD). Research is still needed to help predict which individuals are at the greatest risk for development of this syndrome. Some studies have linked its development to adverse experiences in the ICU. One study found that the presence of delusional memories of events in the ICU—as opposed to factual memories—indicated an increased risk for PTSD-related symptoms and panic following discharge from the ICU.

Differential Diagnosis

Anxiety and fear can be confused with the agitation of delirium. The delirious patient, however, will have significant cognitive impairment that is usually not present in the anxious patient. The physician should continuously assess the anxious patient for organic factors that could contribute to anxiety. Medications such as corticosteroids, theophylline, and lidocaine can produce anxiety and fearfulness. Medical conditions such as hypoxia, pulmonary emboli, pheochromocytoma, Cushing’s disease, and early drug or alcohol withdrawal may have anxiety as a major symptom (Table 18–3).

Table 18–3. Medical disorders commonly associated with anxiety.

Pulmonary disorders

- COPD
- Pulmonary embolus
- Asthma
- Hypoxia

Drugs

- Drug withdrawal
- Drug intoxication (eg, amphetamines, cocaine)

Infections

- Tuberculosis
- Brucellosis

Cardiac disorders

- Mitral valve prolapse
- Paroxysmal atrial tachycardia
- Subacute infective endocarditis
- Angina

Endocrine and metabolic disorders

- Insulinomas
- Carcinoid tumors
- Pheochromocytomas
- Hypoglycemia
- Thyroid disease
- Hypocalcemia
- Porphyria
- Cushing’s disease

Neurologic disorders

- Multiple sclerosis
- Akathisia
- Temporal lobe epilepsy

Treatment

The best treatment of anxiety is prevention. Psychologically preparing a patient for surgery can have a beneficial effect. These efforts, as well as those offered by the patient’s primary physician, can be very effective in preventing anxiety. Similarly, the physician can intervene postoperatively to minimize patients’ anxiety. One study suggests that playing a brief tape-recorded message from the surgeon—explaining that surgery went well, giving an orientation to the ICU, and reassuring the patient about early recovery—markedly reduces anxiety.

Nonetheless, for many patients, fear and anxiety will develop in the ICU. The first step in treating the fearful patient involves exploring precisely what the patient is most fearful about. This information may be obtained directly from the patient who is prepared properly and trusts the physician. The physician can start by saying, “Most people have some worries or fears in this situation. What are yours?” This approach normalizes the presence of fears and makes it easier to talk about them. Whatever the patient brings up as a concern should be explored.

Another valuable technique for helping a patient deal with fear is reframing the patient's view of the situation. For example, one 45-year-old African-American wanted to sign himself out of the coronary care unit, saying he refused to believe that he had had a bad heart attack. The doctors repeatedly tried to warn the patient of the risks of not accepting hospital treatment. The patient responded by doing 10 one-handed push-ups. Finally, psychiatric consultation was requested. The psychiatrist realized that frightening the patient only escalated his fear and increased his need to deny the fear by signing out against advice. The psychiatrist suggested to the patient that it took a strong man to put up with the bed rest and testing the cardiologists wanted. The consultant suggested that the patient could prove his strength in this way. In essence, the patient no longer had to equate staying in the unit as a loss of strength and self-esteem. With this reframing of his medical care, the patient accepted the remainder of his treatment without difficulty.

In some ICUs, the psychiatric consultant or liaison nurse may teach relaxation with the aid of audiotapes. Some patients may be receptive to learning self-hypnosis. These techniques may help by restoring the patient's sense of control over the environment. These techniques also may be helpful in the patient being weaned from the ventilator.

If psychosocial interventions do not work or are not available, medication can be used. Lorazepam is the anti-anxiety drug of choice. Its intermediate half-life (10–20 hours) is long enough to prevent the withdrawal syndrome that can occur with shorter-acting agents but not so long that the drug tends to accumulate. Lorazepam is metabolized in a one-step conjugation and so can be used in patients with liver disease. For most patients with mild to moderate anxiety, the dosage of lorazepam is 1–2 mg (depending on age and weight) every 4–6 hours. For more severe anxiety, one may double these dosages. Antidepressants such as sertraline and citalopram also can be useful against anxiety. As with their use in depression, however, they can take up to 4 weeks to have a significant effect and must be given orally. When anxiety is extreme and interfering grossly with the patient's care, a shift to antipsychotic medications has been advocated. Although haloperidol has been advocated for this purpose, newer agents also should be considered. A recent report described the use of risperidone for patients with irritability and hostility. The authors noted that this agent caused fewer side effects than haloperidol, imposed fewer risks than benzodiazepines, and was effective with a more rapid onset than antidepressants.

Current Controversies and Unresolved Issues

There is a continuing quest for the anxiolytic agent that gives relief without clouding the sensorium or producing troublesome withdrawal states. For example, triazolam is a popular sedative benzodiazepine in some regions because it has a short half-life that makes it unlikely to produce a hangover. The short half-life, however, has a major disadvantage in

that it may lead to withdrawal syndromes the next day, leaving the patient anxious until the next dose is given. Until the neurotransmitter systems involving various agents such as γ -aminobutyric acid are further elucidated, the quest for the ideal agent will have to continue.

► Staff Issues

The ICU staff considered as a group has many psychological features similar to those found in individual health providers. Many doctors and nurses, for example, bring certain psychological motivations to their work. They may feel a strong need to save and rescue their patients. They also may demand perfection from themselves. In some sense, whether it is consciously realized or not, the ICU staff may make the same demand as a group. This may be manifested in attempts to save the unsalvageable patient and reluctance to let any patient die. On the other hand, many patients have unclear prognoses, and these may be particularly challenging for the staff. Research suggests that the most difficult patients for staff to care for are those with multisystem failure and a poor prognosis.

A useful equation for conceptualizing a staff's self-esteem is the following:

$$\text{Self-esteem} = \frac{\text{realistic achievement}}{\text{expectations}}$$

In this equation, how staff feel about themselves is equal to what realistic achievement they can accomplish “divided by” their expectations. The equation represents a shorthand way of viewing how the relationship between expectations and achievements influence self-esteem. In instances where the expectation is one of omnipotence, unless the achievement is perceived as a perfect performance, the staff will end up feeling like a failure. In this equation, we should note that the realistic achievement is relatively fixed within a narrow range accomplished by most competent staff. The variable that can be adjusted most easily is the denominator—expectations. If staff are successful in reducing this value, the staff can feel much more satisfied with their accomplishments. This issue is highlighted when staff have to deal with a dying patient. When staff are able to shift their expectations away from an unrealistic omnipotent fantasy of saving the patient, they can shift to a more realistic one such as providing a comfortable, dignified death. Such a goal is much more easily accomplished.

Identifying Staff Problems

Staff issues often can be identified in staff attitudes toward patients. For example, following a period in which there had been an unusually high number of deaths in an ICU, an 80-year-old patient was admitted to the unit with pneumonia. She required intubation and ventilation. Although her infection was controlled rapidly, she had difficulty being weaned from the ventilator. Staff nurses began to voice concerns such

as, “Why are we putting such effort into an 80-year-old woman? She won’t make it anyhow.” When those concerns were raised in a staff meeting, other staff members pointed out that the patient had been living independently until her pneumonia developed and that her only current problem was one of pulmonary mechanics that should clear with time. This discussion helped the staff to perceive that their view of the patient had been unfairly pessimistic, probably related to the several recent deaths that had led to a sense of inadequacy, helplessness, and group depression. They left the meeting with a clearer understanding of what they could accomplish with the patient. She eventually was weaned from the ventilator and returned to her home.

Interventions

There are various approaches to helping the ICU staff deal with the stress of working with critically ill patients. Units emphasizing a culture of cooperation and communication have a reduced length of stay, increased staff longevity, and a higher perceived quality of care. These observations reinforce earlier recommendations to schedule regular staff meetings, including in the invitation a psychiatrist or social worker familiar with the unit. Ideally, both physicians and nursing staff should attend this meeting. Staff should raise any feelings they have about patients or ward situations. These feelings can be clarified, shared, and discussed with others. Identification of exaggerated expectations or other problems such as group depression can be investigated and resolved. Junior staff can gain broader perspectives from more experienced staff. These meetings also can facilitate communication and humor, which are important ways for a staff to cope. They can help staff deal with the multisystem patient with a poor prognosis. Staff can become more comfortable realizing that they are doing the best job possible with this difficult population and accepting death if it becomes clear that the patient will have to die despite the best critical care that could be offered. Recent studies have found that clinicians perceive conflict in up to 78% of cases requiring decision making for critically ill patients. The conflict was perceived to occur with equal frequency between staff and family members and within the staff. While the presence of conflict was not always felt to be detrimental, it can be disruptive and lead to morale problems. Thus meetings in which such issues can be identified and discussed will benefit the ICU team.

In addition to staff meetings, there are a host of practical interventions that can help staff deal with the stress of working in an ICU. Nursing and physician staff can be encouraged to take adequate time off for restorative recreation and family life. Some institutions schedule fewer but longer shifts in order to provide longer stretches of time off. House staff might be given the afternoon off on the day following a night on call—which is probably the single most important variable in reducing house staff distress. Providing strong medical and nursing directors is extremely helpful for staff dealing with the ambiguities of complex illnesses. Having the

services of an ethicist and a chaplain available on a regular basis can be an invaluable support strategy. Another measure to prevent the development of burnout in ICU staff is creating a system in which staff rotate between the ICU and other settings to remove staff from the constant stress of the ICU.

Current Controversies and Unresolved Issues

The difficulty of working in an ICU undoubtedly will persist. As technological advances allow staff to sustain life in the face of severe, previously untreatable conditions, the ethical and philosophical tensions these situations give rise to are likely to increase. Helping the staff to cope with these stressors will remain an ongoing challenge.

Care of the Elderly Patient

19

Shawkat Dhanani, MD, MPH
Dean C. Norman, MD

The elderly are a highly heterogeneous group, and the physical and medical heterogeneity increases with age. Individuals over 65 years of age—with or without chronic diseases—vary widely in their physical, behavioral, and cognitive functions. Any clinician can relate the “Tale of Two Octogenarians” seen in practice on the same day: the end-stage patient afflicted with Alzheimer’s disease seen at the nursing home and the vigorous retiree seen after his golf game for monitoring of his historically well-controlled hypertension.

Physiologic rather than chronological age is a better predictor of the health status of the elderly. An abrupt decline in physical function or any organ system is almost certainly due to disease and not due to “normal aging.” Therefore, symptoms in the geriatric population should not be attributed automatically to old age, and it is important to look for potentially reversible causes of symptoms. Moreover, treatable conditions should not be undertreated for fear of side effects of medication.

Improvement or maintenance of functional status is the major goal of medical care in the geriatric population. Functional disability occurs faster and takes longer to correct in the elderly, necessitating early preventive measures. Active efforts should be made to maintain functional level even during intensive care. Even small changes in function can make large differences in the quality of life. For example, regaining the ability to oppose the thumb to other fingers may enable a geriatric patient to become independent in feeding. Prevention of iatrogenic diseases is also important. For example, close attention should be paid to prevent the development of pressure ulcers. A pressure ulcer can develop in just few hours, and the mortality rate of those who develop the lesions in the first 2 weeks of intensive care has been reported to be as high as 73%. Other iatrogenic problems in the ICU include aspiration pneumonia, sepsis, GI bleeding, delirium, drug toxicity and interactions, and renal insufficiency.

Multiple concurrent illnesses, cognitive and sensory impairments, age-related changes in physiology and pharmacodynamics, increased vulnerability to delirium, and complications from immobility make management of acute

illness in the elderly a clinical challenge for all physicians and other health care providers who care for patients in this age group.

► Physiologic Changes with Age

The Aging Heart

Heart disease is the leading cause of death in people over 75 years of age and the fourth most prevalent chronic disease in the elderly. Nearly 30% of elderly people have some abnormality affecting the heart. Moreover, occult cardiac disease can cause marked functional impairments in otherwise apparently healthy elderly people. Coronary atherosclerosis increases exponentially with age and, in the elderly, can present as heart failure, pulmonary edema, arrhythmias, or exercise intolerance rather than as angina or obvious myocardial infarction.

In healthy subjects, the resting heart rate does not change with age, but the maximum heart rate with exercise decreases with age (Table 19–1). It can be calculated by the following formula: $208 - (0.7 \times \text{age})$. Age-related changes in collagen and elastin contribute to progressive stiffness and loss of recoil of elastic tissues. In the systemic arteries, this process contributes to an increase in systolic blood pressure. Systolic pressure rises approximately 6–7 mm Hg per decade, but diastolic pressure changes little with age and even may fall starting in the sixth decade. In addition, the systolic pressure may be underestimated by the cuff sphygmomanometer in the elderly. Resistance to blood flow leads to increased left ventricular wall tension and compensatory left ventricular hypertrophy. The myocardium is also affected by changes in collagen and elastin that cause stiffness of the left ventricle that can result in diastolic dysfunction. The left ventricular filling rate during early diastole declines markedly with age (approximately a 50% reduction between age 20 and age 80). Enhanced active filling in late diastole during atrial contraction compensates for decreased passive diastolic filling, and this explains the vulnerability of older persons to congestive

Table 19–1. Summary of age-related change in cardiac physiology.

Heart rate	At rest: unchanged Maximal heart rate with exercise: decreases
Stroke volume	At rest: unchanged With exercise: increases
Ejection fraction	At rest: unchanged With exercise: fails to increase as much as in younger subjects
Cardiac output	At rest: unchanged Low- and medium-intensity exercise: unchanged High-intensity exercise: fails to increase as much as in younger subjects
Early diastolic left ventricular filling rate	Decreases
Late diastolic left ventricular filling rate (atrial “kick”)	Increases
Ventricular compliance	Decreases

heart failure when atrial fibrillation or flutter occurs. Decreased filling also makes the elderly more vulnerable to small decreases in venous filling with volume loss or when given opioids, diuretics, or positive-pressure ventilation. On the other hand, systolic function is relatively preserved in the healthy elderly.

Despite these disturbances, cardiac output at rest remains relatively constant across the life span. During low- and medium-intensity exercise, increases in stroke volume compensate for the lower heart rates observed in the elderly. This increase in stroke volume with exercise is the result of an increase in end-diastolic volume by as much as 30% (Frank-Starling law). However, with high-intensity exercise, a decline in cardiac output is observed owing largely to the age-related decline in maximum heart rate. This hemodynamic profile is strikingly similar to that observed in younger patients who exercise in the presence of β -adrenergic blockade. Since β -adrenergic modulation of pacemaker cells partly explains the increased heart rate during exercise, this observation led to the hypothesis—later confirmed—that diminished response to β -adrenergic modulation is one of the most notable age-related changes in the cardiovascular system. Chronotropic and inotropic responses of the aging heart to norepinephrine, isoproterenol, and dobutamine are diminished. Virtually all studies show higher mean circulating blood norepinephrine and epinephrine levels in the elderly than in younger persons.

Both arterial dilation and venous dilation in response to β -adrenergic stimulation decrease with age. This deficiency

in arterial dilation in addition to any age-related structural changes within the large vessels may contribute to increased vascular impedance in advancing age.

The Aging Lung

Cross-sectional population studies consistently show a progressive age-related decline in pulmonary function. The decrements in flow rates and lung volumes are not uniform throughout life but tend to accelerate with age. Given the large individual differences in the elderly, longitudinal studies would be preferable for observing the change in pulmonary function, which is influenced not only by age but also by environmental factors such as smoking, air pollution, infections, and other comorbid conditions.

Age-related changes in collagen and elastin produce a decrease in lung compliance, but this is not physiologically significant. However, rigidity of the chest wall with aging has measurably negative mechanical implications resulting in significantly increased work of breathing. Starting around age 35 years, there is a decrease in forced vital capacity (FVC) averaging 14–30 mL per year and a decrease in forced expiratory volume in 1 second (FEV_1) averaging 23–32 mL per year for nonsmoking men. Nonsmoking women show slightly lesser rates of decline (FVC 15–24 mL per year and FEV_1 19–26 mL per year). All expiratory flow rates decrease with age and tend to fall faster in men, taller individuals, and those with increased airway reactivity. The decrease in FVC is associated with an elevation in functional residual capacity (FRC) and residual volume (RV). Only minor changes occur in total lung capacity.

Age-related changes in lung structure and chest wall mechanics lead to premature closure of terminal airways. This phenomenon occurs predominantly in the dependent parts of the lungs that are the best perfused, accounting for increasing ventilation-perfusion mismatching that results in a progressive decrease in arterial oxygen tension (PaO_2) and an increased alveolar-arterial oxygen difference— $P(A-a)O_2$ —with age. The following equation predicts PaO_2 at sea level in the adult:

$$PaO_2 \text{ (mm Hg)} = 100 - 0.325 \times \text{age (years)}$$

The normal value for the $P(A-a)O_2$ at rest for a given age can be calculated as follows:

$$P(A-a)O_2 \text{ (mm Hg)} = (\text{age} + 10) \times 0.25$$

Based on this formula, a 90-year-old subject will have a predicted PaO_2 of 71 mm Hg and a maximum normal $P(A-a)O_2$ of 25 mm Hg at sea level.

Changes in position also influence the PaO_2 . PaO_2 is 6–10 mm Hg lower in the supine position than in the upright position in the elderly. Postoperative hypoxemia is especially common in the elderly, in whom it may persist for several days. There is no significant change in arterial pH or PCO_2 with age.

Ventilatory control is also affected by age and is more striking compared with the changes in lung volumes and

Table 19–2. Summary of age-related changes in pulmonary physiology.

Forced vital capacity (FVC)	Decreases
Forced expiratory volume in 1 second (FEV ₁)	Decreases
Residual volume	Increases
Arterial Po ₂	Decreases
Alveolar-arterial oxygen difference	Increases
Arterial Pco ₂	Unchanged
Ventilatory response to hypoxia or hypercapnia	Decreases
Mucociliary clearance	Decreases

flow rates. The ventilatory response to hypoxemia is reduced by half in healthy elderly men 64–73 years of age, whereas the response to hypercapnia is reduced by 40%. Reasons for these decreased responses are unclear. Suggested explanations include altered central or peripheral chemoreceptor function as well as reduction in neuromuscular inspiratory output.

Right atrial, pulmonary artery, and pulmonary capillary wedge pressures are unchanged in the healthy elderly at rest. In contrast, the older person's increases in pulmonary artery and pulmonary capillary wedge pressures with exercise are significant, and increases in pulmonary artery resistance are highly significant with age.

There is a reduction in the effectiveness of cough and mucociliary clearance with aging and a decline in the cellular and humoral components of pulmonary immunity. These changes predispose the older population to pulmonary infections. Similarly, a diminished gag reflex, dyscoordination of swallowing, prolonged periods in the supine position, and sedation contribute to an increased risk of aspiration. Table 19–2 summarizes these findings.

The Aging Kidney

Many cross-sectional and longitudinal studies of large human populations have shown a steady decline in creatinine clearance with age. As in any other area, the decline in renal function with age is highly variable among individuals. In general, changes owing to disease and to aging are in the same direction and are additive. With aging, there is a loss of nephrons at a rate of 0.5–1% per year. By the seventh decade of life, there is a 30–50% loss of functioning glomeruli owing to age alone. This loss occurs primarily in the renal cortex, with relative sparing of the medulla. A progressive reduction in renal plasma flow also has been demonstrated with age. A 50% reduction has been shown between young adulthood and the eighth decade, averaging 10% per decade.

The major clinically relevant renal functional defect arising from these histologic and physiologic changes is a progressive decline, after maturity, in the glomerular filtration rate (GFR). Age-adjusted normative standards for creatinine clearance have been established. The rate of decline has been estimated as 8 mL/min/1.73 m² per decade after the fourth decade (or 0.8 mL/min per year). This rather drastic age-related loss of renal function is not completely reflected in the serum creatinine because of the proportionate decline in skeletal muscle mass. Therefore, in order to make an estimation of the glomerular filtration rate in the elderly, the serum creatinine value should be incorporated in the Cockcroft and Gault formula that takes into account the age, sex, and weight of the patient:

$$\text{Estimated creatinine clearance} = \frac{[140 - \text{age (years)}] \times \text{body weight (kg)}}{72 \times \text{serum creatinine (mg/dL)}}$$

In women, the result should be multiplied by 0.85. For obese individuals (body mass index [BMI] ≥ 30), ideal rather than actual body weight should be used.

For the preceding reasons, dosage adjustments of medications excreted primarily by the kidneys should not be based on serum creatinine values but rather on measured or estimated creatinine clearance. Drugs that are excreted predominantly through kidneys and have low therapeutic indices (eg, digoxin, procainamide, and vancomycin) require close monitoring of serum levels.

Since medullary nephrons, which are relatively spared compared with cortical nephrons, have reduced concentrating ability, the elderly tend to excrete more free water. They release more antidiuretic hormone in response to hypertonicity, yet water retention is less than in younger individuals because of reduced end-organ response in older persons. Older individuals tend to have diminished thirst perception and diminished awareness of volume contraction. The response to aldosterone is impaired, and the ability to conserve sodium is limited.

The age-related decline in other renal functions such as urine concentration and dilution, tubular secretion and reabsorption, and hydrogen ion secretion render the elderly more susceptible to disorders of fluid, electrolyte, and acid-base imbalance. Low renin and aldosterone levels can contribute to hyperkalemia and hyponatremia.

▶ Management of the Elderly Patient in the ICU

Clinical Presentation of Disease in the Elderly

Elderly patients may present with multiple pathologic processes in different organ systems. Various studies have found an average of three to four medical conditions in ambulatory older patients and five to nine medical diagnoses among elderly patients in chronic care facilities.

Owing in part to the progressive decrease in physiologic reserve with age and comorbidity, the elderly may have unusual presentations of diseases. The onset of a disease in the elderly generally affects the most vulnerable organ system first. This explains the frequent apparent lack of relation between the presenting symptom and the underlying disease. Thus delirium, functional impairment, frequent falls, incontinence, and syncope could be the presenting manifestations of a variety of illnesses such as congestive heart failure, pneumonia, myocardial infarction, urinary tract infection, or GI bleeding. Moreover, painless myocardial infarction may occur in up to 30% of cases. This emphasizes the need for a thorough evaluation when searching for the cause of non-specific symptoms.

Drug Therapy

Iatrogenic illness is common and often preventable in the elderly. The incidence of iatrogenic problems among acutely hospitalized geriatric patients is close to one in three. By far the most common iatrogenic disorders in the elderly are adverse drug reactions. Changes in pharmacokinetics and pharmacodynamics and polypharmacy predispose geriatric patients to adverse reactions and drug interactions.

Pharmacokinetics is the study of the time course of absorption, distribution, metabolism, and excretion of drugs and their metabolites from the body. Absorption and metabolism are minimally affected by aging. Distribution is affected by changes in body composition. For example, aging is associated with an increased percentage of fat (50% increase in men and 25% increase in women from age 40 to age 80) and a concomitant decrease of total body water. Thus medications that distribute in the water space (ie, hydrophilic drugs such as digoxin and theophylline) have a lower volume of distribution and tend to reach higher levels in a shorter time in an older patient. On the other hand, drugs that are lipid-soluble (ie, lipophilic drugs such as the psychotropics) will have a larger volume of distribution, resulting in progressive accumulation of these drugs. The net effect of this will be to increase the half-life of these drugs and prolong the duration of action. This effect is further compounded by impaired drug excretion because both renal and, to a lesser extent, hepatic function tend to decrease with age.

In addition, some plasma protein levels may alter with age. For example, serum albumin often falls with chronic comorbid conditions, resulting in higher free drug levels and a potential for greater pharmacologic effect at the same dosage or total serum level for protein bound drugs (eg, phenytoin).

As discussed earlier, renal function tends to decrease with age, but concurrent changes in muscle mass keep the serum creatinine constant at approximately 1 mg/dL, often masking the declining renal function. Thus measurement of creatinine clearance or estimation with the Cockcroft and Gault formula should be used to assess the GFR and make the necessary adjustment in dosages of drugs excreted by the kidneys (see Chapter 4).

Cytochrome P450 enzymatic activity tends to decrease with age. Warfarin and theophylline are examples of drugs eliminated by this system. On the other hand, normal aging does not significantly impair the conjugation capacity of the liver. There is also a decrease in hepatic blood flow with age. Compared with renal function, hepatic function is extremely difficult to quantitate. Only sparse data are available on hepatic drug metabolism in aging human subjects, and evidence for altered hepatic metabolism in humans is largely indirect and frequently inconsistent. For example, in studies with antipyrine (a useful model compound for the study of drug metabolism), large individual variation frequently exceeds the effect of age such that only 3% of the variance in metabolic clearance is explained by age alone.

Pharmacodynamics is the study of the physiologic response to a drug or combination of drugs and is based on drug-receptor interactions. For reasons that are not well understood, the aging process appears to be associated with an altered sensitivity of receptors for many commonly used medications. In general, elderly subjects are more sensitive to some medications, including warfarin, narcotics, sedatives, and anticholinergic medications, and less sensitive to others, such as β -adrenergic agonists and antagonists. However, given the marked heterogeneity of the elderly as a group, careful individualization should be the general rule when drawing conclusions about such matters.

Because of multiple diseases and polypharmacy in the elderly, the clinician always should check for possible drug-drug and drug-disease interactions before prescribing any new medication. The probability of a significant drug-drug interaction is nearly 7% for patients using more than 5 drugs and 24% for those using more than 10 medications. Special attention should be paid when prescribing medications with long half-lives or with anticholinergic or potential CNS side effects.

Adverse drug effects can mimic almost any clinical syndrome in geriatrics and should be considered in the differential diagnosis of vague symptoms or deterioration of function. For example, timolol eye drops—a β -blocker used for glaucoma treatment—may be absorbed systemically and can cause cardiac decompensation in a patient with poor cardiac function.

Hydration and Nutrition

Hydration status is a major concern in the hospitalized elderly. One of the most common reasons for electrolyte abnormalities or fluid disturbances in this population is dehydration. Contributing factors may include laxative or diuretic use, the presence of fever or infection, decreased ability to recognize or express thirst, and limited access to water. There is also an age-related decline in urine concentrating ability, which can lead to frequent urination and fluid loss. Accurate fluid balance assessment is essential in nutritional screening because alterations in hydration state may contribute to inaccurate anthropometric and biochemical markers. Because of the high prevalence of congestive heart

failure in this population, intravenous fluid administration must be individualized and approached cautiously.

As stated earlier, aging is associated with a change in body composition with increase in fat content and a concurrent decrease in muscle mass and total body water. Decrease in muscle mass and a reduction in physical activity result in a fall in total energy expenditure with increasing age. Energy requirements may decrease by about a third between the ages of 30 and 80 years. However, during periods of stress such as trauma, surgery, or infection, daily energy requirements may be more than doubled. In addition to the total energy intake, attention should be paid to macronutrient and micronutrient requirements.

The elderly are particularly vulnerable to malnutrition. The reported incidence of malnutrition in elderly hospitalized patients varies from 17% to 65%. As the duration of hospital stay increases, the likelihood of malnutrition rises. In the elderly, a functional nutritional assessment should include evaluation of sight, taste, smell, dentition, degree of cognitive impairment, presence of depression, swallowing abnormalities, respiratory dysfunction, hand-to-mouth coordination, level of assistance required at meals, and perhaps drug-appetite and drug-nutrient interactions.

Whenever possible, feeding should be started as soon as possible in hospitalized or postoperative elderly patients. The enteral route is greatly preferred, but parenteral nutritional support can be used, if needed. Increased mortality occurs in underweight people, but mortality is not clearly increased in overweight elderly patients.

► Special Considerations

The current disease-oriented model of acute medical care promotes a sequential approach to diagnosis and treatment that generally ignores the practice of restorative care until after the patient is discharged from the hospital. In the frail elderly, this approach may lead to a decline in functional abilities despite effective treatment of acute medical illnesses.

The high rate of delirium and psychological decompensation in the acutely hospitalized elderly may lead to excessive bed rest with accompanying loss of mobility, muscle atrophy, contractures, pressure sores, greater tendency to fall, thromboembolism, incontinence, anorexia, constipation, and lack of motivation. This has been called the “cascade of illness and functional decline.”

Since the physiologic characteristics of the aging population include both a decreased functional reserve and large individual variation, medical management should be individualized with the focus on maintenance of functional status, protection from the hazards of immobility, and low risk of complications from treatment.

Delirium

Approximately one-third to one-half of elderly patients will have a delirious episode during the course of hospitalization

Table 19-3. Risk factors for delirium.

Prior cognitive impairment
Fracture on admission
Age over 80 years
Infection
Male sex
Impaired activities of daily living (ADLs)
Sensory impairment (blindness, deafness)
Polypharmacy (psychoactives, anticholinergics etc.)
Dehydration
Immobility
Bladder catheters

for medical or surgical care. It can be as high as 70% in ICUs. Delirium is often unrecognized and is associated with prolonged hospitalization, greater need for nursing home placement, and increased mortality. The presence of altered level of consciousness, easy distractibility, rambling conversation, illogical flow of ideas, unpredictable switching from subject to subject, perceptual disturbances, and psychomotor agitation or retardation should clue the clinician to the diagnosis of delirium. Risk factors are listed in Table 19-3. Prior cognitive impairment is the most frequent independent risk factor for delirium. Other factors that predispose to the development of delirium include unfamiliar surroundings, social isolation, structural brain disease, concurrent chronic illness, sleep deprivation, and alcohol or drug abuse. Delirium could be the presenting symptom of a variety of illnesses (Table 19-4). Early diagnosis is important because most patients can recover if the underlying cause is recognized and treated. The use of sedatives, psychotropic drugs, or physical restraints to treat delirium could worsen the existing situation, placing the patient at higher risk for aspiration pneumonia, pressure ulcers, and other immobility-related complications (cascade effect).

Table 19-4. Common causes of delirium.

Decreased cardiac output	Fecal impaction
Congestive heart failure	Hypothermia and hyperthermia
Acute myocardial infarction	Metabolic disorders
Acute blood loss	Electrolyte abnormalities
Dehydration	Acid-based disturbances
Infections	Hypoxia
Fractures	Hypercapnia
Stroke	Hypoglycemia and hyperglycemia
Poorly controlled pain	Azotemia
Drugs	Transfer to unfamiliar surroundings
Urinary retention	

The DSM-IV criteria for diagnosis of delirium include the following: (1) disturbances of consciousness (ie, reduced clarity of awareness of the environment) in conjunction with reduced ability to focus, sustain, or shift attention, (2) a change in cognition (such as memory deficit, disorientation, or language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia, (3) development of the disturbance during a brief period (usually hours to days) and a tendency for fluctuation during the course of the day, and (4) evidence from the history, physical examination, or laboratory findings that the disturbance is caused by a general medical condition. The Confusion Assessment Method is a validated tool to assess delirium. With appropriate training, it can achieve more than 95% sensitivity and specificity in the diagnosis of delirium, even in groups with a high prevalence of dementia. In contrast with dementia, delirium generally has an abrupt onset, disturbance of consciousness, fluctuations during the course of the day, and frequently, an identifiable and potentially reversible cause.

The decreased attention span seen in delirium can be assessed by several bedside tests. A simple test is the *A test*, in which the interviewer vocalizes letters at a rate of one per second, and the patient indicates by a sign every time the letter *A* is mentioned. In the *one-tap, two-taps test*, the patient is instructed to tap twice each time the interviewer taps once and vice versa. More complex tests include spelling the word *world* backward or subtracting 7 from 100 each time until 72 is reached (ie, 100, 93, 86, 79, 72). These tests are often abnormal in patients with delirium.

Delirium is indicative of diffuse brain dysfunction and has been associated with four classes of diseases: (1) primary cerebral diseases, such as CNS infections, brain tumors, and stroke, (2) systemic illnesses that secondarily affect brain function, including cardiac disease, pulmonary failure, hepatic dysfunction, uremia, deficiency states, anemia, endocrine disturbances, systemic infections, and inflammatory diseases, (3) intoxication with exogenous substances (eg, alcohol, illicit drugs, prescribed medications, and industrial toxins), and (4) withdrawal from dependency-producing agents (eg, alcohol, barbiturates, and benzodiazepines).

The approach to patients with delirium includes a focused history and physical examination, review of medications, and basic laboratory studies such as complete blood count, serum electrolytes, serum urea nitrogen, glucose, and urinalysis. Further specialized tests can be done in individual patients. These include chest radiography, electrocardiography, pulse oximetry, selected drug levels, selected cultures, vitamin B₁₂ level, thyroid function tests, brain imaging, lumbar puncture, and electroencephalography.

Treatment of delirium should include identification and treatment of the underlying cause and review of the medication regimen. Neuroleptics, opioids, or any medication with high anticholinergic or sedative side effects should be discontinued or reduced in dosage whenever possible. When available, constant observation is preferable to restraints. A

well-lighted and predictable environment, use of eyeglasses and hearing aids, frequent reorientation by family and caregivers, simple explanations of any procedure or confusing stimuli, encouragement to stay awake during the daytime, and nursing routines that permit uninterrupted nighttime sleep are all valuable in the management of delirium. Finally, it may be necessary to treat agitated behavior with medication. Generally, the lowest effective doses of one of the atypical antipsychotics (eg, risperidone or olanzapine) should be used because of the low incidence of extrapyramidal side effects. Complete resolution of symptoms can take days to months.

Communicating with the Elderly Patient

Many elderly patients have hearing and vision problems that interfere with communication and cause difficulty in orientation and adaptation to a new environment. Being able to see and hear properly becomes critical when one must cope with new experiences such as ventilatory support devices and other invasive interventions.

Communication problems generate great anxiety in the patient and frustration in the caregiver. There is a risk of mislabeling the patient as “confused” and disregarding the patient’s role as a participant in health care decisions. The elderly patient who reacts to an unfamiliar situation by becoming “agitated” is at risk for the use of physical restraints or psychotropic medications. This causes worsening of the clinical status and may lead to the *cascade effect* described earlier. The importance of efforts to maximize communication with the elderly individual thus is emphasized, especially in the ICU setting.

Adequate vision makes communication easier, especially for those who have impaired hearing or comprehension. Eye contact helps the caregiver to assess the extent to which the older person hears and understands what is being said. If the patient wears glasses, they should be clean and within reach of the patient. The head of the bed should be elevated so that the patient can see the speaker’s lips and eyes. A glare-free light source coming from behind the patient helps the patient to see the face and lips of the speaker. If the patient has a hearing impairment, background noise should be reduced by turning the television or radio off, by closing the door, and by asking others in the area to be quiet. The speaker should lean forward so that the lips can be seen, but shouting should be avoided. Most elderly people suffer from a selective high-frequency hearing loss with decreased ability to identify high-frequency tones and pitches in the consonants *s*, *f*, *t*, hard *g*, and *j*. Increasing the volume of sound is of little help, and shouting may be misinterpreted as hostility or anger. The manner of speaking should be natural and not distorted by exaggerated lip movements. When it is necessary to repeat a comment or question, it is better to rephrase than to say the same thing in a louder voice. If the patient has a hearing aid, it should be properly in place and in good working condition. Older people are often not aware of their hearing inadequacies, and their perceptions of what they have heard may not be accurate. Therefore, an attempt should be

made to determine whether the patient has properly interpreted what has been communicated.

Health care personnel and family members should not whisper or speak together in low tones near a hearing-impaired older adult. A few words may be heard that will result in misinterpretation, increasing the possibility of unwarranted fears, paranoid behavior, or hostility. Glasses and hearing aids should be worn consistently during the day. If the patient is able to talk, dentures should be in place to facilitate clear speech.

Immobility

Elderly patients are particularly vulnerable to the untoward effects of immobility. Contractures, pressure ulcers, and deconditioning can develop rapidly. Some of the other consequences of immobility include muscle atrophy, deep venous thrombosis, increased calcium mobilization from bone, atelectasis, hypostatic pneumonia, constipation, functional fecal and urinary incontinence, and loss of motivation.

Pressure ulcers are a common and frequent complication of immobility. Any disease process leading to immobility (eg, severe congestive heart failure, respiratory failure, delirium, fractures, complicated postoperative course, or spinal cord injury) places the elderly patient at high risk for development of a pressure ulcer. Sites commonly involved are the sacrum, ischial tuberosities, hip, heel, elbow, knee, ankle, and occiput. More than 50% of pressure ulcers occur in persons over age 70. Their prevalence among patients expected to be confined to a bed or a chair for at least 1 week is as high as 28%. Pressure ulcers generally occur within the first 2 weeks of hospitalization. Moreover, the development of pressure sores has prognostic implications; the mortality rate among those who develop pressure ulcers during the first 2 weeks has been as high as 73%. Sepsis is the most serious complication of pressure ulcers. Among bacteremic patients with a pressure ulcer as the probable source of infection, the in-hospital mortality rate can be as high as 60%.

Frequent repositioning (whether supine or in the sitting position) has been the primary method of preventing pressure ulcers. The evidence of structural changes in experimental animal models has led to the recommendation for repositioning every 2 hours. Repositioning should be performed so that a person at risk is positioned without pressure on vulnerable bony prominences. This is accomplished in practice by positioning patients horizontally with the back resting partially over pillows that maintain the body at a 30-degree angle to the support surface. Additional pillows between the legs and supporting the arms will aid in maintaining optimal positioning. A person with limited ability to change position who must sit in a chair or have the head of the bed elevated should not remain in this position for more than 2 hours at a time. To diminish the shearing forces over the sacral area, the head of the bed should not be elevated more than 30 degrees. Particulate matter (eg, food crumbs) should be removed from the bed. Sheets should be loose, and

tucking of the sheet at the foot of the bed should be avoided so that movement is not restricted and the feet can assume their natural position. Heels and elbows should be protected by raising them with pillows to avoid direct pressure over bony prominences. Patients should be lifted, not dragged. The skin should be patted dry, not rubbed. Moisture control depends on timely skin care. The evaluation and management of urinary and fecal incontinence are of crucial importance in these patients.

In high-risk patients, pressure-relieving devices such as constant low-pressure supports, alternating-pressure supports, or pressure-relieving cushions may be needed. Attention also should be directed toward proper nutrition, hydration, and pain control.

Educational programs aimed at physicians, nurses, and other caregivers; family members; and the patients themselves have beneficial results. One study found that when physicians ordered preventive measures for high-risk patients, the incidence of pressure ulcers was half that for patients for whom such orders were not written.

Bed rest also results in immobility and loss of weight-bearing forces on joints. These effects cause changes in periarticular and articular structures that result in joint contractures and changes similar to those of osteoarthritis. Changes in periarticular tissues occur within days. Muscles that bridge the immobilized joint shorten. These changes produce decreased range of motion that can be permanent, depending on the length of immobilization.

Bed rest is accompanied by progressive cardiovascular deconditioning with exaggeration of the hemodynamic changes normally seen with standing, as manifested by orthostatic intolerance and decreased exercise tolerance. Although orthostatic hypotension is not always documented, signs and symptoms of orthostatic intolerance such as tachycardia, nausea, diaphoresis, and syncope are common after prolonged bed rest. A decrease in coordination, as measured by pattern tracing and a marked increase in body sway in a standing position, has been documented after several weeks of bed rest.

The rate of decrease in muscular strength may be as high as 5% per day and varies with the degree of immobility. Leg muscles tend to lose strength about twice as fast as arm muscles. For some elderly patients who normally use 100% of their quadriceps muscle strength just to stand up, a loss of 5% per day results in significant loss of function in a short time.

Given the numerous complications resulting from immobility, early mobilization of the elderly patient in the ICU setting should be a high priority. The rate of loss of muscle strength will slow when active contraction of muscles is encouraged, particularly if resistance is added. Simple devices such as elastic fabrics (Theraband) make exercise against resistance available for patients in beds or chairs. Active movement in bed and full range-of-motion exercises should be encouraged in alert patients. For other patients, passive full range of motion should be done on every nursing shift.

Intermittent sitting—and standing when possible—will reduce the frequency of orthostatic hypotension. The sitting position also improves oxygenation and diminishes cardiac work because cardiac output and stroke volume decrease in the sitting position. Finally, rehabilitation service consultation may be useful in the management of elderly patients in the ICU.

Critical Care of the Oncology Patient*

Darrell W. Harrington, MD
Darryl Y. Sue, MD

20

Several complications of cancer may require critical care for palliative management. These include (1) acute CNS disorders (eg, spinal cord compression and increased intracranial pressure), (2) severe metabolic disorders (eg, hypercalcemia, hypocalcemia, tumor lysis syndrome, hyponatremia, hyperglycemia, hypoglycemia, and hypokalemia with ectopic adrenocorticotropic hormone [ACTH] production), (3) orthopedic disorders (eg, pathologic fracture), (4) urologic disorders (eg, hematuria, hemorrhagic cystitis, and acute obstructive uropathy), (5) general surgical disorders (eg, GI bleeding, bowel perforation, bowel obstruction, extrahepatic biliary obstruction, and intraabdominal abscess formation), (6) malignant effusions (eg, pericardial effusion with cardiac tamponade and pleural effusion with lung compression), (7) complications of chemo- and radiotherapy, and rarely, (8) superior vena cava syndrome. CNS disorders, metabolic disorders, and superior vena cava syndrome are addressed in this chapter.

CENTRAL NERVOUS SYSTEM DISORDERS

▶ Spinal Cord Compression

ESSENTIALS OF DIAGNOSIS

- ▶ Axial (back) pain that may radiate to arms or legs or bandlike discomfort around the chest.
- ▶ History of malignancy (may be initial presentation of cancer).
- ▶ Neurologic deficits (ie, motor, sensory, or autonomic).
- ▶ Abnormal images of spine: MRI (preferred), plain x-rays, CT scan, CT or planar myelography.

General Considerations

Spinal cord compression from epidural metastases is a potentially devastating complication in cancer patients. It occurs in about 5% of cancer deaths and therefore will develop in about 25,000 of the annual 500,000 cancer deaths. The most common primary tumors that cause spinal cord compression are cancers of the lung, breast, and prostate; lymphomas; and multiple myeloma. Cord compression also can be seen in patients with leukemia (chloroma) and a wide range of other solid tumors. It may present as the first and only manifestation of cancer, but it is postulated that prolonged survival from initial diagnosis of cancer will increase the incidence of spinal cord compression.

Epidural spinal cord compression develops via two mechanisms: (1) by metastatic spread to the vertebral bodies, from where the tumor expands and erodes into the epidural space, and (2) by cancerous involvement of the paravertebral region with extension into the epidural space through the intervertebral foramina. Bone scans and spine x-rays may be normal in the latter cases but usually are abnormal in the former. Vertebral body metastases account for epidural spinal cord compression in approximately 85% of patients with solid tumors and 25% of patients with lymphomas. In the 70% of cancer patients with metastases at death, metastases to the spine are found in 40%. Epidural metastases extend from the paravertebral region in the remainder. In addition to spinal cord compression, sudden irreversible spinal dysfunction may occur from vascular compromise, resulting in spinal cord infarction.

The thoracic spine occupies 47% of the total length of the spine but is the affected area in approximately 70% of patients, the lumbar spine occupies 30% and is affected in 20%, and the cervical region occupies 22% and is affected in 10% of patients. Spinal cord involvement may occur at multiple levels in 10–38% of patients. The greater chance of thoracic spine involvement may be related to the presence of physiologic kyphosis and the narrower spinal canal in this region. Metastases never traverse the intervertebral disks and rarely traverse the dura.

*Darrell W. Harrington, MD, and Hassan J. Tabbarah, MD, were the authors of this chapter in the second edition.

Clinical Features

A. Symptoms and Signs—The clinical presentation of epidural spinal cord compression is well known and depends on the level of spinal involvement. Axial pain is the most common presenting symptom (prodromal phase), occurring in 95% of adults and 80% of children with epidural spinal cord compression. Therefore, spinal cord compression should be considered in any patient with cancer and axial pain. The local pain corresponds to the site of the lesions and is described as dull and aching. Tenderness over the affected spinal element is usually readily elicited. Approximately 15% of patients will develop paraplegia despite a long duration of painful symptoms (compressive phase), because spinal cord compression was not anticipated. Pain may persist for several weeks or months before symptoms of radiculopathy are manifested. Cervical or lumbar disease usually but not always presents as unilateral radiculopathy, whereas thoracic disease produces bilateral symptoms resulting in a bandlike distribution of pain. Radicular pain may be accompanied by sensory or motor loss, as determined by the involved nerve root, and may be easily confused with disk herniation. Pain is usually worse at night and is aggravated by movement, coughing, or the Valsalva maneuver. Because midthoracic back pain is less likely to be due to benign causes, any patient localizing pain and tenderness to this area regardless of a history of malignancy should be evaluated carefully.

Neurologic deficits seen in spinal cord compression usually begin with motor impairment. These are seen more commonly in the distal part of the body or the lower extremities owing to the greater frequency of thoracic and lumbar spine involvement. Anterior spinal cord compression is more common than posterior involvement. Accordingly, patients usually have more motor than sensory disability, at least in the early stages. Sensory impairment follows, parallels the development of motor deficit, and is present in half of patients at the time of diagnosis of spinal cord compression. Autonomic dysfunction occurs later and is present in half of cases.

The neurologic deficit is caused either by mechanical compression by the tumor on the spinal cord or cauda equina or by destruction of a vertebral body sufficient to make it collapse and compress the spinal cord. Once spinal cord compression occurs, progression may be very rapid. Therefore, the presence of myelopathy is a neurologic emergency. Disease presentation and progression depend on the level of spinal involvement. For example, high cervical cord lesions (C3–5) may be life-threatening because both quadriplegia and respiratory muscle impairment are common features. Involvement of the thoracic cord typically is characterized by identification of a sensory level on the trunk. In addition, lower extremity weakness and autonomic dysfunction may accompany thoracic cord compression. The specific site of lumbosacral spinal cord compression is less easily determined by physical examination. Patients may present with radiculopathy and loss of associated reflexes or with isolated autonomic dysfunction as seen in the conus

syndrome. It is important that each patient have a complete neurologic examination, paying close attention to subtle asymmetries in muscle strength and reflexes. It is important to note that patellar and ankle reflexes provide information only about L4 and S1 nerve roots, respectively. Therefore, normal reflexes of the lower extremity should not be used to exclude the presence of significant myelopathy.

B. Laboratory Findings—A histologic diagnosis of malignancy is rarely necessary in a patient with a known preexisting malignancy. However, it is prudent to specifically identify malignancy causing spinal cord compression in an individual without an underlying history of cancer. This is so because localized infection causing spinal cord compression may mimic malignancy. In the presence of complete blockage of the spinal canal and to avoid worsening of neurologic status, only a few drops of cerebrospinal fluid (CSF) should be removed and sent for cytologic examination and protein determination. Additional studies are sent to exclude infection. Lumbar puncture otherwise should be reserved for patients suspected of concomitant leptomeningeal dissemination of tumor. CSF may have elevated protein, normal or low glucose, and a lymphocytic pleocytosis.

C. Imaging Studies—MRI is the diagnostic study of choice to evaluate spinal cord compression, but plain x-rays of the involved area and planar or CT myelography are potentially useful or necessary (especially if MRI is unavailable or cannot be performed). It is critical that imaging should be acquired as early as possible and should not be delayed more than a few hours in patients with neurologic symptoms and signs.

The most important attribute of MRI is its ability to evaluate directly the full length of the cord, thus making it possible for multiple levels of compression to be identified and to determine whether these lesions are related or unrelated to bony erosion or bone destruction by tumor. At least 35% of patients who present with focal symptoms have evidence of subclinical epidural compression at other sites along the spine. MRI also can determine the number of segments and vertebrae involved, the location of a compressive mass, if present (anterior, posterior, or encircling), and perhaps the percentage loss of bone mass. Imaging of the entire spine is usually not done because of the length of time needed (as much as 3 hours), but not taking the time may miss lesions that cause later neurologic compromise. MRI is comparable to myelography and CT scanning with contrast material in detecting leptomeningeal metastasis. However, MRI may be inadequate in patients who may have had previous spinal surgery because metal-induced artifacts may be seen or the patient's movements cannot be controlled.

Vertebral metastases can be seen on unenhanced T₁-weighted images as foci of low signal intensity (dark) that contrast with the adjacent high signal intensity (bright) of normal adult bone marrow. The administration of gadolinium results in normalization of the tumor, making its appearance similar to that of the marrow. Vertebral metastases rarely cross the disk space, as often seen in infection. However, it

sometimes may be difficult to distinguish between malignancy and infection with MRI. Diffuse bone marrow involvement may make interpretation by MRI difficult. This is also true in younger patients with relatively little fatty marrow. MRI is superior to CT scanning with and without intrathecal contrast material (CT myelogram).

Plain x-rays may be helpful in localizing the anatomic origin of compression symptoms. Hematologic malignancies less often are manifested by abnormal plain spine x-rays than solid tumors. The most common findings include loss of pedicles, destruction of the vertebral body, and vertebral body collapse. Plain x-rays will, however, be unsuccessful in identifying up to 20% of vertebral body lesions and also will fail to demonstrate paravertebral masses that spare vertebral body destruction but encroach on the epidural space via the intervertebral foramina. The overall diagnostic sensitivity of plain spine films is about 83%.

CT scans can assess the extent of a paravertebral mass, detect small areas of bone destruction, quantify the extent and characterize the direction of spinal cord impingement, and assess response to treatment. CT scans cannot investigate multiple levels of involvement without extensive scanning and may miss the area of maximal impingement if CT scan “cuts” are too widely spaced.

CT myelography remains an important diagnostic method for epidural spinal cord compression, especially when MRI is unavailable. Water-soluble contrast media are preferred. Once a complete block of the spinal canal is demonstrated by a lumbar myelogram, a C1–2 or suboccipital myelogram should be done to define the upper level of block. Myelography may disclose silent epidural metastasis. Lumbar myelography may cause further deterioration of neurologic findings in approximately 14% of patients even with the removal of only a small amount of CSF. Myelography has been associated with complications such as headaches, seizures, allergic reactions, and deterioration of neurologic status.

The role of radionuclide bone scans is unclear in the setting of suspected epidural spinal cord compression. Bone scans are less accurate than plain spine x-rays in predicting epidural involvement. Moreover, bone scans often will suggest multiple areas of abnormality without identifying the level associated with pain or neurologic deficit. Bone scans may not reflect the extent of vertebral involvement. These studies are reserved for patients with skeletal pain, negative plain x-rays, and a low suspicion for spinal cord compression.

Differential Diagnosis

The differential diagnosis of spinal cord compression includes intervertebral disk herniation, vascular disease (eg, hemorrhage or infarction), infectious processes such as epidural abscess, benign neoplasms (eg, meningioma, neurilemoma, and chordoma), neurologic disorders (eg, multiple sclerosis and amyotrophic lateral sclerosis), transverse myelitis, leptomeningeal carcinomatosis, and paraneoplastic syndromes (eg, necrotizing myelopathy and carcinomatous neuropathy).

Treatment

Early recognition, diagnosis, and treatment of epidural spinal cord compression are of utmost importance. Either the presence of neurologic symptoms or radiographic evidence of epidural compression is sufficient to justify beginning treatment. Cord compression diagnosed after the onset of myelopathy has the most profound impact on the patient's quality of life. The drastic difference is between 2 and 6 months of ambulatory survival versus 2–6 months of bed or wheelchair confinement with a urinary catheter, potential urosepsis, pneumonia, and decubiti—and dependence on professional care or family members. In one study, 70% of patients with malignant spinal cord compression had progression of symptoms from initial symptoms and onset of treatment. Reasons for delay included lack of recognition by the patient but also delays in diagnostic evaluation.

Although median survival after treatment for spinal cord compression is short, two factors appear to predict a good prognosis for recovery of function: a normal pretreatment neurologic examination and urgent appropriate treatment. Other prognostic factors include the rate and onset of progression of neurologic dysfunction, histologic features of the primary tumor (eg, myeloma, lymphoma, breast, and prostate have a better prognosis), the presence of vertebral collapse, and the location of the compressing lesion (anterior or posterior). In general, if patients are ambulatory before the start of treatment, two-thirds will remain ambulatory after treatment. If patients are paraparetic before treatment, one-third will be ambulatory after treatment, but if patients are paraplegic (especially if unresponsive to dexamethasone therapy), only a few—if any—will become ambulatory after treatment. The most commonly used treatment regimen consists of high-dose corticosteroid therapy plus external-beam radiation. Surgery is used selectively either as initial treatment or when specifically indicated.

A. Corticosteroids—To reduce edema of the cord adjacent to the tumor, corticosteroids are used frequently in the treatment of spinal cord compression. These should be started as soon as the diagnosis is suspected. Delaying therapy while awaiting formal studies is unnecessary and may lead to further progression of the neurologic deficit. These drugs clearly improve the initial rate of neurologic recovery and often lead to stabilization of the neurologic deficit. Randomized trials support the benefit of corticosteroids in those treated subsequently with radiotherapy. The optimal dose of corticosteroids is not known, but almost all recommendations support “high doses” in the range of 16–100 mg dexamethasone. Some studies have shown both a higher likelihood of benefit from the highest dosages and more complications of therapy. One recommendation is to vary the dose with the degree of neurologic impairment. With pain or radiculopathy alone, dexamethasone, 16 mg intravenously, followed by 4–6 mg intravenously or orally every 6 hours, is adequate. Patients with rapidly progressive symptoms or significant

myelopathy should be treated with dexamethasone, 100 mg intravenously, followed by 24 mg intravenously every 6 hours. Therapy should be continued until benefit is demonstrated from definitive therapy (ie, radiation or surgery) or neurologic deficits are considered irreversible. Tapering of corticosteroids is accomplished by reducing the dose by about one-third every 3–4 days over a period of 2–3 weeks. Corticosteroids should be reinstated if neurologic deficits recur. Patients failing to improve after a 7-day trial at 100 mg/day should be rapidly tapered to the lowest dose that will maintain stable neurologic function. Such steroid regimens do not appear to be toxic, although vaginal burning may occur with rapid intravenous administration of dexamethasone. Conversely, corticosteroids may result in serious and fatal complications when used in high doses for more than 40 days or when given to patients with serum albumin concentration of less than 2.5 g/dL.

B. Radiation Therapy—Radiation therapy alone produces neurologic improvement in 30–50% of patients with epidural spinal cord compression. Pain relief is obtained in the majority of patients with radiation therapy. Radiation-sensitive tumors such as hematologic malignancies and seminomas have the best outcome, breast and prostate cancer have moderately good outcomes, and lung and renal cancer, sarcomas, and melanoma are radioresistant and have the worst outcomes. Radiation therapy and surgical therapy appear to be of equal effectiveness in the treatment of radiosensitive tumors. The usual dose of radiation is 3000–4000 cGy over a period of 3–4 weeks. There are few differences reported between various radiotherapy protocols (ie, dose, number of fractions, and total duration). Complications of radiation therapy include radiation myelopathy and impaired wound healing in patients who undergo subsequent surgery.

C. Surgery—The surgical approach selected—laminectomy, anterior surgical decompression, or posterolateral surgical decompression—depends on several variables, including the specific element of vertebral involvement, cord level, and stability of the spine. The concept that surgery is not indicated in the treatment of spinal cord compression is based on retrospective analysis of several surgical series that compared decompressive laminectomy followed by radiation therapy with radiation therapy alone. No difference in neurologic outcome was reported initially. Better understanding of the pathogenesis of cord compression combined with advances in operative technique and materials have resulted in improved outcomes after surgical decompression. For example, in 54 patients with cord compression in whom laminectomy or vertebral body resection was performed, all 54 improved, and 23 of 25 patients surviving for 2 years remained ambulatory. The 30-day mortality rate in this series was 6%, and the morbidity rate was 15%.

Surgery is a major procedure associated with a significant rate of complications. Therefore, surgery should be used only in patients who have less extensive disease and longer life expectancy. In the absence of medical contraindication,

surgery may be considered (1) when the diagnosis is not known or is in doubt, (2) when there is spinal instability or bone deformity, (3) when there is failure to respond to radiation therapy, (4) when there is a history of previous radiation therapy up to cord tolerance, (5) when there is high cervical spinal cord compression (because of the danger of respiratory failure), (6) in the presence of a radioresistant tumor, especially when the onset of signs is rapid and complete block is present, (7) when atlantoaxial compression is present, (8) when a solitary spinal cord metastasis is present, and (9) as a form of primary treatment before radiation therapy. When possible, it is recommended that adjuvant chemotherapy be delayed for 3–6 weeks after surgical therapy to minimize wound complications.

Table 20–1 offers an approach to the patient with known or suspected malignancy that presents with back pain and possible spinal cord compression.

- ▶ Abnormal brain CT or MRI diagnostic or suspicious of intracranial tumor or metastases.

Table 20–1. Management of patients with back pain and suspected malignancy.

Other Clinical Findings	Diagnostic Studies	Treatment
Normal neurologic examination Normal plain spine x-rays	MRI for high-risk tumors or in the presence of other metastatic disease. If MRI is not available, then CT, CT with myelography, or myelography. Observe closely for low-risk primary tumors.	Treatment depends on MRI or CT findings.
Normal neurologic examination Abnormal plain spine films	None. MRI, or CT with myelography.	Radiation therapy to symptomatic vertebral metastases without further imaging. Advantages: No delay in treatment, no further expense. Disadvantages: May miss other sites of disease that may become symptomatic later and compromise further radiotherapy because of overlapping radiation therapy ports. Disadvantages reduced if x-ray of entire spine is obtained, radiation port includes two segments above and below lesions, or bone scan is performed to document that disease is limited to one area of the spine. Treatment depends on MRI or CT findings.
Abnormal neurologic examination Abnormal or normal plain spine x-rays	MRI of symptomatic area to identify adjacent levels of involvement. If MRI is unavailable, consider CT with myelography.	Treatment (radiation therapy) depends on MRI or CT findings. Consider selective surgery.

General Considerations

Increased intracranial pressure (ICP) can cause neurologic damage either directly or indirectly by way of herniation of the cerebellar tonsil or uncal or by secondary vascular compromise. It is essential that prompt management be instituted in order to prevent loss of cerebral function or death.

The closed cranium means that any increase in volume of any intracranial component must result in increased pressure. A tumor increases ICP by adding its bulk or localized edema to the normal components of brain tissue, CSF, and vessels within the cranium.

Increased ICP can result from primary or metastatic tumors. At least one-fourth of patients dying from malignancy will have brain metastases discovered at autopsy. Hematogenous spread is the most common route of dissemination. Thus most lesions (approximately 80%) are supratentorial. The most common cancers found include lung, renal, breast, and melanoma. Brain metastases from choriocarcinoma, melanoma, and breast cancer more often undergo hemorrhagic transformation. The metastatic tumors may be single or multiple and should be distinguished from diffuse infiltrative processes that also may cause increased ICP. Leukemic meningitis and diffuse leukemic infiltration also can cause increased ICP but without the focal neurologic or radiographic findings usually

seen in primary or metastatic brain tumors. In diffuse processes, ICP increases without evidence of other concomitant findings (eg, localizing findings from a mass lesion).

Brain edema results from leakage of plasma into the parenchyma through dysfunctional capillaries (ie, vasogenic edema). Studies on the formation, speed, and resolution of brain edema have concluded that increased capillary permeability occurs within the brain tumor itself and not in the surrounding brain tissue. This increased capillary permeability varies depending on the histology of the tumor and its size. Brain edema occurs preferentially in the cerebral white matter. Vascular endothelial growth factors may contribute to dysfunction of tight junctions. It is not clear how brain edema results in neurologic dysfunction, but it is thought to be related to ischemia from a mass effect or from metabolic abnormalities in the surrounding extravascular fluid.

Untreated, metastatic brain tumors ultimately lead to progressive neurologic dysfunction and death. The median survival in this setting is 4–6 weeks.

Clinical Features

A. Symptoms and Signs—Headache, nausea, vomiting, mental deterioration, lethargy, somnolence, and confusion are key findings in patients with increased ICP. Flexor or extensor posturing may occur. In addition, decrease in

heart rate, increase in blood pressure, and abnormal respiratory pattern (Cushing's triad) often can be present but are late findings. Cerebellar masses may, however, have a reversed clinical picture. Dilation of one or both pupils suggests rapid and significant increases in ICP. Focal neurologic deficits and abnormal reflexes may be found. Early diagnosis is usually based on the timely observation of subtle alterations in the mental status or state of consciousness of the patient.

B. Laboratory Findings—Lumbar puncture for diagnosis is to be discouraged because removal of fluid from the intrathecal sac may result in an acute drop in intratentorial pressure, thereby precipitating or worsening herniation.

C. Imaging Studies—Head CT scan and MRI are the most useful diagnostic tests. The size and location of a tumor mass or masses, the amount of peritumoral edema, shifts in intracranial structures, and ventricular size can be determined easily. No test is completely accurate in predicting risk of herniation. MRI is more sensitive than CT scan for finding tumor, especially when evaluating lesions of the posterior fossa. However, CT scan may better detect bony involvement of the skull. Both non-contrast- and contrast-enhanced CT scans are recommended because the combination not only may detect hemorrhagic lesions (non-contrast-enhanced) but also may allow detection of small lesions (contrast-enhanced).

Differential Diagnosis

The differential diagnosis of increased ICP includes metabolic encephalopathy (eg, hypo- and hypernatremia, hypercalcemia, uremia, hypoxemia, hypoglycemia, and thyroid dysfunction), CNS infection, cerebrovascular disease (especially intracranial hemorrhage), drug-induced encephalopathy (eg, sedatives and analgesics), and nutritional deficiencies.

Treatment

A. Medical Treatment—If signs of cerebral herniation are evident, emergent reduction of ICP is warranted. Emergent maneuvers include elective intubation and hyperventilation to maintain P_{aCO_2} between 25 and 30 mm Hg, followed by administration of mannitol, 1–1.5 g/kg intravenously every 6 hours. Some recommend following serum osmolality as a guide to dosing mannitol. Use of mannitol should be avoided when definitive therapy (surgery or radiation) is delayed. In any case, hypotonic fluids may be harmful and should not be given. Early corticosteroid (eg, dexamethasone) administration and fluid restriction appear to be the best means of achieving a decrease in ICP and brain edema. The specific mechanism of action of corticosteroids on brain edema is not known. These agents may either decrease edema production or increase edema resorption. Corticosteroids appear to decrease tumor capillary permeability and alter the exchange of sodium and water across the endothelial cells and decrease

CSF production at the choroid plexus. Corticosteroid administration may result in symptomatic improvement within 4–5 hours, but more commonly such improvement occurs gradually over several days, with 70% of patients showing late significant clinical improvement. Dexamethasone is administered at a dosage of 16 mg/day in four divided doses, and the dosage may be increased to 100 mg/day. Some patients must remain on corticosteroids for long periods and whenever they undergo definitive treatment such as surgery or radiation. Patients are subject to the risks and side effects of high-dose corticosteroids if administered for long enough time.

Preemptive antiseizure medications are frequently administered, but their value is controversial. Because patients with malignancy have a high risk for venous thromboembolism, deep venous thrombosis prophylaxis is recommended despite the theoretical risk of hemorrhage from primary or metastatic brain tumor.

B. Surgical and Radiation Treatment—Surgery and radiation therapy are important methods of treatment of primary and metastatic brain tumors either as initial or as adjunctive therapy. Candidates for surgical resection should be patients with solitary lesions and limited systemic disease. Radiation therapy usually involves the whole brain and requires an average of 3000 cGy. Most recently, radiosurgery has evolved as a new technique to deliver a single large dose of radiation to a specific target. Local control rates appear to be equal to those achieved with surgery. Radiosurgery is especially useful in patients with multiple or poorly accessible lesions.

METABOLIC DISORDERS

▶ Hypercalcemia of Malignancy

ESSENTIALS OF DIAGNOSIS

- ▶ Mental status changes, lethargy, confusion, weakness.
- ▶ Altered deep tendon reflexes without localized neurologic signs.
- ▶ History of malignancy, usually far-advanced.
- ▶ Elevated serum calcium, chloride:phosphate ratio, and (often) parathyroid hormone-related polypeptide (PTHrP).

General Considerations

Hypercalcemia is the most serious metabolic disorder associated with cancer. Between 10% and 20% of patients with cancer will develop hypercalcemia at some point, and life expectancy is poor in these patients, even when they are actively treated. Treatment of hypercalcemia of malignancy is usually palliative because most of these patients have advanced disease. However, symptoms are usually improved with treatment, and many patients may be made well enough to go home from the hospital. While treatment of hypercalcemia may not prolong survival, it clearly improves quality of life.

Pathogenesis

Serum calcium is regulated by hormones and locally acting cytokines at three main sites: the gut, the skeletal system, and the kidneys. Parathyroid hormone (PTH) increases the number and function of osteoclasts, inhibits osteoblasts, and increases renal tubular reabsorption of calcium, all of which increase extracellular calcium levels. The hormone also increases production of active vitamin D, which increases the absorption of calcium from the gut.

In all cases of cancer-related hypercalcemia, there is increased calcium resorption from bones relative to bone formation (Figure 20-1). Increased bone resorption is maintained through the destructive action of tumor cells by increased osteoclast activation mediated through the action of PTH-related polypeptide (PTHrP) and by locally acting cytokines. Squamous cell carcinomas originating in the lung, head and neck, esophagus, uterine cervix, vagina, and penis—as well as cancers of the breast, lung, and kidney—produce PTHrP. This hormone shares homology with the amino-terminal portion of parathyroid-produced PTH only in 8 of the first 13 amino acids. It has predicted isoforms of 139, 141, and 173 amino acids compared with 84 amino acids in PTH. PTHrP, like PTH, can mediate bone resorption of calcium and renal tubular absorption of

calcium, but unlike PTH, serum calcium levels do not regulate its secretion. Recently, an aberrant extracellular calcium-sensing receptor (CaR) has been associated with a counterproductive increased release of PTHrP by tumor cells, as well as potentially stimulating cell growth and inhibiting apoptosis.

PTH and PTHrP are distinguishable by radioassay, and for this reason, it is possible to distinguish humoral hypercalcemia of malignancy from coexisting primary hyperparathyroidism. Despite a high frequency of bony metastases, prostate, small cell lung cancer, and colorectal carcinoma are rarely associated with hypercalcemia.

In addition to PTHrP, a number of locally active cytokines augment resorption of calcium from bone, including interleukin 1 (IL-1), IL-3, IL-6, IL-8, and IL-11 and tumor necrosis factors (TNF- α and TNF- β)—all of which are components of what was formerly called *osteoclast-activating factor*. Furthermore, transforming growth factor (TGF- α), platelet-derived growth factor, and certain hematopoietic colony-stimulating factors such as granulocyte-macrophage colony-stimulating factor (GM-CSF) also can augment bone resorption. In patients with myeloma, increased bone resorption from cytokines is the primary mechanism of hypercalcemia. Prostaglandin E₂ also can increase bone resorption. Two locally acting cytokines also decrease the amount of calcium from bone: interferon- γ and transforming growth factor β (TGF- β). Both inhibit osteoclasts and bone resorption, and TGF- β promotes osteoblast activity.

Some Hodgkin's and non-Hodgkin's lymphomas can 1-hydroxylate sufficient amount of vitamin D to its more highly active form. This increases gut absorption of calcium and, together with the calcium resorption from cytokines acting locally in bone, may produce hypercalcemia. Hypercalcemia is a prominent feature of adult T-cell lymphomas (45% of cases) and of lymphomas and leukemias associated with HTLV-1 (90%).

Clinical Features

When hypercalcemia results from malignancy, the cancer is rarely occult. Patients with severe hypercalcemia (serum calcium >14 mg/dL) are usually symptomatic. These symptoms are often related to the rapidity of onset of hypercalcemia.

The clinical features of hypercalcemia and, in particular, its neuromuscular manifestations tend to be much more prominent in the elderly. Other factors such as the patient's performance status, recent chemotherapy, sites of metastasis, and the presence of hepatic or renal dysfunction may increase the severity of symptoms. Since calcium is a critical regulator of cellular function, patients with hypercalcemia may have a wide range of symptoms affecting different organ systems. Conversely, the most common symptoms of hypercalcemia may be nonspecific and are similar to those seen in patients with chronic or terminal illnesses, such as nausea, anorexia, weakness, fatigue, lethargy, and confusion. In late

▲ **Figure 20-1.** Mechanisms of hypercalcemia of malignancy. Osteoclast activity can be stimulated by hormones, cytokines, and other substances from certain primary tumors distant from bone or by tumor in the bone marrow. In other patients, local production of cytokines known as *osteoclast-activating factors* are the primary mediators of increased calcium mobilization. Both peripheral blood and marrow lymphocytes produce cytokines that affect osteoclasts. 1,25(OH)₂ vitamin D increases calcium absorption from the small intestine. Other local cytokines have an inhibitory effect on osteoclast activity. [1,25(OH)₂D = vitamin D; PTHrP = parathyroid hormone-related polypeptide; IL = interleukin; TGF- α and TGF- β = transforming growth factors α and β ; TNF- α and TNF- β = tumor necrosis factors α and β ; PDGF = platelet-derived growth factor; GM-CSF = granulocyte-macrophage colony-stimulating factor.]

stages, patients may be stuporous or comatose, and their symptoms may mimic a neurologic emergency.

A. Neurologic—The major neurologic manifestations include weakness, altered mental status, and altered deep tendon reflexes. Initial manifestations may include subtle personality changes, impaired concentration, apathy, mild confusion and irritability, lethargy, hallucinations, and psychosis, with progression to stupor and coma. Focal neurologic signs are usually absent.

B. Gastrointestinal—Because of the depressive action of hypercalcemia on autonomic nervous tissue, nonspecific

symptoms such as anorexia, nausea, and vomiting may occur. These often progress to include abdominal pain, constipation, frank obstipation, increased gastric acid secretion, and acute pancreatitis.

C. Renal—Hypercalcemia causes a reversible tubular defect in the kidney that limits urinary concentrating ability and promotes dehydration or hypovolemia. If able, patients will admit to polyuria, nocturia, and polydipsia. Metabolic alkalosis is common, and acidosis occurs only when azotemia supervenes. This contrasts with the effects of PTH, in which a mild hyperchloremic acidosis is seen. Hypercalcemia also can lead to precipitation of calcium phosphate crystals in the

kidneys and ureters and the formation of renal calculi. Such complications, however, are not commonly associated with hypercalcemia of malignancy, and when they occur, the possibility of coexisting primary hyperparathyroidism should be considered.

D. Cardiovascular—Hypercalcemia may cause electrocardiographic disturbances such as prolongation of the PR and QRS intervals and shortening of the QT interval. With severe hypercalcemia (>16 mg/dL), the T wave widens, increasing the QT interval. At higher serum calcium concentrations, bradyarrhythmias and bundle branch block may develop, followed by complete heart block and cardiac arrest in systole.

E. Bone and Extraskelatal Tissues—Hypercalcemia can result either from humorally mediated bone resorption or from osteolytic metastasis. Pain, fractures, and skeletal deformities can occur. Metastatic calcification occurs in long-standing and very severe hypercalcemia. Extraskelatal deposition of calcium has been observed with hypercalcemia in several organs, including the heart, lungs, kidneys, skin, joints, and conjunctivae.

F. Laboratory Findings—Serum calcium, phosphate, and albumin levels should be determined in all patients. Ionized calcium is responsible for clinical manifestations and is almost half the total serum calcium in normal subjects (the rest is protein-bound). Measured ionized calcium is the most accurate predictor of clinical features. A clinical estimate of the “effect” of ionized calcium is the corrected serum calcium equal to the measured calcium + 0.8 × (4 – measured albumin). This calculation is especially helpful when hypoalbuminemia coexists with hypercalcemia. Hypophosphatemia in the presence of hypercalcemia strongly suggests the presence of PTHrP or primary hyperparathyroidism. Elevated alkaline phosphatase is usually not helpful because it is seen in both primary hyperparathyroidism and hypercalcemia of malignancy. Direct measurement of PTH and PTHrP may be necessary in some patients.

G. Radiographs—Nephrocalcinosis and nephrolithiasis may be present in long-standing hypercalcemia and suggest hyperparathyroidism.

Differential Diagnosis

The differential diagnosis of hypercalcemia of malignancy includes a wide variety of conditions (Table 20–2). Among all patients, the two most common causes of hypercalcemia are malignancy (35%) and primary hyperparathyroidism (54%). Among hospitalized patients with hypercalcemia, 77% have malignancies, 4% have coexistent hyperparathyroidism, 2% have vitamin D intoxication, 2% have tamoxifen-induced hypercalcemia, and 16% are due to other causes. Table 20–3 lists features that may be used to

Table 20–2. Causes of hypercalcemia.

I. Primary hyperparathyroidism (54%)
II. Cancer (35%)
A. Caused by hormones (HHM) (80%)
1. Most common: Lung cancer (especially epidermoid) and renal cell carcinoma.
2. Less common: Head and neck cancer, ovarian cancer, hepatoma, pancreatic cancer, bladder cancer, endometrial cancer, lymphomas, leukemia, multiple myeloma.
3. Isolated case reports: Esophageal cancer, colon cancer, rectal cancer, cervical cancer, uterine leiomyosarcoma, vulvar cancer, cancer of the penis, prostate cancer, adrenal cancer, melanoma, hemangiopericytoma, branchial rest cancer, parotid cancer, breast cancer, mammary dysplasia.
B. Caused by metastatic destruction of bone (20%). Breast cancer (most common), multiple myeloma, lymphoma, and leukemia.
III. Others (11%)
A. Nonparathyroid endocrine disorders: Thyrotoxicosis, pheochromocytoma, adrenal insufficiency, vasoactive intestinal polypeptide hormone-producing tumor.
B. Granulomatous diseases: 1,25-(OH) ₂ vitamin D excess, sarcoidosis, tuberculosis, histoplasmosis, coccidioidomycosis, leprosy.
C. Medications: Thiazide diuretics, lithium, estrogens, and antiestrogens.
D. Milk-alkali syndrome.
E. Vitamin A or vitamin D intoxication.
F. Familial hypocalciuric hypercalcemia.
G. Immobilization.
H. Parenteral nutrition.

HHM = humoral hyperglycemia of malignancy.

differentiate primary hyperparathyroidism from hypercalcemia of malignancy.

Treatment

There is no one regimen that should be applied to the acute management of all cases of hypercalcemia. Moderate hypercalcemia with minimal symptoms may be managed with administration of intravenous 0.9% NaCl. If the hypercalcemia is more severe and is symptomatic, furosemide and calcitonin may be added. Since the effects of calcitonin are not long-lasting, the use of bisphosphonates early in treatment is indicated. In patients with lymphoma or myeloma and hypercalcemia, corticosteroids are useful because of the significant role of cytokines in the hypercalcemia. Intravenous administration of sodium phosphate can lower the serum calcium level rapidly, but its use is dangerous because calcium phosphate complexes will deposit in blood vessels, lungs, and kidneys with resulting severe organ damage and even fatal hypotension. Therefore, intravenous phosphates are not recommended. Oral phosphates are of limited value because diarrhea often develops with an intake of more than 2 g/day. Azotemia and hyperphosphatemia are contraindications to phosphate therapy.

Table 20-3. Features used to differentiate primary hyperparathyroidism from malignancy-related hypercalcemia.

	Primary Hyperparathyroidism	Hypercalcemia of Malignancy
Symptoms	Mild or absent	Symptomatic
Serum calcium	Mildly increased (<14 mg/dL)	Significantly increased (>14 mg/dL)
Serum phosphorus	Decreased	Variable
Serum potassium	Normal	Usually decreased
Serum chloride	Increased*	Low or normal
Serum bicarbonate	Decreased (hyperchloremic acidosis)	Normal or increased
Urinary calcium	Increased	Markedly increased
Urinary cAMP	Increased	Variable
1,25-(OH) ₂ vitamin D	Increased	Usually decreased

*Serum chloride:phosphate ratio is increased.

Therapy for hypercalcemia in cancer patients centers on four main mechanisms: (1) correction of volume depletion, (2) inhibition of bone resorption of calcium, (3) enhancement of renal calcium excretion, and (4) treatment of the underlying malignancy. Table 20-4 summarizes the available drugs and their dosages.

A. Fluid and Electrolytes—Volume and electrolyte repletion are the first priorities. Normal saline (0.9% NaCl), usually containing potassium chloride (10–20 meq/L), is given at a rate of 2–3 L/day. Loop diuretics such as furosemide (40–80 mg intravenously) are used to induce calciuresis and preclude volume overload once fluid deficits are corrected. Judicious fluid administration or central venous pressure monitoring may be appropriate in patients with poor urine output or congestive heart failure. As a result of calcium-related renal tubular impairment and the resulting polyuria, urine output may not be a reliable measure of intravascular volume repletion.

B. Calcitonin—Calcitonin is a useful adjunct in the initial phase of therapy. It is nontoxic and acts within 4–24 hours. Calcitonin promotes renal excretion of calcium, inhibits bone resorption, and inhibits gut absorption of calcium. The effects of calcitonin, however, are minor and of short duration. Calcitonin is usually administered over 24 hours as an intravenous infusion in a dose of 3 units/kg or 100–400 units subcutaneously every 8–12 hours.

C. Corticosteroids—Corticosteroids decrease intestinal calcium absorption and inhibit bone resorption and in that way act as vitamin D antagonists. They also inhibit the action of

some of the locally acting cytokines that mediate calcium mobilization from bone. They are effective primarily in hematologic malignancies and breast cancer, essentially to control chronic hypercalcemia.

Table 20-4. Treatment of hypercalcemia of malignancy.

- IV fluid replacement with 3–6 L of 0.9% NaCl with 40–80 mg of potassium chloride per liter over 24 hours.
- Furosemide, 40–160 mg IV over 24 hours.
- Bisphosphonates:
 - Pamidronate, 60–90 mg in 1 L 0.9% NaCl over 4–24 hours.
 - Etidronate, 7.5 mg/kg in 300 mL 0.9% NaCl over 3 hours for 3–5 days.
- Calcitonin: Extremely useful in patients with life-threatening hypercalcemia. It has the most rapid action: 2–4 hours.
 - 600 IU in 1 L 0.9% NaCl over 6 hours.
 - 6–8 IU/kg IM every 6–8 hours for 2–3 days.
- Corticosteroids: 200–300 mg of hydrocortisone per day or equivalent.
- Gallium nitrate: 200 mg/m² in 1 L 5% dextrose over 24 hours for 5 days.
- Plicamycin: 25 µg/kg for total dose of 1.5–2 mg IV administered in brief infusion or over 12 hours. No benefit from prolonged infusion.
- Phosphates: Oral phosphates, 0.5–3 g/d diluted in water. IV phosphates should not be given.

Formula to correct serum calcium for changes in serum albumin concentration: Corrected serum calcium = measured total calcium value (mg/dL) – serum albumin value (g/dL) + 4.

D. Bisphosphonates—Bisphosphonates are used routinely because of their efficacy and low toxicity. They are potent inhibitors of osteoclasts and bind to hydroxyapatite in bone to inhibit dissolution. A single dose of pamidronate (60–90 mg in 1 L of normal saline over 4–24 hours) by intravenous infusion is safe and effective. Significant reductions in serum calcium usually occur in 1–2 days and persist for several weeks. Zoledronic acid is a more potent bisphosphonate that has been associated with a higher proportion of correction of hypercalcemia and more rapid normalization than pamidronate. It is given intravenously as 4 mg over not less than 15 minutes. The dose must be adjusted for renal insufficiency. Rare complications of bisphosphonates include acute systemic inflammatory reaction, eye inflammation, renal failure, nephrotic syndrome, and hypocalcemia. Jaw osteonecrosis is seen primarily with long term use of bisphosphonates.

E. Dialysis—Hemodialysis is very effective in the treatment of hypercalcemia but is usually reserved for management in the setting of renal failure or life-threatening manifestations.

F. Other Therapies—Plicamycin and gallium nitrate decrease bone resorption. Prostaglandin synthetase inhibitors and other investigational drugs such as amifostine (WR-2721) have been used. Amifostine inhibits PTH secretion and bone resorption and facilitates urinary excretion of calcium.

All patients should be encouraged to avoid immobilization and ambulate. In addition, liberal fluid intake and avoidance of large amounts of foods rich in calcium are also suggested.

▶ Hypocalcemia in Malignant Disease

ESSENTIALS OF DIAGNOSIS

- ▶ Tetany; paresthesias of the face, hands, and feet.
- ▶ Positive Chvostek and Trousseau signs.
- ▶ Muscle cramps, laryngeal spasm, headache, lethargy.
- ▶ Low serum calcium (corrected) or low ionized calcium.
- ▶ Osteoblastic metastases (breast or prostate cancer) or tumor lysis syndrome with elevated serum phosphorus.

General Considerations

Hypocalcemia is a rare complication of cancer resulting from osteoblastic metastasis secondary either to rapid bone healing

in patients with prostate or breast cancer receiving hormonal therapy or to hyperphosphatemia in patients with tumor lysis syndrome. The most common neoplasm associated with hypocalcemia is prostate cancer, and 31% of patients with prostate cancer and extensive osteoblastic bone metastasis develop hypocalcemia. The skeleton in these patients has been described as a “calcium sink.” Hypocalcemia secondary to tumor lysis syndrome may be severe and appears to result from a rise in the serum calcium \times phosphorus product, leading to precipitation of calcium in soft tissues, including the kidneys, and the development of secondary hyperparathyroidism.

Hypocalcemia also may occur secondarily in patients with low circulating $1,25(\text{OH})_2$ vitamin D and calcifying chondrosarcoma. Magnesium deficiency results in hypocalcemia in patients with prolonged nasogastric drainage, parenteral hyperalimentation without magnesium supplementation, cisplatin therapy, long-term diuretic therapy, chronic diarrhea, and chronic alcoholism and does not respond to calcium replacement alone. Treatment of hypercalcemia with plicamycin, bisphosphonates, or intravenous phosphate also may cause hypocalcemia.

Clinical Features

The diagnosis of hypocalcemia is made with ease in patients who develop tetany. Paresthesias of the face, hands, and feet associated with muscle cramps, laryngeal spasm, diarrhea, headache, lethargy, irritability, or seizures are the common clinical manifestations. Chvostek’s and Trousseau’s signs are usually present. The ECG usually shows a prolonged QT interval. In long-standing cases, dry skin, papilledema, and cataracts may develop.

Differential Diagnosis

The differential diagnosis of hypocalcemia should include severe alkalosis secondary to vomiting, nasogastric suction, or hyperventilation and severe muscle cramps resulting from vincristine or procarbazine therapy.

Treatment

Treatment of acute severe hypocalcemia (serum calcium $<$ 6 mg/dL) consists of intravenous administration of calcium gluconate or calcium chloride, 1 g every 15–20 minutes until tetany disappears, and magnesium sulfate, 1 g intravenously or intramuscularly every 8–12 hours if the serum magnesium level is less than 1.5 mg/dL or is unknown. In patients with moderate hypocalcemia (serum calcium $>$ 7 mg/dL), calcium and magnesium may be replaced more slowly.

Maalouf NM et al: Bisphosphonate-induced hypocalcemia: Report of 3 cases and review of literature. *Endocr Pract* 2006;12:48–53. [PMID: 16524863]

► Tumor Lysis Syndrome

ESSENTIALS OF DIAGNOSIS

- Lethargy, tetany, muscle cramps, convulsions.
- Administration of chemotherapy to patient with rapidly proliferating malignancy.
- Elevated serum uric acid, potassium, phosphate, and urea nitrogen.

General Considerations

When given to a patient with a highly responsive (usually rapidly growing) malignancy, chemotherapy may trigger release of massive amounts of potassium, phosphate, uric acid, and other breakdown products of dying tumor cells into the bloodstream. Hypocalcemia owing to hyperphosphatemia may occur. This syndrome of tumor lysis occurs most commonly in patients with rapidly proliferating and chemotherapy-sensitive malignancies, such as acute leukemia and Burkitt's lymphoma and, on rare occasions, following treatment of solid tumors and chronic lymphocytic leukemia (CLL). Tumor lysis syndrome has been reported after chemotherapy, radiotherapy, monoclonal antibody treatment, corticosteroids, and rarely spontaneously. Life-threatening complications may occur, including renal failure from hyperuricemia and cardiac arrhythmias induced by hyperkalemia or hypocalcemia.

Diagnosis

Diagnosis of tumor lysis syndrome is made most often from laboratory studies. However, lethargy, tetany, muscle cramps, and convulsions occurring in a patient with an appropriate tumor who has just received chemotherapy should prompt evaluation. Hyperkalemia, hyperphosphatemia, azotemia, and oliguria usually are present.

Treatment

Early recognition of risk is the key to prevention and treatment of this complication of cancer therapy. Despite appropriate treatment, renal insufficiency still may occur. However, prognosis is good, and recovery to baseline renal function is expected.

A. Hyperkalemia—Immediate treatment of hyperkalemia consists of administration of 50–100 mL of 50% dextrose in water and 10 units of regular insulin. Removal of potassium can be achieved with oral sodium polystyrene sulfonate, 20–30 g every 6 hours. Hemodialysis may be necessary for the management of refractory hyperkalemia.

B. Hyperphosphatemia—Hyperphosphatemia is typically severe, with serum levels ranging from 6 up to as much as

35 mg/dL resulting from tumor cell lysis and subsequent renal failure. Patients should be given 20% dextrose in water and insulin until the serum phosphate level falls below 7 mg/dL. Aluminum hydroxide, 30–60 mL orally every 2–6 hours, is used to bind phosphate in the intestines. Oral fluids are given at the rate of 2–4 L every 24 hours. Dialysis may be necessary for patients with renal failure. Hyperphosphatemia may be accompanied by hypocalcemia as well.

C. Hyperuricemia and Hyperuricosuria—Increased urinary uric acid excretion may occur in untreated patients with rapidly growing malignancies or during their treatment with chemotherapy or radiation therapy. Uric acid nephropathy secondary to the precipitation of uric acid crystals in the kidneys may result. Nephrolithiasis with urate stones or urate interstitial nephritis also may occur. When massive doses of allopurinol are used to prevent uric acid production, renal oxypurinol stones may form occasionally.

Prevention of anticipated hyperuricemia is the cornerstone of management. Allopurinol should be given to patients with myeloproliferative disorders and hematologic malignancies at least 12 hours before starting chemotherapy. Rasburicase, a recombinant urate oxidase, does not cause xanthine and hypoxanthine to accumulate but rather converts urate to allantoin, a much more soluble product. Rasburicase is much more effective and rapid in lowering plasma uric acid levels. However, rasburicase is highly immunogenic, with development of antirasburicase antibodies occurring in the majority of patients exposed. This limits the use of this agent to those with severe and poorly responsive hyperuricemia.

D. Hydration—Vigorous hydration and alkalinization of the urine decrease the risks of urinary tract precipitation of uric acid and may decrease hyperkalemia. Urine flow should be maintained at a rate of more than 100 mL/h, and urine pH should be between 7.0 and 7.5. Sodium bicarbonate or acetazolamide is given to alkalinize the urine. The ideal choice of intravenous fluid is not clear, but usually dextrose 5% in 0.45% NaCl is given with 50–100 meq of NaHCO₃ added per liter starting 24–48 hours before treatment, if possible. A rare complication of urinary alkalinization is precipitation of calcium phosphate stones.

► Hyponatremia in Malignancy

ESSENTIALS OF DIAGNOSIS

- ▶ Nausea, anorexia, lethargy, confusion, weakness, convulsions, coma.
- ▶ Low plasma sodium with persistent excretion of concentrated urine.
- ▶ Normal renal function with low serum urea nitrogen, absence of fluid retention, and absence of intravascular volume contraction.
- ▶ History of malignancy, most frequently associated with small cell carcinoma of the lung.

General Considerations

Hyponatremia in malignant disease is most often associated with the syndrome of inappropriate antidiuretic hormone secretion (SIADH), resulting from secretion of ADH by the tumor. SIADH causes an increase in total body water with moderate expansion of plasma volume, hyponatremia, plasma hypo-osmolality, and inability to excrete maximally diluted urine. It may occur with any malignancy but is most frequently associated with small cell carcinoma of the lung and mesothelioma. Other causes of SIADH are the administration of thiazide diuretics, vincristine, cyclophosphamide, chlorpropamide, tolbutamide, carbamazepine, intravenous opioids, and psychotropic drugs (eg, amitriptyline and thioridazine) in the setting of treatment of the cancer patient.

Clinical Features

A. Symptoms and Signs—Lethargy, nausea, anorexia, and generalized weakness are the most common symptoms. Such symptoms, however, are nonspecific and may be caused by the primary cancer rather than hyponatremia. Confusion, convulsions, coma, and death may occur if hyponatremia is severe or of rapid onset.

B. Laboratory Findings—Plasma sodium concentration is less than 135 meq/L, and there is persistent excretion of urinary sodium. Renal function tests are normal, and edema and intravascular volume contraction do not occur. Blood urea nitrogen (BUN) concentration is characteristically low.

Diagnostic criteria for SIADH include hyponatremia with low serum urea nitrogen (<10 mg/dL), absence of intravascular volume contraction, persistent urinary excretion of sodium (>30 meq/L), absence of fluid retention such as peripheral edema or ascites, normal renal function, and plasma hypotonicity in the presence of urine that is not

maximally dilute (urine osmolality >100–150 mOsm/L with plasma osmolality <260 mOsm/L).

Differential Diagnosis

The differential diagnosis of low plasma sodium consists of a long list that includes edematous states (eg, heart failure, nephrotic syndrome, and cirrhosis), myxedema, salt-wasting states (eg, mineralocorticoid deficiency, glucocorticoid deficiency, and chronic renal failure), GI electrolyte losses with hypotonic fluid replacement, compulsive water drinking, and hypothalamic disorders. Pseudohyponatremia secondary to hyperglycemia, mannitol administration, and paraproteinemia should be excluded.

Treatment

Treatment of hyponatremia is discussed in Chapter 2. The management of severe hyponatremia (plasma sodium < 110 meq/L) should be aggressive in a patient who is comatose or convulsing, with the goal of raising plasma sodium above 120 meq/L but no higher than 130 meq/L. In other patients, a maximum increase in plasma sodium of 8 meq/L in 24 hours should be the target because of the complication of osmotic demyelination syndrome.

Patients with plasma sodium levels of 125 meq/L or less should be restricted to 500–700 mL of fluid a day. Patients with higher plasma sodium concentrations are restricted to 1000 mL/day. Severe hyponatremia or symptomatic hyponatremia of any severity may require other treatment. Administration of 0.9% NaCl will not correct hyponatremia in patients with SIADH who have a urine osmolality of more than 308 mOsm/L. In these patients, hypertonic saline (3% NaCl, 1000 mL over 6–8 hours) and furosemide (40–80 mg every 6–8 hours as needed) may be necessary. Central venous pressure monitoring can reduce the risk of the precipitous development of pulmonary edema. Plasma sodium and potassium concentrations should be monitored hourly. Furosemide and hypertonic saline are discontinued when plasma sodium exceeds 110 meq/L and fluid restriction is started.

Direct antagonism of inappropriately secreted arginine vasopressin should facilitate water elimination. Conivaptan, a new vasopressin antagonist approved for euvolemic hyponatremia, is given with an intravenous loading dose of 20 mg, followed by 20 mg administered as a continuous intravenous infusion over 24 hours.

For chronic hyponatremia, demeclocycline, 150–300 mg orally four times daily, may be given to patients who cannot tolerate chronic fluid restriction or do not improve with fluid restriction. Demeclocycline induces nephrotoxic diabetes insipidus and may cause azotemia.

► Hypokalemia & Ectopic ACTH Secretion

A number of tumors secrete ACTH, stimulate adrenal production of corticosteroids, and result in Cushing's syndrome. These tumors include small cell lung cancer; carcinoid tumors of the bronchi, pancreas, thymus, and ovary; islet cell tumors; and cancers of the ovary, thyroid, and prostate, as well as pheochromocytoma, hematologic malignancies, and sarcomas. Unfortunately, most malignant causes of ectopic ACTH production are rapidly fatal. Patients typically present with weakness, cachexia, and hypertension. Typical features of nonmalignant chronic Cushing's syndrome are often absent.

The differential diagnosis of hypokalemia includes GI losses associated with alkalosis, vomiting, prolonged nasogastric suction, villous adenoma of the colon, Zollinger-Ellison syndrome, and chronic laxative abuse. Hyperaldosteronism, hypercortisolism, hypercalcemia, and licorice ingestion also may cause hypokalemia.

The most effective treatment of hypokalemia is control of the underlying tumor. Carcinoid, thyroid tumors, pheochromocytoma, and islet cell tumors are treated surgically if they are resectable. If the tumors are nonresectable, chemotherapy may be used (eg, mitotane, metyrapone, ketoconazole, and aminoglutethimide). Potassium replacement should be accomplished as early as possible. Spironolactone, 100–400 mg daily, is helpful.

► Hypophosphatemia in Malignancy

Hypophosphatemia (serum phosphorus <3 mg/dL) is occasionally associated with rapidly growing tumors (eg, acute leukemia) and marked nutritional deprivation and cachexia. Symptoms may include generalized weakness, respiratory muscle weakness causing respiratory failure, decreased myocardial function, platelet dysfunction, and leukocyte dysfunction. Hemolysis and rhabdomyolysis may occur with serum phosphorus levels of less than 1 mg/dL. The management of severe hypophosphatemia (serum phosphorus <1 mg/dL) consists of intravenous administration of a solution of 30–40 mmol/L of neutral sodium phosphate or potassium phosphate at the rate of 50–100 mL/h. Intravenous administration of phosphates should be monitored very carefully. Patients with mild hypophosphatemia (serum phosphorus 1–2 mg/dL) can be given inorganic phosphate supplements orally unless severely symptomatic.

► Hyperglycemia in Malignancy

Hyperglycemia not due to insulin deficiency is present in many patients with cancer. It occurs in patients with glucagonoma, somatostatinoma, pheochromocytoma, and ACTH-secreting tumors. Nonketotic hyperglycemia with hyperosmolar coma may occur as a complication of treatment with cyclophosphamide, vincristine, or prednisone in patients with mild diabetes mellitus and in patients who are receiving hyperalimentation.

Hyperglycemia caused by a tumor may respond to treatment of the primary tumor with surgical resection, radiation therapy, or chemotherapy. Hyperosmolar coma is treated with replacement of fluid losses (intravenous NaCl solutions) and insulin administration.

► Hypoglycemia in Malignancy

Hypoglycemia may be secondary to inappropriate secretion of insulin (insulinoma) or to nonsuppressible insulin-like substances that are produced by some tumors. Large retroperitoneal fibrosarcomas, mesotheliomas, and renal, adrenal, and primary hepatocellular carcinomas are the most common tumors associated with hypoglycemia. Patients with extensive hepatic metastases may develop severe hypoglycemia secondary to depletion of glycogen and impaired gluconeogenesis. Other causes of hypoglycemia include administration of drugs such as insulin, oral hypoglycemic agents, alcohol, and salicylates. Starvation, chronic liver disease, hypoadrenalism, hypopituitarism, and myxedema also may cause hypoglycemia. Pseudohypoglycemia may occur in patients with marked granulocytosis, especially in the setting of myeloproliferative disorders.

Tumor-associated hypoglycemia produces changes that are characteristic of hypoglycemia in the fasting state, such as fatigue, convulsions, or coma. On the other hand, tremors, sweating, tachycardia, and hunger are symptoms more characteristic of reactive hypoglycemia in the postprandial state.

Intravenous glucose is the treatment of choice and should be given to all patients with blood glucose levels below 40 mg/dL and symptomatic patients with glucose levels below 60 mg/dL. Continuous infusion of 10–20% dextrose in water should be given at a rate to maintain a blood glucose level above 60 mg/dL. If blood glucose levels cannot be increased to a safe level, prednisone, diazoxide, or glucagon may be considered.

► Lactic Acidosis

Lactic acidosis is seen in the ICU most often because of severe hypoperfusion from septic or cardiogenic shock. Rarely, patients with leukemia or lymphoma without obvious shock appear to have tumor overproduction of lactic acid, possibly related to increased anaerobic metabolism from lack of perfusion to tumor. There may be associated

hypoglycemia. Treatment of the underlying tumor may help, but lactic acidosis in cancer patients has a poor prognosis.

Spinazze S, Schrijvers D: Metabolic emergencies. *Crit Rev Oncol Hematol* 2006;58:79–89. [PMID: 16337807]

SUPERIOR VENA CAVA SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Distention of neck and anterior chest wall veins.
- ▶ Edema of the face; cyanosis and edema of upper extremities.
- ▶ Clinical evidence of intrathoracic malignancy.

General Considerations

There are no clinical or experimental data to support the concept that superior vena cava obstruction is an oncologic emergency, except perhaps on very rare occasions when the patient presents with symptoms caused by tracheal obstruction or severe cerebral edema.

Superior vena cava syndrome was first described in 1751. Malignant tumors are the most common cause (60%), but recently, benign causes have increased in proportion to the number of intravascular devices placed in the large systemic veins in the thorax. Bronchogenic carcinoma is the leading cause of superior vena cava syndrome and is responsible for nearly 80% of all malignant causes. Approximately 5% of all patients with bronchogenic carcinoma develop superior vena cava syndrome during their lifetime, but the frequency of this syndrome in small cell cancer is much higher. Malignant lymphomas are responsible for approximately 15% of malignant cases. Other causes (<5%) include metastatic disease to the mediastinal lymph nodes (from primary breast and testicular cancer and, rarely, sarcomas). Benign causes are now most commonly from complications of intravascular devices (eg, catheters and pacemakers), with mediastinal fibrosis secondary to histoplasmosis, tuberculosis, pyogenic infection, and radiation therapy to the mediastinum much less common. Very rarely, superior vena cava syndrome may be caused by benign mediastinal tumors such as dermoids, teratomas, thymomas, retrosternal goiters, sarcoidosis, and aneurysms of the ascending thoracic aorta.

Malignant obstruction of the superior vena cava may be caused by the tumor compressing its thin wall or invading it. Thrombosis with clot formation is usually present. Collateral circulation develops gradually. The collateral circulation involves the internal mammary, intercostal, azygos, hemiazygos, superior epigastric, and inferior epigastric veins. It should be noted that in rapidly growing tumors, engorgement of the venous collateral circulation may be absent. Incompetence of the valves of internal jugular veins may

result only rarely in severe cerebral edema. Obstruction of the trachea by mediastinal tumors is a serious associated complication.

Clinical Features

The most common physical findings in superior vena cava syndrome are neck and anterior chest wall vein distention (60%), tachypnea (50%), edema of the face (50%), and cyanosis and edema of the upper extremities (15%). The diagnosis of superior vena cava syndrome is made on clinical grounds in almost all patients. Superior vena cavography may be used to verify the diagnosis and localize the site of obstruction. Chest radiographs, CT scans, and MRI demonstrate, evaluate, and define the extent of the mediastinal lesion. Chest radiographs readily demonstrate a mass in more than 90% of patients. MRI has no specific advantage over CT scan in this disorder.

Although the symptoms of superior vena cava syndrome are quite distressing to the patient, attempts to obtain a definite histopathologic diagnosis should be pursued vigorously at the earliest opportunity. More than 60% of these patients have small cell lung cancer or lymphomas that are appropriately treated with chemotherapy, and early treatment with radiation therapy or corticosteroids before making a definite histopathologic diagnosis may make subsequent diagnosis difficult or impossible. The diagnosis may be established by sputum cytology, bone marrow biopsy, bronchoscopy, lymph node biopsy, mediastinotomy, and anterior thoracotomy. Mediastinoscopy with biopsy is not recommended owing to the high incidence of severe hemorrhage, increasing neck edema, and failure of wound healing. Adequate tissue biopsy and a touch-preparation for pathologic examination should be done when the diagnosis of lymphoma is suspected. Ample data support the safety of invasive diagnostic procedures in patients with superior vena cava syndrome except those with tracheal obstruction or laryngeal edema.

Treatment

Supportive therapy should be instituted as soon as the patient is admitted to the hospital. Upper airway obstruction from tracheal compression with resulting hypoxia must be addressed promptly. Corticosteroids may reduce associated brain and possibly tracheal edema and lessen secondary inflammatory reaction. Endotracheal intubation should be avoided if possible in patients with tracheal obstruction to prevent further edema. Frequently, the tracheal obstruction is present in the more distal part of the trachea and cannot be bypassed with endotracheal intubation. Tracheostomy is rarely indicated for the same reasons. Placement of a self-expanding metal endoprosthesis stent provides rapid relief and is successful in over 90% of patients.

Chemotherapy is the treatment of choice for patients with small cell lung cancer, lymphomas, and germ cell tumors—more than 60% of patients with superior vena cava

syndrome. Radiation therapy is the only treatment available for other cancers. Spiral saphenous vein bypass grafting also may be useful in selected patients. Anticoagulants and antifibrinolytic agents are of no value and may be harmful. Diuretics are of little help.

Overall, it has been observed that improvement in symptoms occurs in 50–70% of patients over a period of 1–2 weeks of treatment rather than within the first few days. It is suggested that such improvement may be due to the development of collateral circulation rather than to relief of the vena

caval obstruction. Studies have shown that in patients with complete clinical symptomatic relief, the superior vena cava lumen remained completely obstructed in 46% on venography and in 76% at autopsy. Individual mortality is related to the underlying malignancy rather than to the presence of superior vena caval obstruction.

Cardiac Problems in Critical Care

Shelley Shapiro, MD, PhD
Malcolm M. Bersohn, MD, PhD

21

Critically ill patients can present challenging cardiac problems for both diagnosis and management. Many critically ill patients develop cardiac problems secondary to the metabolic and hemodynamic consequences of their underlying illness. Others have preexisting cardiac conditions that are either well compensated or asymptomatic prior to presentation to the ICU and become clinically relevant during their ICU course. A final group of patients is treated in the ICU for known cardiac conditions or has their heart condition diagnosed during their ICU admission. In all of these patients, the interplay of the cardiac illness with other medical problems critically influences the patient's outcome. Therefore, defining the type and severity of the underlying cardiac problem, considering their relationship to other medical problems, and treating the heart disease are important considerations. As always, the key factor in the management of cardiac problems is a high degree of suspicion and early diagnosis. Methods for identifying and diagnosing cardiac disease in critically ill ICU patients will be emphasized throughout this chapter.

► Congestive Heart Failure

ESSENTIALS OF DIAGNOSIS

- ▶ **Cardiomegaly, decreased ventricular ejection fraction or abnormal ventricular wall motion, elevated pulmonary artery wedge pressure, low cardiac output.**
- ▶ **May have a previously known cause such as valvular heart disease or cardiomyopathy but also may present as a result of ischemia or secondary to severe systemic hypertension.**
- ▶ **Acute pulmonary edema: dyspnea, orthopnea, rales, and wheezing; abnormal chest x-ray with perihilar congestion; hypoxemia.**
- ▶ **Cardiogenic shock: hypotension; abnormal renal, hepatic, and CNS function due to decreased perfusion; lactic acidosis.**

General Considerations

Congestive heart failure is a major therapeutic and diagnostic challenge because of the number of its possible causes, the number of patients who have heart failure, and the associated disability. Congestive heart failure is the most frequent diagnostic category coded in Medicare patients. Determining the cause and severity of congestive heart failure is extremely important for effective treatment. Although coronary artery disease is a frequent cause of congestive heart failure, particularly in the elderly, there are many other causes. For example, congestive heart failure with pulmonary edema secondary to mitral stenosis is managed quite differently from that due to dilated cardiomyopathy. Therapy effective in treating congestive heart failure in a patient with severe mitral regurgitation could be lethal in a patient with critical aortic stenosis. With the ability to perform valve replacement and repair, coronary bypass grafting and angioplasty, and the possibility of cardiac transplantation, a specific cardiac diagnosis has implications for interventional management as well as drug therapy.

The causes of chronic congestive heart failure may be very different from the causes of acute failure. Acute congestive heart failure in critically ill patients is due to myocardial ischemia or infarction, acute valvular insufficiency (eg, mitral or aortic regurgitation), worsening aortic stenosis or mitral stenosis, acute myocarditis (rare), cardiotoxic drugs, alcohol, and sepsis. Often, volume overload (owing to fluid volume administered in the ICU for treatment of hypotension or as part of administration of therapy for other disease processes) precipitates heart failure in the ICU setting. This may be compounded by anemia and/or by reduced renal function resulting in additional fluid retention and volume expansion. The role of excessive fluid resuscitation and accumulating volume overload in ICU patients cannot be too highly emphasized. Hypoalbuminemia also can add to the picture by allowing fluid to transudate at lower oncotic pressures. Recently, a new acute form of heart failure has been described in patients suffering acute severe stress resulting in

acute severe myocardial dysfunction (mimicking myocardial infarction or acute cardiomyopathy). This syndrome, more common in females, appears to be reversible but presents as life-threatening heart failure. Chronic congestive heart failure is often idiopathic, although in many cases it is associated with ischemic heart disease, chronic valvular heart disease, and hypertension. The additional stress of the ICU and associated critical illness may worsen preexisting myocardial dysfunction and heart failure in a previously stable patient.

A high degree of suspicion of congestive heart failure is required to identify subtle cases or patients with coexisting heart failure. Patients in the ICU with dyspnea and hypoxemia often have combined heart and lung disease, and patients with known pulmonary disease can develop cardiac disease as a result of the increased stress of sepsis, hypoxia, or deterioration of pulmonary function. Any patient with unexplained hypoxemia, hypotension, or a worsening clinical state requires assessment of cardiac function.

A. Cardiac Function in the Normal Heart—Cardiac output is the product of stroke volume and heart rate. Stroke volume is determined by three factors: preload, afterload, and contractility. In the intact heart, preload is the end-diastolic tension or wall stress and is ultimately determined by the resting length of the muscle or the degree of stretch of the muscle fibers. Preload is directly related to the compliance of the ventricle and the end-diastolic pressure. Although preload is a measure of force, in conceptual terms it can be thought of as being most closely related to the end-diastolic volume of the ventricle. As the ventricular volume and pressure increase, so does the preload. Pulmonary capillary wedge pressure is often used when clinically describing a patient's preload.

Afterload is the resistance against which the ventricle ejects blood. Afterload or tension on the left ventricle can be described by the formula $\Delta P \times r/h$, where ΔP is the transmural pressure during ejection, r is the radius of the left ventricular chamber, and h is the thickness of the ventricular wall. Stroke volume is inversely proportional to afterload.

Contractility is the inherent ability of the muscle to contract and is independent of the loading conditions on the heart (ie, preload and afterload). Circulating catecholamines and increased sympathetic efferent activity increase contractility. Cardiac performance can be improved for a given level of myocardial contractility by changing the loading conditions.

B. Cardiac Function in Congestive Heart Failure—Congestive heart failure develops when cardiac function is inadequate to maintain sufficient cardiac output to supply the metabolic needs of the body at normal filling pressures and heart rate. In mild heart failure, cardiac function may be adequate at rest. However, exercise or illness can increase metabolic demands that may not be met when cardiac reserve is inadequate. Thus congestive heart failure may be precipitated by critical illness with attendant fever, anemia, and vasodilation. In heart failure owing to

decreased left ventricular function with reduced stroke volume, cardiac output may be transiently maintained by increased heart rate or by increased preload with ventricular dilation and increased volume. The increasing use of beta-blockers in the treatment of chronic congestive heart failure, ischemia, and chronic coronary artery disease may blunt the sympathetic response and tachycardia necessary to maintain cardiac output. Acutely, however, cardiac output may be insufficient, and signs and symptoms of hypoperfusion including hypotension, cyanosis, and peripheral vasoconstriction, may be present (*forward failure*). Inadequate ventricular emptying (*low forward flow*) results in elevated left atrial and left ventricular end-diastolic volume and pressure that are transmitted back into the lungs and the pulmonary venous system with transudation of fluid. Clinically, this is manifested by rales, hypoxemia, and dyspnea (*backward failure*).

A number of neurally and hormonally mediated responses develop in an attempt to compensate for inadequate cardiac performance. These compensatory responses include renal-mediated fluid retention and peripheral vasoconstriction, tachycardia, and ventricular dilation which attempt to maintain systemic blood pressure and cardiac output. However, these compensations frequently are counterproductive and worsen hemodynamic status. For example, vasoconstriction, while maintaining systemic blood pressure, increases ventricular afterload, ultimately decreasing stroke volume and cardiac output; fluid retention increases preload (improving stroke volume), but it also raises pulmonary venous pressure and is detrimental to oxygenation and gas exchange. Tachycardia increases cardiac output but also increases myocardial oxygen demand which is particularly devastating in the setting of myocardial ischemia and decreases diastolic time needed for optimal ventricular filling, which is particularly problematic in patients with diastolic dysfunction (problems with ventricular stiffness).

It is now well recognized that vasoconstriction and tachycardia, previously considered compensatory and useful to the patient, play important roles in the progression of congestive heart failure. This is why afterload-reduction therapy with angiotensin-converting enzyme (ACE) inhibitors or other vasodilating agents and aggressive diuretic therapy have greatly improved survival in this disorder. Beta-adrenergic blockade in stable patients with compensated heart failure is useful and prolongs life by decreasing the disadvantageous effects of adrenergic stimulation. The benefit of beta-blockers must be weighed against worsening heart failure and should be withheld until heart failure is well controlled.

Clinical Features

A. Symptoms and Signs—Patients with congestive heart failure may develop symptoms slowly or acutely. They may complain of peripheral edema or of congestive symptoms such as dyspnea, orthopnea, or paroxysmal nocturnal dyspnea. Symptoms consistent with decreased cardiac output

include fatigue and exercise intolerance. Chest pain may be a feature of acute-onset congestive heart failure associated with myocardial ischemia, infarction, or severe hypertension. Because of sedation and decreased activity in the critical care setting, ICU patients may not complain of any symptoms at all. An increasing heart rate, decreasing oxygen saturation, or increasing oxygen requirement may be the only clues.

Patients who present with acute pulmonary edema may have pink frothy sputum, rales, expiratory wheezes, and central along with peripheral cyanosis. Tachycardia and hypotension are manifestations of decreased cardiac output; in these patients, low output may be accompanied by peripheral vasoconstriction, with peripheral cyanosis, cold extremities, and diaphoresis. In patients in whom severe systemic hypertension is causally related to congestive heart failure, blood pressure may be high despite low cardiac output. In patients with cardiogenic shock, hypotension is accompanied by evidence of very poor peripheral perfusion. On examination, patients with dilated cardiomyopathy may have an S_3 gallop, a murmur consistent with mitral regurgitation, and elevated jugular venous pressure. Other findings depend on the specific cause and may include murmurs consistent with valvular heart disease and an S_4 gallop. However, in an ICU setting, many of the findings may be blunted or difficult to appreciate. Patients with long-standing chronic heart failure may have high filling pressures and severe heart failure without the development of rales or an S_3 owing to the development of chronic pulmonary hypertension and other compensatory mechanisms. They are in heart failure nevertheless and respond to appropriate therapy once the diagnosis is established.

B. Laboratory Findings—Patients may present with hypoxemia, metabolic acidosis from lactic acidosis, and hyponatremia. In patients with hypotension or shock, renal and hepatic function tests may be abnormal.

C. Electrocardiography—The ECG should be examined for evidence of myocardial ischemia or infarction, atrial hypertrophy, and ventricular hypertrophy. Rhythm disturbances (eg, atrial fibrillation or flutter) may be a cause or an effect of congestive heart failure. Patients with dilated cardiomyopathy or severe left ventricular hypertrophy owing to hypertension or hypertrophic processes may have conduction or voltage abnormalities consistent with left ventricular hypertrophy. Tachycardia may indicate poor hemodynamic performance.

D. Imaging Studies—

1. CHEST X-RAY—Chest x-ray may show cardiomegaly in patients with dilated or hypertrophic cardiomyopathy. However, patients with valvular heart disease may have only a mild increase in heart size or isolated chamber enlargement. Ventricular dilatation may not be present in acutely developing heart failure and therefore not seen on x-ray. Cardiogenic pulmonary edema is usually marked by central

or perihilar infiltrates, increased size of vessels serving the upper portions of the lungs in the upright position, and increased prominence of interlobular septa—usually bilateral and symmetric. Pleural effusions are common. Chest x-rays are very important to exclude pulmonary disease that may mimic heart failure, in particular acute respiratory distress syndrome (ARDS) and severe pneumonia.

2. ECHOCARDIOGRAPHY—Noninvasive testing, particularly in a critically ill patient, may be difficult but gratifying if successful in identifying a treatable cause of congestive heart failure. Echocardiography, because of its portability, reproducibility, and ability to evaluate myocardial and valvular function, is a valuable tool in the assessment of ICU patients. Hemodynamic data, including an estimate of right ventricular pressure, left atrial pressure, valve areas, left ventricular ejection fraction, and ventricular volumes, can be obtained at the bedside if image quality is adequate. Cardiac output can be estimated with echo Doppler using the continuity equation. Myocardial ischemia can be inferred by identification of segmental wall motion abnormalities at rest or during special interventions designed to bring out abnormalities in ischemic regions. Dobutamine or adenosine infusion can be performed with echocardiography and ECG monitoring to obtain a bedside stress test. Pericardial effusions can be diagnosed and measured and their hemodynamic impact evaluated. Echocardiography is a sensitive technique for diagnosing cardiac tamponade. Assessment of valvular regurgitation and monitoring the response to therapy are other uses for echocardiography.

Echocardiography is technically difficult in about 10% of patients overall. Although echo-enhancing contrast agents can improve image quality, ICU patients, because they are often mechanically ventilated and have multiple intravenous or central lines in place, are difficult to position ideally and often are more difficult to image properly with echocardiography. Transesophageal technology has increased the value of echocardiography by providing images of good quality in patients who have had inadequate transthoracic studies. With transesophageal echocardiography, the heart is imaged via a transducer inserted into the esophagus through the mouth. The close proximity of the esophagus to the left atrium provides an excellent acoustic window resulting in better images. Views unobtainable with conventional transthoracic echocardiography are possible with this technique. The pulmonary veins, both atrial appendages, and the ascending and descending aorta can be well imaged in addition to the ventricles and valves.

3. RADIONUCLIDE ANGIOGRAPHY—Radionuclide angiography can measure right and left ventricular ejection fractions and evaluate wall motion. Myocardial uptake of technetium pyrophosphate at times can be useful to identify myocardial infarction or cardiac contusions. A number of radionuclide techniques are used to assess coronary artery disease. These studies are not performed at bedside and are of no utility in ICU patients.

4. CT SCAN—In patients who can be moved to the scanner, CT scanning provides high-resolution tomographic imaging of the heart and great vessels and can assess right and left ventricular size. CT scans also can assess lung parenchyma to rule out a primary pulmonary process and differentiate congestive heart failure from other lung diseases. With the use of contrast material, pulmonary thromboembolism or proximal pulmonary artery thrombosis can be seen with spiral CT scanning (CT angiogram).

5. CARDIAC CATHETERIZATION/PULMONARY ARTERY CATHETERIZATION—When noninvasive studies cannot fully answer questions about cardiac function, bedside balloon-tipped flow-directed (Swan-Ganz catheter) pulmonary artery catheterization is performed. The catheter is used to measure a variety of hemodynamic parameters, including left ventricular end-diastolic pressure (pulmonary artery wedge pressure) and thermodilution cardiac output. Newer modified catheters can continuously measure cardiac output and oxygen saturation. The catheter is placed transvenously into the pulmonary artery by way of the right atrium and right ventricle, usually without fluoroscopic guidance. The catheter is often of critical importance in defining cardiac function and differentiating cardiac from pulmonary disease in patients with pulmonary infiltrates and dyspnea. The pulmonary artery catheter is particularly useful for monitoring the effect of intravenous drugs on hemodynamics when cardiac output is low. In patients with acute severe congestive heart failure, the goal is to maximize cardiac output while lowering wedge pressure in order to relieve pulmonary edema.

In selected patients, left-sided heart catheterization allows direct measurement of left ventricular pressures and function, imaging of the coronary arteries to rule out critical obstruction, and angiographic measurement of cardiac output and left ventricular ejection fraction. Left-sided heart catheterization requires fluoroscopy and cannot be done in most ICUs.

Differential Diagnosis

Patients with clinical features of congestive heart failure presenting with dyspnea, orthopnea, rales, and wheezing instead may have pneumonia, ARDS, fluid overload, or exacerbation of chronic obstructive pulmonary disease (COPD) or asthma. Cardiomegaly may be due to ventricular hypertrophy, right ventricular dilatation, or pericardial effusion rather than an enlarged left ventricle itself. In patients who present with symptoms and signs of primarily right-sided heart failure—such as elevated jugular venous pressure, ascites, edema, and evidence of right ventricular hypertrophy—lung disease resulting in cor pulmonale, or pulmonary arterial hypertension (eg, pulmonary arteriopathy, idiopathic or secondary pulmonary arterial hypertension, or pulmonary emboli) should be considered. Patients with hypotension from cardiac failure should be distinguished from those with volume depletion, sepsis, and pulmonary embolism.

Treatment

A. General Measures—After determining the underlying cause of congestive heart failure, treatment in the ICU consists of quickly reversing the hemodynamic problem without adding further ones. In very ill patients, initial management of congestive heart failure should use intravenous medications. In this form, medications can be titrated rapidly and stopped quickly if necessary. Intravenous administration of drugs guarantees absorption, particularly in patients with bowel edema and decreased bowel motility. Although some intravenous agents have long half-lives and slow onsets of action, nitroprusside, nitroglycerin, nesiritide, dopamine, dobutamine, and milrinone act quickly and are easily reversed.

Cardiogenic shock may require the initial or concomitant use of vasopressor drugs such as dopamine and inotropic drugs such as dobutamine or milrinone to allow the institution of afterload-reduction therapy. Nitroprusside is a potent reducer of left ventricular afterload and is particularly valuable in treating severe congestive heart failure. Disadvantages include toxicity in patients with renal insufficiency who are given nitroprusside over a prolonged period of time. Intravenous preparations of ACE inhibitors are effective and have longer durations of action. Digoxin and diuretics are still important despite development of newer classes of drugs. Because of negative inotropic effects, calcium channel blockers and beta-blockers are used with extreme caution, if at all, in patients with acute congestive heart failure. Occasionally, however, congestive heart failure may be secondary to tachyarrhythmias, left ventricular diastolic dysfunction, or severe transient ischemia, and these drugs then play an important role. Close hemodynamic monitoring, usually with a pulmonary artery catheter, allows the physician to titrate multiple drugs optimally. In cases of severe cardiogenic shock with low cardiac output, use of mechanical devices including intraaortic balloon pump or left ventricular assist devices is a consideration. The use of these devices involves decisions regarding long-term treatment options, prognosis, and underlying disease etiologies. The decision to intervene at this level requires consultation with a cardiac catheterization team and the heart transplant team or heart failure specialists.

General treatment of congestive heart failure in critically ill patients includes oxygen, bed rest, and reduction of metabolic derangements that increase myocardial oxygen demand (eg, fever and anemia). Endotracheal intubation and mechanical ventilation usually are not necessary, except in severe cardiogenic pulmonary edema.

B. Specific Treatment of Congestive Heart Failure—

Patients with congestive heart failure can be subdivided into several groups for which specific treatments can be described as follows:

1. SYSTOLIC DYSFUNCTION WITHOUT HYPOTENSION—These patients have low stroke volumes and ejection fractions and usually have tachycardia. Pulmonary edema may accompany systolic dysfunction. Digoxin, diuretics, and ACE inhibitors are the mainstays of therapy. Several studies have shown that ACE

inhibitors prolong life in patients with chronic congestive heart failure owing to left ventricular dysfunction and in patients with myocardial infarction associated with reduced left ventricular function. If the patient is felt to be stable enough to tolerate oral therapy, small doses of an ACE inhibitor and digoxin can be initiated. Hypotension may accompany ACE inhibitor therapy if cardiac output fails to increase after vasodilation, and inotropic drug support of blood pressure may be required. Withholding or reducing the dosage of diuretics when ACE inhibitors are added often can prevent the development of hypotension. Serum creatinine and potassium levels must be observed carefully because of the effect of ACE inhibitors on renal function (particularly in patients with renal artery stenosis) and on the renin-aldosterone system.

Diuretics are useful in reducing volume overload, particularly when signs of right-sided failure such as peripheral edema, elevated jugular venous pressure, and liver engorgement are present. Intravenous furosemide can be given in a dose of 10–80 mg (more in patients with poor response) and repeated as needed. Continuous infusion of furosemide at a rate of 5–10 mg/h is also effective. Metolazone or hydrochlorothiazide can augment the effectiveness of furosemide by further inhibiting reabsorption of sodium. Sustained diuresis with any of these agents is associated with significant loss of potassium and magnesium. Nesiritide is a recombinant human B-type natriuretic peptide that is indicated for intravenous treatment of acutely decompensated congestive heart failure. It is given as an initial bolus of 2 µg/kg, followed by continuous infusion of 0.01 µg/kg per minute for less than 48 hours. Hypotension is a known side effect. Spironolactone has been shown to decrease mortality in chronic congestive heart failure and can be added to help spare potassium loss in the acute situation. Finally, patients in severe congestive heart failure with renal dysfunction may be unable to excrete large amounts of sodium and water, so ultrafiltration may be needed to correct volume overload. Newer devices allow removal of fluid at rates up to 400 mL/h using specially designed 18-gauge peripheral lines and therefore eliminate the need for a large-bore vascular catheters. However, if electrolyte abnormalities and renal dysfunction compound the volume overload, dialysis may be required.

Noninvasive positive-pressure ventilation using tight-fitting masks can be useful in acute pulmonary edema. A significant reduction in the need for mechanical ventilatory support has been demonstrated in patients present with acutely decompensated congestive heart failure with the use of this noninvasive form of ventilation compared to standard therapy. It appears that the positive-pressure breathing lowers preload and left ventricular afterload, improves oxygenation, and provides time for pharmacologic therapy to work.

The effect of various drugs on filling pressures and cardiac output can be demonstrated on the Frank-Starling curve (Figure 21–1). Both digoxin and afterload-reducing agents improve the patient's cardiac output or stroke volume for a given filling pressure (move the patient to a more effective curve). In contrast, diuretics lower the left ventricular filling pressure, relieving symptoms of dyspnea, but they also may

▲ **Figure 21–1.** Curves demonstrating the relationship between stroke volume and left ventricular end-diastolic pressure (preload) and showing the normal range for each variable. End-diastolic pressures greater than 25 mm Hg are associated with pulmonary edema. Curve 1 represents severely depressed left ventricular function, with normal stroke volume being achieved only at substantially elevated preload (high left ventricular end-diastolic pressure). Curve 2 demonstrates a normal relationship between stroke volume and preload. Curve 3 represents a condition of increased inotropy. Treatment with afterload-reducing agents or inotropic drugs can improve stroke volume by moving an individual from curve 1 to curve 2 (solid arrow). Diuretics can lower filling pressure by moving a patient along his or her own curve (dashed arrow).

reduce cardiac output. The patient moves down along the same function curve. Optimal treatment, therefore, should use agents that move the patient to a better function curve, and diuretics are employed to help lower filling pressures—if they remain elevated—and to expedite symptomatic improvement. In some patients with mild to moderate congestive heart failure, bed rest alone will result in significant diuresis. In addition, improvement of cardiac output with afterload-reducing agents and digoxin ultimately will result in diuresis. On the other hand, both preload- and afterload-reducing agents can result in venodilation and thus fluid retention, so diuretics may be needed to counteract this unwanted side effect.

Although major emphasis has been placed on ACE inhibitors in the treatment of chronic congestive heart failure, other drugs are effective, including preload-lowering agents such as nitrates and afterload-reducing agents such as hydralazine. For example, the combination of hydralazine and nitrates has been shown to prolong life in patients with chronic congestive heart failure.

2. SEVERE CONGESTIVE HEART FAILURE WITH HYPOTENSION (CARDIOGENIC SHOCK)—Patients with severe congestive heart failure associated with hypotension, pulmonary edema, and metabolic acidosis require aggressive and immediate

intervention. These patients often have some reason for acute deterioration such as ischemia, myocardial infarction, new or worsening valvular insufficiency, poor adherence to medical therapy, volume overload, or concomitant medical problems. Even before invasive hemodynamic monitoring is instituted, hemodynamic support can be started using intravenous agents. With severe hypotension, blood pressure support is required—intravenous dopamine should be administered in dosages titrated to achieve a systolic blood pressure of approximately 90 mm Hg or greater. An exception to this precept would be a patient with cardiomyopathy whose known systolic blood pressure is chronically 80 mm Hg. In such cases, clinical markers of hypoperfusion such as decreased mental status or acidosis should help to determine the appropriate blood pressure goal. The inotropic drugs dobutamine and milrinone can be used in conjunction with or as an alternative to dopamine to increase cardiac output. Dobutamine has the further advantage of peripheral vasodilation with reduction in left ventricular afterload.

In patients with either adequate blood pressure (systolic blood pressure >100 mm Hg) or even marginal pressure (systolic pressure 90–100 mm Hg), nitroprusside can be started at small dosages (0.01–0.1 $\mu\text{g}/\text{kg}$ per minute) and titrated upward every 3–5 minutes while blood pressure is observed closely. Although these are low starting doses, they may avoid the significant and rapid hypotension that sometimes occurs with larger doses, and rapid dose adjustments make it possible to reach the effective dose in a relatively short period. The goal of reducing left ventricular afterload with nitroprusside is to increase cardiac output. However, if peripheral resistance drops in response to nitroprusside without an increase in cardiac output, hypotension will occur. The drop in blood pressure following nitroprusside administration can be dealt with by immediately discontinuing the drug and providing inotropic support if needed. The extremely short half-life of intravenous nitroprusside makes this a safe and valuable agent to try even before invasive hemodynamic monitoring can be started.

Loop diuretics are also extremely valuable in this setting if marked volume overload (pulmonary edema) is evident, as furosemide causes a lowering of preload even before diuresis occurs. Intravenous furosemide can be given in a dose of 10 to 40 mg (more in patients with poor response) and can be repeated as needed. Continuous infusion of furosemide at a rate of 5–10 mg/h is also very effective. Intravenous nitroglycerin has preload-reducing as well as some afterload-reducing properties and can be used alone or in conjunction with intravenous nitroprusside to improve cardiac output and reduce left-sided pressures. Nesiritide must be used with caution in cardiogenic shock to avoid worsening of hypotension.

Intraaortic balloon pumps and left ventricular assist devices have been used to treat patients with extreme cardiogenic shock. They are used acutely to allow time to explore opportunities for additional interventions including angioplasty, cardiac surgery, or heart transplantation. This level of tertiary management is undertaken in referral centers with appropriate equipment, resources, and surgical staff and in selected patients with potential for good outcomes.

Echocardiography assists in the management of patients with cardiogenic shock in several ways: (1) by identifying surgically correctable valvular abnormalities such as severe aortic or mitral valvular disease that may be contributing to failure, (2) by identifying segmental wall motion abnormalities suggestive of ischemia, and (3) by establishing baseline left ventricular function in patients with new onset congestive heart failure.

A pulmonary artery catheter will enable the physician to adjust medications more carefully, with the goal of maximizing cardiac output at acceptably high end-diastolic filling pressures. The pulmonary artery catheter is strongly recommended to help guide the management of congestive heart failure patients who have hypotension and congestive symptoms. Using a pulmonary artery catheter, a cardiac index (cardiac output divided by body surface area) of less than 2 L/min/m² is considered cardiogenic shock and is incompatible with prolonged survival. Heart rate and cardiac output need to be considered in optimizing hemodynamics, particularly in patients with congestive heart failure and myocardial ischemia. If an adequate cardiac index is maintained by an increased heart rate rather than improved stroke volume, ultimate outcome will be poor. Conversely, patients with bradycardia in the setting of congestive heart failure may have dramatically improved cardiac output with a pacemaker or the use of pharmacologic agents that increase the heart rate.

Calculation of stroke volume to assess therapy is very useful. The mixed venous oxygen (O_2) saturation ($\text{S}\bar{\text{v}}\text{O}_2$) is another way of assessing severity of disease and response to therapy. It reflects delivery and utilization of O_2 and the effectiveness of cardiac output. Some pulmonary artery catheters have an oximeter probe at their tips to continuously monitor $\text{S}\bar{\text{v}}\text{O}_2$ in addition to pulmonary artery pressures. A decrease in $\text{S}\bar{\text{v}}\text{O}_2$ can be an early marker of decreased cardiac output and function. A desirable goal of therapy in treating cardiogenic shock is to attain a mixed venous O_2 saturation of greater than 70%.

After optimizing hemodynamic variables with intravenous medications and attaining a period of stability, a gradual change to oral medication is appropriate. Oral afterload-reducing agents (eg, ACE inhibitors, angiotensin-receptor blockers, or hydralazine) should be added while reducing the dosages of intravenous agents. An intravenous ACE inhibitor such as enalaprilat given every 6 hours is an alternative to oral ACE inhibitors.

3. CONGESTIVE HEART FAILURE WITH SEVERE SYSTEMIC HYPERTENSION—

Treatment is directed at the pathophysiologic mechanisms of congestive heart failure in severe hypertension, including reduction of systemic blood pressure and intravascular volume. In these patients, left ventricular systolic function may be normal, whereas left ventricular diastolic dysfunction is a major problem resulting in congestion and pulmonary edema. Systolic dysfunction, if present, may improve significantly following afterload reduction.

Control of blood pressure with reduction of left ventricular afterload is the major focus of initial therapy. If systolic function is unknown, an intravenous agent such as nitroprusside or nitroglycerin is recommended to lower systemic pressures and to improve filling pressures acutely. Intravenous

enalaprilat also can be considered (see the section “Hypertensive Crisis”). For continued treatment of hypertension, β -adrenergic blockers or calcium channel blockers can be added after congestive heart failure has improved and acceptable left ventricular systolic function has been documented. However, these agents should be used with caution in patients with high filling pressures and severe hypertension because they may depress myocardial function without adequately reducing the afterload. The net result may be worsening congestive heart failure or hemodynamic collapse. Pulmonary artery catheterization may be helpful when considering the use of β -adrenergic blockers or calcium channel blockers in these patients, but catheterization is not needed to initiate therapy with nitroprusside unless hypotension develops early in treatment, raising the possibility of complicating cardiac or pulmonary problems.

4. HIGH-OUTPUT OR VOLUME-OVERLOAD CONGESTIVE HEART FAILURE—These patients present with congestive symptoms and signs (eg, pulmonary edema and peripheral edema), but systolic cardiac function is normal, and cardiac output may be elevated. Treatment should be directed at the cause of the high cardiac output (eg, anemia, thiamine deficiency, sepsis, and hyperthyroidism) or volume overload state (eg, renal failure, iatrogenic volume overload, and excessive sodium intake). Rapid lowering of intravascular volume by ultrafiltration may improve blood pressure, hypoxemia, and edema, especially in patients who do not respond well to diuretic therapy. In the ICU patient, volume overload may be due to obligate fluid intake from hyperalimentation, blood product replacement, or antibiotic therapy.

5. CONGESTIVE HEART FAILURE WITH DIASTOLIC DYSFUNCTION—Diastolic dysfunction means that ventricular filling is impaired, and left ventricular end-diastolic pressures may be elevated. Diastolic dysfunction is the most difficult form of heart failure to treat. Systolic function is preserved, but ventricular relaxation and filling are inadequate. Diastolic dysfunction is seen commonly in patients who have hypertension with left ventricular hypertrophy and/or ischemia. Patients with hypertrophic cardiomyopathy also can have significant diastolic heart failure with preserved systolic function. Elderly patients can have undiagnosed diastolic heart failure with or without systemic hypertension. Patients with amyloidosis also have low ventricular compliance resulting in diastolic dysfunction, but systolic dysfunction often accompanies this clinical picture. Patients with diastolic dysfunction have congestive symptoms (eg, shortness of breath and pulmonary edema) despite normal ejection fraction and normal systolic wall motion. Diuretics usually are required to reduce preload and symptoms related to elevated left atrial pressure. Beta-adrenergic blockade to slow the heart rate, allowing more time for diastolic filling, can be helpful. On occasion, too aggressive diuretic therapy becomes counterproductive in patients with diastolic dysfunction by reducing stroke volume, systemic blood pressure, and cardiac output. Because cardiac output is the product of heart rate and stroke volume, excessive bradycardia from beta-blockers or calcium channel blockers also can

worsen the clinical situation by causing an inadequate cardiac output.

6. ISOLATED RIGHT-SIDED HEART FAILURE WITH PULMONARY HYPERTENSION—Patients may have isolated right-sided heart failure secondary to pulmonary arterial hypertension (PAH). Pulmonary hypertension may be related to congenital heart disease, lung disease, medications, liver disease (eg, portopulmonary hypertension), HIV infection, and collagen vascular diseases (eg, scleroderma and mixed connective tissue disease) or may be idiopathic. PAH owing to pulmonary emboli or proximal pulmonary arterial thrombus need to be considered and excluded with appropriate diagnostic tests before concluding that pulmonary hypertension is due to a pulmonary arteriopathy. Pulmonary venous hypertension also must be excluded (ie, left-sided heart disease). In PAH, the pathophysiologic mechanism of the dyspnea and orthopnea is not entirely clear, although gas exchange in the lungs is inefficient because of maldistribution of perfusion. Compression of the left ventricle with abnormal septal motion and relative left ventricular filling difficulties because of right ventricular encroachment into the pericardial space is another possible mechanism.

Diuretics are used to reduce right atrial pressure and right ventricular and right atrial volume. Oxygen may reduce pulmonary hypertension in patients with PAH or lung diseases. As oxygenation improves, liver engorgement, abdominal distention, and lung mechanics improve. One goal is to reduce right atrial pressure to less than 10 mm Hg. Finally, digoxin may be helpful by increasing right ventricular function. Reduction of pulmonary artery pressures and right ventricular afterload with nitric oxide or intravenous prostacyclin should be considered when a clear diagnosis of PAH is made (in the absence of left-sided heart failure). In the last 3 to 4 years, there have been dramatic advances in the treatment of PAH in terms of chronic management, including the use of endothelin-receptor blockers (eg, bosentan), phosphodiesterase-5 inhibitors (PDE-5) including sildenafil, and prostacyclins (eg, epoprostenol, treprostinol, and iloprost). Acute treatment with inhaled nitric oxide can restore oxygenation and stabilize a patient until long-term treatment issues can be addressed. This is in the realm of tertiary care at institutions able to administer such therapy.

▶ Valvular Heart Disease

ESSENTIALS OF DIAGNOSIS

Valvular insufficiency:

- ▶ Dyspnea, pulmonary edema, new murmur.
- ▶ Echocardiogram with Doppler demonstrating regurgitation.

Valvular stenosis:

- ▶ Dyspnea, pulmonary edema, murmur, syncope, hypotension; decreased carotid pulses (aortic stenosis).
- ▶ Atrial fibrillation (mitral stenosis), left ventricular hypertrophy (aortic stenosis).
- ▶ Echocardiogram documenting decreased valve area.

Prosthetic valve dysfunction:

- ▶ New onset of symptoms of congestive heart failure, syncope; change in examination (new murmur, change in intensity of valve sounds).
- ▶ Echocardiographic evidence of increased valve pressure gradient, thrombosis, or other dysfunction.

Infective endocarditis:

- ▶ May or may not have history of valvular heart disease or prosthetic valve.
- ▶ New onset of heart failure with valvular insufficiency or unexplained fever and pathologic heart murmur.
- ▶ Echocardiographic evidence of valvular disease, positive blood cultures.

General Considerations

As with congestive heart failure, treating valvular heart disease in the ICU setting involves considering the possibility and proceeding to assess its severity. Few ICUs can afford the luxury of a quiet place to auscultate the heart, but with patience and perseverance, the experienced clinician can detect important murmurs. The acoustic qualities of the murmurs are affected by cardiac output. Patients in shock with low-output states and febrile or anemic patients with high-output states may present with misleading physical findings that under- or overestimate the severity of their valvular heart disease. At the bedside, echocardiography affords the physician a convenient window on the heart and a way to quantitate valve dysfunction and clarify the relationship between valve function and myocardial function.

Acute valvular insufficiency with regurgitation may be due to endocarditis, trauma, papillary muscle dysfunction (mitral valve), or ischemia. Patients may present with worsening of chronic valvular disease from myxomatous degeneration or prolapse with and without connective tissue disorders or rheumatic heart disease. Isolated aortic valve insufficiency may be due to aortic diseases such as aortic dissection, cystic medial necrosis, and syphilitic aortitis. Most commonly, however, chronic aortic regurgitation results from a congenital bicuspid aortic valve. Mitral stenosis is almost always due to rheumatic heart disease. Aortic stenosis is occasionally due to rheumatic heart disease but more often is due to progressive valvular calcification in the elderly, either of a normal valve or of a congenital bicuspid valve.

Patients with previous valve surgery with prosthetic or bioprosthetic valves represent a special circumstance. These valves are subject to a variety of chronic and acute complications, including infective endocarditis, calcification with simultaneous stenosis and incompetence, thrombosis with valve dysfunction, and peripheral embolic events such as strokes, valve dehiscence, and paravalvular leaks. Valve repairs also can be subject to some of the same problems, including endocarditis, recurrent valve dysfunction, and relative valve stenosis, after repair of valvular regurgitation.

Clinical Features

A. Symptoms and Signs—Specific findings depend on which valve is abnormal. Patients with aortic or mitral valvular stenosis or insufficiency may present with congestive heart failure, including pulmonary edema and evidence of decreased cardiac output. Physical findings include rales, S_3 gallop, wheezing, peripheral vasoconstriction, tachycardia, and murmurs. Other important findings to be sought include the character of arterial pulses, intensity of the heart sounds, and changes in the quality of murmurs with different maneuvers such as the Valsalva maneuver. Chest pain is a frequent accompanying symptom in patients with significant aortic stenosis or aortic regurgitation. Atrial arrhythmias frequently accompany mitral valve disease with left atrial enlargement.

B. Electrocardiography—The ECG may suggest features of specific valvular as heart diseases—for example, left ventricular hypertrophy as seen in aortic stenosis and regurgitation, and left atrial enlargement and right ventricular hypertrophy as seen in mitral stenosis.

C. Imaging Studies—The chest x-ray may show cardiomegaly with specific chamber enlargement. Echocardiography is extremely useful in assessing valvular heart disease. It can provide evidence of leaflet abnormalities, including vegetations and decreased motion of valve leaflets, as well as estimates of valve cross-sectional area in valvular stenosis. The size of the atria and ventricles can be determined and wall motion and ejection fraction estimated. With Doppler techniques, one can quantitatively estimate regurgitant blood flow across an abnormal valve, measure valve pressure gradients and calculate valve areas.

D. Additional Studies—Pulmonary artery catheters directly measure pulmonary artery pressures and cardiac output and provide an estimate of left atrial pressure (pulmonary artery wedge pressure). Cardiac catheterization is usually required to assess valve function prior to surgery and to identify coexistent coronary artery disease.

Treatment: Native Valves

A. Valvular Regurgitation—The management of left-sided valvular regurgitation is determined by the severity of the regurgitation, the specific cause, and the degree of left ventricular dysfunction. The severity of regurgitation can be estimated echocardiographically using color-flow and continuous-wave Doppler and calculating left ventricular and left atrial pressures noninvasively. Echocardiography also will help to define operability and determine the cause of the valve dysfunction. Mild to moderate aortic or mitral regurgitation without symptoms requires no treatment. In patients with more severe left-sided valvular regurgitation, associated congestive heart failure (pulmonary edema) can be treated with diuretics and digoxin. However, the most important therapy is the use of unloading agents such as ACE inhibitors, hydralazine, and, if needed, nitroglycerin and nitroprusside. These drugs work by decreasing downstream resistance and increasing downstream compliance. Forward blood flow increases while regurgitant flow decreases, so ventricular filling pressures decline while cardiac output improves. The management of congestive heart failure owing to aortic or mitral regurgitation is quite similar to the management of congestive heart failure owing to systolic ventricular dysfunction.

In patients with such severe valvular regurgitation that cardiac output is very low and there is hypotension (cardiogenic shock), emergent valve surgery may be necessary. Invasive hemodynamic monitoring with a pulmonary artery catheter is essential, and maximal unloading of the left ventricle with intravenous nitroprusside should be started immediately. Inotropic drugs such as dopamine may be required to

maintain adequate systemic blood pressure even though—by increasing afterload—valvular regurgitation may be transiently worsened. Mitral regurgitation associated with cardiogenic shock may benefit from an intraaortic balloon pump, but this therapy is contraindicated in those with aortic valve regurgitation.

B. Valvular Stenosis—Aortic stenosis is treated with surgery when it results in congestive heart failure. Choices for medical management are limited, but possible pharmacologic interventions include mild diuresis and the use of digoxin. Systemic vasodilators, useful in other forms of heart failure, may cause severe hypotension in patients with aortic stenosis. In selected patients with combined stenosis and ventricular dysfunction, judiciously used intravenous unloading therapy has been employed with hemodynamic monitoring. This type of hemodynamic manipulation is performed in the catheterization laboratory or under the guidance of a cardiologist and is not the standard of care. Dopamine can be tried if shock develops, but by this time, surgery is essential. A rapid and limited search for confounding problems can be undertaken to try to find ways to improve the patient acutely. Atrial fibrillation, for example, because it results in a decrease in left ventricular filling in the patient with severe aortic stenosis, should be treated aggressively with the goal of returning the patient to sinus rhythm. Successful cardioversion of atrial fibrillation may result in acute improvement in cardiac output.

Severe mitral stenosis is also a surgical problem, although it is somewhat more amenable to pharmacologic therapy. The most important goal is to decrease the heart rate, thereby prolonging diastolic filling time and allowing the left atrium to empty. Left atrial pressure and, therefore, pulmonary venous pressure are determined by the degree of left atrial emptying. In patients with mitral stenosis, left atrial emptying is limited by decreased mitral orifice size, and the smaller the valve area, the longer it takes for the atrium to empty. Inadequate time for emptying leads to increased left atrial pressure and volume and worsening pulmonary congestion. Thus, by slowing the heart rate and lengthening diastole, the left atrium has more time in which to empty. Therefore, if left ventricular function is preserved and there is only mild to moderate mitral regurgitation, heart rate control using beta-blockers or calcium channel blockers (or digoxin, if the patient has atrial fibrillation) often will greatly improve symptoms.

Treatment: Prosthetic Valves

A. Transvalvular Dysfunction of Prosthetic Valves—This entity can be a true medical emergency resulting in rapid deterioration of a stable patient and can lead to death if not recognized and treated promptly. Bioprosthetic valves tend to calcify and become both stenotic and incompetent over time. Once the valve becomes dysfunctional, further progression can be rapid, with a rigid leaflet suddenly becoming severely incompetent and producing fulminant congestive

heart failure. Mechanical prosthetic valves are more durable, with, for example, Starr-Edwards valves (ball-cage valves) functioning for more than 30 years. However, ingrowth of tissue (pannus formation) or thrombosis secondary to inadequate anticoagulation can result in the development of valve dysfunction with either obstruction, regurgitation, or both depending on where the tissue ingrowth or clot develops. Progressive thrombosis, particularly on a single-leaflet mechanical valve, can result in death because the valve may stick in the closed position. The St. Jude valve, because it is a bileaflet device, usually develops both insufficiency and stenosis. Other less frequent problems have resulted from mechanical damage to the valve, such as strut fracture with Björk-Shiley-type valves and loss of poppets owing to ball variance and fractures in the older Starr-Edwards valves. In evaluating patients with suspected prosthetic valve dysfunction, physical examination may show evidence of congestive heart failure. The murmurs that accompany the prosthetic valve may be fainter than usual because of low cardiac output or high filling pressures. The key to the diagnosis of prosthetic valve dysfunction is a high degree of clinical suspicion and noninvasive assessment of valvular function. Patients with prosthetic valves who present with worsening heart failure should undergo Doppler evaluation of the valves to assess gradients across the valves and to estimate valve area. Transesophageal echocardiography is extremely useful in this setting and can confirm valve obstruction by demonstrating the presence of a clot and reduced prosthetic leaflet motion. A large pressure gradient across the valve or the presence of substantial transvalvular regurgitation is suggestive of valve thrombosis. Cinefluoroscopy can be used to assess opening angles of the mechanical prosthetic valves by measuring the angle on still frames. The angle of opening for specific valve models is known. If the valve does not open to the expected amount, valve dysfunction and thrombosis can be suspected.

Treatment includes immediate heparinization if thrombosis is suspected, hemodynamic monitoring, and surgical evaluation for urgent valve replacement. Valve replacement is critical and can be lifesaving. Patients who present with severe heart failure in this setting sometimes can be helped dramatically by use of thrombolytic agents, including alteplase or streptokinase. Risks of thrombolytic therapy include embolization of lysed clots and CNS hemorrhage, but the risks may have to be accepted when cardiogenic shock occurs secondary to valve thrombosis and surgery is considered too hazardous. Results with alteplase can be seen within 90 minutes. Heparinization must be continued after thrombolytic therapy to prevent immediate thrombosis.

B. Emboli—Thrombi forming on prosthetic valves are a source of thromboemboli, which can cause complications based on where the emboli lodge, including strokes, renal infarction, ischemic limbs, pulmonary emboli, and coronary artery occlusion. Emboli occur uncommonly in anticoagulated patients; however, inadequate anticoagulation or discontinuation of anticoagulation—particularly with mechanical

valves—can result in embolic events. Treatment is supportive with use of intravenous anticoagulation for treatment of peripheral embolization and prevention of further emboli. Surgical removal of emboli can be performed if they are in accessible locations, such as in limb vessels. In patients who are already adequately anticoagulated with warfarin, the addition of aspirin or dipyridamole has been shown to decrease the frequency of recurrent embolization.

In patients with cerebral emboli, the decision to anticoagulate may be difficult because of the risk of conversion of a bland embolic stroke to a hemorrhagic one. Most neurologists recommend waiting 48–72 hours before anticoagulating such patients unless the concern for recurrent emboli is felt to outweigh these risks. Finally, surgical replacement of a partially thrombosed valve in a patient with stroke is associated with a very high risk of perioperative intracerebral hemorrhage owing to the combination of low cerebral perfusion and the need for heparin during the procedure.

C. Paravalvular Leaks and Valve Dehiscence—Valve dehiscence is another form of valve dysfunction seen with both bioprosthetic and mechanical valves. The artificial valve is attached to the myocardium or to the annulus where the native valve previously resided. Paravalvular leaks can be a result of technical problems occurring at the time of surgery or may develop years later as a result of prosthesis infection (endocarditis). Paravalvular leaks are a result of space developing between the sewing ring of the valve and the annulus or cardiac tissue. Small, hemodynamically insignificant leaks are often seen as a result of minor surgical imperfections and can remain stable for years. Paravalvular leaks secondary to infective endocarditis often are associated with valve dehiscence, and these paravalvular leaks tend to progress—often rapidly. This results in severe hemodynamic dysfunction, further dehiscence of the valve, instability of the valve, and frequently, hemolysis owing to mechanical destruction of red blood cells as they pass through the disordered valve. However, paravalvular leaks can develop over time even in the absence of infection.

Development of a paravalvular leak in the setting of endocarditis is a surgical emergency. Complications include progressive uncontrollable congestive heart failure, sepsis, and complete dehiscence of the valve resulting in death. Echocardiography—particularly transesophageal—or cardiac catheterization is required to define the severity of the valve lesions, assess overall cardiac function, and guide valve replacement. In the absence of infection, the decision with regard to valve replacement is determined by the degree of regurgitation and associated heart failure. Paravalvular leaks that increase over time suggest instability of the valve and necessitate valve replacement.

Treatment: Infective Endocarditis (Prosthetic or Native Valve)

Infective endocarditis is a pleomorphic disease that can be rapidly progressive when caused by invasive organisms or can be slowly progressive and debilitating resulting in

chronic congestive heart failure and wasting. Diagnosis and identification of the organism are essential for proper management. Clinical features of endocarditis, including fever, heart murmur, unexplained anemia, and peripheral or immunologic stigmata, should alert the physician. In particular, endocarditis needs to be considered in any febrile patient with a known history of valvular heart disease, a pathologic murmur, or a prosthetic valve. Patients with community-acquired *Staphylococcus aureus* or *Streptococcus viridans* bacteremia have a high incidence of endocarditis (20% and 80%, respectively) and should be considered to have endocarditis until proven otherwise.

The diagnosis of endocarditis is made on clinical grounds (see Chapter 15). Positive blood cultures are found in as many as 90% of patients, but the frequency of this finding depends on the type of organism and the number of blood cultures obtained. Therefore, one should obtain an adequate number of samples of blood for culture before starting antibiotic therapy or specify laboratory techniques to minimize the effect of antibiotics on the culture results.

Obtaining cultures for fungi, anaerobic bacteria, and fastidious or slow-growing organisms may increase the likelihood of an etiologic diagnosis in susceptible patients. Echocardiography, especially using the transesophageal approach, is extremely useful in detecting valvular vegetations in endocarditis and for assessing the degree of valvular incompetence, if any (Figure 21–2).

Effective antibiotic therapy requires selection of bactericidal or fungicidal drugs to which the organism is sensitive and then delivering intravenous antibiotics in adequate quantities for a prolonged period. Fungal endocarditis is almost never eradicated using pharmacotherapy. The duration of therapy, in part, depends on the organism. Prosthetic valve endocarditis often necessitates valve replacement because antibiotics fail to eliminate the infection or because of valve dysfunction, valve dehiscence, or ring abscess.

The outcome of both native and prosthetic valve endocarditis depends on cardiac function. Patients developing congestive heart failure do quite poorly without valve replacement. Valve replacement, even while the patient is still

▲ **Figure 21–2.** Transesophageal echocardiogram demonstrating mitral valve endocarditis with a prolapsing and partial flail mitral valve leaflet (*arrow*). A vegetation can be seen as well. The left ventricle and left atrium are indicated by *LV* and *LA*, respectively. At surgery, the valve was found to be necrotic. The mitral valve was incompetent, with severe mitral regurgitation, as seen on color-flow Doppler, but this is not shown in this still-frame image.

infected or septic, can be lifesaving after congestive heart failure has developed. When to operate in cases of native valve endocarditis depends in part on the hemodynamic consequences of the infection (eg, severe valvular regurgitation, intracardiac shunts, or congestive heart failure). Surgery is required if antibiotic therapy fails to clear the infection, if there are persistent fevers or a valve ring abscess, or if cultures have identified a fastidious organism known to be difficult to eradicate medically. Patients who have more than one major embolic episode with left-sided endocarditis almost always undergo valve replacement. Larger vegetations, particularly on the left side of the heart, are associated with higher complication rates and poorer outcomes.

In patients suspected of having infective endocarditis, echocardiography should be performed to identify valvular vegetations or valve destruction and to qualitatively assess the degree of valvular regurgitation present. Echocardiography then can be used to monitor therapy. Increase in vegetation size, worsening of regurgitation, or the development of mycotic aneurysms, intramyocardial abscesses, or a fistula suggests treatment failure and the need for further intervention. In patients with left-sided endocarditis, aortic valve ring abscess, left-to-right shunts, valvular incompetence, and large vegetations have important implications for outcome and the need for valve surgery. Transesophageal echocardiography has superior sensitivity for identifying valvular vegetations, valve ring abscesses, and intracardiac shunts. It is particularly valuable for visualizing lesions in patients with prosthetic valve endocarditis. For these reasons, transesophageal echocardiography is recommended for all patients suspected of having left-sided endocarditis, aortic valve endocarditis, or suspected prosthetic valve endocarditis and for patients with endocarditis who are hemodynamically unstable or deteriorating. The transesophageal echocardiogram also should be used in the preoperative and intraoperative management of these patients to identify unsuspected pathologic findings, including aortic-to-atrial fistulas and valve ring infection, and to verify the adequacy of surgical repair.

▶ Cardiac Tamponade

ESSENTIALS OF DIAGNOSIS

- ▶ Evidence of elevated pericardial pressure manifested as elevated systemic venous pressure, decreased cardiac output and hypotension; evidence of decreased peripheral perfusion.
- ▶ Echocardiography: diastolic collapse of right ventricle, systolic collapse of right atrium, large pericardial effusion.
- ▶ Pulmonary artery catheter monitoring: equalization of right atrial, left atrial, and left ventricular end-diastolic pressures.

General Considerations

Pericardial effusions occur in a variety of patients seen in the ICU, including those with malignancy, tuberculosis, fungal infections, myocardial infarction, trauma, acute and chronic renal failure, thyroid disease, autoimmune conditions, and more rarely, those with endocarditis or aortic dissection. Patients after cardiac surgery can develop pericarditis and pericardial effusions for several reasons. The size of the effusion and the rapidity with which it develops are the major determinants of its hemodynamic effects. Cardiac tamponade ensues when adequate ventricular and atrial filling are prevented by increased intrapericardial pressure owing to the presence of a pericardial effusion. Left atrial, right atrial, left ventricular end-diastolic, and right ventricular end-diastolic pressures increase and equalize. Stroke volume, cardiac output, and systemic blood pressure fall greatly, and patients may develop shock with evidence of end-organ hypoperfusion.

Clinical Features

A. Symptoms and Signs—Symptoms and signs may reflect the underlying cause of the pericardial effusion, especially if there is inflammation of the pericardium with acute pericarditis. Chest pain that is pleuritic and positional suggests this diagnosis. However, patients with tamponade need not have chest pain, especially if tamponade is due to other causes such as malignancy or uremia. When cardiac tamponade develops, patients may have associated dyspnea and orthopnea.

Physical findings in cardiac tamponade include distended neck veins, tachycardia, hypotension, and pulsus paradoxus. Elevated pericardial pressure will cause distended neck veins (which should be looked for in the upright position because the meniscus may not be visible in a semisupine patient when the pressures are markedly elevated), pulsus paradoxus (ie, augmented respiratory variation in the pulse pressure, usually >10 mm Hg), and usually hypotension. Although in general the blood pressure is reduced, normal or elevated blood pressure can be seen with tamponade in patients with previous hypertension. Tachycardia, tachypnea, and orthopnea are important supporting signs suggesting elevated pressures affecting the left side of the heart. Heart sounds as well as the left ventricular impulse may be muted because the heart is surrounded by fluid and farther away from the chest wall. Hepatomegaly and peripheral edema may be present.

Patients rarely may present with “low pressure” cardiac tamponade, in which classic signs may be absent but there is evidence of reduced cardiac output. These patients have decreased intravascular pressures relative to pericardial pressures, but the diagnosis usually can be made by echocardiogram.

B. Laboratory Findings—Laboratory abnormalities may identify a specific cause of pericardial effusion. If a diagnostic pericardiocentesis is performed, a specific diagnosis may be made from bacterial, fungal, or mycobacterial cultures; cytologic examination; and other studies.

C. Electrocardiography—Electrocardiography may show decreased voltage. Acute pericarditis may present with diffusely elevated ST segments or PR depression on ECG. Electrical alternans is an important clue supporting the diagnosis of cardiac tamponade but is neither sensitive nor specific.

D. Imaging Studies—The chest x-ray may show cardiomegaly with a characteristic “water bottle” shape, but if the development of pericardial effusion is rapid, heart size may be only slightly increased. At the bedside, echocardiography can rapidly and accurately determine if pericardial fluid is present and estimate ventricular function (Figure 21-3). In addition, there are several echocardiographic criteria for the diagnosis of tamponade in patients with pericardial effusions. These findings include the

▲ **Figure 21-3.** Two-dimensional echocardiogram taken from the subcostal window demonstrating a large pericardial effusion with cardiac tamponade. *PEF* locates the pericardial effusion surrounding the heart. *R* and *L* indicate the right and left ventricles, respectively. Note that the chambers are quite small because of the massive pericardial effusion.

“swinging heart,” right ventricular diastolic or right atrial systolic collapse, respiratory variation in the left ventricular and the right ventricular chamber sizes, and right atrial indentation. Although helpful, these signs are neither sensitive nor specific. Therefore, after identifying a moderate to large pericardial effusion by echocardiography in a symptomatic patient, a bedside pulmonary artery catheter should be placed to confirm the hemodynamic findings of tamponade.

Treatment

Initial treatment of cardiac tamponade consists of rapid intravenous fluid loading and dopamine. The goal is to increase intravascular pressures enough to overcome the increased pericardial pressure as well as maintain adequate systemic blood pressure. Although these agents may improve the hemodynamic status for a short time, pericardiocentesis when tamponade is present is essential to avoid hemodynamic collapse and death. This procedure should be performed rapidly to relieve the hemodynamic compromise and to determine the cause of the effusion.

An intrapericardial catheter can be placed through a subxiphoid approach using a wire placed through a thin-walled needle (Seldinger technique). Positioning is done using electrocardiographic guidance, echocardiographic guidance, or fluoroscopy. The catheter should remain in place to permit repeated aspirations of fluid. Fluid should be sent for culture, cytologic examination, and serologic testing. Patients with moderate to large effusions and elevated filling pressures but not satisfying the criteria for cardiac tamponade should have hemodynamic measurements made before and after pericardiocentesis to verify hemodynamic benefit as well as to obtain fluid for diagnosis. Cardiac tamponade secondary to renal failure may benefit from injection of a non-absorbable corticosteroid into the pericardial space after drainage of the fluid.

In patients with malignant pericardial effusion and cardiac tamponade, drainage followed by sclerotherapy using bleomycin or fluorouracil may decrease the recurrence of tamponade. Alternatively, balloon pericardiectomy may allow drainage of fluid into the pleural or mediastinal space—thus preventing reaccumulation of fluid, which would result in tamponade. However, in patients whose life expectancy is greater than 6 months (a small number of patients with malignant pericardial effusions and tamponade) and in those whose effusion cannot be controlled with sclerosis of the pericardial space, pericardiectomy should be considered.

▶ Hypertensive Crisis & Malignant Hypertension

ESSENTIALS OF DIAGNOSIS

- ▶ **Hypertensive crisis:** systemic blood pressure >240/130 mm Hg without symptoms or elevated blood pressure with chest pain, headache, or heart failure; may have intracranial hemorrhage, aortic dissection, pulmonary edema, myocardial infarction, or unstable angina.
- ▶ **Malignant hypertension:** severe hypertension associated with encephalopathy, renal failure, or eye findings including retinal hemorrhage, exudates, or papilledema.

General Considerations

Hypertension in adults is usually a chronic condition that, if untreated, is a significant risk factor for the long-term development of coronary, cerebral, and peripheral vascular disease. Mild to moderate hypertension usually poses no immediate danger to the patient if the pressure is below 170/110 mm Hg. Patients with mild to moderate hypertension are often asymptomatic, and control of their blood pressure can be achieved using oral medications and modification of diet. Antihypertensive treatment usually is begun on an outpatient basis after documentation of persistent hypertension and evaluation for potentially reversible causes.

A subset of patients present with or develop severe life-threatening hypertension or have other coexisting medical problems requiring urgent control of blood pressure; these patients are defined as having a *hypertensive crisis* (sometimes called a *hypertensive emergency*). For example, patients with acute myocardial infarction or unstable angina benefit greatly from reduction of elevated blood pressure and lowering of left ventricular afterload. Blood pressure represents a major factor in myocardial oxygen demand. When congestive heart failure owing to left ventricular dysfunction or aortic or mitral regurgitation is associated with severe hypertension, rapid lowering of blood pressure will accelerate treatment of the hemodynamic dysfunction. Patients with acute aortic dissection and elevated blood pressure have greatly increased stress on the aorta, and urgent control of blood pressure is mandatory. Patients with intracranial hemorrhage—intracerebral or subarachnoid—also require control of blood pressure and may become acutely hypertensive as a result of the CNS event. Severe hypertension results in local and systemic effects that start a cascade of events that

further elevates blood pressure. Dilation of cerebral blood vessels results in hypertensive encephalopathy, and damage to the blood vessel wall can increase permeability, resulting in edema or bleeding.

Malignant hypertension is defined by some as severe hypertension associated with specific end-organ damage, namely encephalopathy, nephropathy, or eye findings, including retinal hemorrhages, exudates, or papilledema. Treatment of malignant hypertension is important because rapid and effective lowering of blood pressure is essential for reversal of complications.

Any of the causes of hypertension can be associated with hypertensive crisis, including essential, renovascular, or endocrine-mediated (eg, pheochromocytoma) forms of hypertension. Most patients who present with hypertensive crises have preexisting hypertension.

Clinical Features

A. Symptoms and Signs—Patients with severely elevated blood pressure are frequently asymptomatic, but most will present with headache, confusion, stupor, seizure, or coma depending on the severity of the hypertension and the degree of end-organ involvement. Chest pain may be due to angina pectoris, unstable angina, or myocardial infarction associated with hypertension, but chest pain also should raise the possibility of aortic dissection. In malignant hypertension, papilledema, retinal hemorrhages, or exudates are present by definition and may be accompanied by encephalopathy. Acute oliguric renal failure as well as signs and symptoms of congestive heart failure may be seen. The blood pressure is usually quite elevated, with diastolic blood pressure exceeding 130 mm Hg. Ophthalmoscopic examination may demonstrate retinal hemorrhages and exudates as well as papilledema. Patients may have evidence of congestive heart failure. Neurologic findings owing to severe hypertension may include focal motor or sensory abnormalities as well as altered mental status. However, other causes of acute neurologic impairment with hypertension must be excluded, including primary CNS events such as strokes, tumors, head injury, encephalitis, and collagen vascular disease.

B. Laboratory Findings—Serum creatinine and urea nitrogen may be elevated. In those with acute hypertensive nephropathy, urinalysis shows red blood cells, red blood cell casts and proteinuria.

C. Electrocardiography—Electrocardiography may show left ventricular hypertrophy, particularly with chronic hypertension. Acute ST-segment and T-wave changes may be secondary to hypertension but also may represent acute ischemia.

D. Imaging Studies—The chest x-ray may show cardiomegaly and pulmonary edema. Aortic dissection should be considered when reviewing the film. Imaging of specific organs depends on symptoms and signs and may include head CT scan (eg, strokes and focal neurologic findings), renal ultrasound (eg, acute renal insufficiency), and echocardiography (eg, aortic dissection).

Treatment

The most important consideration in patients with hypertensive crisis is rapid reduction of blood pressure with a short-acting, easily titratable agent. The goal is to prevent permanent vascular and neurologic damage and to avoid worsening the heart failure or causing uncontrollable hypotension. Blood pressure should be controlled aggressively in these patients, and therapy should be instituted even while etiologic investigation is still under way. Of particular concern, patients with strokes or other types of neurologic dysfunction may sustain further neurologic damage if blood pressure is lowered too abruptly or excessively. Therefore, the initial goal of antihypertensive therapy within the first 6 hours is to lower the blood pressure by 25% of the starting blood pressure value or to no less than 150/110 mm Hg. Further lowering should take place more gradually.

A. Nitroprusside—Intravenous nitroprusside, which acts as a peripheral arteriodilator, is the drug of choice in hypertensive crises because it can be titrated rapidly and safely. Excessive hypotension can be avoided by careful blood pressure monitoring, usually with an arterial catheter, but a non-invasive automated cuff manometer is usually satisfactory. If hypotension occurs with nitroprusside therapy, discontinuation of the drug results in rapid restoration of blood pressure. Nitroprusside is given intravenously at a rate of 0.25–10 µg/kg per minute. Usually one begins at a low infusion rate and adjusts the rate as needed every 5 minutes over a period of 1–2 hours. Thiocyanate toxicity can occur, particularly in patients with renal failure. However, over the first 24 hours, when control of blood pressure is essential, this is not a major concern. After blood pressure is lowered to a satisfactory level, institution of oral antihypertensive drugs is begun with the goal of discontinuing nitroprusside within 24–48 hours.

B. Other Antihypertensive Agents—Other parenteral agents that can be used in patients with severe hypertension include esmolol, hydralazine, labetalol, nitroglycerin (usually a mild blood pressure-lowering agent), and enalaprilat, an ACE inhibitor. Esmolol is a short-acting β-adrenergic blocker indicated for short-term use. It should be avoided in patients with bronchospasm, severe heart failure, heart block, or bradycardia. Hydralazine is a peripheral vasodilator that can be given orally or intravenously. Reflex tachycardia is common, and β-adrenergic blockers are almost always given simultaneously. Labetalol has both α- and β-adrenergic blocking effects. Nitroglycerin has primarily venodilator effects. The degree of lowering of blood pressure with intravenous nitroglycerin varies from patient to patient, and there is some risk of lowering cardiac output excessively with this drug. On the other hand, nitroglycerin has the advantage of being a coronary artery vasodilator and therefore is useful in patients with hypertension and myocardial ischemia. Enalaprilat is the only intravenous ACE inhibitor available. It is converted to the active drug enalapril after infusion. It has modest antihypertensive effects

at the dosages recommended (starting dose 0.625 mg). Side effects include worsening of renal failure and hyperkalemia.

Oral calcium channel blockers, including amlodipine and diltiazem, are useful in less severe hypertension. In patients with severe hypertension and heart failure, calcium channel blockers and beta-blockers may result in unacceptable depression of ventricular function, in some cases worsening congestive heart failure. However, β -adrenergic blockers must be used in patients with dissecting aortic aneurysms before systemic vasodilators (eg, hydralazine and nitroprusside) are given to prevent an increase in shear stress on the aortic wall. Diuretics may be needed in addition to the antihypertensive medication to help relieve the volume overload associated with treatment with many of the vasodilator drugs.

Stable patients with severe hypertension without encephalopathy may be managed with oral agents, including beta-blockers, calcium channel blockers, clonidine, hydralazine, and ACE inhibitors. Combinations of drugs are often necessary to maximize effects and minimize side effects and toxicities.

► Complications of Cardiac Catheterization

ESSENTIALS OF DIAGNOSIS

- Bleeding or thrombosis at vascular access site.
- Peripheral arterial emboli from clot at access site.
- CNS complications from cerebrovascular emboli.
- Arrhythmias, myocardial infarction, cardiac tamponade from myocardial perforation, aortic dissection.

General Considerations

Patients may be admitted to the ICU after cardiac catheterization for monitoring or because of complications from the procedure. Complications may result from the underlying cardiac problem, but complications from the cardiac catheterization procedure itself should be anticipated. Complications can be grouped into problems related to the vascular access site, the aorta, and the heart.

A. Vascular Access Complications—Vascular access, particularly in an atherosclerotic vessel, can result in the development

of dissection or occlusion at the vascular site or may provide a nidus for thrombus with or without peripheral embolization. In addition, large hematomas may develop at the entry site if adequate hemostasis is not achieved or if vascular damage with a pseudoaneurysm or intimal tear has occurred. The use of heparin, clopidogrel, aspirin, and glycoprotein IIb/IIIa receptor inhibitors for treatment of unstable angina and prolonged catheter placement after catheterization have increased the risk of bleeding and the need to pay close attention to local hemostasis. Several kinds of devices have been developed to close arterial catheter puncture sites when catheterization is completed, including those with arterial sutures and devices that provide internal compression with a collagen plug. These devices have reduced the risk of bleeding significantly.

In patients with bleeding at the access site, the hematoma should be measured, outlined with a marker, and then observed for any increase in size. An enlarging hematoma or swelling at the access site indicates a need for rapid evaluation to exclude or control significant bleeding. Distal peripheral pulses, leg temperature, and the arterial site should be checked and findings recorded frequently. Doppler studies are indicated if changes occur or pain develops in the distal portion of the extremity or if a pseudoaneurysm or dissection is suspected. Patients undergoing percutaneous transluminal coronary angioplasty (PTCA) and stent placement may have the arterial sheath left in place for 12–24 hours or may undergo repeat catheterizations to treat multiple lesions. These repeat and prolonged interventions may increase the risk of complications and require diligent anticoagulation to avoid arterial thrombosis. Newer coated stents have improved outcomes dramatically with angioplasty and higher patency rates but require prolonged treatment with a combination of clopidogrel and aspirin. Discontinuation of these agents, in particular clopidogrel, can result in acute stent thrombosis and abrupt myocardial infarction. This complicates the management of bleeding complications after catheterization and also poses problems for ICU patients requiring surgical noncardiac interventions where postoperative bleeding may be an issue.

B. CNS Complications—Strokes can occur during and after cardiac catheterization because of embolization of intracardiac thrombi, aortic intimal plaque disruption, catheter thrombosis and embolization, and more rarely, dissection of carotid arteries or air injected inadvertently during catheterization. Strokes owing to catheterization are not infrequent occurrences. A careful neurologic evaluation prior to cardiac catheterization makes evaluation after catheterization more useful. Interpretation of neurologic findings can be complicated by the use of sedation for catheterization; however, a localizing finding such as hemiplegia or aphasia is highly suggestive of postcatheterization embolization. A CT scan or MRI of the head or cerebral arteriography should be performed immediately to help determine whether the event is associated with hemorrhage. In the absence of hemorrhage, intervention with thrombolysis is an option to lyse the clot.

This can be done by localized infusion during cerebral angiography or with systemic thrombolytic agents. Prolonged use of heparin or use of other anticoagulants during catheterization may preclude the use of systemic thrombolysis, and decisions are made on an individual basis with the help of a stroke team.

C. Other Complications—Cardiac complications related to catheterization include myocardial infarction, arrhythmias, cardiac tamponade, and aortic dissection. Echocardiography should be performed with little hesitation in patients complaining of dyspnea or chest pain after catheterization, and this technique can be useful to look for new cardiac wall motion abnormalities, aortic dissection, or the development of a pericardial effusion.

Pericardial effusions developing after catheterization are relatively rare but require close observation for development of tamponade, particularly in patients who have had interventions (eg, angioplasty) or are receiving platelet inhibitors or anticoagulation. Tamponade with hemodynamic collapse can develop rapidly in these situations. Acute shortness of breath with chest pain may be due to acute ischemia, and this must be differentiated from acute cardiac tamponade.

Radiologic contrast medium–related problems include histamine-mediated reactions (eg, urticaria, angioedema, and hypotension), volume depletion and hypotension secondary to the osmotic diuresis, and acute renal failure. Close monitoring of patients after cardiac catheterization requires attention to electrolyte and fluid balance. Patients with diabetes and preexisting renal disease are at increased risk of acute renal failure. Urticaria and other histamine reactions can be reduced by pretreatment with antihistamines and H₂-blockers one hour before the procedure. Patients with known allergic reactions to contrast media also should be pretreated with corticosteroids 8–12 hours before the procedure. Hydration before and after contrast administration is the best way to prevent renal failure. Patients with renal insufficiency or preexisting diabetes may have a reduced risk of further deterioration if given acetylcysteine prior to the administration of contrast material.

▶ Aortic Dissection

ESSENTIALS OF DIAGNOSIS

- ▶ Severe chest pain without features of ischemic heart disease in the presence of hypertension.
- ▶ Widened mediastinum on chest x-ray.
- ▶ Aortic dissection identified by echocardiogram, CT scan, or MRI.

General Considerations

Acute aortic dissection is seen in patients with underlying atherosclerotic vascular disease, hypertension, and connective tissue abnormalities such as Marfan's syndrome. Aortic dissection is the acute development of a tear in the intima of the aorta. Arterial blood under high pressure enters the intima, extending the tear and causing progressive destruction of the aortic media. This process is potentially catastrophic. The path the dissection takes is quite variable, spiraling superiorly and retrograde to the aortic valve and the coronary arteries, antegrade to the abdominal aorta, or both. The hemodynamic manifestations and clinical findings will depend on the path the dissection takes.

Dissections occur most frequently in the ascending aorta near the aortic valve or in the proximal descending aorta beyond the takeoff of the left subclavian artery. There are several classification systems for describing the location of aortic dissection. The easiest to understand and most relevant in terms of clinical decision making divides aortic dissections into two types. The proximal or ascending (type A) dissection involves the proximal aorta but may extend beyond the aortic arch. This type is analogous to the DeBakey type I and type II classification of aortic dissections. Descending or distal (type B) dissection involves only the descending portion of the aorta, similar to DeBakey type III. Type A dissections are often lethal, causing acute aortic insufficiency, congestive heart failure, pericardial effusions, often with tamponade, and acute myocardial infarctions. Treatment is almost always surgical. Type B dissections are initially treated medically but may require surgery after stabilization.

Clinical Features

A. Symptoms and Signs—The most common clinical presentation of patients with aortic dissections is the abrupt onset of severe chest or back pain. The pain is at maximum intensity at onset. The pain tracks the progression or pathway of the dissection and often is described as tearing or ripping in quality. The severity of the pain may precipitate vagal reflexes, including hypotension and bradycardia. If the aortic valve or coronary arteries are involved, congestive heart failure or myocardial ischemia can develop acutely. Cardiac tamponade may occur if the tear extends into the proximal aortic root, allowing blood to enter the pericardial space. Physical findings include diminished or unequal peripheral pulses and blood pressures.

A murmur of aortic regurgitation may be heard along with findings consistent with acute pulmonary edema or tamponade.

In this age of thrombolytic therapy and anticoagulation for acute myocardial infarction, it is critically important to distinguish aortic dissection from myocardial ischemia. Although both present with chest pain, the pattern of pain—quality, location, duration, and onset—should help to distinguish between the two. Pain from aortic dissection is more abrupt in onset, more often reaches maximum intensity immediately, and is often described as tearing in quality. Location is more often in the back than substernal. Unlike myocardial pain, the pain of aortic dissection usually does not respond to nitrates or beta-blockers acutely but may do so if a reduction in blood pressure decreases the stress on the aorta. Also unlike myocardial ischemia, aortic dissection pain usually is unrelated to activity. In contrast, ischemic pain usually begins slowly and increases in intensity. It radiates to the neck, jaw, and arm but never below the umbilicus. Beta-adrenergic blockers and nitrates usually relieve ischemic pain, although not necessarily the pain of myocardial infarction. Ischemia and infarction often have electrocardiographic findings of ST-segment and T-wave changes. On examination, the presence of a new aortic diastolic murmur, unequal peripheral

pulses, and absence of rales in a patient with chest pain should raise the question of aortic dissection.

If aortic dissection is a consideration, diagnostic tests should be undertaken expeditiously because the treatment—lowering the blood pressure, decreasing myocardial contractility with beta-blockers, and surgical repair—must be administered urgently. Anticoagulation and thrombolytic therapy are clearly contraindicated. Unfortunately, because aortic dissection can cause acute myocardial infarction by involving coronary arteries in the dissection, the distinction between aortic dissection and myocardial ischemia is not always clear.

B. Imaging Studies—Initial evaluation with chest x-ray may identify a widened mediastinum, but more definitive information can be obtained using transthoracic echocardiography. Although the sensitivity for identifying aortic dissection is relatively low with transthoracic echocardiography, this test provides other useful additional information on cardiac function, ventricular wall motion, and valvular abnormalities and can identify the presence of pericardial effusion. In addition, the echocardiogram can be used to measure the aortic root size, and Doppler echocardiography can determine the degree of aortic valvular regurgitation (Figure 21-4).

▲ **Figure 21-4.** Aortic dissection and aneurysm with an intimal flap demonstrated by transthoracic echocardiography. The aneurysm of the ascending aorta is at A. The aortic valve is at V. The arrow points to the intimal flap approximately 2 cm above the aortic valve in the proximal ascending aorta.

Transesophageal echocardiography, MRI, and CT scan are 80–100% sensitive and specific for the diagnosis of aortic dissection. MRI is probably the most sensitive and specific procedure, but the availability of transesophageal echocardiography and the ability to monitor the patient more closely during echocardiography than during MRI or CT scanning are important considerations. Monitoring patients during MRI scanning can be difficult, and unstable or hypotensive patients should undergo transesophageal echocardiography at the bedside instead. One of these tests should make the diagnosis rapidly (Figure 21–5). If the imaging technique identifies aortic dissection, therapy is based on the location of the dissection and the extent of aortic involvement. Further studies may be indicated to assess coronary anatomy and aortic valve function. Cardiac catheterization may be needed to help guide the surgical intervention.

Treatment

In general, type A aortic dissections require surgery because medical management alone for proximal ascending aortic dissection has a high short-term and 1-year mortality rate. Type B aortic dissections that involve the descending portion of the thoracic aorta only are managed medically unless there is compromise of the renal or mesenteric circulations. Complicated dissections involving the arch and arch vessels have high surgical and medical mortality rates, making therapeutic decisions more difficult.

Immediate management of all aortic dissections requires aggressive medical and pharmacologic therapy to

reduce systolic blood pressure and to decrease the peak systolic velocity of aortic blood flow and thereby reduce shear forces on the aortic wall. The goals of therapy include control of pain, reduction of systolic blood pressure to 100–120 mm Hg (as long as renal, myocardial, and cerebral perfusion is maintained), and stabilization of the patient's hemodynamic variables to permit a thorough diagnostic evaluation. Beta-adrenergic blockers are used aggressively to decrease the force of ventricular contraction. Heart rate is used as a guide to the degree of beta-blockade, and enough β -adrenergic blockade should be given to lower the heart rate to 55–65 beats/min. Nitroprusside is used to control blood pressure initially and is adjusted as required when beta-blockade is achieved. Calcium channel blockers, because of their negative inotropic and antihypertensive properties, are ideal alternatives in patients who are unable to tolerate beta-blockers. Hydralazine and other direct vasodilators should not be given to control blood pressure in the absence of β -adrenergic blockade. Although blood pressure will fall, the force of aortic blood flow may increase, further increasing stress on the damaged aortic wall.

Survival rates approach 80–90% when appropriate therapy is instituted rapidly in both type A and type B aortic dissections. Outcome is determined in part by the degree of damage to vital organs (eg, kidneys, brain, heart, and bowel), the underlying condition of the aorta, and the extent of the repair needed.

ATRIAL ARRHYTHMIAS

Critically ill patients—particularly those with pulmonary disease and respiratory failure—are at high risk for developing atrial arrhythmias. Atrial distention, electrolyte imbalances, hypoxemia, and high catecholamine levels all contribute to electrical instability and increased atrial automaticity. Identifying the type of supraventricular arrhythmia is essential in choosing the correct treatment. A 12-lead ECG permits more careful evaluation of P-wave morphology and axis than a single-lead ECG from the bedside monitor or “rhythm strip.” The morphology of the ST segments and T waves should be examined for evidence of ischemia. The PR interval and initial activation of the QRS segment can identify the presence of an atrioventricular (AV) nodal bypass tract and show evidence of preexcitation.

Treatment is directed primarily toward eliminating or reversing the precipitating or exacerbating causes. Correction of alkalosis, hypokalemia, hypomagnesemia, or hypoxemia will increase the likelihood of rate control and eventual conversion to sinus rhythm. The major goal of acute treatment is to slow the ventricular rate so as to improve cardiac output and blood pressure. In the setting of hemodynamic compromise (eg, hypotension, syncope, chest pain, or electrocardiographic evidence of ischemia), rapid treatment using electrical cardioversion may be indicated. This treatment also should be performed immediately if the ventricular rate is extremely rapid or the patient will not tolerate prolonged tachycardia because of other conditions such as aortic or mitral stenosis, hypertrophic cardiomyopathy, or unstable angina. The high likelihood of recurrence of these arrhythmias makes rhythm identification and appropriate pharmacologic treatment important even if initially corrected by electrical cardioversion.

▶ AV Nodal or Reentrant Tachycardia

AV nodal reentrant (circus movement) tachycardias are rhythm disturbances that depend on the properties of the AV node for initiation and propagation. The arrhythmia results from an endless circle of electrical impulses conducted down

one pathway and up another with slow and fast pathways cooperating to facilitate and maintain the circuit. Alteration of refractoriness or conduction velocities in either pathway in the AV node can stop the arrhythmia immediately. The arrhythmia can be prevented by altering the electrical properties of the involved pathways or by decreasing the frequency of the premature atrial contractions that often initiate the cycle.

AV nodal reentrant tachycardias usually have ventricular rates of 140–220 beats/min, and AV conduction is usually 1:1 but rarely 2:1. The P wave may not be obvious if atrial and ventricular depolarization occur simultaneously, although a retrograde P wave may be seen. The differential diagnosis includes sinus tachycardia, atrial tachycardia, atrial flutter, and orthodromic AV reentry using an accessory pathway. If the diagnosis is unclear, adenosine (6–12 mg intravenously) usually will stop either AV nodal reentry or AV reentry causing the ventricular rate to fall all at once to the underlying sinus rate and rhythm. A brief intervening period of sinus bradycardia or complete heart block may occur. Sinus tachycardia will slow gradually in response to adenosine and then return to the pretreatment rate. If the rhythm is atrial tachycardia, atrial flutter, or atrial fibrillation, increasing AV block with adenosine usually will make the diagnosis apparent.

AV nodal reentrant tachycardias are treated effectively with adenosine (6–12 mg IV bolus), verapamil (5 mg IV bolus), diltiazem (0.25 mg/kg infusion given over 2 minutes), or β -adrenergic blockers (eg, metoprolol, 5 mg intravenously up to a total of three doses given every 5 minutes if needed). These drugs alter conduction velocity through the AV node. Because of adenosine’s extremely short half-life (measured in seconds), it is the drug of choice for acute treatment of narrow-complex tachyarrhythmias, but it is not useful in preventing recurrences. Therefore, if the risk of recurrence is great in patients with an underlying predisposing medical condition, one of the other drugs can be administered to decrease the likelihood of recurrence and can be tried if adenosine fails to convert the patient to sinus rhythm. In patients with compromised ventricular function, digoxin may be a more appropriate long-term drug than either calcium channel blockers or β -adrenergic blockers, both of which are myocardial depressants.

Procainamide is effective in treating atrial arrhythmias by preventing premature atrial beats and decreasing atrial automaticity. When the AV reentry tachycardia uses concealed retrograde conduction through a bypass tract, procainamide also may help by slowing conduction through the bypass tract. A bypass tract may be suspected when the ventricular rate exceeds 200 beats/min in an adult or when a baseline ECG demonstrates a short PR interval and evidence of preexcitation. Digoxin, β -adrenergic blockers, and calcium channel blockers can be dangerous in patients with bypass tracts who have atrial fibrillation because these drugs block AV nodal conduction and thereby facilitate conduction through the bypass tract. The ventricle is bombarded by an increased number of impulses from the atria, resulting in a very rapid ventricular rate. Ventricular fibrillation may

follow. Class Ic and class III antiarrhythmic agents such as flecainide and amiodarone also can be helpful for medical management of patients with bypass tracts. The development of transvenous radiofrequency ablation of bypass tracts obviates the need for long-term pharmacologic therapy for most patients and has largely replaced surgical ablation. AV nodal reentry arrhythmias without bypass tracts and atrial flutter are also treated effectively with transvenous ablation techniques.

▶ Atrial Tachycardia

Atrial tachycardia is an automatic rhythm (repetitive single focus) and does not depend on the AV node and reentry to continue. Atrial tachycardia is less common than AV nodal reentrant rhythms and usually has a regular ventricular rate of 140–220 beats/min, although AV block may cause the ventricular rate to be considerably slower. The P waves have uniform morphology and relationship to the QRS complex.

Although calcium channel blockers, beta-blockers, and digoxin usually will not terminate these atrial arrhythmias, they will decrease the ventricular response rate by slowing AV nodal conduction and therefore can effectively improve hemodynamics. Slowing of the ventricular rate may be helpful in identifying underlying atrial activity on the ECG so that a distinction can be made between atrial tachycardia, AV nodal reentry, atrial flutter, and atrial fibrillation. After the ventricular rate is controlled, conversion to sinus rhythm can be attempted with class Ia, Ic, or III antiarrhythmic agents or electrical cardioversion. Radiofrequency ablation can be considered in selected patients when the focus of the arrhythmia can be localized and the arrhythmia occurs frequently.

▶ Atrial Flutter

Atrial flutter is a macroreentrant arrhythmia and in many ways behaves like atrial tachycardia. Atrial flutter always should be considered when a patient presents with supraventricular tachycardia with a rate of approximately 150 beats/min. The atrial flutter rate usually is approximately 300 beats/min, but because of normal delays in conduction through the AV node, the ventricular response rate is slower than the atrial rate, with only every other (2:1 AV block) or every third (3:1 AV block) beat effectively conducted to the ventricle. Increasing the degree of AV nodal block with drugs (adenosine) or by carotid massage brings out the underlying flutter waves on the ECG and establishes the diagnosis.

Drugs that increase AV nodal block usually—though not always—can control the ventricular rate at rest, but conversion to sinus rhythm usually requires either antiarrhythmic drugs or, more commonly, electrical cardioversion. Ibutilide, sotalol, or amiodarone can be tried. In general, atrial flutter is more resistant to pharmacologic conversion than AV nodal reentrant tachycardia. However, unlike atrial fibrillation and atrial tachycardia, atrial flutter can be converted using fairly small amounts of electrical energy, usually less than 50 J.

Atrial flutter also can be converted to sinus rhythm with overdrive pacing using a transvenous right atrial pacemaker electrode or an esophageal pacemaker electrode. Atrial flutter is a rhythm that is amenable to radiofrequency ablation, with success rates approaching those for other supraventricular tachycardias. Given the difficulty of treating atrial flutter and converting it with medical therapy, ablation provides effective long-term treatment.

A subset of patients with atrial tachyarrhythmia may develop bradycardia after electrical cardioversion or drug therapy. Patients with tachy-brady syndrome pose a particular problem in designing therapy and may require temporary pacing if cardioversion is attempted. They also may require a permanent pacemaker to generate an adequate ventricular rate when receiving necessary drug therapy to control the tachyarrhythmias.

▶ Atrial Fibrillation

Atrial fibrillation is a chaotic arrhythmia probably owing to multiple reentry circuits within the atria that results in loss of atrial contraction and an irregular, often rapid ventricular rate. Because of the rapid but unpredictable bombardment of the AV node by the atrial fibrillatory impulses and variable penetration of the impulses through the AV node to the ventricle, the ventricular rate is highly variable. An irregularly irregular ventricular rate with the absence of P waves is the hallmark of atrial fibrillation and makes it easily distinguishable from the other more organized and regular atrial arrhythmias. Patients with acute atrial fibrillation may develop hypotension, myocardial ischemia, decreased perfusion of vital organs, and acute congestive heart failure. Those with chronic atrial fibrillation have an increased risk of atrial mural thrombus formation, usually in the left atrial appendage, with the risk of subsequent systemic embolization. Atrial fibrillation is very common in patients with mitral stenosis, lung disease, sepsis, and hyperthyroidism, as well as in any form of heart disease or after cardiac surgery.

Therapy is directed at slowing the ventricular rate initially, followed, in appropriate patients, by conversion of atrial fibrillation to sinus rhythm. Slowing of the ventricular rate can be achieved with β -adrenergic blockers, calcium channel blockers, or digoxin, all of which increase the AV nodal refractory period. Control of the ventricular rate is particularly important in patients with ischemia and chest pain, congestive heart failure, mitral stenosis, and hypotension. Intravenous diltiazem can be given at a dose of 5–10 mg followed by a continuous infusion. Alternatively, intravenous digoxin is effective when given at a dosage of 0.125–0.25 mg every 4–6 hours until the desired rate is achieved or until 1–1.5 mg has been given. In some patients, combinations of these drugs are necessary, but excessive AV nodal blockade should be avoided. The goal of rate control is to lower the ventricular rate to about 80–100 beats/min.

Ibutilide, an intravenous short-acting class III antiarrhythmic agent, can be used to convert atrial fibrillation to normal sinus rhythm. When given before direct current (DC)

cardioversion, it increases the likelihood of success. It has proarrhythmic effects, including torsade de pointes, that necessitate close monitoring during its infusion and for several hours thereafter. Intravenous magnesium is given frequently prior to ibutilide to reduce this risk. Combined use with amiodarone may increase heart block or arrhythmias. Sotalol, a class III antiarrhythmic with β -adrenergic blocking properties, also can be used. These agents can be continued to help maintain normal sinus rhythm. Long-term use of sotalol and amiodarone, however, may result in bradycardia, which may be prolonged with amiodarone because of the 32-day half-life.

Today, conversion to sinus rhythm is only rarely attempted using class Ia antiarrhythmic drugs such as quinidine or procainamide. Before administering class Ia drugs, the ventricular response rate must be well controlled because acceleration of the ventricular rate may occur when these drugs are given. This problem is also seen with atrial flutter and atrial tachycardia. It also should be noted that the administration of quinidine may result in nearly a doubling of the serum digoxin level. Thus, a patient with atrial fibrillation whose ventricular rate is controlled with digoxin and who has no evidence of digoxin toxicity may develop digoxin toxicity when quinidine is given. Procainamide therefore may be a better short-term choice in the critically ill patient receiving digoxin. Neither quinidine nor procainamide is well tolerated as a long-term oral medication, and both also have significant proarrhythmic effects. They are being replaced by the newer class Ic agents flecainide and propafenone, which can be used safely in patients without coronary disease, left ventricular hypertrophy, or left ventricular dysfunction, and by the class III agent dofetilide. The latter is safe in patients with left ventricular dysfunction but does require initial inpatient monitoring for excessive QT-interval prolongation. Sotalol is also effective, but it too carries a risk of QT-interval prolongation and torsades de pointes, necessitating initial monitoring for safest administration. Amiodarone is probably the most effective medication for maintaining sinus rhythm, but its myriad of potentially dangerous side effects indicate the need for caution in using it to treat an arrhythmia that is not lethal.

Electrical cardioversion of atrial fibrillation to sinus rhythm is effective at least acutely but generally requires higher amounts of electrical energy than other atrial arrhythmias, often more than 200 J. Newer biphasic defibrillators have a higher success rate and require less energy. In a hemodynamically unstable patient with rapid atrial fibrillation, electrical cardioversion is the appropriate first treatment. Patients with acute myocardial infarction, hypertrophic cardiomyopathy, severe systolic left ventricular dysfunction, critical aortic stenosis, or recent major surgery are patients who would benefit from rapid restoration of normal sinus rhythm but who might not tolerate the hypotensive episode or further hypotension caused by the antiarrhythmic agents used to chemically treat the atrial fibrillation.

Atrial fibrillation poses a risk of embolization because the noncontracting atria are potential sites for thrombus formation, and the risk of embolization increases with cardioversion. The greatest risk of embolization is associated with atrial enlargement and atrial fibrillation of long duration. Therefore, patients who have had atrial fibrillation for more than 2–3 days should be anticoagulated for 3–4 weeks before conversion is attempted. Alternatively, it has been shown to be safe to undertake cardioversion if a transesophageal echocardiogram performed while the patient is on anticoagulation demonstrates no atrial thrombi and anticoagulation is continued for 4 weeks after cardioversion. This approach allows fairly prompt cardioversion of patients in whom the duration of atrial fibrillation is unknown and avoids leaving the patient in atrial fibrillation for several additional weeks. Patients without mitral stenosis who develop acute atrial fibrillation can be cardioverted within the first few days without anticoagulation.

Patients with atrial fibrillation who cannot be converted to sinus rhythm are managed by controlling their ventricular rates. Anticoagulation with warfarin should be considered in patients with chronic atrial fibrillation because of the increased frequency of embolic strokes even in the absence of intrinsic heart disease. Patients at higher risk for embolic events include the elderly; those with ischemic, valvular, or hypertensive heart disease; diabetics; and patients with a history of stroke or TIA. Aspirin may be an alternative in otherwise healthy younger patients with lone atrial fibrillation or in those with contraindications to anticoagulation with warfarin.

► Multifocal Atrial Tachycardia

Multifocal atrial tachycardia is an atrial arrhythmia that can be confused with atrial fibrillation, but it is managed quite differently. This arrhythmia generally is seen in patients with severe lung disease and respiratory failure. The hallmark of this atrial tachycardia is an irregular ventricular rate but with multiple atrial foci (P waves with different morphologic appearances). Atrial fibrillation also has an irregular ventricular response, but P waves are absent.

Treatment of the underlying lung disease and respiratory failure usually corrects the arrhythmia. Once the precipitating pulmonary process resolves, sinus rhythm often returns. Multifocal atrial tachycardia responds poorly to digoxin, with neither slowing of the ventricular rate nor conversion to sinus rhythm. Verapamil may be effective sometimes in slowing ventricular rate and decreasing the frequency of ectopic atrial beats.

VENTRICULAR ARRHYTHMIAS

Management of ventricular arrhythmias in the ICU is often more complicated than management of atrial arrhythmias because the treatment is sometimes worse than the disease, and because these arrhythmias may be poorly tolerated by

critically ill patients. Rapid ventricular arrhythmias (eg, ventricular tachycardia) require immediate treatment, particularly in patients who have severe underlying cardiac disease. Almost all antiarrhythmic agents used for the treatment of ventricular arrhythmias may facilitate arrhythmias (proarrhythmic effect) and have a variety of other unpleasant or life-threatening side effects. Therefore, treatment of ventricular arrhythmias should be limited to those known to cause hemodynamic compromise or those that occur in the setting of underlying myocardial disease. In general, the more malignant the arrhythmia appears—that is, the more rapid the rate, the longer the duration of the arrhythmia, the more frequent the occurrence, and the greater the hemodynamic compromise (eg, hypotension or syncope)—the more important it is to treat. In addition, the presence of ventricular tachycardia always should raise the question of ischemia with underlying coronary artery disease.

The nuances of evaluation and management of sudden cardiac death and nonsustained and sustained ventricular tachycardia in the presence or absence of ventricular dysfunction are beyond the scope of this text. However, development of significant ventricular arrhythmia justifies and necessitates consultation with an electrophysiologist to determine whether medical therapy is indicated, to assess drug efficacy, and to consider more definitive treatment, including implantable defibrillators and transvenous ablation. The development of sudden cardiac death and sustained ventricular tachycardia in patients without known cardiac disease should result in a careful search for cardiac disease, particularly ischemia. Cardiac catheterization with coronary arteriography may be indicated.

▶ Ventricular Ectopy (Premature Ventricular Contractions)

Treatment of asymptomatic ventricular ectopy (ie, premature ventricular contractions [PVCs]) is usually not indicated, particularly in light of many studies demonstrating both the lack of efficacy and potential catastrophic side effects resulting from treatment of non-life-threatening ventricular arrhythmias in certain populations. Ventricular ectopy is often benign and requires no treatment. However, development of PVCs may be a clue to the presence of digoxin toxicity or electrolyte or other metabolic imbalance—particularly hypokalemia but also hypomagnesemia, alkalosis, hyperkalemia, hypoxemia, and ischemia. Correcting these abnormalities often eliminates the PVCs. High catecholamine states, including treatment in an ICU, recent surgery, and prolonged pain, can result in PVCs. Beta-adrenergic blockade may help to reduce the frequency of PVCs in these patients.

Unifocal PVCs, bigeminy, and couplets (paired PVCs) usually do not require treatment even in a patient with myocardial ischemia. Antiarrhythmic therapy should be reserved for patients with sustained or nonsustained ventricular tachycardia accompanied by hemodynamic compromise. However, the indications for short-term therapy of

PVCs are less rigorous than the indications for long-term antiarrhythmic treatment, and short-term therapy to suppress PVCs may be appropriate while a patient is medically unstable in the ICU. In patients with congestive heart failure and ventricular ectopy, PVCs may not generate an adequate stroke volume, and frequent PVCs may result in a reduced cardiac output. Suppression of the ectopy therefore may be indicated to increase cardiac output. This goal often can be achieved with administration of intravenous lidocaine. Procainamide and quinidine are alternatives that are essentially no longer used. Their long- and short-term toxicity generally outweighs any perceived benefit.

Lidocaine toxicity is seen most often in elderly patients and those with decreased liver function or congestive heart failure, and the proarrhythmic effects of lidocaine are minimal. Both quinidine and procainamide can cause torsade de pointes and worsening of ventricular arrhythmias; use of these agents calls for close monitoring and careful consideration of indications for therapy. The use of beta-blockers, particularly in a patient who has evidence of a high-catecholamine state (eg, tachycardia, agitation, and hypertension), may result in a reduction in PVCs, heart rate, and blood pressure.

▶ Ventricular Tachycardia

Ventricular tachycardia is defined as three or more consecutive ventricular beats and is most commonly a reentrant type of tachycardia. Nonsustained ventricular tachycardia lasts for less than 30 seconds and terminates spontaneously, in contrast to sustained ventricular tachycardia. Myocardial ischemia is the most common situation in which ventricular tachycardia is seen, but valvular heart disease, myocarditis, and other forms of heart disease also predispose to this arrhythmia. Patients with prolonged QT intervals with or without administration of quinidine or another drug that prolongs the QT interval (such as a tricyclic antidepressant) may have a form of ventricular tachycardia known as *torsade de pointes*. This arrhythmia presents as ventricular tachycardia marked by a pattern of multiform ventricular beats with the axis shifting with each beat, yielding an undulating QRS pattern (Figure 21–6). Rapid ventricular tachycardia often deteriorates into ventricular fibrillation.

In the presence of underlying cardiac disease, ventricular tachycardia often deserves therapy. Nonsustained ventricular tachycardia in the setting of acute ischemia or infarction justifies antiarrhythmic suppression at least over the first 24–48 hours. A similar arrhythmia in a healthy 20-year-old postoperative patient might be observed without therapy, or the patient might be given a β -adrenergic blocker to decrease the effects of excess catecholamines. Electrolyte imbalances (particularly hypokalemia, hypomagnesemia, and alkalosis) and hypoxemia increase ventricular irritability and therefore may predispose to ventricular arrhythmias. In addition, there is evidence that magnesium administration may decrease or prevent ventricular arrhythmias even in the

▲ **Figure 21-6.** Four-channel ECG demonstrating torsade de pointes. This multiform ventricular tachycardia changes its axis with changing height and direction of the QRS complex shifting over the episode. The arrhythmia was initiated by a premature ventricular contraction during a period of high-degree heart block. Note that not all the P waves are conducted to the ventricle and that the ventricular rate is quite slow.

absence of hypomagnesemia. Digoxin toxicity, alcohol withdrawal, and ischemia also must be considered in ICU patients who develop ventricular arrhythmias.

As a general rule, patients with sustained ventricular tachycardia that produces hemodynamic instability with syncope, obtundation, hypotension, congestive heart failure, or chest pain should be electrically cardioverted immediately using 100–200 J. Persistent myocardial ischemia or hypotension that occurs while trying various pharmacologic agents puts the patient at risk of further deterioration and ventricular fibrillation. As the ventricle becomes more ischemic, stabilization becomes more difficult, and intractable ventricular fibrillation and death may ensue.

Pharmacologic conversion of ventricular tachycardia can be used in patients with ventricular tachycardia who are tolerating this rhythm without chest pain, hypotension, or congestive heart failure. Initial therapy is lidocaine administered by an intravenous bolus of 1–2 mg/kg, followed by an intravenous infusion of 1–4 mg/min. Procainamide can be given intravenously as a loading dose (500–1000 mg given at a rate of 50 mg/min), followed by an intravenous infusion (2–4 mg/min) as an alternative if lidocaine fails. Intravenous amiodarone is an effective alternative that is being used more frequently, and it is now recommended as the initial antiarrhythmic medication for refractory ventricular arrhythmia in Advanced Cardiac Life Support (ACLS). Amiodarone has a fairly complicated loading schedule: 150 mg is given over 10 minutes followed by 1 mg/min for 6 hours and then 0.5 mg/min for 18 hours. Loading of amiodarone can be repeated if ventricular tachycardia recurs. Bretylium, another class III antiarrhythmic agent, is no longer available. Overdrive pacing to suppress ventricular arrhythmias is helpful in occasional patients.

Patients with torsade de pointes or polymorphic ventricular tachycardia with a long QT interval are treated differently. Antiarrhythmic drugs that prolong the QT interval should not be given including class Ia (eg, quinidine or procainamide), class Ic (eg, flecainide or propafenone), and some class III agents (eg, amiodarone or sotalol). These drugs should be stopped if the arrhythmia occurs during their use. Isoproterenol or ventricular overdrive pacing may be helpful in suppressing the initiating ectopic beats and shortening the QT interval; this is unlike other ventricular arrhythmias in which β -adrenergic agonists may exacerbate the arrhythmia.

Indications for implantable defibrillators in the treatment of ventricular arrhythmias are changing rapidly. They are not generally placed in the acute setting for the management of ICU-related ventricular arrhythmias. Patients with reduced left ventricular function after myocardial infarction or owing to cardiomyopathy, patients with complex ventricular arrhythmias and depressed left ventricular function, and patients at high risk for sudden arrhythmic death owing to underlying heart disease are appropriate candidates. The presence of an implantable cardiac defibrillator in an ICU patient can complicate management of the arrhythmias, including pacemaker-mediated tachycardia; inappropriate shocks in an ICU setting in the presence of a variety of atrial

tachycardias could lead to inappropriate therapies. In an emergency when there are incessant inappropriate implantable cardiac defibrillator shocks, placement of a magnet over the implantable cardiac defibrillator usually will inhibit the defibrillator from delivering therapy. Patients with implantable cardiac defibrillators and increasing arrhythmias in the ICU should have their device interrogated by an electrophysiologist to determine the extent and type of arrhythmia and to potentially modify the programming of the device to better control the rhythm.

HEART BLOCK

Heart block occurs when one or more segments of the cardiac conduction system transmit impulses at an inadequate rate. Heart block can be divided into (1) sinus node problems including sinus arrest, sinus node Wenckebach, and some forms of sinus bradycardia; (2) AV nodal block including first-degree AV block, and second-degree Mobitz type I block (Wenckebach); and (3) infranodal block including bundle branch block, Mobitz type II AV block, and third-degree heart block. Both Mobitz type II block and third-degree heart block also can occur in the AV node, but they are more commonly manifestations of infranodal disease. In addition to degeneration caused by aging of the conduction system, heart block can be induced iatrogenically with medications or may be due to myocardial ischemia or infarction; metabolic abnormalities; enhanced vagal tone from tracheal irritation, suction, or intubation; abdominal distention; or severe vomiting. Heart block sometimes can be confused with other cardiac dysrhythmias.

It is important to determine whether the arrhythmia is due to an inadequate impulse formation or poor conduction from the atrium to the ventricles (default) or to a fast nodal or ventricular rate relative to the atrial rate (usurpation). Accelerated idioventricular rhythms, junctional tachycardia, and isorhythmic dissociation are not due to heart block but rather result from an acceleration of AV nodal or infranodal pacemakers. Since there is no heart block, speeding of the atrial rate will entrain the ventricles normally.

Heart block is managed differently depending on whether the ventricular rate is adequate or there is clinically significant bradycardia. Treatment of heart block should focus on several issues: (1) identification of reversible causes, (2) the hemodynamic consequences of the arrhythmia, (3) the potential to progress or recur, and (4) the patient's underlying medical condition. For example, the management of patients with second-degree heart block secondary to the combined use of a calcium blocker and a β -adrenergic blocker for hypertension is different from management of a similar degree of heart block owing to intrinsic conduction system disease. Time, calcium, and perhaps isoproterenol may obviate the need for even temporary pacing support in the former, but permanent pacing probably will be required for the latter.

External cardiac pacing may be used for short periods of time, permitting stabilization with adequate ventricular rates

and decreasing the urgency of the need for temporary transvenous pacing. Temporary transvenous pacing should be used in patients who are hemodynamically compromised by heart block. Indications for both temporary and permanent pacing in coronary artery disease are discussed in Chapter 22.

► Heart Block & Conduction Disturbances

Sinus Bradycardias

The name *sick sinus syndrome* has been given to a variety of bradyarrhythmias arising in the sinus node including sinus arrest and symptomatic sinus bradycardia. When seen in association with alternating bradycardia and supraventricular tachycardia, the term *tachy-brady syndrome* is sometimes used. Many patients with sinus bradyarrhythmias have intrinsic heart disease, but digoxin, beta-blockers, calcium channel blockers, and other drugs may precipitate bradycardia with syncope, hypotension, and heart failure. In patients with drug-related bradyarrhythmias, discontinuation of the drug is necessary; in others with symptomatic bradycardia, a pacemaker may be necessary. As described earlier, treatment of supraventricular tachycardia associated with alternating bradycardia may require drug treatment of the tachycardia (eg, digoxin and beta-blockers) and a pacemaker (because of drug-induced bradycardia).

AV Block

Temporary or permanent alteration of conduction through the AV node or bundle of His is classified as AV block. Patients with prolonged PR intervals (>210 ms) have first-degree AV block; this can be due to intrinsic conduction system disease, increased vagal tone, or more commonly, cardiac medications or ischemia. First-degree AV block is usually benign. Second-degree AV block is diagnosed when atrial impulses are conducted intermittently through to the ventricles. In Mobitz type I second-degree AV block (Wenckebach block), the PR interval lengthens on successive beats prior to a nonconducted atrial beat (P wave without a following QRS complex). The electrocardiographic pattern that emerges is grouped beating in which the number of ventricular complexes is equal to the number of P waves minus 1. This rhythm is usually due to increased vagal tone and is seen often in conjunction with reversible ischemia of the AV node. Treatment of symptomatic or severe bradycardia with Mobitz type I block is begun with atropine. Isoproterenol and dopamine may be tried; a temporary pacemaker is necessary occasionally if the ventricular response is inadequate and prolonged.

Mobitz type II second-degree AV block is usually due to disease in the infranodal conduction system. The PR interval is constant in conducted beats. The QRS interval is usually mildly prolonged secondary to the infranodal conducting system disease. In the nonconducted or blocked beats, a P wave is seen without a QRS interval. This form of block may

occur in a pattern or may occur randomly. Several P waves without accompanying ventricular beats may be seen (3:1 or 4:1 block). A temporary pacemaker is often necessary with this type of block because of the higher likelihood of progression to complete AV block, and the escape pacemaker with type II block, which originates in the ventricle, may not generate an adequate ventricular rate.

During complete heart block (ie, third-degree AV block), no atrial impulses are conducted to the ventricles because of usually infranodal or severe AV nodal conduction system disease. There is no relationship between P waves and the QRS interval (AV dissociation). The prolonged QRS interval indicates that ventricular activation is initiated by a ventricular pacemaker (automatic focus). Ventricular rates of 25–40 beats/min are seen with these ventricular escape rhythms and usually are inadequate to maintain acceptable cardiac output and blood pressure. Temporary and often permanent pacing is required in adults with type II second-degree heart and third-degree heart block.

► Malfunction of Permanent Artificial Pacemakers

Permanent pacemakers are used to support cardiac electrical activity and maintain adequate heart rate by providing electrical stimulation to the cardiac chambers. Pacemaker leads are placed transvenously, although occasionally they may be placed epicardially in association with other cardiac surgery. Pacemakers have become increasingly more complex and sophisticated in the last 10–15 years. In addition to the familiar single-lead pacemakers, which sense and pace in the ventricular chamber, pacemakers now are often dual-chamber, sensing and pacing in both the atrium and the ventricle, and sometimes they have an additional left ventricular lead for cardiac resynchronization to treat congestive heart failure. Pacemakers can be programmed to interrupt arrhythmias by overdrive pacing or by administering ectopic beats. Pacemakers can have rate-responsive features that allow the heart rate to increase in response to increased physiologic demand. When the pacemaker's rate-responsive sensor is minute ventilation (measured by transthoracic impedance), inappropriate tachycardia may be observed during mechanical ventilation.

Because of these added features, assessing pacemaker function has become extremely complex and requires knowledge of the type of pacemaker, understanding of the algorithms the pacemaker uses, and information about the mode in which the pacemaker is functioning. For example, for a rate-responsive pacemaker, knowing the rate at which the pacemaker should be inhibited involves not only knowing its backup settings but the ramp used to adjust the pacing rate and the stimulus to which it is responding.

In a critically ill patient, the major concerns about permanent pacemaker function are (1) that the electrical impulse from the pacemaker results in stimulation and electrical activation in the heart, (2) that the pacemaker is providing an

adequate heart rate to meet the patient's needs, and (3) that the pacemaker is sensing the intrinsic cardiac activity and not competing with it. A properly functioning pacemaker is able to sense the intrinsic electrical activity of the heart so that the pacemaker-generated rhythm and intrinsic rhythm are not competing with each other. Failure to sense the intrinsic rhythm raises the possibility of pacemaker-induced arrhythmia; for example, ventricular tachycardia may result from a pacemaker-triggered QRS interval occurring on a T wave from the intrinsic rhythm.

In general, in the absence of battery failure, pacemaker failure is almost always due either to lead malfunction from wire fracture, loss of insulation, or fibrosis at the endocardial contact site or to dislodgment in the cardiac chamber or disconnection at the connection between the pacemaker and the pacemaker lead. Lead malfunctions produce problems with both sensing and capturing, but often the malfunction is intermittent, occurring when the lead is moved in a particular way, making detection difficult. Interrogation of the pacemaker using the programming device provided by the manufacturer will produce information about the pacemaker's settings as well as lead impedance, thresholds, amplitude of sensed electrical activity, and strength of the battery. This information often can differentiate lead malfunction from component malfunction. Unfortunately, the older the pacemaker, the less information can be derived from the programmer, and the older the pacemaker, the more likely it is that malfunction will occur.

Programmability of the pacemaker, the ability to change the rate of pacing or the relationship of ventricular to atrial activation, allows manipulation of the patient's hemodynamics. For example, in a febrile or septic patient or one with heart failure, increasing the ventricular rate may be needed to increase cardiac output. In patients who develop atrial tachyarrhythmias, changing the pacemaker function to ignore the atrial activity sometimes can allow much better rate control.

CARDIAC PROBLEMS DURING PREGNANCY

Pregnant patients with cardiac disorders may pose difficult management problems. One always must consider the impact of therapy on both the patient and the fetus. It is often possible to pick a medication that will achieve the desired clinical effect without injuring the fetus. However, when the issue of fetal injury secondary to medication arises, the risks need to be defined and the patient advised. Knowledge of which medications cross the placenta and have known teratogenic effects is mandatory. Ultimately, it is the patient and physician who need to make the decision about fetal risks to be accepted or avoided.

Common cardiac problems that occur in pregnant women and may lead to admission to the ICU include valvular heart disease, arrhythmias, congestive heart failure, and pulmonary hypertension.

▶ Valvular Heart Disease During Pregnancy

Valvular heart disease may be unsuspected in a woman of childbearing age who has been previously healthy. Rheumatic heart disease resulting in mitral stenosis is seen with increased frequency in regions that have large Hispanic and Asian populations.

Clinical Features

Women with mitral stenosis often are asymptomatic until the normal increase in blood volume and cardiac output occurring during pregnancy leads to elevated left atrial pressures and pulmonary venous hypertension. Tachycardia or atrial fibrillation is seen often in the acute presentation. These patients present with signs and symptoms mimicking asthma and, if heart disease is unsuspected, become progressively worse owing to drug-induced tachycardia from treatment with β -adrenergic agonists. Atrial fibrillation also may result in atrial thrombus formation, so the initial presentation may be a stroke.

The rapid heart rate does not allow time for atrial emptying, and left atrial pressures therefore rise, resulting in pulmonary edema. The presence of a diastolic murmur and opening snap consistent with mitral stenosis and an echocardiogram showing decreased mitral valve area and increased right ventricular pressure should lead to appropriate management.

Treatment

When mitral stenosis is the dominant cardiac lesion, β -adrenergic blockers should be used to slow the heart rate and allow more time for ventricular filling. In general, cardioselective β -adrenergic blockers such as atenolol are preferred because they cross the placental barrier less effectively than noncardioselective beta-blockers such as propranolol. If atrial fibrillation rather than sinus tachycardia is present, digoxin also can be used to slow the ventricular rate. Although calcium channel blockers such as diltiazem and verapamil also will slow heart rate, their effects on the fetus need to be considered. In pregnant patients with tight mitral stenosis and especially those with atrial fibrillation, anticoagulation is important to reduce the risk of a stroke. Depending on the stage of pregnancy, unfractionated heparin or low-molecular-weight heparin may be most appropriate.

Returning the patient to normal sinus rhythm may improve cardiac function by allowing better rate control, and restored atrial contraction will aid in left ventricular filling. Cardioversion must be done with the patient fully anticoagulated—with plans to continue anticoagulation—and it is necessary to demonstrate that atrial thrombi are not present by transesophageal echocardiography. Finally, in patients with severe mitral stenosis who continue to have severe congestive heart failure symptoms despite medical therapy, percutaneous valvuloplasty can be considered. Patients should be chosen based on appropriate valve morphology and the absence of significant mitral regurgitation. Fetal age and viability should be considered in the timing of the intervention, and neonatologists and obstetricians should be involved in weighing the risk and benefit to the fetus.

In patients with other types of valvular heart disease, management is directed toward maximizing the patient's cardiac output. However, some of the unloading agents used to treat left ventricular dysfunction and left-sided valvular regurgitation may decrease blood supply to the placenta and therefore to the fetus. Thus the risks of treatment must be

weighed carefully. Fetal monitoring can be used to help assess the impact of therapy.

► Arrhythmias During Pregnancy

Atrial and ventricular arrhythmias are often benign. However, sustained rapid atrial or ventricular tachycardia has the potential to impair uterine blood flow resulting in compromised fetal oxygenation. Late in pregnancy, when systemic venous return is limited by compression of the inferior vena cava by the enlarged uterus, a tachyarrhythmia may result in profound hypotension and syncope. Therefore, pregnant women who complain of dizziness or syncope must be evaluated and monitored carefully, usually in an inpatient setting. Because of toxic side effects and potential effects on the fetus, antiarrhythmic drugs should be used only for documented sustained arrhythmias, with drugs and dosages chosen to minimize effects on the fetus. Beta-blockers and digoxin generally are safe in pregnancy.

► Congenital Heart Disease and Pulmonary Hypertension During Pregnancy

Pregnancy in patients with cyanotic congenital heart disease is associated with a high incidence of fetal loss as well as maternal death. Pulmonary hypertension, atrial tachyarrhythmias, inability to increase cardiac output with increased demand, and hypoxemia all result in inadequate cardiac output to the mother and the fetus. Postpartum, acute exacerbation of pulmonary hypertension and sudden death occur frequently. Treatment during the pregnancy is supportive, including restricting activity, avoiding volume overload, and treating polycythemia. A controlled elective delivery using an epidural block or cesarean section to minimize myocardial demand should be considered. Inhaled nitric oxide or intravenous prostacyclin can be used to help manage the worsening pulmonary hypertension seen after delivery in patients with Eisenmenger's syndrome with cyanosis.

TOXIC EFFECTS OF CARDIAC DRUGS

Cardiac medications have changed the treatment of patients with heart disease dramatically, improving the quality and duration of life, but these drugs have side effects both major

and minor. Some of the toxic effects are extensions of a drug's therapeutic effects, whereas others are idiopathic or autoimmune in nature. In some patients, toxicity may develop only when metabolic changes occur that result in decreased clearance of the drug, but reactions may occur unpredictably even when drug levels are in the therapeutic range. Thus drug levels that produce a desirable drug effect in one patient may produce a life-threatening side effect in another. Toxicity also may develop when several drugs interact. Both the toxic and the therapeutic effects of drugs, their interaction with other drugs, and drug metabolism should be understood and considered in making treatment decisions and in evaluating patients receiving cardiac medications.

Discussed below are some of the more common and important side effects of frequently used cardiac medications. The key to treating critically ill patients with cardiac drugs is always to consider the possible or likely side effects and interactions of the drugs, especially when the patient has unexplained problems.

► Digoxin

Pharmacology

Digoxin is a glycoside that inhibits $\text{Na}^+\text{-K}^+$ ATPase and thereby changes the intracellular Na^+ concentration. By altering the amount of Na^+ available for the $\text{Na}^+\text{-Ca}^{2+}$ exchanger, the net effect of digoxin is to increase the intracellular calcium. Similarly, the effect of digoxin on $\text{Na}^+\text{-K}^+$ ATPase also alters the transmembrane potential of other cells and therefore affects cell excitability, conduction velocity, and refractory periods. Various cell types are affected differently; this accounts for the differing effects of digoxin on atrial, AV nodal, and ventricular tissue. Digoxin, like other cardiac glycosides, also has neurally mediated effects that alter autonomic balance and sympathetic output.

In appropriate doses, digoxin functions as an inotropic agent, increasing contractility. Its clinically important electrophysiologic effect is to block the AV node, thereby decreasing the ventricular response rate in atrial fibrillation and inhibiting reentrant supraventricular tachycardia. Digoxin has a fairly long half-life of 36–48 hours. It also has a relatively narrow therapeutic range. Digoxin is cleared primarily by the kidneys with, perhaps, some clearance through the GI tract.

In critically ill patients, rapidly changing renal function and the requirement for multiple other drugs make the development of digoxin toxicity more frequent. Electrolyte abnormalities such as hypokalemia, hypomagnesemia, and hypercalcemia enhance digoxin toxicity. Serum levels of digoxin are affected by a variety of drugs. Quinidine alters the renal clearance and volume of distribution of digoxin. Therapeutic levels of quinidine double digoxin serum concentrations. Therefore, the dose of digoxin should be reduced by half when instituting quinidine therapy.

Amiodarone, verapamil, and propafenone have similar effects on renal clearance of digoxin and digoxin serum level, although the magnitude of the effect is smaller. Periodic determination of drug levels with appropriate dose reduction or cessation can avoid the worse complications.

Toxicity

Digoxin serum levels generally are considered therapeutic in the range of 0.8–2 ng/mL, which, unfortunately, overlaps with the range in which toxicity may be seen. Toxicity is rare in patients with serum levels under 1.4 ng/mL but is seen with increased frequency when serum levels exceed 2 ng/mL. The positive inotropic effect of digoxin increases in a dose-related manner, and this effect persists even in the face of high drug levels. The toxic effects of digoxin can be broken down into systemic and electrolyte effects and mild and severe arrhythmias. With mild toxicity, the patient may develop nausea, visual disturbances, and decreased appetite. At higher serum levels of digoxin, as the $\text{Na}^+\text{-K}^+$ ATPase is poisoned, hyperkalemia develops that may lead to cardiac arrest. Arrhythmias seen at low levels of toxicity reflect the effect of digoxin on automaticity, resulting in paroxysmal atrial tachycardia, junctional tachycardia, and ventricular ectopy (particularly bigeminy). Because digoxin increases AV nodal block, the atrial tachycardias are associated with heart block.

Treatment

Treatment depends on the severity of toxic manifestations. Withholding digoxin and correcting hypoxemia, hypokalemia, and the acid-base disturbances that exacerbate digoxin toxicity usually correct arrhythmias over time. Marked bradycardia in the setting of atrial fibrillation can be treated with atropine in mild cases and temporary pacing in more severe situations. Lidocaine or phenytoin often can control the less serious ventricular arrhythmias. Electrical cardioversion may be necessary acutely to treat sustained ventricular tachycardia from digoxin toxicity when drugs and other measures have failed, but there is an increased risk of arrhythmic complications because of increased ventricular automaticity caused by digoxin. Using less electrical energy (fewer joules) may decrease the risk.

In cases of severe digoxin toxicity that include the development of hyperkalemia, severe bradyarrhythmia, recurrent ventricular tachycardia, or ventricular fibrillation, digoxin immune Fab (ovine) can be lifesaving. This preparation is a sheep antibody fragment that has a high affinity for digoxin, rapidly binding to the drug and reversing its effect. The Fab fragments have a lower molecular weight than complete antibodies and thus have a greater rate and volume of distribution. The Fab-digoxin complexes are excreted in the urine, thus enhancing renal clearance of the drug. Digoxin antibody is indicated in the setting of life-threatening digoxin toxicity or when the ingestion of large amounts of digoxin makes the development of toxic side effects likely. The dosage of digoxin immune Fab depends on the digoxin level and the

estimated volume of distribution. However, if the desired effect is not achieved with the calculated dose, treatment with the maximum dose is indicated in life-threatening situations. Side effects from digoxin immune Fab are minimal. The drug is expensive, and its use therefore is reserved for patients with severe life-threatening digoxin toxicity. In most patients, prevention of digoxin toxicity is preferable and achievable with forethought. For example, for elderly patients or critically ill patients in the ICU with acute renal failure or cardiogenic shock, digoxin should not be given as a standing order for more than 1 day without careful review and adjustment if necessary.

▶ Antiarrhythmic Drugs

Lidocaine

Because lidocaine is metabolized by the liver, hypotension, right-sided heart failure, and liver failure may result in decreased clearance of this drug. Lidocaine has minimal proarrhythmic and myocardial depressant effects. Its side effects are primarily neurologic consisting of acute onset of agitation, tremulousness, psychosis, and seizures. Withdrawal of the drug and time are the treatments. If indicated, another antiarrhythmic agent can be used when lidocaine is discontinued.

Procainamide and Quinidine

Procainamide, used for treatment of both atrial and ventricular arrhythmias, is cleared by the kidneys. Both the drug and its by-product, *N*-acetyl procainamide (NAPA), accumulate in patients with renal failure. Procainamide is a myocardial depressant and can cause hypotension. It also can cause QT-interval prolongation with the development of polymorphic ventricular tachycardia similar to the effects of quinidine. Unlike quinidine, procainamide does not alter serum digoxin levels. A number of noncardiac side effects are caused by procainamide, the most important being agranulocytosis and the development of a lupus-like syndrome. Agranulocytosis is reversible, but the patient may present with sepsis. The lupus-like syndrome is generally a late development in the course of prolonged administration with manifestations such as fever, pleuropericarditis, and arthralgias. There are serum antihistone antibodies associated with this drug-induced syndrome as well. This side effect may be seen more frequently in patients who metabolize the drug slowly (*slow acetylators*). The syndrome is reversible with discontinuation of the drug.

Quinidine should not be used as a routine drug in the ICU and virtually never should be started as a new agent. Quinidine, a class Ia agent whose indications are similar to those of procainamide, has less myocardial depressant effects but is only available orally. Its proarrhythmic effects are well known, with QT-interval prolongation resulting in ventricular tachycardia and syncope. GI side effects are frequent, and the development of nausea and diarrhea often limits its use.

Neurologic side effects include tinnitus, hearing loss, and confusion. Autoimmune thrombocytopenia or hemolytic anemia occasionally develops unexpectedly, resulting in hemorrhage or death. Quinidine-induced thrombocytopenia is treated as autoimmune thrombocytopenia.

If polymorphic ventricular tachycardia (*torsade de pointes*) develops during treatment with quinidine or procainamide, the drug should be stopped, and other class Ia and Ic agents should be avoided. Beta-adrenergic agonists such as isoproterenol can be used to speed up the heart rate and shorten the QT interval. Overdrive pacing with a transvenous pacing wire also can be used in patients with recurrent ventricular tachycardia until the offending drug is cleared or metabolized. When monitoring the QT interval during administration of quinidine or procainamide, the drug should be discontinued if the QT interval exceeds 500 ms.

Flecainide

Flecainide is a class Ic antiarrhythmic agent that is well tolerated, with minimal noncardiac side effects. It is proarrhythmic, however, and can cause significant and sustained ventricular tachycardia that is resistant to other antiarrhythmic agents. Flecainide slows conduction throughout the conducting system, which can result in bradycardia as well as heart block. It is poorly tolerated by patients with depressed left ventricular function and should not be used for those patients.

Amiodarone

Amiodarone is a powerful antiarrhythmic agent with minimal proarrhythmic effects. However, it has a number of cardiac and noncardiac side effects that are magnified by its long half-life. Resulting toxicities can last from days to months depending on the duration of therapy and the dose. Amiodarone slows conduction throughout the heart, resulting in bradycardia and heart block, which may require permanent pacing. GI side effects include nausea and decreased appetite resulting in weight loss and necessitating dose reduction or termination of therapy. Either hypo- or hyperthyroidism can result from amiodarone's effect on iodine metabolism. Deposits in the skin can result in darkening of skin especially in sun-exposed areas. Intracytoplasmic lamellar deposits can occur in several parts of the eyes, most commonly causing corneal epithelial opacities in more than 70% of patients and lens opacities in 50–60%. Neither impairs visual acuity, and amiodarone treatment can be continued. Pulmonary fibrosis is a frightening and potentially life-threatening complication that can further compromise patients who already have significant cardiac impairment. Baseline and follow-up pulmonary function tests are mandatory to monitor the development of pulmonary involvement. Amiodarone interacts with and changes the metabolism of a myriad of drugs. Its interactions with digoxin, β -adrenergic blockers, calcium channel blockers, and warfarin should be monitored carefully.

Sotalol

Sotalol is a class II (β -adrenergic blocker) and class III antiarrhythmic drug that is excreted renally and therefore must be monitored carefully in patients with changing renal function. It is an effective agent for atrial and ventricular arrhythmias, but—like most antiarrhythmic agents—it has proarrhythmic effects, occurring particularly while therapy is being initiated. It can cause significant bradycardia and heart block when used in conjunction with digoxin or calcium channel blockers.

▶ Calcium Channel Blockers

These drugs can be categorized into three subclasses: verapamil-like drugs, diltiazem-like drugs, and nifedipine-like drugs. Some of the toxic effects are the logical result of their therapeutic mechanisms and may be beneficial in certain settings. For example, slowing of the heart rate in patients with ischemia is a desirable effect of some of the calcium channel blockers. However, verapamil and diltiazem also can slow AV nodal and sinus node conduction excessively, resulting in bradyarrhythmias and hypotension. Because they are myocardial depressants, these drugs may precipitate or exacerbate congestive heart failure. The bradycardiac effects of diltiazem and verapamil can be augmented by concomitant use of β -adrenergic blockers or digoxin. In contrast, nifedipine and other drugs in its dihydropyridine class of calcium channel blockers have no effect on the AV node but can cause reflex tachycardia and hypotension from vasodilation. Calcium administered intravenously may reverse some of the toxic effects of the calcium channel blockers, at least temporarily.

▶ Beta-Adrenergic Blockers

Beta-adrenergic blockers are extremely useful drugs for controlling hypertension, treating atrial arrhythmias, and alleviating myocardial ischemia. In a patient with myocardial dysfunction, β -adrenergic blockers can precipitate profound heart failure and block the normal tachycardiac response to hypotension and low cardiac output. Despite this, however, these drugs have been shown to improve long-term survival in patients with chronic congestive heart failure, including in patients with class III to IV heart failure.

These drugs are myocardial depressants, block the AV node, and by blocking the action of catecholamines,

decrease the sinus nodal rate. In patients with conduction system disease, β -adrenergic blockers may cause profound bradycardia. The effects of Beta-adrenergic blockers and calcium channel blockers on the myocardium, the sinus node, and the AV node can be additive, resulting in severe hypotension and heart block. Beta-adrenergic agonists may be used to counteract the excessive depressant effects of β -adrenergic blockers.

▶ ACE Inhibitors

ACE inhibitors (eg, captopril, enalapril, benazepril, lisinopril) are commonly used vasodilators valuable in the treatment of congestive heart failure and hypertension. These drugs can cause hyperkalemia even in patients without overt renal disease. Therefore, potassium levels must be observed carefully when initiating or maintaining therapy with ACE inhibitors. Rapidly developing renal failure may occur in patients with renal artery stenosis when ACE inhibitors are started. Angioedema is a significant and concerning side effect that should result in terminating this entire class of drug from the patient's medical regimen. Cough is another side effect that patient's may find bothersome with this class of medications. In fact, the cough may be confused with the cough owing to heart failure but responds fairly quickly to removal of the drug. Angiotensin-receptor blockers have effects similar to those of ACE inhibitors and may be substituted for management of the cough complaint. As with other antihypertensive agents, profound hypotension may develop when starting ACE inhibitors, particularly in patients who are hypovolemic. In critically ill patients, the benefits and side effects of these drugs need to be considered carefully.

Coronary Heart Disease

Kenneth A. Narahara, MD

Atherosclerotic coronary artery disease is the leading cause of death in the United States. Each year approximately 1.5 million patients experience a myocardial infarction. Approximately 20% of these individuals die before they reach the hospital, and an additional 7–15% die during hospitalization. This chapter will consider the major coronary artery disease syndromes: angina pectoris, acute coronary syndromes (unstable angina and non-ST-segment-elevation myocardial infarction), and acute ST-segment-elevation myocardial infarction.

► Physiologic Considerations

Coronary Anatomy

The right and left coronary arteries arise from ostia in the right and left sinuses of Valsalva. Their function is to deliver oxygen and nutrients and to remove toxic metabolites. The origin of the left coronary artery is called the *left main coronary artery* and divides into the *left anterior descending coronary artery*, which feeds the anterior wall of the left ventricle and the left ventricular septum, and the *left circumflex artery*, which supplies the lateral and posterior walls of the left ventricle. The *right coronary artery* supplies the right ventricular free wall and in 90% of cases gives off the *posterior descending artery*, which, in turn, provides the blood supply for the posterior right ventricle as well as the inferior left ventricular wall and septum. The coronary artery that gives rise to the posterior descending artery is referred to as *dominant*. Thus 90% of people have a *right-dominant circulation*. The remaining 10% have a posterior descending artery that originates from the left circumflex coronary artery. Coronary collateral vessels span the area between the right and left coronary artery territories. These vessels are very small and difficult to demonstrate even during cardiac catheterization. However, as coronary stenoses develop in the major epicardial coronary arteries, collateral vessels may increase in size and number and provide a protective effect by allowing increased blood supply from the opposite coronary circulation.

Coronary Blood Flow

Coronary blood flow at rest is ordinarily 70–100 mL/min per 100 g of heart tissue. Approximately 80% of the coronary flow occurs during diastole. As a consequence, coronary blood flow is highly dependent on diastolic blood pressure and resistance to coronary flow within the coronary circulation.

In the absence of disease and with a constant myocardial oxygen requirement (MVO_2), coronary blood flow is kept constant by autoregulation of the coronary vasculature by both myogenic and metabolic factors. Diastolic perfusion pressure provides the driving pressure for coronary blood flow. Metabolic factors, particularly adenosine, affect regional myocardial blood flow. As tissue oxygen decreases, ADP is converted to AMP and then to adenosine by the enzyme 5'-nucleotidase. Adenosine then diffuses out of the cell and causes relaxation of local vascular smooth muscle. This action of adenosine is terminated by its deamination to inosine.

Myocardial Oxygen Consumption

Over 90% of the heart's energy is derived from aerobic metabolism, primarily from oxidation of fatty acids. The absence of oxygen forces a transition to anaerobic metabolism of glucose and glycogen. Myocardial O_2 requirements are multiple: 20% of the MVO_2 is used to support the basal metabolism of the heart, less than 5% is used to support electrical activity, and approximately 15% is used to move calcium into the sarcoplasmic reticulum. The most important determinant of MVO_2 is myocardial contractility, accounting for 60% of MVO_2 .

A. Heart Rate and Systolic Blood Pressure—An important concept about coronary artery disease is the relation of MVO_2 to the heart rate (HR) and systolic blood pressure (SBP). $HR \times SBP$ is commonly referred to as the *double product*. The double product is proportional to MVO_2 and can be used as a measure of myocardial work and thus myocardial O_2 consumption. The inotropic state of the myocardium is another important determinant of MVO_2 and myocardial

work. However, it is somewhat difficult to measure clinically; fortunately, the heart rate and systolic blood pressure usually provide sufficient information for clinical decision making.

B. Balance of Oxygen Demand and Supply—Myocardial ischemia represents an imbalance between myocardial oxygen demand and myocardial blood supply. A fixed coronary artery stenosis will limit coronary blood supply. In this circumstance, demand for coronary blood flow may increase, but the stenosis will limit the available blood flow. Hence demand will exceed supply, and myocardial ischemia will result. The ability of the coronary artery to respond to sympathetic stimulation and other local factors also can result in an inadequate blood supply through coronary artery spasm. However, coronary artery spasm (ie, variant angina and Prinzmetal's angina) is seldom the sole cause of inadequate coronary blood flow. More often, fixed coronary artery stenoses exist in combination with some degree of coronary spasm or vasoconstriction to cause a myocardial O₂ demand-supply imbalance.

▶ Myocardial Ischemia (Angina Pectoris)

ESSENTIALS OF DIAGNOSIS

- ▶ Complaint of heavy, pressure-like or viselike discomfort; sometimes choking, a constricting feeling in the throat, or a sensation of strangling; discomfort located diffusely in substernal region, left arm, jaw, or neck—rarely localized to a single point.
- ▶ Discomfort lasts 30 seconds to 15 minutes.
- ▶ May be provoked by exertion, emotional distress, eating, and cold.
- ▶ Should decrease with rest and may be relieved in 1–2 minutes after sublingual nitroglycerin.

General Considerations

Resistance to blood flow in the coronary arteries becomes significant when there is sufficient narrowing of the coronary artery diameter by atherosclerotic plaques (diameter decreased by more than 50%). The physiologic consequence is that coronary artery blood flow becomes fixed at some value rather than increasing to meet increased myocardial demands. Coronary blood flow may be adequate to supply the myocardium at rest but becomes insufficient during exertion when the myocardial oxygen demand increases. This explains why, in patients with stable angina pectoris, symptoms are seen with exercise and disappear with rest.

Clinical Features

The diagnosis of angina pectoris is typically a clinical one. Pain with the qualities described below should be considered

the primary diagnostic criterion—that is, the history is the most important diagnostic clue to ischemic heart disease and myocardial ischemia (angina pectoris).

A. Symptoms—There are six major features of the clinical manifestations of myocardial ischemia (angina pectoris): the quality of the discomfort (patients do not always complain of “pain”), the location, the duration, provoking factors, sources of relief, and actions taken by the patient during the episode.

1. QUALITY OF DISCOMFORT—Patients with myocardial ischemia frequently describe the discomfort as a heavy, pressure-like, or viselike sensation. They may describe choking or a constricting feeling in the throat. Indigestion or a sensation of strangling is also frequently described. The patient should be asked about “discomfort” because many patients do not perceive angina or myocardial ischemia as “pain.”

2. LOCATION OF DISCOMFORT—The discomfort of myocardial ischemia usually is located in the substernal region but also may be located in the arms (the left more often than the right), the jaw, the neck, the left interscapular region, or occasionally, the epigastrium. It is often useful to ask the patient to define the extent of the pain with one finger. The pain of myocardial ischemia is not likely to be localized to a single point.

3. DURATION OF DISCOMFORT—Angina pectoris usually lasts 30 seconds to 15 minutes. Longer episodes of ischemic pain are associated with unstable angina or myocardial infarction.

4. PROVOCATION OF DISCOMFORT—Exertion, emotional distress, eating, cold weather, and sexual activity are frequent initiating events.

5. RELIEF OF DISCOMFORT—Pain from myocardial ischemia should decrease with rest or a reduction in exertion. Sublingual nitroglycerin should relieve angina within 1–2 minutes, and this feature can be used both for diagnosis and for treatment.

6. ACTIONS TAKEN BY THE PATIENT—Angina pectoris is not relieved by inspiration or movement of the upper extremities or torso nor by antacids or food. Pain relief achieved in this way should make one think of other disorders.

B. Physical Findings—During an episode of angina, an S₃ gallop, pulmonary rales, or the murmur of mitral regurgitation may appear. However, these findings are more likely to be noted during stress testing, when the patient's chest pain is provoked with a physician present.

C. Electrocardiography—

1. RESTING ECG—If ST-segment and T-wave changes (ie, ST-segment depression, T-wave inversion, or both) are present during an episode of pain and return to normal with spontaneous relief of pain or after administration of nitroglycerin, the diagnosis of myocardial ischemia is confirmed.

2. EXERCISE STRESS ECG—The resting ECG frequently is normal in patients with myocardial ischemia owing to coronary artery disease or coronary artery spasm because the pain usually has subsided by the time the patient reaches medical attention. For this reason, stress testing during bicycle or treadmill exercise is frequently employed to reproduce the supply and demand imbalance that triggers myocardial ischemia. The patient is asked to walk on a treadmill or pedal on a bicycle as the work load is increased progressively. Continuous electrocardiographic monitoring permits detection of ST-segment depression. Exercise causes an increase in heart rate and blood pressure (an increase in the double product); thus patients with a fixed (and inadequate) myocardial blood supply owing to coronary artery disease frequently will experience angina with ST-segment depression as myocardial work exceeds a fixed O_2 supply.

D. Imaging Studies

1. STRESS TESTING—Specialized forms of exercise stress testing, including thallium scintigraphy and stress ventriculography, have been introduced to diagnose myocardial ischemia in patients who have resting ECGs that would make the diagnosis of myocardial ischemia difficult on the basis of exercise electrocardiography. For example, patients with resting ST-segment and T-wave abnormalities owing to left ventricular hypertrophy, from administration of digitalis glycosides, or from prior myocardial infarction may have a stress ECG that is difficult or impossible to interpret with precision. In these circumstances, the use of myocardial perfusion scanning with thallium-201 or technetium-99m sestamibi may be useful. These perfusion agents are taken up by viable myocardium in proportion to coronary blood flow. As coronary blood flow requirements increase (such as during exercise), myocardium supplied by normal coronary vessels will have a normal uptake of the tracer. Conversely, areas of myocardium served by stenotic coronary arteries will have reduced coronary blood flow during exercise. As a consequence, the reduced uptake of the perfusion agent will appear as a “cold spot.”

Exercise ventriculography using echocardiography, cine-CT scanning, or radionuclide angiography can identify the presence of myocardial ischemia by the development of a new or worsened wall motion abnormality during stress. As myocardial O_2 requirements outstrip the available supply, regional wall motion abnormalities will develop as nutrient flow to the myocardium remains fixed in the face of an increasing metabolic demand. Initially, a localized wall motion abnormality will appear or will worsen (if a previous infarction is present). Next, the global left ventricular ejection fraction will fall. Although these tests are substantially more expensive than the standard electrocardiographic stress test, they may provide a definitive noninvasive means of diagnosing myocardial ischemia.

2. CORONARY ANGIOGRAPHY—Anatomic diagnosis of coronary atherosclerosis is made by injection of radiopaque

contrast material directly into the coronary arteries. Patients are taken to the catheterization laboratory, where careful hemodynamic monitoring can be performed. Significant atherosclerotic lesions are seen as a reduction in the diameter of the coronary artery, and the anatomic information can be used to decide whether medical therapy or interventional procedures such as coronary angioplasty or coronary artery bypass surgery might be useful.

Differential Diagnosis

Other causes of chest pain that may have features suggestive of angina pectoris include pericarditis (pain is often positional and related to respiration); esophageal spasm (related to meals and swallowing); chest wall pain (often reproduced by applying pressure to the chest wall); aortic dissection (classically “tearing” in quality and radiating to the back; pulses in the arms may be unequal); GI pain from esophagitis, gastritis, cholecystitis, and cholelithiasis (often associated with meals and, for esophagitis and gastritis, relieved by antacids); and hyperventilation.

Treatment

The treatment of myocardial ischemia is directed at both reducing myocardial O_2 consumption (myocardial O_2 demand and double product) and increasing myocardial blood supply. Initially, medical therapy is used in an attempt to reduce myocardial O_2 consumption (eg, use of beta blockade to reduce heart rate and blood pressure) or to increase myocardial O_2 supply by using coronary vasodilators such as calcium channel blocking agents or either short-acting (sublingual nitroglycerin) or long-acting nitrates (isosorbide dinitrate).

More aggressive therapy, such as percutaneous transluminal coronary angioplasty and coronary artery bypass surgery, increase coronary blood supply directly. While effective in reaching this goal, as well as in relieving angina, these strategies are invasive and cause a variable degree of morbidity. To date, with the exception of patients with left main coronary artery disease or three-vessel coronary artery disease in the presence of left ventricular dysfunction, neither coronary angioplasty nor coronary bypass surgery will reduce the mortality rate from coronary artery disease. The high cost and stress on the health care network of these procedures would suggest that the management of myocardial ischemia with medical therapy is a reasonable first step.

A. Long-Acting Nitrates—Nitrates are the oldest form of anti-ischemic therapy. Their continued use is a testament to their efficacy as well as their safety. Therapy with long-acting nitrates aims to improve coronary blood flow. Twenty milligrams of isosorbide dinitrate three times a day is a typical starting dose. Although lower doses may be used, they usually have little more than a placebo effect in patients with coronary artery disease. After initial dosing with 20 mg three times daily for 3–5 days, the dose can be increased to either

40 or 60 mg three times daily. A target dose of at least 40 mg three times daily would be a reasonable therapeutic goal, assuming that the patient does not suffer from headaches or symptoms of hypotension. Alternatively, extended-release isosorbide mononitrate in a dose of 30–120 mg once or twice daily may enhance compliance.

“Nitrate headaches” occur frequently during the first few days of therapy with isosorbide dinitrate. The patient should be encouraged to continue the medication (perhaps with administration of acetaminophen) because the headaches frequently subside with time and the antianginal efficacy of the long-acting nitrates persists. Doses of isosorbide dinitrate larger than 60 mg three times daily generally are not necessary for therapy of angina pectoris and produce a smaller incremental improvement in symptoms compared with the increase from 20 to 40 or 60 mg three times daily. However, in the treatment of unstable angina or for patients who have severe angina pectoris that is not amenable to revascularization, such high doses of long-acting nitrates may be useful in providing an asymptomatic or moderately symptomatic state.

B. Beta-Adrenergic Blockade— β -adrenergic blockers are particularly effective in the treatment of patients who have coexisting angina and hypertension. Likewise, the combination of β -blocker therapy with a long-acting nitrate may be hemodynamically desirable because the long-acting nitrates tend to produce a modest reflex tachycardia that can be blunted or eliminated by beta blockade. In the treatment of exertional angina, beta blockade can be particularly advantageous because it will block catecholamine-induced increases (from exercise or emotional stress) in heart rate and blood pressure.

Initial therapy with β -blockers can commence with metoprolol, 50 mg twice daily (or 50–100 mg of sustained-release metoprolol daily); atenolol, 50 mg once daily; or betaxolol, 10 mg once daily. In the elderly patient, these initial doses should be reduced at the initiation of therapy. Titration of the dose upward can commence after four to five half-lives have elapsed, that is, 2–3 days for metoprolol, 3–4 days for atenolol, and 5–7 days for betaxolol or extended-release metoprolol (eg, Toprol XL). Upward titration of the dose of β -blocker should be considered if the resting heart rate or blood pressure are not affected by the initial dose of therapy.

As a general rule, patients who may be operating machinery or driving automobiles should be warned of the possibility of drowsiness or lethargy when taking β -blockers. Frequently, the administration of longer-acting agents such as extended-release forms of metoprolol or betaxolol at bedtime can be useful in reducing symptoms of fatigue and reduced attentiveness during the daytime.

Concern is frequently raised about the use of beta blockade in patients with diabetes. However, if the patient does not suffer from episodes of hypoglycemia, judicious therapy with beta blockade is often rewarded by substantial reduction in angina pectoris. In addition, β -blocker use in diabetic patients with coronary artery disease is associated with a

reduction in mortality. The major concern regarding the coadministration of beta blockade with hypoglycemic agents is blunting of the symptoms of hypoglycemia. However, this effect is related primarily to a reduction of tachycardia; diaphoresis and hunger are not blunted by β -blocker therapy. Of course, β -blockers should be avoided in the brittle type 1 diabetic or in diabetics with a history of ketoacidosis.

C. Calcium Channel Blocking Agents—

1. DIHYDROPYRIDINES—This class of calcium antagonists is characterized by both a systemic and coronary vasodilator effect. The dihydropyridines have no effect on sinoatrial (SA) or atrioventricular (AV) nodal function. Therefore, coadministration of a dihydropyridine with β -blockers for the combined therapy of angina and hypertension is frequently highly effective. Both agents tend to lower blood pressure, and the bradycardic effect of beta blockade will prevent any reflex tachycardia that may be engendered by the dihydropyridine.

Nifedipine, the first-generation dihydropyridine, had a relatively short half-life and frequently caused symptoms of vasodilation, including flushing, headaches, and peripheral edema. Sustained-release nifedipine is still used for refractory hypertension in doses of 30–90 mg/day or more. However, for the treatment of coronary artery disease, nifedipine and the second-generation dihydropyridines have been superseded.

Amlodipine and felodipine are “long acting” dihydropyridine calcium channel antagonists. Amlodipine has an inherently long half-life of over 30 hours, whereas felodipine gains its once-a-day dosing from an enteric coating that results in the gradual release of the agent. Amlodipine is approved for both angina and hypertension; felodipine is approved for hypertension only.

Amlodipine is the only calcium channel blocking agent that can be used safely in patients with impaired left ventricular function. Hence the agent can be used for antianginal treatment in addition to nitrates and β -blockers, particularly when coexisting hypertension is present. The starting dose for amlodipine is 2.5–5 mg/day with a recommended maximum of 10 mg/day. Higher doses of amlodipine may afford additional antianginal and antihypertensive effects, but side effects such as peripheral edema become more pronounced. Given the long half-life of amlodipine, the dose of this agent should not be increased more than once weekly.

2. VERAPAMIL—Verapamil is a vasodilating calcium channel blocking agent that, in addition to causing coronary artery vasodilation, has a negative chronotropic effect. Conduction through both the SA node and the AV node can be slowed by this agent. Verapamil has a side-effect profile similar to that of nifedipine. In addition, verapamil causes constipation, and the patient’s bowel habits should be evaluated carefully. Many clinicians will start patients on stool softeners or prophylactic milk of magnesium when commencing therapy with verapamil.

Verapamil is a fairly potent peripheral vasodilator and therefore is an effective antihypertensive agent. Additionally, with its bradycardic effect, it may be particularly useful in patients with ischemic heart disease who are intolerant of β -blockers, such as those with asthma or type 1 diabetes. It should be recalled that, on balance, verapamil exerts the greatest negative inotropic effect of the currently available calcium channel blockers and should be avoided in patients with a history of congestive heart failure or a known reduction in ejection fraction. Short-acting verapamil typically is administered in a dosage of 80–120 mg every 8 hours. However, the long-acting verapamil preparations generally are preferred for the sake of compliance and convenience. Long-acting verapamil should be initiated at a dosage of 180 mg once daily with upward titration to 240 mg/day. Titration can occur at weekly intervals for symptoms of angina or control of hypertension. Patients should be warned to avoid chewing or crushing the long-acting preparations of verapamil because the entire daily dose may be released rapidly. Long-acting verapamil should be initiated at a dosage of 120 mg/day in the elderly or in underweight patients.

3. DILTIAZEM—Diltiazem has a modest effect on heart rate and blood pressure in normotensive patients. Like all calcium channel blocking agents, it exerts a coronary vasodilating effect. Diltiazem's antianginal properties are the result of both coronary vasodilation and a reduction in the product of heart rate and systolic blood pressure. Diltiazem has a favorable side-effect profile characterized by minor occurrences of dyspnea, rash, and edema. Because diltiazem depresses SA and AV nodal function, concomitant administration of β -blockers warrants careful attention to the heart rate.

Starting dosages for diltiazem are 60 mg every 8 hours, and this can be increased to 120 mg every 6–8 hours. Long-acting preparations of diltiazem have been introduced. Therapy with these sustained-release preparations can be initiated at a dosage determined by therapy with the short-acting preparation (eg, patients who tolerate 60 mg every 8 hours can be converted directly to 180 mg/day of the long-acting preparation). Frequently, clinicians initiate therapy with 180 mg of the sustained-release compound and increase the dose weekly up to 360 mg/day. For elderly and underweight patients, a starting dose of 120 mg/day may be preferable.

Like all calcium channel blocking agents currently marketed (with the exception of amlodipine), diltiazem should be avoided in patients with reduced left ventricular function. A large multicenter trial demonstrated that the administration of diltiazem to patients with left ventricular ejection fractions of less than 0.40 or with pulmonary congestion after acute myocardial infarction is associated with an approximately 1.4-fold increase in cardiovascular death. Similar results have been seen in trials with verapamil.

▶ Acute Coronary Syndromes: Unstable Angina and Non-ST-Segment-Elevation Myocardial Infarction

ESSENTIALS OF DIAGNOSIS

- ▶ Increase in the frequency, severity, or duration of stable angina or angina occurring at a lower threshold (unstable angina with low-risk characteristics).
- ▶ Prolonged (>20 minutes) angina at rest now resolved, plus diabetes, age over 65, deep T-wave inversions in more than three leads, angina on walking one to two blocks on the level or climbing one flight of stairs at a normal pace in the past 2 weeks, nocturnal angina, or pathologic Q waves (unstable angina with intermediate-risk characteristics).
- ▶ Ongoing (>20 minutes) chest pain, ST-segment depression = 1 mm or more, angina plus heart failure, or angina plus hypotension (unstable angina with high-risk characteristics).
- ▶ Any of the preceding plus cardiac enzyme markers of myocardial necrosis (troponin I, troponin T, or CK-MB) (non-ST-segment-elevation myocardial infarction).

General Considerations

Patients with non-ST-segment-elevation (non-Q-wave) myocardial infarctions represent the severe end of the spectrum of the pathology associated with unstable angina. Fissuring or rupture of an atherosclerotic plaque precedes unstable angina. If the plaque disruption can be stabilized spontaneously or through medical intervention, unstable angina develops. If not, then non-ST-segment-elevation myocardial infarction may occur.

The American College of Cardiology/American Heart Association (ACC/AHA) has issued guidelines for the management of unstable angina pectoris and non-ST-segment-elevation myocardial infarction (non-STEMI). The intensity

of medical therapy and interventional procedures, as well as the urgency of starting treatment, should be guided by both symptoms and objective findings.

Clinical Features

A. Symptoms and Signs—The signs and symptoms of unstable angina and non-STEMI are the same as those of stable angina pectoris. The distinction between stable angina and unstable angina or non-STEMI is in the longer duration of the pain episodes, the reduced amount of exertion required to produce angina (including pain at rest), and the increased frequency of chest discomfort.

B. Diagnostic Testing—As in stable angina, patients with unstable angina frequently have normal ECGs. However, the presence of new ST-segment depression, T-wave inversion, or both that resolve spontaneously or with the administration of sublingual nitroglycerin identifies a category of patients at high risk for subsequent cardiac events, including myocardial infarction or death. Chest pain with ST-segment depression now can be managed by specific therapy defined by large randomized clinical trials.

A non-STEMI is diagnosed when markers of myocardial necrosis (ie, elevated levels of troponins or CK-MB) are present in the absence of ST-segment elevation on the ECG.

C. Evaluation of the Stabilized Patient—In patients whose symptoms become well controlled on antianginal therapy after an episode of unstable angina pectoris, three approaches may be followed: (1) Perform coronary arteriography with the anticipation of elective coronary artery angioplasty or coronary artery bypass surgery. If catheterization and revascularization can be accomplished within 48 hours of presentation, this approach can reduce morbidity and mortality in patients with troponin-positive non-STEMIs and in patients with unstable angina with 1 mm or more of labile ST-segment depression on presentation. (2) Treat the patient conservatively with increased doses of antianginal medications. (3) Perform a functional test to select patients most likely to benefit from more invasive therapies.

A “low level” stress test can be used in ACC/AHA low- and intermediate-risk unstable angina patients to identify those who are at high or low risk for development of subsequent myocardial infarction, further unstable angina, and death after an initial episode of unstable angina. These exercise stress tests, which are limited either by workload (5–7 mets [ie, five to seven times the resting metabolic rate]) or heart rate (<120 beats/min or less than 65% of predicted maximum heart rate), are used to determine whether ischemia is present at levels of exercise likely to be encountered in ordinary daily activities. Safety is the primary reason for limiting the test to a lower target workload or heart rate than might be the goal for diagnosis of angina in a patient with chest pain. Furthermore, it makes little sense intuitively to challenge with a conventional stress test a patient who has recently had symptoms with minimal exertion.

A negative low-level stress test is associated with a relatively good outcome, with over 70% of patients with a negative study having no or mild angina pectoris in the ensuing 6 months to 1 year. Conversely, a positive low-level stress test, with development of ST-segment depression or chest pain, is associated with a greater than 80% incidence of subsequent undesirable outcomes (eg, recurrent unstable angina, myocardial infarction, or death). Thus the low-level stress test can be used to identify patients at high risk and therefore more likely to benefit from early aggressive management of ischemic heart disease.

Treatment

Patients who experience an increase in the frequency or duration of angina pectoris or a marked decline in the amount of exertion required to provoke chest pain are candidates for hospitalization. This will both reduce the work of the heart (hospitalization itself) and initiate or intensify pharmacologic therapy for ischemic heart disease.

A. Aspirin—Over two decades ago, two major studies attested to the importance of aspirin in the therapy of unstable angina pectoris. Both the Veterans Administration and the Canadian Cooperative trials demonstrated a 50% reduction in deaths and myocardial infarctions in patients with unstable angina who take one to four 325-mg aspirin tablets a day. The observation that patients with unstable angina or non-STEMI have large amounts of thrombus in patent but atherosclerotic coronary arteries at the time of coronary angiography or coronary arteriography provides the pathophysiologic basis for this remarkably successful and inexpensive form of therapy. Patients with true allergies to aspirin can substitute clopidogrel, 75 mg/day.

B. Beta-Blockers—The prevention of the ischemia that underlies unstable angina pectoris and non-STEMI is accomplished most easily by reducing the work of the heart. By lowering both the heart rate and blood pressure, β -blockers perform this task efficiently and inexpensively. In patients with high-risk characteristics of unstable angina or evidence of a non-STEMI, intravenous administration of β -blocking agents followed by oral β -blockers is appropriate and desirable. Metoprolol should be administered intravenously in 5-mg increments more than 2 minutes apart to a total dose of 15 mg (or more if better control of the heart rate is desired). Following intravenous loading of β -blockers, oral metoprolol, 50 mg twice daily, or oral atenolol, 50 mg once daily, should be initiated.

For patients with contraindications to beta blockade (eg, bronchospastic lung disease), calcium channel blocking agents may be substituted. Calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, or angiotensin II receptor blockers may be added to beta blockade if additional antihypertensive therapy is required.

C. Nitrates—Oral nitrates may be initiated as 20-mg isosorbide dinitrate three times per day with a target dose of 40–60 mg

three times per day. Long-acting isosorbide mononitrate can be initiated at a dosage of 20 mg/day with a target dosage of 60–120 mg/day. These agents usually are administered to low- and intermediate-risk patients who need additional anti-ischemic therapy after β -blockers.

Intravenous nitrate therapy may be particularly useful in the patient with high-risk unstable angina pectoris who has ongoing pain or the non-STEMI patient with hypertension that is difficult to control. Patients receiving intravenous nitroglycerin should be monitored closely, and the rate of infusion should be titrated to relieve pain as well as to meet blood pressure goals while avoiding hypotension.

D. Thrombolytic Therapy—There is no role for thrombolytic therapy in unstable angina or non-STEMI. Trials designed to test the efficacy of thrombolytic therapy in these settings are negative (thrombolytics increased morbidity and mortality).

E. Clopidogrel—The thienopyridine clopidogrel is an antiplatelet agent that inhibits platelet aggregation induced by adenosine diphosphate (ADP), whereas aspirin blocks the thromboxane-mediated pathway. The CURE trial randomized 12,562 patients with acute coronary syndromes to clopidogrel 75 mg/day (after a 300-mg oral loading dose) or a placebo. Clopidogrel therapy was associated with a substantial reduction in the composite endpoint of death from cardiovascular causes, nonfatal myocardial infarction, or stroke. Although approved for all forms of acute coronary syndromes, the benefit of this agent was demonstrated only in patients with unstable angina and ST-segment depression and patients with non-STEMIs.

F. Anticoagulation—The ESSENCE and TIMI 11B trials have provided convincing evidence supporting the use of the low-molecular-weight heparin enoxaparin in high-risk unstable angina pectoris and non-STEMI patients. While also approved for use in intermediate-risk unstable angina, a close look at the data suggests that the greatest benefit from this agent occurs in patients with pain at rest and 1 mm or more of ST-segment depression or who have elevated troponins or CK-MB. The dose of enoxaparin is 1 mg/kg subcutaneously every 12 hours for 48–72 hours.

Intravenous unfractionated heparin can be given for non-STEMI as well as for intermediate- and high-risk unstable angina. However, given the advantages of low-molecular-weight heparin, unfractionated heparin seems most useful as an adjunct to the glycoprotein IIb/IIIa inhibitors or in renal failure, where enoxaparin is not desired because it is cleared by the kidneys.

Recently, the synthetic pentasaccharide fondaparinux, which also binds to activated factor Xa, has been shown to reduce ischemic events in acute coronary syndromes much the same as enoxaparin. Fewer bleeding events were observed.

G. Glycoprotein IIb/IIIa Receptor Inhibitors—This class of drugs blocks the affinity of the glycoprotein IIb/IIIa receptor for fibrinogen on platelets activated by products released

from plaque rupture. In this manner, platelet plugging and clot formation in atherosclerotic lesions are retarded or inhibited.

Like enoxaparin, the glycoprotein IIb/IIIa receptor antagonists (ie, eptifibatid and tirofiban) are indicated for the treatment of intermediate- and high-risk unstable angina and for non-STEMI patients. Eptifibatid is approved for use in preventing complications of percutaneous revascularization. Both agents are administered with unfractionated heparin at a dose titrated to result in a twofold increase in the partial thromboplastin time. Eptifibatid is initiated with an intravenous bolus of 180 μ g/kg, followed by an infusion of 2 μ g/kg per minute for 72–96 hours. Tirofiban is given as an intravenous loading dose of 0.4 μ g/kg per minute for 30 minutes, followed by an infusion of 0.1 μ g/kg per minute for 48–96 hours.

Both glycoprotein IIb/IIIa receptor antagonists reduce the combined endpoint of death or myocardial infarction or the need for urgent revascularization. Like enoxaparin, the greatest benefit from these agents appears to be conferred on the more ill patients (ie, those with prolonged chest pain, 1 mm or more of ST-segment depression, or elevated troponins or cardiac enzymes). The decision to use these costly agents may hinge on the likelihood of side effects of bleeding.

H. Coronary Angioplasty and Coronary Artery Bypass Grafting

—Debate continues regarding the advantages of conservative compared with aggressive management of these patients. The clinician may elect to initiate or enhance the therapy of patients with low-risk unstable angina and simply follow the patient symptomatically with or without hospitalization. This option is based on the observation that low-risk patients have a risk of serious events (eg, death and myocardial infarction) that is similar to that borne by patients with stable angina. Even intermediate-risk unstable angina pectoris patients who stabilize their symptoms on medical therapy are at risk only for an increased rate of recurrent unstable angina during the ensuing year. Hence, for stabilized patients, watchful waiting appears to carry little risk and may avoid unneeded revascularization procedures.

Recurrent ischemic pain despite adequate medical therapy should prompt urgent coronary angiography in anticipation of coronary bypass grafting or coronary angioplasty. This recommendation also applies to patients with recurrent pain during treatment of non-STEMI.

Data from TACTICS and TIMI 18 suggest that patients with rest pain plus ST-segment depression or those who have a non-STEMI may benefit from an early (but not emergent) cardiac catheterization in anticipation of expeditious coronary revascularization.

Table 22–1 outlines basic evidence-based treatment strategies for acute coronary syndromes. The terms *low*, *intermediate*, and *high risk* refer to ACC/AHA guideline estimates of risk for adverse outcome (eg, recurrent unstable angina, myocardial infarction, and death).

Table 22-1. Treatment of unstable angina pectoris (UAP) or non-ST-segment-elevation myocardial infarction (non-STEMI)

	Non-STEMI (Elevated Troponin)	High-Risk UAP (Chest Pain and ≥ 1 mm ST- Segment Depression)	High-Risk UAP (<1 mm ST-Segment Depression)	Intermediate- Risk UAP	Low-Risk UAP
Aspirin	+	+	+	+	+
β -Adrenergic blockers	+	+	+	+	+
Clopidogrel	+*	+*			
Low-molecular-weight heparin (enoxaparin)	+†‡	+†‡			
IIb-IIIa inhibitor and unfractionated heparin	+§	+§			
Consider cardiac catheteri- zation and revasculariza- tion within 48 hours	+	+			

Note: Recurrent chest pain in the hospital is an indication for expeditious catheterization and intervention.

*For 30 days.

†Avoid if creatinine ≥ 2.5 mg/dL.

‡Substitute IIb-IIIa inhibitor + unfractionated heparin if urgent catheterization is planned.

§Avoid if creatinine ≥ 4 mg/dL; adjust dose if creatinine ≥ 2 .

▶ Acute Myocardial Infarction with ST-Segment Elevation

ESSENTIALS OF DIAGNOSIS

- ▶ Precordial chest pain with or without radiation to the left arm, shoulder, or jaw.
- ▶ Pain may be identical in quality and description to that of angina pectoris but may last from 10 minutes to several hours.
- ▶ Greater than 1 mm ST-segment elevation in two contiguous leads with or without Q-wave formation.
- ▶ Confirmation by serial changes in ECGs plus elevation of cardiac enzymes (ie, CK-MB, troponin I, or troponin T).
- ▶ Complications may include arrhythmias, pulmonary edema, hypotension and shock, ventricular rupture, and pericarditis.

General Considerations

Coronary thrombosis is the immediate cause of acute myocardial infarction in over 90% of patients with this syndrome of acute myocardial infarction with ST-segment elevation (STEMI). Although early autopsy investigations suggested a variety of other causes of acute myocardial infarction—including coronary vasospasm and emboli—over 86% of those with acute myocardial infarction had coronary artery thrombi when coronary angiography was performed within 4 hours of the onset of symptoms.

Current concepts of acute myocardial infarction support the view that the nidus for thrombosis is an atherosclerotic plaque in a coronary artery. The plaque itself may or may not result in stenosis of the artery severe enough to cause symptoms, although more severe atherosclerotic stenoses may be associated with exertional angina. The pathophysiologic sequence of events then probably includes plaque rupture with exposure of the subintimal components of the plaque to coronary blood flow. Platelet activation occurs as the contents of the atherosclerotic plaque (including cholesterol and calcium) interact with circulating blood components. Platelet activation releases thromboxane A_2 , a vasoconstrictive substance that may lead to localized vasospasm, which further impedes coronary artery blood flow. The net result of these events is interruption of coronary blood flow by thrombus formation followed by myocardial necrosis if therapy is not effective.

New information regarding the treatment of unstable angina and non-STEMI appears almost weekly. The therapies of unstable angina, non-STEMI, and STEMI are now driven by large clinical trials that define current pharmacologic and revascularization strategies.

Clinical Features

A. Symptoms—Acute myocardial infarction is classically associated with precordial chest pain with or without radiation to the left arm, shoulder, or jaw. The pain is identical to that described in the section on angina pectoris but often more severe. The only deviation is duration. The chest pain of myocardial infarction lasts from 10–15 minutes to several hours. The pain is poorly responsive to nitroglycerin and may require morphine for relief. Diaphoresis, syncope, and lightheadedness may be present. Dyspnea and orthopnea may be associated with acute congestive heart failure and pulmonary edema.

B. Signs—During myocardial infarction, an S_3 gallop, pulmonary rales, or the murmur of mitral regurgitation may appear. Myocardial infarction may be associated with decreased intensity of S_1 and S_2 . Patients should be examined carefully for murmurs of mitral regurgitation and for the presence of pericardial friction rubs. Rales and wheezes may indicate acute pulmonary edema from congestive heart failure.

C. Laboratory Findings—Venous blood should be obtained routinely to measure the cardiac-specific CK-MB and

troponin I or troponin T on admission to hospital and every 6–8 hours thereafter for the first 24 hours. Daily CK-MB and troponin levels may be useful during the balance of the patient's hospital stay to detect silent recurrent myocardial necrosis. A partial thromboplastin time should be obtained on admission and repeated if unfractionated heparin therapy is indicated. Arterial blood gases should be measured if hypoxemia is suspected from physical findings, chest x-ray, or pulse oximetry.

D. Electrocardiography—By definition, acute STEMI is associated with specific electrocardiographic findings. However, with modern management, the classic electrocardiographic changes of ST-segment elevation followed by T-wave inversion with development of Q waves may be retarded or even abolished. A substantial proportion of patients with myocardial infarction will not develop Q waves after initial ST-segment elevation and may demonstrate only T-wave changes or no changes in their ECGs. The development of Q waves portends a worse prognosis.

E. Imaging Studies—Imaging studies should not delay prompt management of acute myocardial infarction.

1. CHEST X-RAY—The chest x-ray should be reviewed for cardiomegaly, pulmonary edema, and pleural effusions. In upright chest x-rays, fullness and congestion of vessels leading to the upper lung fields sometimes is taken as evidence of mild pulmonary edema from heart failure.

2. ECHOCARDIOGRAPHY—Echocardiography is useful in defining coexisting heart disease—especially valvular or congenital disease—identifying pericardial effusion, evaluating unexplained tachycardia, and assessing ventricular function. Patients with acute myocardial infarction should have an echocardiogram if there is hypotension or shock. Other indications for echocardiography include suspicion of ventricular septal rupture or severe mitral regurgitation (both potentially requiring surgery), a large myocardial infarction as judged from CK-MB or troponin elevation, suspected pericardial effusion, or left ventricular dysfunction that may be worsened by β -adrenergic blockade or calcium channel antagonists.

An evaluation of left ventricular function by echocardiography or radionuclide ventriculography should be performed in almost all patients after an acute myocardial infarction to help define prognosis and guide appropriate prophylactic therapy. ACE inhibitors given after myocardial infarction will prolong survival, and the greater the degree of reduction in ejection fraction or severity of heart failure as defined by New York Heart Association (NYHA) functional class, the greater is the benefit from the routine use of these agents. Similar statements can be made for the β -blocker carvedilol in patients with NYHA class II and class III symptoms.

3. PULMONARY ARTERY CATHETERIZATION (RIGHT-SIDED HEART CATHETERIZATION)—Right-sided heart catheterization allows the determination of right atrial, right ventricular,

pulmonary artery, and pulmonary capillary wedge pressures. Since the latter value is a rough estimate of the left ventricular end-diastolic pressure, pulmonary capillary wedge pressure can provide valuable information regarding the necessity for volume expansion or diuresis. The right-sided heart catheters are equipped with a temperature-measuring thermistor that allows determination of cardiac output by thermodilution.

Right-sided heart catheterization should be considered at any point during the course of an acute myocardial infarction when a question exists regarding fluid volume status. For example, a patient with acute myocardial infarction and possible pneumonia may have a lung examination that could represent pulmonary edema, pneumonia, or both. On the other hand, treatment of hypotension in the presence of suspected right ventricular infarction usually can commence without right-sided heart catheter guidance. Patients with an acute inferior infarction who experience hypotension and have clear lungs and no S_3 gallop should receive 500–1000 mL normal saline to see if volume expansion will increase the blood pressure without causing rales. However, should further volume supplementation seem necessary or should incipient left-sided heart failure be present or suspected, right-sided heart catheterization would be invaluable in determining the true volume status of the patient.

For patients in whom hypotension persists for more than an hour despite use of vasopressors, right-sided heart catheterization is strongly advised.

4. CARDIAC CATHETERIZATION—Cardiac catheterization after acute STEMI generally is reserved for patients who develop instability. The routine use of cardiac catheterization after acute myocardial infarction for the purpose of elective angioplasty or bypass surgery has not found justification in randomized trials of elective revascularization after acute STEMI. Rather, patients who have an uncomplicated myocardial infarction (no recurrent chest pain) can safely undergo stress testing (usually with a low-level exercise protocol) prior to hospital discharge to identify those at high risk for reinfarction or death who should undergo further study.

Cardiac catheterization before hospital discharge is indicated in two classes of patients: (1) patients who develop chest pain after acute myocardial infarction, which is thought to be ischemic in nature, and (2) patients who have chest pain or evidence of ischemia on electrocardiography or myocardial perfusion scintigraphy during low-level exercise stress testing. These patients have “failed” medical therapy by virtue of having chest pain in the hospital (presumably while on adequate medication) and are likely to be best served by undergoing coronary angioplasty or coronary bypass grafting if their anatomy is found to be suitable by angiography.

Differential Diagnosis

The differential diagnosis of myocardial infarction is essentially the same as that of angina pectoris (see above).

Treatment

Treatment may be divided into immediate and later phases. Immediate therapy is empirical and is initiated after obtaining the history, performing a physical examination, and examining the ECG.

A. Initial Outpatient Treatment—Sublingual nitroglycerin tablets or nitroglycerin spray should be self-administered if the patient has either drug. Otherwise, sublingual nitroglycerin should be administered by paramedics or by personnel in the emergency department. A sublingual nitroglycerin tablet (usually 0.3 mg) can be administered every 3–5 minutes (if pain persists) for an initial total of three to five tablets. Repeat doses of nitroglycerin can be administered once blood pressure monitoring is available and the patient has no significant side effects such as dizziness or severe headaches.

B. Immediate Hospital Therapy—Initial therapy of a patient in the hospital suspected of having myocardial infarction consists of nitroglycerin as indicated earlier. Oxygen therapy, usually 2 L/min by nasal cannula, is frequently begun empirically and adjusted based on pulse oximetry. One aspirin tablet (325 mg) should be chewed and swallowed by the patient to reduce subsequent morbidity and improve chances for survival. For aspirin-allergic patients or patients already taking prophylactic aspirin, oral clopidogrel, 75 mg, may be substituted.

1. REPERFUSION—All patients with STEMI must be considered for an early strategy for reperfusion at the time of initial contact. The choice of strategy depends on duration of symptoms, availability of resources, and relative risks of the patient and the treatments.

Fibrinolysis (ie, thrombolytic therapy) and an invasive strategy (eg, angioplasty with stent) are the two options. There is no preference for either strategy if presentation time is less than 3 hours and there is no delay for an invasive strategy. Otherwise, an invasive strategy generally is preferred if the procedure can be performed within 60–90 minutes, the patient is at high risk of complications from STEMI (eg, cardiogenic shock or pulmonary edema), thrombolysis is contraindicated because of increased bleeding risk, or STEMI diagnosis is in doubt. Thrombolytic therapy is preferred if an invasive strategy is not an option or there is a potential delay of angioplasty of more than 1 hour from hospital arrival to onset of the procedure.

a. Thrombolytic therapy—If the patient has a classic history for acute myocardial infarction and has more than 1 mm of ST-segment elevation in two contiguous leads [eg, in two inferior leads (II, III, or aVF), or in leads I and aVL, or in two contiguous chest or V leads], thrombolytic therapy should be an option. The presence of a left bundle branch block not known to be old is also an indication for thrombolytic therapy.

Tenecteplase, intravenous streptokinase, or anisoylated plasminogen streptokinase activator complex (anistreplase;

APSAC) can be administered if the patient does not have one or more of the following contraindications: active internal bleeding; history of stroke; intracranial or intraspinal surgery or trauma within 2 months; intracranial neoplasm, arteriovenous malformation, or aneurysm; known bleeding diathesis; or severe uncontrolled hypertension. Age over 75 has been used as a contraindication to thrombolytic therapy, but this remains controversial.

Following thrombolysis, patients receive heparin, either unfractionated heparin titrated to the activated partial thromboplastin time or, preferably, low-molecular-weight heparin (LMWH). In comparison trials, LMWH was associated with improved survival and a lower rate of recurrent myocardial infarction and restenosis compared with unfractionated heparin.

b. Primary angioplasty—Facilities with an available catheterization laboratory may opt for urgent coronary angiography and percutaneous angioplasty (usually with stenting). If the patient can be brought to the angiographic laboratory in an expeditious manner, the angiographer may initiate a glycoprotein IIb/IIIa inhibitor, which binds to the platelet glycoprotein IIb/IIIa receptor and inhibits platelet aggregation, to reduce the incidence of subsequent myocardial infarction and death.

Whether angioplasty or thrombolytic treatment is chosen as the therapy for acute STEMI, the administration of aspirin and intravenous beta blockade should not be delayed.

2. BETA-ADRENERGIC BLOCKADE— β -adrenergic blockade with intravenous metoprolol should be accomplished as soon as possible after the diagnosis of acute myocardial infarction has been established by history and electrocardiography. Intravenous beta blockade can be initiated provided the patient has an initial heart rate over 50 beats/min, a systolic blood pressure over 90 mm Hg, rales less than one-third the way up the back, a PR interval less than 0.28 s, and no other contraindications (eg, asthma). Metoprolol should be administered intravenously in 5-mg increments more than 2 minutes apart to a total dose of 15 mg (or more if greater control of the heart rate is desired). Following intravenous loading of β -blockers, oral metoprolol, 50 mg twice daily, or oral atenolol, 50 mg once daily, should be initiated.

3. INTRAVENOUS NITROGLYCERIN—Intravenous nitroglycerin frequently was administered to all patients with known or suspected myocardial infarction in the hope of reducing morbidity and mortality. Large trials of patients with STEMI have failed to justify the enthusiasm for the routine use of this agent in asymptomatic patients with acute myocardial infarction. Current recommendations for intravenous nitroglycerin include relief of ischemic pain and reduction of systolic blood pressure. A dose of 0.5 μ g/kg per minute (35 μ g/min for an average-sized patient) can be initiated and the rate of administration increased until pain relief or a reduction in systolic blood pressure to less than 90–100 mm Hg is seen. The rate of administration should not be increased further if the patient develops dizziness or other evidence of decreased organ perfusion. If long-term nitrate therapy is desired, long-

acting nitrates such as isosorbide dinitrate or isosorbide mononitrate should be started within 24 hours. The continuous administration of intravenous nitroglycerin can rapidly lead to “nitrate tolerance” and loss of anti-ischemic effect.

4. MORPHINE SULFATE—Morphine beginning with 2 mg intravenously should be administered if nitroglycerin does not provide prompt relief of pain. Incremental doses of morphine can be administered to a total that is usually less than 20 mg. Much lower doses may be effective. As morphine doses exceed 10–15 mg, the possibility of respiratory depression must be considered.

5. ANTIARRHYTHMIC THERAPY—Patients with acute myocardial infarction who have hemodynamically unstable ventricular arrhythmias (eg, ventricular fibrillation or ventricular tachycardia) lasting for more than 30 seconds or causing hemodynamic collapse or hypotension should be electrically cardioverted. Sustained monomorphic ventricular tachycardia not associated with symptoms or hypotension (blood pressure < 90 mm Hg) should be treated with one of the following.

a. Lidocaine—An intravenous bolus of lidocaine (1–1.5 mg/kg) is given, followed by supplemental boluses of 0.5–0.75 mg/kg every 5–10 minutes to a maximum loading dose of 3 mg/kg. Loading is followed by an intravenous infusion of lidocaine at a rate of 2–4 mg/min. Nursing staff must be alert to changes in the patient’s mental status (eg, somnolence, disorientation, or dysesthesias) that may signal lidocaine toxicity. The elderly are particularly susceptible.

b. Amiodarone—Give 150 mg intravenously over 10 minutes, followed by an infusion of 1 mg/min for 6 hours and then a maintenance infusion of 0.5 mg/min.

c. Procainamide—Give a loading dose by intravenous infusion of 12–17 mg/kg at a rate of 20–30 mg/min, followed by an infusion of 1–4 mg/min.

The acute administration of antiarrhythmics allows time to diagnose and correct electrolyte abnormalities such as hypokalemia and hypomagnesemia, correct hypoxemia, and allow anti-ischemic therapy (beta blockade) to be intensified.

6. SEDATION—Sedatives such as intravenous or oral benzodiazepines may be useful in reducing the level of anxiety engendered by the ICU setting.

C. Additional Care in the ICU—

1. GENERAL MEASURES—The patient should be placed at complete bed rest during the first 24 hours. Thereafter, in stable uncomplicated patients, the patient should be encouraged to sit up in bed, dangling the legs over the side several times a day, and then spend increasing amounts of time sitting in a chair or ambulating with assistance. The patient should be provided with a clear-liquid diet for the first 8–12 hours of hospitalization for acute myocardial infarction. Stool softeners are useful to prevent straining during defecation.

Subcutaneous heparin, 5000 units twice daily, should be considered—if no contraindication exists—to prevent deep venous thrombosis and pulmonary embolism. Additional

supportive measures for patients in the coronary care unit include daily monitoring of serum electrolytes (including serum Mg^{2+}) for at least 72 hours. In patients with normal renal function, potassium supplements should be administered to keep the serum K^+ greater than 4.5 meq/L, and magnesium should be given intravenously to maintain serum Mg^{2+} levels at greater than 2.0 mg/dL. These maneuvers will reduce the incidence of ventricular arrhythmias in a safe and physiologic manner. While prophylactic Mg^{2+} administration does not reduce mortality overall, there is some suggestion that high-risk groups (nonreperfused patients) may benefit. Magnesium sulfate [10 g (40 mmol) in 100–200 mL D_5W administered over 2–3 hours] usually will increase the steady-state serum levels of Mg^{2+} about 0.3–0.4 mg/dL in patients with normal renal function. Hyperglycemia is a risk factor for poor outcome in acute myocardial infarction; tight glycemic control may decrease complications.

2. ASPIRIN—One aspirin tablet per day (eg, enteric-coated aspirin, 160–325 mg) should be administered to all patients after myocardial infarction unless there are contraindications. Regardless of whether thrombolytic therapy has been given or not, prophylactic aspirin therapy has reduced the post–myocardial infarction mortality rate by 23%. For aspirin-allergic patients, clopidogrel, 75 mg/day, can be substituted.

3. BETA-ADRENERGIC BLOCKADE—Any of the following—propranolol, 180 mg daily in divided doses; timolol, 10 mg twice daily; metoprolol, 100 mg twice daily; or atenolol, 100 mg once daily—should be administered after acute myocardial infarction to prevent sudden death in patients who can tolerate this class of drugs. The criteria used to define patients eligible for prophylactic β -adrenergic blockade are similar to those applicable in the immediate post–myocardial infarction period: systolic blood pressure greater than 90–100 mm Hg, heart rate greater than 50 beats/min, no rales, PR interval less than 0.28 s, and no contraindications (eg, asthma or “brittle” diabetes).

Randomized trials of over 50,000 patients in the United States and Europe have consistently demonstrated a 25–35% decrease in post–myocardial infarction sudden death with the prophylactic use of beta blockade. Of particular interest is the observation that if a patient can tolerate beta blockade after acute myocardial infarction, the greatest benefit accrues to those in whom some of the most serious concerns against beta blockade are raised. Specifically, a patient who has had heart block, sudden death (eg, ventricular fibrillation or ventricular tachycardia), or heart failure after myocardial infarction and can tolerate beta blockade subsequently (ie, if heart failure clears with one or two doses of diuretics) gains the greatest cardioprotective effect from beta blockade. For example, assuming a pool of patients with prior congestive heart failure who subsequently stabilize, it is estimated that prophylactic treatment with β -blockers of only 26 patients is required to save one life. Carvedilol, a nonselective β - and α -blocker has been approved by the Food and Drug Administration (FDA) for post-MI patients with LV dysfunction.

4. ANTIHYPERTENSIVE AGENTS—Patients with hypertension have an obvious need for lowering systolic blood pressure. A goal for systolic blood pressure of approximately 120 mm Hg or less would be desirable, although any evidence of cerebral hypoperfusion may frustrate this goal in some patients.

While most antihypertensive drugs are potentially suitable for treatment of hypertension in patients with acute myocardial infarction, preference should be given to agents likely to treat both hypertension and the underlying coronary artery disease. For example, β -blockers would seem an ideal antihypertensive choice because they reduce the work of the heart (by lowering both heart rate and blood pressure) as well as providing a cardioprotective effect that reduces the incidence of sudden death following acute myocardial infarction.

ACE inhibitors may be useful for the treatment of hypertension and should be strongly considered if the patient has any element of congestive heart failure (eg, rales, cardiomegaly, or known reduction of ejection fraction) in conjunction with an acute myocardial infarction. Survival benefit in the post–myocardial infarction setting has been demonstrated for a host of ACE inhibitors, with greater improvement in survival being observed in the patients with the greatest reductions in ejection fraction. For patients intolerant of ACE inhibitors, the angiotensin II receptor blocking agents (eg, losartan, valsartan, candesartan, and others) are suitable alternatives.

The calcium channel blockers diltiazem and verapamil are reasonable alternatives to β -adrenergic blockade in patients with brittle diabetes or bronchospastic lung disease. Both agents have a modest bradycardic effect in addition to their antihypertensive effects. It should be remembered that these agents should be reserved for patients with preserved left ventricular function because these drugs increase mortality substantially in patients with ejection fractions under 0.40.

5. DILTIAZEM—In patients with acute myocardial infarction who do not develop Q waves on the ECG (acute non-Q-wave myocardial infarction or subendocardial myocardial infarction), strong consideration should be given to administering diltiazem in a dose of 60 mg four times daily or 90 mg every 8 hours. At these doses, this agent has been shown to prevent reinfarction in the month following an acute non-Q-wave myocardial infarction.

Complications

A. Arrhythmias—

1. ATRIAL FIBRILLATION—This disorder, characterized by a narrow QRS complex and an irregular rhythm, is frequently associated with extensive damage to the myocardium. If rapid atrial fibrillation is associated with symptomatic hypotension or with chest pain, conservative measures should be abandoned, and synchronized electrical cardioversion should be performed immediately.

Typically, initial therapy would consist of digoxin given intravenously in a dose of 0.25–0.5 mg to slow the ventricular

response and improve left ventricular function. Subsequent doses of 0.125–0.25 mg of intravenous digoxin can be given up to a total of 1–1.5 mg over the initial 24 hours after myocardial infarction. Oral digoxin, usually 0.125–0.25 mg/day, is administered for maintenance therapy. The goal of digoxin therapy is to reduce the ventricular rate to less than 90–100 beats/min.

Concomitant therapy with either β -adrenergic blockers or the calcium channel blocking agent diltiazem will achieve acceptable heart rate control in a shorter period of time than with digoxin alone. For example, 5 mg intravenous metoprolol can be administered every 5 minutes to achieve prompt control of rapid atrial fibrillation while digoxin therapy is being initiated. An oral maintenance dose of metoprolol, 50 mg twice daily, can be initiated once the resting heart rate is controlled with the intravenous preparation. Intravenous diltiazem, a loading dose of 20 mg (or 0.25 mg/kg) over 2 minutes, can be given and repeated in 15 minutes. A maintenance infusion of 10–15 mg/h can be prescribed for 24 hours if necessary. Heparin should be given in the absence of contraindications.

2. VENTRICULAR PREMATURE BEATS—Prophylactic abolition of *asymptomatic* ventricular ectopy after myocardial infarction results in a marked increase in mortality rate. The results of the Cardiac Arrhythmia Suppression Trial (CAST) have documented conclusively that routine use of antiarrhythmic therapy for asymptomatic ventricular ectopy is contraindicated. It is worth noting, however, that the prophylactic use of β -adrenergic blockade has been associated with a decrease in the frequency of ventricular ectopy. Since β -blockers prolong survival after a myocardial infarction, they should be considered the primary form of nonspecific antiectopy therapy.

Isolated ventricular premature beats need not be treated, but repetitive forms of ventricular ectopy such as couplets and ventricular tachycardia (ie, more than three ventricular premature beats in a row) are indications for prophylactic lidocaine if they are associated with hypotension (see above). If longer-term antiarrhythmic therapy is believed necessary, intravenous procainamide (2–4 mg/min) or oral sustained-release procainamide (750 mg every 6 hours) would be potentially beneficial. Alternative agents include quinidine sulfate (200 mg every 6 hours) and sustained-release quinidine gluconate (324 mg every 8 hours), as well as tocainide, mexiletine, and amiodarone.

B. Heart Failure—Heart failure complicating acute myocardial infarction will increase the mortality rate from 2–3% to as high as 50% per year. A primary goal of therapy for acute myocardial infarction is to prevent the progression of uncomplicated myocardial infarction to reinfarction with development of heart failure. The administration of intravenous, cutaneous, or oral nitrates, as well as β -adrenergic blockade therapy and thrombolytic therapy, is directed toward this goal.

If congestive heart failure develops after myocardial infarction, initial therapy may include the following.

1. DIURETICS—Rales and S_3 gallop sometimes are eradicated by a single intravenous dose of furosemide (20–40 mg intravenously in patients who have not previously received this agent). Larger doses of intravenous furosemide may be used as the initial diuretic dose if the patient is known to have been receiving diuretic therapy in the past.

2. VASODILATORS—ACE inhibitors are first-line therapy for the treatment of congestive heart failure in acute myocardial infarction. In addition to their beneficial hemodynamic effects, these agents improve survival by altering favorably the “remodeling” of the left ventricle that occurs with myocardial infarction. Captopril can be initiated in dosages of 12.5 mg every 8 hours and then increased to 100 mg every 8 hours. Dose escalation can occur daily (or more frequently) if no orthostatic symptoms are noted. Corresponding doses of enalapril range from 2.5–10 mg twice daily—and for lisinopril, 5 mg once daily initially, titrated upward to 10–20 mg/day. Ramipril is another ACE inhibitor with proof of efficacy and survival benefit in the treatment of congestive heart failure complicating acute myocardial infarction.

Cough and elevation of the serum creatinine can limit the use of ACE inhibitors. Some clinicians have substituted angiotensin II receptor antagonists such as losartan and valsartan for ACE inhibitors. Clinical trials in chronic heart failure would support this practice, although the ACE inhibitors remain the vasodilators of choice for prolongation of life with heart failure and depressed left ventricular function. Another alternative therapy for heart failure with proven survival benefits is the combination of the vasodilator hydralazine with isosorbide dinitrate. Hydralazine can be started at 25 mg orally with the dose increased every 3–6 hours to a target of 100 mg every 8 hours. Isosorbide dinitrate can be initiated at 20 mg three times daily and increased with each dose to a target of 60 mg three times daily.

A serum sodium level of less than 135 meq/L developing during the course of acute myocardial infarction or chronic congestive heart failure suggests that the patient’s blood pressure is critically dependent on various compensatory mechanisms designed to support blood pressure, such as production of antidiuretic hormone and angiotensin. In such patients, heart failure therapy with ACE inhibitors may result in substantial or profound hypotension.

3. DIGOXIN—Digoxin is frequently administered to patients with heart failure who do not respond to one or two doses of intravenous furosemide. Since digoxin may increase myocardial O_2 consumption and may aggravate ventricular arrhythmias, it should be given orally at a dose of 0.125–0.25 mg daily. The administration of a “loading dose” of digoxin is unnecessary unless rapid atrial fibrillation coexists with heart failure and rapid control of ventricular rate is desired.

C. Cardiogenic Shock—The mortality rate for cardiogenic shock complicating acute myocardial infarction still remains over 50%. Treatment may include the following.

1. INCREASE INTRAVASCULAR FLUID VOLUME—Volume expansion with 250–500 mL of normal saline may be used as the first treatment for cardiogenic shock if no evidence of left ventricular failure is present (ie, no rales and absent S₃ gallop). If no clear response is seen (ie, blood pressure does not increase), more fluid may be administered, but consideration of pressor agents or right-sided heart catheterization (or both) should be high on the list of subsequent priorities.

2. VASOACTIVE AND INOTROPIC AGENTS—Intravenous dopamine in the range of 5–25 µg/kg per minute may be given to raise the systolic blood pressure to more than 90 mm Hg or to otherwise maintain organ perfusion. Intravenous dobutamine given in doses of 2.5–25 µg/kg per minute is frequently helpful in cardiogenic shock. This agent is particularly useful because it is both a vasodilator and an inotropic agent. Despite its vasodilator properties, in patients with a markedly reduced cardiac output, dobutamine infusions frequently result in an increase in blood pressure as a result of increased cardiac output.

If either of these agents is required for more than a few minutes to an hour, placement of a pulmonary artery catheter is warranted so that the dose of each agent can be adjusted to meet hemodynamic goals. The simultaneous administration of dopamine (6–7 µg/kg per minute initially) and dobutamine (3–4 µg/kg per minute initially) may be useful in increasing both the blood pressure and the cardiac output in patients with acute myocardial infarction and severely compromised hemodynamics. These dosages are an empirical starting point. A right-sided heart catheter is required for rational adjustment of these two pressor agents.

Milrinone has a hemodynamic profile similar to that of dobutamine, but it is much more costly. This phosphodiesterase inhibitor does not demonstrate the rapid tachyphylaxis seen with β-adrenergic agonists. If long-term high-dose catecholamine support is required to maintain cardiac output, milrinone may be a suitable alternative.

3. INTRAORTIC BALLOON PUMP—The intraortic balloon pump should be considered if acute ischemia is suspected as the primary cause of cardiogenic shock. If a patient has continued chest pain after myocardial infarction and develops cardiogenic shock, intraortic balloon pumping may provide a bridge to surgical therapy of shock. The intraortic balloon is inflated in the descending aorta during diastole, thereby increasing coronary perfusion pressure. By deflating during systole, it “unloads” the left ventricle.

D. Heart Block

1. INFERIOR MYOCARDIAL INFARCTION AND HEART BLOCK—Heart block frequently occurs along with acute inferior wall myocardial infarction during which the blood supply to the AV node has been compromised either by ischemia or by infarction. However, temporary pacing is not necessarily indicated if the heart block is Mobitz I (Wenckebach) and the patient's blood pressure and clinical status are stable.

Atropine is very useful for increasing the heart rate in patients with symptomatic bradycardia. An increase in heart rate and blood pressure is seen frequently after a 1-mg intravenous bolus of atropine sulfate. Atropine can be repeated once or twice if necessary. However, serious side effects (eg, dry mouth, blurred vision, and even psychosis) preclude its continued use. Therefore, the development of heart block with hemodynamic compromise (ie, fall in blood pressure, decrease in mentation, or other evidence of peripheral hypoperfusion) should lead to serious consideration of a transvenous temporary pacemaker.

2. TEMPORARY TRANSCUTANEOUS PACING—Transcutaneous pacing may be very helpful as a temporary expedient. The technique is very painful to the patient and should be replaced by transvenous pacemaker placement in high-risk patients likely to require pacing. Transcutaneous pacing is indicated for symptomatic bradycardia (heart rate < 50 beats/min) or bradycardia with hypotension (systolic blood pressure < 80 mm Hg) unresponsive to drug therapy, Mobitz type II second-degree AV block, third-degree heart block and bilateral bundle branch block (BBB)(ie, alternating BBB), new BBB or fascicular block, and right or left BBB with first degree AV block.

3. TEMPORARY TRANSVENOUS PACING—Temporary transvenous pacing in the acute myocardial infarction patient is indicated for the following conditions: asystole, symptomatic bradycardia unresponsive to medications and type I second-degree AV block, bilateral BBB, a new BBB or fascicular block and first-degree AV block, and Mobitz type II second-degree AV block.

4. PERMANENT PACING AFTER ACUTE MYOCARDIAL INFARCTION—Consideration for permanent pacemaker implantation should take place in the presence of persistent Mobitz type II second-degree AV block or complete heart block after myocardial infarction, transient second- or third-degree AV block plus BBB, and symptomatic AV block at any level.

E. Right Ventricular Infarction—Right ventricular myocardial infarction complicates roughly one-third of all acute inferior wall myocardial infarctions. The right ventricle is a very thin-walled structure that is poorly adapted to acute demands of either pressure or volume. The diagnosis of this entity can be made through echocardiography, radionuclide ventriculography, cardiac catheterization, or electrocardiography.

1. DIAGNOSIS—ST-segment elevation in the right-sided electrocardiographic chest leads is the most sensitive test for detecting an acute right ventricular infarction. Lead V₄R is the most sensitive and most specific lead. However, all electrocardiographic criteria begin to dissipate within hours of an acute right ventricular infarction, and the hemodynamic consequences may be more apparent than changes on the ECG. Right ventricular infarction should be suspected in all

patients with acute inferior wall myocardial infarction with hypotension, especially if there is evidence that left ventricular function is preserved. The hallmarks of a hemodynamically significant right ventricular infarction include the presence of elevated neck veins with clear lungs but evidence of poor cardiac output.

2. Treatment

Since right ventricular infarction is a common complication in patients with acute inferior wall myocardial infarction, initial doses of nitroglycerin should be given cautiously to these patients. This is so because right ventricular output may decrease markedly in response to systemic venodilation by nitroglycerin. These patients also may be particularly sensitive to diuretics such as furosemide.

To increase blood pressure and cardiac output in the face of a known or suspected acute right ventricular myocardial infarction, initial therapy should consist of intravenous fluids, provided there is no evidence of pulmonary congestion or a left ventricular S_3 gallop. Patients who fail to respond to fluid infusion with an increase in blood pressure and improved systemic perfusion should be treated next with intravenous dobutamine, preferably with a pulmonary artery catheter to help guide therapy.

F. Other Complications

1. PERICARDITIS—Pericarditis is a common complication of myocardial infarction. If the infarction process involves the epicardium of the left ventricle, irritation of the pericardium may occur. The patient typically complains of chest pain exacerbated by respiration and supine posture; the patient frequently feels more comfortable sitting upright. The appearance of a three-component friction rub representing the left ventricular epicardium rubbing against an inflamed pericardium confirms the diagnosis.

Treatment is generally straightforward. An asymptomatic friction rub heard on routine daily examinations need not be treated. Symptomatic episodes of pericarditis can be treated with either aspirin, 325 mg every 4–6 hours, or nonsteroidal anti-inflammatory agents. Rarely, corticosteroids are required to control post–myocardial infarction pericarditis pain.

Most episodes of pericarditis are self-limited and require no more than symptomatic therapy. If a question regarding a patient's symptoms arises, an echocardiogram that demonstrates an increase in pericardial fluid may be helpful in establishing the diagnosis of pericarditis.

Thrombolytic therapy and heparin (except for subcutaneous heparin for prevention of deep venous thrombosis) should be terminated if pericarditis is suspected or diagnosed after myocardial infarction. Rarely, post–myocardial infarction pericarditis leads to a pericardial effusion sizable enough to cause hemodynamic compromise. The hallmarks of a significant pericardial effusion include an increase in heart rate, an increase in the magnitude of paradoxical pulses,

a decrease in the systolic pressure, a decrease in the systemic pulse pressure, elevated neck veins, and, in advanced stages, evidence of low cardiac output (eg, cool extremities, decreased mentation, and decreased urine output). Should a hemodynamically significant pericardial effusion be suspected, urgent echocardiography should be performed to confirm the diagnosis and to localize the effusion. While the echocardiogram is being performed, cardiac catheterization laboratory personnel should be preparing to perform pericardiocentesis if necessary.

2. PAPILLARY MUSCLE RUPTURE AND VENTRICULAR SEPTAL RUPTURE—These are rare but life-threatening complications of acute myocardial infarction. A murmur consistent with acute mitral regurgitation may be heard in up to 50% of patients with acute myocardial infarction during the first 24–48 hours after the event. However, these mitral regurgitant murmurs usually represent transient papillary muscle ischemia and disappear with time or remain hemodynamically unimportant.

Papillary muscle rupture or an acute ventricular septal rupture should be suspected in patients who develop sudden hypotension or evidence of severe heart failure. The hallmark of both lesions is a loud systolic murmur, often with a thrill palpable over the left chest. The diagnosis of these lesions can be confirmed by echocardiography. Alternatively, since these lesions are usually associated with heart failure and a low cardiac output, a pulmonary artery catheter should be placed to help guide subsequent management. The presence of high (near systemic) O_2 saturation in a right atrial blood sample confirms the diagnosis of ventricular septal rupture (with left-to-right shunting of blood). The presence of a large v wave in the pulmonary capillary wedge pressure tracing may lend support to the diagnosis of left ventricular papillary muscle rupture.

Both these conditions are acute emergencies. Conservative measures usually are insufficient to allow survival. Consideration should be given to urgent cardiac catheterization with anticipation of emergent open-heart surgery.

Cardiothoracic Surgery

Edward D. Verrier, MD

Craig R. Hampton, MD

Primary cardiovascular disease is the most common single indication for ICU care and monitoring. Many patients with other diseases requiring intensive care develop secondary cardiovascular complications. Moreover, cardiac surgery patients remain the most common group of surgical patients requiring intensive care and monitoring. Many of the ICU concerns relevant to cardiac surgical patients are covered in other sections of this text, but certain aspects are unique to this common subset of patients. The following sections cover these unique problems and include aneurysm and dissection of the great vessels, postoperative arrhythmias, perioperative coagulopathy, complications of artificial circulation, and postoperative low-output states.

ANEURYSMS, DISSECTIONS, & TRANSECTIONS OF THE GREAT VESSELS

ESSENTIALS OF DIAGNOSIS

- ▶ Chest pain.
- ▶ Differential peripheral pulses.
- ▶ Aortic insufficiency.
- ▶ Widened mediastinum on chest x-ray.
- ▶ Cardiovascular collapse.
- ▶ End-organ ischemic symptoms.

General Considerations

Disease of the great vessels often presents dramatically and is often lethal if not managed expeditiously. Timely surgical correction or, when appropriate, medical therapy may be lifesaving. However, despite considerable progress in surgical approaches and medical therapies, a minority of patients still faces the specter of complications: potential paraplegia, pre- or postoperative mortality, end-organ injury, delayed

recovery from surgical incisions, or subsequent surgery from disease progression after initial medical or surgical therapy.

Terminology is frequently confusing owing, in part, to the nature of the pathology and because of various classification schemes. Aortic dissections, transections, and aneurysms are related but distinct entities. Aortic dissections and transections predispose to false (pseudo) aneurysms, and aneurysms predispose to dissections, but because of therapeutic and prognostic considerations, it is desirable and usually possible to determine which came first. These three entities frequently present simultaneously as a combined lesion, but the relative contribution of each component of the disease should be considered separately—while appreciating their interrelationships.

Aneurysms of the great vessels (ie, aorta, innominate artery, carotid artery, ductus arteriosus, and subclavian artery) are pathologically either true aneurysms composed of all three layers of the vascular wall or false aneurysms containing only adventitia and periaortic fibrous tissue. True aneurysms result from transmural degeneration of the structural components of the vessel (eg, Marfan's syndrome, residual ductus arteriosus tissue, ectatic vein grafts, and aortic disease associated with obstructive lung disease) or from a localized degeneration of vascular layers (eg, atherosclerosis and vasculitis). False aneurysms usually are due to prior dissection, trauma, prior great vessel surgery, or rarely, tumor. Descriptively, both true and false aneurysms are either saccular or fusiform (Figure 23–1). Classification of great vessel aneurysms based on location and extent is helpful for diagnosis, prognosis, and therapy. Aneurysms that involve the arch are more technically complex than those isolated to the ascending or descending aorta. Because they usually require circulatory arrest for repair, they have an increased potential for neurologic injury. Repair of aneurysms that traverse the diaphragm are more prone to cause paraplegia because of their proximity to the arterial supply of the anterior spinal artery. Aneurysms that involve the aortic root are likely to require coronary reimplantation

▲ **Figure 23-1.** Types of thoracic aortic aneurysms. **A.** Fusiform. **B.** Saccular. (Reproduced, with permission, from Way LW (ed), *Current Surgical Diagnosis & Treatment*, 10th ed. Originally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

and valve resuspension or replacement. Hence they have increased risk for myocardial ischemia and the potential complications associated with valvular surgery. Extensive aneurysms of the entire aorta may require a staged approach with initial replacement of the ascending aorta, followed by the arch, and subsequently by the descending thoracic and abdominal portions.

Aneurysms presumably cause symptoms by expansion, compression of local structures, distal embolism of contained material, secondary dissection, and either contained or free rupture. The frequency of these complications increases exponentially with aneurysm size.

Etiology

A. Aortic Transection—Aortic transection occurs most commonly after significant blunt trauma and generally occurs at points of relative aortic fixation—in descending order of frequency, near the ligamentum arteriosus, at the diaphragmatic hiatus, at the ascending aorta, and at the abdominal aorta. Shearing stress from rapid deceleration has been regarded as the primary biomechanism of this injury, but recent evidence suggests that lateral-impact collision forces with simultaneous acceleration of the victim and increased hydrostatic pressure within the aorta also may be important mechanisms. In survivable cases, tenuous vascular integrity is maintained by the adventitia. Early symptomatic presentation usually is exsanguinating rupture or distal dissection, whereas late presentation is in the form of a pseudoaneurysm. Aortic transection occasionally is due to penetrating violent injury or to iatrogenic trauma during cardiac or other surgery.

B. Aortic Dissection—Aortic and other great vessel dissections represent pathologic separation of the vessel layers, thereby creating a true lumen and a false one. Since aortic tissue is intrinsically stable, there is usually associated pathology

such as disease of the intima or media (eg, atherosclerosis, cystic medial necrosis, or Marfan's syndrome), increased wall tension (eg, preexisting aneurysm or hypertension), or trauma (blunt or sharp). Indeed, the two conditions most frequently associated with aortic dissection are hypertension (about 80%) and Marfan's syndrome. Mechanistically, rupture of the vasa vasorum is probably the most important inciting event. It is not clear whether spontaneous bleeding into the aortic wall (ie, intramural hematoma) may cause aortic dissection. Dissections are usually complex anatomically and dynamic in presentation. Once the intimal tear occurs, there is progressive separation of the adventitia and the intima. This separation typically propagates distally but occasionally may extend proximally. As the separation extends, branch vessels may be themselves dissected, occluded, or completely unaffected depending on the location and extent of the aortic dissection. Ultimately, the dissection reaches an equilibrium between the vessel's intrinsic resistance and shear forces that promote propagation. The dissection then either reenters the true lumen via a second or third tear in the intima or creates a blind pouch. These "neostuctures" then may remain permanently patent because of continued flow down the false channel, or they may thrombose owing to stasis. These dynamics of aortic dissection are a function of the balance between tissue strength and continued shear forces. Shear forces, in turn, are determined by blood pressure, change in blood pressure with time (dp/dt), size and location of the intimal tear, and blood vessel diameter.

Two classification schemes are used commonly, based on the location and extent of dissection—the Stanford and DeBakey classifications. A Stanford type A dissection begins in the ascending or transverse aorta with variable amounts of aortic involvement. Type B dissections begin distal to the takeoff of the last great vessel, usually the left subclavian artery. By comparison, a type I DeBakey lesion is analogous to an extensive Stanford type A dissection. Both begin in the ascending aorta and extend across the arch and down the descending aorta. A DeBakey type II dissection involves only the ascending aorta, whereas a type III DeBakey lesion is analogous to a Stanford type B dissection.

These classification schemes are vital to management and prognosis, with particular emphasis on identifying involvement of the ascending aorta. Type A dissections have an 80% mortality within 48 hours without surgical treatment, whereas selected type B dissections frequently can be managed medically with only a 10% mortality at 30 days. These vastly different outcomes are based primarily on the proximity of type A dissections to vital structures, including the heart, coronary arteries, aortic valve, and carotid vessels. Myocardial infarction, acute aortic insufficiency, intrapericardial rupture causing tamponade, and stroke are all frequent consequences of proximal dissections. In addition, progression of a type A dissection may result in all the complications normally associated with a type B dissection such as intrathoracic rupture, paraplegia, visceral ischemia, extremity ischemia,

and intraabdominal rupture. Fortunately, many of the structures affected by type B dissections are either paired (eg, renal), tolerate ischemia for long periods of time (eg, extremities), or have collateral pathways (eg, GI tract) for blood supply.

Other changes related to the dissection process include (1) lability of the blood pressure to fluid shifts, cardiac decompensation, baroreceptor involvement, and underlying etiology, (2) coagulopathy from massive blood exposure to tissue, (3) metabolic derangements from hypoperfusion, (4) respiratory compromise from systemic inflammation and local airway compression, (5) any variety of neurologic, renal, GI, cardiac, and extremity complications, and (6) progression to chronic pseudoaneurysm or, rarely, stenosis or obstruction of the aortic lumen. The surgical risks and adverse effects of therapy multiply with extent and acuity of the disease process.

Clinical Features

A. Symptoms and Signs—Any patient with significant chest pain should be assumed to have an aortic catastrophe until another cause is established. Discrepancies in peripheral pulses and blood pressures occur frequently, particularly in the presence of aortic valve insufficiency. Changes in pulse contour or distribution may help to localize the extent of a dissection or transection. Patients with recent or remote trauma, a family history of Marfan's syndrome, hypertension, or prior surgery of the aorta are at increased risk.

Dissections in particular—and sometimes aneurysms—have myriad presentations, making them a diagnostic challenge. By far the most common symptom accompanying aneurysms, transections, and dissections is chest pain, usually sharp and, less frequently, tearing or ripping, with radiation to the back or abdomen.

Aneurysms may present with pressure symptoms related to the recurrent laryngeal nerve, great veins, trachea, esophagus, or chest wall. Significantly, aneurysms may be asymptomatic until they rupture and present with circulatory collapse.

Any number of end organs may become ischemic temporarily or permanently with their own characteristic symptoms. Temporary neurologic findings are particularly common, but any vascular organ can present with initial or subsequent ischemia.

B. Electrocardiography—Because primary coronary artery disease is more common than significant aortic disease, a normal ECG with normal cardiac enzymes should heighten the suspicion of dissection or aneurysm as a cause of chest pain. However, if a type A dissection extends into a coronary (more commonly the right coronary) artery, an ECG cannot make this distinction. Moreover, electrocardiographic findings occur in about 70% of dissection patients, including nonspecific ST-segment–T-wave changes, left ventricular hypertrophy, ischemia, myocardial infarction with old Q waves, or myocardial infarction with new Q waves.

C. Imaging Studies—A normal chest x-ray is helpful but does not exclude disease. Overlying structures may compromise aortic visibility. Tortuosity of the aorta may falsely suggest enlargement. Aortic transections and dissections may be present in an aorta of normal caliber. However, the majority of cases will show mediastinal widening that mandates further investigation. To evaluate mediastinal widening, a posteroanterior chest x-ray should be obtained because anteroposterior views are frequently misleading. If available, prior films should be examined. Other radiographic findings, in decreasing order of frequency, are abnormal aortic or cardiac contour, displacement or calcification of the aorta, and pleural effusion.

Many patients will have more than one special imaging study to determine the presence and extent of disease. All the examinations mentioned below have sensitivities and specificities greater than 90% when performed and interpreted properly. Probably the most important consideration is to establish *in advance* which approach will be used based on resources and expertise because diagnosis must be rapid.

In the past, angiography was standard for evaluating aortic disease, and it still has many advantages over other techniques. Angiography has sensitivity and specificity similar to those of other examinations, provides an assessment of flow to vessels from both the true and false lumens, permits coronary angiography to be obtained simultaneously in selected patients, allows evaluation of aortic insufficiency, and frequently establishes the etiology of the disease. Disadvantages include its invasive nature, the possibility of iatrogenic catheter injury, peripheral access problems secondary to dissections or underlying obstructive disease, contrast load, occasional inadequate visualization of a nonperfused false channel, and nonvisualization of surrounding structures. Furthermore, angiography is more time-consuming than other diagnostic techniques (see below), and delay in diagnosis may contribute to further morbidity and mortality. With these considerations, echocardiography and CT scanning are the diagnostic tests of choice.

CT scanning and MRI provide similar views. CT scanning is more widely available than MRI and usually can be obtained rapidly, but it requires contrast material administration. The sensitivity and specificity of these modalities are excellent, and both provide information about surrounding structures.

Echocardiography—particularly transesophageal echocardiography—has emerged as a valuable technique in the diagnosis of aortic disease and is considered by many to be the preferred diagnostic modality. For adequate visualization, a biplane transesophageal probe is required. Expertise in evaluating the images is crucial. The technique is limited by the presence of intervening structures, particularly those containing air, and distance of the probe from the vessel.

Differential Diagnosis

Pericarditis, myocardial infarction, and primary aortic insufficiency are common cardiac diseases that can have similar presentations. Similarly, pain from esophageal diseases such

as spasm, rupture, tumor, achalasia, and reflux can be confused with aortic symptomatology. Tortuosity and atherosclerosis of the aorta may have a similar appearance on chest x-ray. Tumors may widen the mediastinal silhouette, and pulmonary diseases such as pleural effusions and pulmonary emboli can cause densities on radiographs that may be difficult to differentiate from aortic disease. When this occurs, CT scanning or MRI can be of value. Minor ruptures of the aortic vasa vasorum can widen the aortic shadow without actually producing aortic disruption.

Treatment

A. General Measures—The disease extent and, if applicable, the site of intimal injury should be determined based on clinical examination and studies already available. Patients who are exsanguinating may require immediate operation based on chest x-ray findings alone. Others should be evaluated rapidly and, if ascending aortic disease or aortic transection is confirmed, repaired immediately. Many elderly patients with type B dissections or asymptomatic small (<5 cm) aneurysms may best be managed initially with medical therapy.

Regardless of disease type, patient age, or initial treatment, vigorous continuous medical control of shear forces with antihypertensives and negative inotropes is essential if there is residual abnormal aorta. Patients with aortic transections and localized aneurysms frequently have curative surgery with no remaining diseased aorta. Commonly, when an aortic dissection is present, only a portion of the aorta is repaired, and residual disease requires vigorous treatment and long-term follow-up.

Since diseases of the thoracic aorta can cause morbidity and mortality owing to complex disease, significant comorbidities, and acuteness of presentation, they provide a logical potential application for newer catheter-based therapies that have proliferated in the past decade for the treatment of cardiovascular disorders. Indeed, endovascular stent grafts have been used in both elective and emergent settings for thoracic aortic dissection, aneurysmal disease, and blunt injury to the thoracic aorta. Furthermore, percutaneous fenestration of the intimal flap has been performed successfully to restore perfusion to end organs when ischemia results from dissection. As long-term results of these therapies become available and as new technology develops, the indications for the use of percutaneous-based therapies in diseases of the thoracic aorta will become clearer.

B. Blood Pressure Control—Rapid, continuous control of blood pressure and pulse pressure should be pursued aggressively immediately following diagnosis. Systolic blood pressure should be kept below 110 mm Hg systolic. The force of left ventricular contraction (dP/dt) should be minimized by administering negative inotropes.

An intraarterial monitoring line is vital during the early phases of treatment because of the potential for rapid alterations in blood pressure. The arterial line should be used until documented continuous blood pressure control is accomplished.

Central venous pressures should be monitored and fluid status optimized. Patients with severe blood loss, intrapericardial blood and tamponade, or end-organ ischemia may require volume replacement. Cardiovascular function is frequently labile, and inotropes and vasopressors may be required while definitive diagnosis is established.

A single, ideal drug applicable to every situation does not exist, but several aspects of the many available antihypertensives are useful. The rapidity of onset, half-life, potency, distribution, metabolism, degradation products, side effects, and physiologic effects all should be considered. Use of a short-acting vasodilator (eg, IV nitroprusside) in combination with a negative inotropic agent (eg, IV esmolol) effectively reduces both blood pressure and the force of blood ejection.

Vasodilators commonly used include nitroprusside, hydralazine, and nitroglycerin. Nitroprusside is well tolerated, extremely potent, rapid-acting, and has a short half-life. Its disadvantages include an increase in dP/dT when used alone, elevation of pulmonary shunt, and creation of a toxic metabolite (cyanide) with prolonged high-dose use. Hydralazine is longer-acting and available orally, making it a suitable agent for long-term use. Nitroglycerin decreases cardiac output and blood pressure through direct venodilation but has little effect on arterial relaxation. Thus its usefulness for disorders of the thoracic aorta is limited, and it should not be regarded as a first-line agent.

β -Blockers are available in short-acting (eg, esmolol) and long-acting (eg, atenolol) forms. As such, they are usually a part of both short- and long-term management. Of the many β -blockers available, esmolol offers the advantage of an extremely short half-life, allowing precise and frequent dosing adjustments toward optimal blood pressure. Labetalol is also an efficacious agent because of its blockade of both β -adrenergic and β -adrenergic receptors. With this said, for acute blood pressure control, β -blocker therapy combined with sodium nitroprusside, as needed, is regarded as the therapy of choice.

Calcium blockers produce both decreased blood pressure and decreased contractility. They are of greatest benefit in long-term management. Their relatively long half-life limits use acutely during unstable periods.

Central sympatholytics include trimethaphan, clonidine, methyldopa, and reserpine. They are used less commonly but do have a role in acute and chronic care as adjuncts to standard drug regimens.

▶ Postoperative Arrhythmias

ESSENTIALS OF DIAGNOSIS

- ▶ Variable heart rate.
- ▶ Regular or irregular rhythm.
- ▶ Electrocardiographic abnormalities.
- ▶ Altered peripheral perfusion.

General Considerations

Significant cardiac dysrhythmias occur in up to one-third of postoperative cardiac surgical patients. Age is the most consistently identified predictor of postoperative arrhythmias, although many other risk factors exist, including valvular disease, cardiomyopathy, ischemia, reperfusion, adequacy of myocardial protection, metabolic derangements, adrenergic states, medications, temperature, and mechanical irritants.

Arrhythmias should be classified first by ventricular rate. The rhythm then is subclassified according to its origin—supraventricular or ventricular—by establishing the rate of the atrium and evaluating the status of the atrioventricular (AV) conduction system. Bradycardias include sinus bradycardia, heart block, sinus arrest, and slow junctional rhythms. Tachycardias include (1) supraventricular arrhythmias (eg, atrial fibrillation, atrial flutter, premature atrial contractions, paroxysmal atrial tachycardia, and fast junctional rhythms) and (2) ventricular tachycardia, flutter, fibrillation, and premature ventricular contractions. Conduction defects include heart block, bundle branch block, and preexcitation. Sometimes, the origin of a rapid arrhythmia is indeterminate and should be referred to as a *nonspecific wide complex tachycardia*.

Etiology

The etiology of perioperative arrhythmias is multifactorial. Mechanistically, they can be separated into ectopic foci and reentrant circuits. Both originate either from abnormal cardiac tissue affected by ischemia, hypertrophy, dilation, cardiomyopathy, and scar or from normal cardiac tissue induced by inotropes, endogenous catecholamines, autonomic stimulation, and metabolic derangements.

A. Intrinsic Factors—Age is associated with supraventricular arrhythmias and heart block in both cardiac and other thoracic surgical patients. The etiology of this association is unclear, but the incidence in patients over 65 years of age is high enough to warrant prophylactic therapy in many cases. To this end, β -blockers (eg, sotalol) and amiodarone are commonly used agents. Although routine preoperative prophylaxis against postoperative arrhythmias (particularly atrial fibrillation) remains controversial, it is increasingly supported by emerging data. Intrinsic cardiac disease, including cardiomyopathy, acute coronary insufficiency, valvular heart disease, congenital lesions, pulmonary hypertension, ventricular outflow obstruction, and ventricular failure, also increases the incidence and severity of arrhythmias in both the preoperative and postoperative periods.

Cardiomyopathy, both ischemic and nonischemic, as well as dilated and nondilated, frequently causes both atrial and ventricular rhythm irregularity and is one of the more common presenting complaints. Surgical therapy (excluding aneurysm resection and endocardial ablation) frequently does not eliminate the cause. Atrial arrhythmias can result from primary involvement of atrial muscle or secondary dilation of atrial chambers by ventricular failure. Ectopic foci and reentrant circuits are the primary underlying causes, but the metabolic complications of diuresis and inotropes frequently contribute. Ventricular rhythm disturbances develop by these same mechanisms and are often life-threatening.

Acute coronary arterial insufficiency frequently presents with severe arrhythmias (particularly ventricular) or heart block. They can recur or present postoperatively from residual or recurrent ischemia and reperfusion injury.

Valvular heart disease frequently has residual that predispose to arrhythmias despite correction of the valvular lesion. The conduction system is anatomically close to valvular structures and is easily interrupted.

Endocarditis is particularly likely to be associated with heart block pre- and postoperatively. Aortic disease leads to left ventricular hypertrophy or ventricular dilatation, both of which predispose to reentrant circuits or arrhythmic foci. Mitral and tricuspid valve disease most commonly causes atrial arrhythmias, primarily fibrillation. These should be expected to recur with almost 100% certainty in the postoperative period.

Congenital lesions frequently are associated with abnormalities of the location and function of the conduction system and with chamber enlargement or hypertrophy. All these factors contribute to ectopic foci and reentry. Wolff-Parkinson-White syndrome is a common congenital lesion of the conduction system predisposing to reentrant AV rhythms. Gross anatomic disease is also occasionally associated with specific rhythm changes. In particular, Ebstein's anomaly may be complicated by Wolff-Parkinson-White syndrome, tetralogy of Fallot is associated with right ventricular arrhythmic foci, and certain types of transposition result in abnormal conduction anatomy and an increased incidence of perioperative heart block. Pulmonary and pulmonary

vascular abnormalities are superimposed on all these lesions and result in right ventricular enlargement and hypertrophy, tricuspid regurgitation, and secondary atrial arrhythmias.

B. Extrinsic Factors—Mechanical irritants (eg, chest tubes, central catheters, blood, and tamponade), metabolic derangements (eg, hypo- or hypermagnesemia, -kalemia, -phosphatemia, and -calcemia), adrenergic or vagotonic states, and cardiovascular drugs are frequent in the postoperative period and can induce and aggravate arrhythmias.

Clinical Features

The approach to the diagnosis of rhythm disturbances in the postoperative period is similar to that presented elsewhere. However, because of the unique perioperative factors that contribute to arrhythmias, an organized, rapid, and complete evaluation is crucial.

A. Symptoms and Signs—Patients with cardiac arrhythmias in the perioperative period have findings identical to those seen in nonsurgical patients. They may have more profound and acute circulatory compromise owing to residual anesthetic agents, cardiopulmonary bypass effects, ongoing hemorrhage, metabolic derangements, volume shifts, hypothermia, and residual cardiac disease.

B. Electrocardiography—Unique to cardiac surgical patients is the frequent presence of ventricular or atrial pacing wires, which can provide valuable information and management options. Twelve-lead surface electrocardiographic tracings should be compared with preoperative and earlier postoperative examinations for evidence of ischemia, rhythmicity, conduction abnormalities, QRS-complex and ST-segment abnormalities, and QT-interval prolongation.

If the rhythm cannot be diagnosed conclusively, an atrial ECG should be obtained by attaching one or more of the atrial pacing wires (if not in use for pacing) to the electrocardiographic machine or bedside monitor. A predetermined configuration on the 12-lead machine is usually used, and the tracings based on the atrial wires will emphasize the atrial portion of the rhythm despite its small muscle mass.

Signal-averaged ECGs and programmed electrical stimulation are beyond the scope of this text but should be pursued on an individual basis to establish a diagnosis, stratify risk, and evaluate the effects of treatment.

C. Laboratory Findings—Arterial blood gases and electrolytes should be obtained to exclude acidosis, alkalosis, and electrolyte abnormalities. Serum potassium and calcium levels merit particular attention.

Invasive Hemodynamic Monitoring

Invasive hemodynamic monitoring with arterial lines and flow-directed pulmonary artery catheters typically is performed to assist with management after cardiac surgery. Analysis of these data is invaluable in the diagnosis and management of postoperative arrhythmias. Furthermore,

confirmation of appropriate waveforms (eg, pulmonary capillary wedge pressure and pulmonary artery pressure) with the pulmonary artery catheter may decrease the suspicion of mechanical irritation from the catheter, significantly contributing to the arrhythmias.

Differential Diagnosis

Problems peculiar to postoperative cardiac surgical patients that may lead to arrhythmias include hypovolemia, bleeding, pericardial tamponade, tension pneumothorax, thrombosis or dehiscence of a prosthetic valve, coronary ischemia, and hypoxia. Care must be exerted to ensure that the bedside monitor is working correctly and that observed rhythms are not due to electrical interference.

Treatment

A. Antiarrhythmics—Arrhythmias are frequent postoperatively, and prophylaxis with a variety of agents appears effective. In particular, β -blockers reduce the incidence and severity of atrial arrhythmias and probably prevent some ventricular arrhythmias. Although there is conflicting evidence, magnesium appears to have some antiarrhythmic effects and may reduce the incidence of atrial fibrillation, atrial flutter, and ventricular arrhythmias as well. Calcium channel blockers may have similar benefits, but these agents are less well studied in the postoperative context. Amiodorone, a class III agent, has been shown recently, albeit in a very small study, to reduce the incidence of postoperative arrhythmias when administered perioperatively. Further discussion of the medical treatment of arrhythmias is found in detail in Chapter 22.

B. Cardioversion—In addition to pharmacologic measures, preparation should be made for rapid cardioversion in patients at high risk for severe ventricular arrhythmias. Patients who have had ventricular fibrillation perioperatively may require immediate cardioversion. Equipment should be ready at the bedside and attached to the patient. Much of the morbidity of severe ventricular arrhythmias can be avoided by immediate cardioversion.

The rhythm type and chamber of origin—atrial, junctional, or ventricular—should be established. If the atrial arrhythmia is fast and poorly tolerated (ie, symptomatic), immediate electrical conversion is warranted. To convert atrial fibrillation or flutter, high-energy shock usually is required and always should be synchronized. Overdrive atrial pacing may be performed at the bedside using the atrial epicardial pacing wires. This is most effective for supraventricular tachyarrhythmias such as atrial flutter and paroxysmal atrial or AV junctional reentrant circuits. Rapid atrial pacing also can interrupt a reentrant circuit such as atrial fibrillation, thereby restoring sinus rhythm, although less effectively. When performing overdrive pacing, great vigilance must be exercised to ensure that the atrial leads—rather than the ventricular leads—are attached to the generator.

Ventricular tachycardia frequently can be terminated with low-energy synchronized cardioversion. Ventricular fibrillation should be treated immediately with high-energy defibrillation, usually unsynchronized. Both defibrillation and cardioversion can worsen the existing rhythm, so one must be prepared to increase electrical output rapidly and defibrillate again. If the rhythm is bradycardiac or becomes so following electrical or chemical conversion, ventricular pacing should be instituted immediately. After an adequate heart rate is obtained with ventricular pacing, the patient can be converted to atrial or AV sequential pacing if wires are available. If wires are not available or do not function, temporary transvenous pacing (eg, balloon-guided or pacing pulmonary artery catheter wires) can be attempted.

C. Supportive Measures—If prophylaxis has been unsuccessful, the first objective is to maintain adequate oxygen delivery and pH control with optimal ventilation. Circulatory support with cardiopulmonary resuscitation (CPR) may be necessary while preparations are made for electrical cardioversion. CPR procedures in cardiac surgery patients are similar to those followed under other circumstances. Closed chest compressions are effective in cardiac surgery patients and should be used when indicated, as in any other resuscitation effort. If a pulse is obtained with CPR, continued efforts at external electrical conversion can be pursued, but if perfusion is inadequate or external electrical conversion is unsuccessful, open cardiac massage and internal paddle defibrillation should be considered.

After initial control with electrical conversion in unstable patients—and primarily in stable patients—the rhythm should be evaluated for type and probable causes. Many rhythms are caused by temporary derangements and are best treated by eliminating the primary cause. Almost all antiarrhythmic drugs have adverse side effects even when used appropriately, and many (perhaps all) are proarrhythmic. Careful consideration of the risks and benefits of drug therapy is vital because the complications of therapy sometimes are worse than the underlying arrhythmia. The safest therapies are to optimize electrolytes, decrease sympathetic stimulation, remove mechanical causes, treat ischemia, and allow some temporary arrhythmias (owing to reperfusion) to resolve spontaneously with careful monitoring.

Atrial arrhythmias are particularly common and usually cannot be allowed to persist because they are accompanied by symptomatic tachycardia. The rate of conduction of atrial fibrillation and flutter through the AV node can be blocked with digoxin, β -blockers, and calcium channel blockers singly or in combination. After adequate rate control is established, conversion of the arrhythmia can be accomplished with a class Ia antiarrhythmic agent (eg, procainamide or quinidine). The risk of treating relatively benign atrial arrhythmias with class I agents should be appreciated because there is a chance of inducing ventricular arrhythmias.

Ventricular arrhythmias in the postoperative period require individual evaluation of the circumstances, prior

therapy, and risks of drug treatment. Unless a specific cause is found and removed, most arrhythmias will recur, requiring drug or device therapy to block the effects. For this reason, symptomatic ventricular arrhythmias (eg, tachycardia or fibrillation) almost always should be corrected.

▶ Bleeding, Coagulopathy, & Blood Product Utilization

ESSENTIALS OF DIAGNOSIS

- ▶ Excessive chest tube output.
- ▶ Hypovolemia.
- ▶ Bleeding from needle puncture sites.
- ▶ GI or endotracheal tube bleeding.
- ▶ Rash, hematuria.
- ▶ Abdominal or groin distention.
- ▶ Respiratory compromise.
- ▶ Neurologic event.
- ▶ Evidence of tamponade.

General Considerations

Hypocoagulable and hypercoagulable states are known complications of all major surgery but are particularly common following cardiovascular surgery. Both may adversely affect outcome. Factors contributing to a hypocoagulable state include the underlying pathology and anatomy of the heart or great vessel disease itself and a variety of intrinsic coagulation abnormalities owing to hepatic failure, uremia, drugs, and cardiopulmonary bypass. Hypercoagulability results from intravascular stasis, endothelial injury, implanted foreign bodies, and derangement of the normal anticoagulant factors by blood loss, surgical complications, cardiopulmonary bypass, and drugs.

Etiology

A number of causes combine to make both bleeding and excessive coagulation two of the most common complications of cardiovascular surgery. Both are reviewed here because of the delicate balance between normal coagulation and pathologic bleeding or clotting. Factors favoring coagulation and decreased bleeding are complicated by the sequelae of excessive thrombosis: myocardial infarction, stroke, or peripheral embolus.

A. Hypocoagulability—The frequency of blood product administration varies widely among institutions, but the incidence of blood and coagulation factor loss in cardiothoracic surgery patients is significant at all centers. The majority of coronary, valvular, congenital, and ascending aortic or arch aortic surgeries performed by current techniques use total cardiopulmonary bypass and systemic anticoagulation with heparin, with or without hypothermia. This remains true even with the recent increased popularity of minimally invasive techniques (“keyhole” surgery) and “beating heart” (ie, off-pump) surgery. Descending thoracic aortic surgery is performed frequently using partial bypass or the “clamp and sew” technique, both of which eliminate or reduce the need for anticoagulation with heparin. Total cardiopulmonary bypass circuits consist of priming solutions, pumps, cannulas, tubing, reservoirs, filters, and oxygenators. Each of these components causes a variety of coagulation changes, including dilution of all blood components by priming solution, consumption and impairment of clotting factors and platelets by contact with component surfaces, release of cytokines and complement, blood and factor injury by direct air contact in the operative field, and injury by turbulence and mechanical stress. Additionally, many operations use hypothermia, which further decreases the activity of existing clotting factors. The length of cardiopulmonary bypass and the degree of hypothermia employed are related to the severity of these changes.

In addition to these deleterious changes are the effects produced by heparin. High-dose heparin (100 units/kg) is necessary for current bypass circuits to prevent circuit thrombosis. With the use of heparin-bonded bypass circuits, lower-dose heparin may be as efficacious, although this is currently the focus of active investigation. The majority of heparin's effects are counteracted by protamine administration after weaning from cardiopulmonary bypass. Protamine, however, is itself a weak anticoagulant, and the heparin-protamine complex thus formed impairs platelet and factor function until cleared from the bloodstream by the reticuloendothelial system. Occasionally, heparin-induced antibodies or protamine intolerance complicates the perioperative course and requires specific therapy as outlined below. The development of bypass circuits with improved biocompatibility (eg, heparin-bonded circuits) may decrease the heparin—and thus the protamine—requirements. Further, there is ongoing investigation of heparin alternatives, particularly direct thrombin inhibitors

(eg, bivalirudin), for use in cardiac surgery. Partial bypass circuits and shunts that do not require an oxygenator (eg, left atrial to femoral or descending aorta) can be accomplished with little or no heparin in many instances. This is particularly important in traumatic aortic injuries, where anticoagulation is usually contraindicated.

Numerous risk factors identify patients more likely to have hemorrhagic complications and require transfusion therapy. Platelet inhibitors commonly used for treatment and prevention of cardiovascular disorders include newer agents such as the platelet glycoprotein IIb/IIIa receptor inhibitors (eg, abciximab), although aspirin remains the most commonly used medication. Platelet function is reduced dramatically by aspirin for up to 10 days following a single dose. Nonsteroidal anti-inflammatory agents have similar effects but usually are more transient. Heparin therapy preoperatively can result in heparin-antibody-platelet complexes with subsequent thrombocytopenia or occasional thrombotic complications. Warfarin therapy preoperatively typically is reversed by withholding warfarin for several days until measured coagulation tests are normal. Thrombolytics usually are combined with both heparin and antiplatelet therapy and have the additional effect of depleting fibrinogen levels. Antibiotics occasionally result in vitamin K-dependent factor loss. High-dose penicillin-like antibiotics can cause profound platelet dysfunction.

A number of systemic diseases cause specific defects. Uremia primarily affects platelet function, and hepatic failure (primary or secondary to alcohol or congestive heart failure) results in decreased levels and delayed restoration of clotting factors. Cyanotic disease is believed to cause factor and platelet dysfunction. Thrombocytopenia and factor deficiency frequently occur with septicemia associated with endocarditis. Von Willebrand's disease and other inherited platelet and factor abnormalities usually can be identified by a careful preoperative history. Poor tissues are associated with malnutrition, age, organ failure, advanced endocarditis, and connective tissue disease. Transfusion reactions are sometimes difficult to detect but can cause severe coagulopathies.

Reoperations and procedures requiring multiple suture lines, work on abnormal tissue, and extensive operative dissections increase the risk for bleeding. These include all reoperations, aortic dissections and aneurysms, multiple-valve and combined procedures, complex congenital heart disease, and patients who require ventricular support.

Prolonged cardiopulmonary bypass, hypothermia, circulatory arrest, a history of massive intraoperative blood loss, and perioperative cardiovascular collapse all decrease the level and function of platelets and clotting factors. A history of heparin resistance or a protamine reaction frequently heralds a fibrinolytic state, intravascular coagulation, or severe platelet or factor deficiency.

Recent efforts to modify the bypass circuit with heparin bonding or to improve surgical techniques (eg, by minimally invasive or “beating heart” surgery) appear to ameliorate the inflammation and coagulation abnormalities after cardiac

surgery. However, even with these advances, current techniques are only partially effective; thus coagulation abnormalities continue to be a major cause of morbidity after cardiac surgery.

B. Hypercoagulable States—Hypercoagulable states are classically explained by Virchow's triad of stasis, endothelial injury, and systemic hypercoagulability. Stasis is present during low-flow states, periods of immobility, during certain arrhythmias, and intraoperatively during vessel or chamber cannulation or clamping. The risk of major arterial thrombosis and deep venous thrombosis appears to be low in patients who have undergone full anticoagulation. In procedures such as descending aortic replacement with heparinless shunts or without bypass, the risk is similar to that of other thoracotomy and vascular surgery patients. Endothelial injury (ie, abnormal endothelium) is ubiquitous in cardiovascular surgery and includes coronary anastomotic sites, vascular clamp sites, tears in aortic dissection patients, conduits, valves, intravascular or cardiac patches, and numerous arterial and venous catheters. Systemic hypercoagulability occurs after all types of major surgery presumably owing to coagulation factor activation and derangements of factor levels. Naturally occurring anticoagulants, including proteins A, C, and S and antithrombin III, are also frequently depleted, particularly in patients receiving heparin, warfarin, or thrombolytics. In addition to coagulation abnormalities caused by the disease process and its treatment, both inherited and acquired hypercoagulable states (eg, activated protein C resistance), which are being recognized increasingly, also may coexist and contribute to a perioperative hypercoagulable state.

Hypercoagulability is less common than hypocoagulability but has dramatic consequences. Liver disease, either primary or secondary (eg, congestive hepatopathy), also may result in anticoagulant factor depletion. Antifibrinolytics (eg, aprotinin) and desmopressin can result in a hypercoagulable state, and their use should be evaluated critically. Heparin-induced thrombocytopenia (HIT) is an increasingly recognized phenomenon in cardiac surgery and may be a significant contributor to associated morbidity and mortality. HIT can result in thromboembolic complications with significant associated morbidity and mortality. Patients with prior deep venous thrombosis, pulmonary embolism, or thrombophlebitis are especially prone to recurrent thrombosis, and early anticoagulation should be considered. Patients undergoing coronary endarterectomy appear to have an increased risk of graft thrombosis and usually are started on antiplatelet agents immediately after surgery. Areas of stasis are always at risk for thrombosis. These include the deep veins in immobile patients and the left atrium in those with atrial fibrillation or akinetic endocardium after a myocardial infarction. The presence of intravascular foreign bodies may increase the risk of thrombosis. Catheters, patches, valves, conduits, balloon pumps, and ventricular assist devices may cause thrombosis and embolism.

In summary, hemostatic and coagulation abnormalities are very common in cardiac surgical patients and clearly

contribute to associated morbidity and mortality. The etiology often is complicated, involving myriad interrelating factors. Nonetheless, appreciation of these causative factors is important to optimize care of the cardiac surgical patient.

Clinical Features

A. Chest Tube Output—Chest tube output varies widely among patients and over time in individuals. It should be considered in the context of chest x-ray findings, hemodynamics, previous outputs, surgical findings, and the patient's history. Chest tube output is frequently miscalculated as a result of autotransfusion, multiple tubes and containers, and in unrecorded intervals such as during patient transport. These possible errors should be considered, and a reproducible technique of recording and reporting outputs should be established. Many valid definitions of excessive chest tube output exist; in the descriptions that follow, output greater than 200 mL/h for 2 hours is considered significant, whereas output greater than 400 mL/h for 2 hours is considered severe. Chest tube output during the first 2 hours following operation is extremely variable owing to retained blood in the pleural space and lack of drainage during transport. Increased drainage can be expected during this period. Greater than 200 mL/h of drainage after the initial period may indicate the need for reexploration. The average chest tube output over 24 hours is approximately 1200 mL in primary low-risk coronary artery bypass graft patients, but it may be significantly higher after more complex procedures.

If chest tubes are clotted or do not communicate with the bleeding site, cardiovascular instability consistent with hypovolemia frequently will be the presenting sign. Inadequate resuscitation of prior or ongoing severe bleeding presents in a similar fashion.

Patients with excessive drainage from chest tubes should be thoroughly examined for diffuse oozing from other sites such as needle punctures, wounds, and nasogastric tubes. A generalized rash and hematuria should alert one to the possibility of hemolysis owing to a transfusion reaction. Other findings suggestive of bleeding include abdominal or groin distention, respiratory compromise owing to intrapleural blood, low cardiac output owing to tamponade, and neurologic changes from hypoperfusion or intracranial hemorrhage.

B. Thrombosis—An uncommon result of a relative hypercoagulable state is prosthetic valve thrombosis. Although most common in patients not adequately anticoagulated chronically, valve thrombosis can occur at any time in the hospital course and requires immediate diagnosis. A new murmur suggesting outflow or inflow obstruction or valvular insufficiency should be investigated immediately with echocardiography. Hemodynamic changes may be severe.

Arterial occlusions owing to primary thrombosis or secondary to embolus may be subtle or dramatic and are quite common. The arteries at highest risk for primary thrombosis are recent coronary or peripheral grafts, peripheral cannulation sites, and arteries with preexisting stenosis. An arterial

embolus will have a similar presentation, but multiple emboli commonly occur with combined neurologic, coronary, GI, and peripheral findings. Subtle neurologic changes are sensitive indicators of arterial thrombi or emboli. Findings associated with arterial occlusion under normal circumstances may be blurred by perioperative low-flow states, systemic hypothermia, and preexisting arterial disease.

Venous thrombosis or venous embolism (ie, pulmonary embolism) is not seen commonly following cardiac surgery presumably because of systemic anticoagulation during cardiopulmonary bypass. Since lower extremity edema following cardiac surgery is common, owing to increased extravascular water and venectomy incisions, lower extremity venous duplex ultrasound examination is critical for diagnosis when deep venous thrombosis is suspected. In congenital disease, systemic and pulmonary venous patches and conduits are potential sites for thrombosis.

C. Imaging Studies—The routine postoperative chest x-ray should be reviewed in any patient with suspected bleeding. Changes in mediastinal width (corrected for technique), pleural accumulations, and other lesions causing hemodynamic compromise can be diagnosed rapidly.

D. Laboratory Findings—Activated clotting times (ACTs) are obtained routinely to determine the adequacy of anticoagulation during bypass and to assess its reversal by protamine. A normal ACT is between 100 and 120 seconds. Anticoagulation during bypass increases it to over 400 seconds. Limited anticoagulation usually falls in the range of 150–250 seconds.

Thromboelastography gives a rapid assessment of the adequacy of the coagulation cascade and can help to predict the subgroup of patients whose bleeding is due to an underlying disorder. Thromboelastography also can identify unsuspected hypercoagulable patients. Five parameters are measured (Figure 23–2). The specific cause of an abnormal thromboelastogram can be further investigated by routine coagulation tests (described below).

Platelet counts should be obtained in patients with long or complex bypass runs and those with excessive bleeding. However, platelet dysfunction is common perioperatively despite adequate platelet numbers and is probably the most common cause of excessive bleeding. Unfortunately, no simple reproducible test of *in vivo* platelet function is currently available. Template bleeding time can provide some information but is not recommended on a routine basis. It should be obtained in patients with a history of bleeding or refractory postoperative blood loss. A very prolonged template bleeding time (>8 minutes) is suggestive of significant platelet dysfunction.

Routine coagulation tests—international normalized ratio (INR),* partial thromboplastin time (PTT), thrombin time (TT), fibrinogen level, and fibrinogen degradation

▲ Figure 23–2. Quantification of thromboelastograph variables: r = reaction time (time from sample placement in the curette until thromboelastograph tracing amplitude reaches 2 mm [normal range 6–8 min]). This represents the rate of initial fibrin formation and is related functionally to plasma clotting factor and circulating inhibitor activity (intrinsic coagulation). Prolongation of the r time may be a result of coagulation factor deficiencies, anticoagulation (heparin), or severe hypofibrinogenemia. A small r value may be present in hypercoagulability syndromes. K = clot formation time (normal range 3–6 min), measured from r time to the point where the amplitude of the tracing reaches 20 mm. The coagulation time represents the time taken for a fixed degree of viscoelasticity to be achieved by the forming clot as a result of fibrin buildup and cross-linking. It is affected by the activity of the intrinsic clotting factors, fibrinogen, and platelets. Alpha angle (α° ; normal range 50–60°) = angle formed by the slope of the thromboelastograph tracing from the r to the K value. It denotes the speed at which solid clot forms. Decreased values may occur with hypofibrinogenemia and thrombocytopenia. Maximum amplitude (MA; normal range 50–60 mm) = greatest amplitude on the thromboelastograph trace and is a reflection of the absolute strength of the fibrin clot. It is a direct function of the maximum dynamic properties of fibrin and platelets. Platelet abnormalities, whether qualitative or quantitative, substantially disturb the MA. A_{60} (normal range = MA – 5 min) = amplitude of the tracing 60 minutes after MA is achieved. It is a measure of clot lysis or retraction. The clot lysis index (CLI; normal range >85%) is derived as $A_{60}/MA \times 100$ (%). It measures the amplitude as a function of time and reflects loss of clot integrity as a result of lysis. (Reprinted, with permission, from Mallett SV, Cox DJA: Thromboelastography. *Br J Anaesth* 1992;69:307–13.)

products (FDPs)—should be obtained in any patient with severe bleeding who will be receiving factor replacement. The INR is frequently mildly elevated early postoperatively in all patients, but an INR greater than 1.7 in a patient with excessive bleeding should be corrected. TT is extremely sensitive to the presence of heparin, whereas PTT accurately reflects the level of heparin activity. Fibrinogen deficiency and elevated FDPs usually indicate excessive fibrinolysis consistent with consumption coagulopathy. Using the preceding guidelines,

*The INR is the equivalent of the prothrombin time (PT) corrected for the wide interlaboratory variation in reagents and PT results.

the results of routine coagulation tests are used to direct therapy at the specific defects outlined below.

To monitor the proper perioperative anticoagulation in patients with artificial valves and other indications for systemic anticoagulation, the INR is obtained on a daily basis before and after beginning warfarin therapy. The INR is superior to the PT because it minimizes interlaboratory reagent variation. Appropriate levels for given circumstances are outlined below. In occasional patients at high risk for thrombosis or those who may need further invasive procedures postoperatively, heparin is started when deemed safe, and anticoagulation is maintained at a level appropriate for the relative risks using PTT assays or the ACT. When HIT is suspected based on clinicopathologic findings, antibodies to heparin–platelet factor 4 complex should be sought (ie, HIT antibody test), and heparin administration is stopped immediately.

Differential Diagnosis

Bleeding is usually easy to diagnose while chest tubes are in place if they are not clotted and if they communicate with the bleeding site. If the patient is hypothermic on arrival to the ICU owing to surgical techniques, then core rewarming over the first 1–2 hours can be associated with progressive vasodilation, hemodynamic changes, and a fluid requirement that can be mistaken for ongoing bleeding. Pleural accumulations of blood or serous fluid are common, and their drainage can be alarming but benign, as can mediastinal collections. Hemolysis is rarely confused with significant bleeding but should be considered. Intrinsic cardiac dysfunction and congestive heart failure may present with hypotension, hemodilution, and congestion similar to hypovolemia or tamponade, as can any other cause of shock and hypotension.

Arterial thromboembolic complications easily can be confused with poor perfusion owing to low-output states and vasoactive drugs. Vascular spasm is particularly common with mammary artery grafts and can mimic occlusion. Spasm of peripheral vessels may be observed. Cholesterol emboli from an atherosclerotic aortic wall are probably much more common than thromboemboli owing to disseminated clotting. Cholesterol emboli usually present immediately postoperatively and are frequently multiple.

Treatment

A. Bleeding—If postoperative bleeding is apparent, one must immediately ensure the availability of adequate supplies of blood products. Careful fluid balances are crucial and should be reported in a reproducible fashion at appropriate intervals. Patients should be rapidly stratified according to the level of bleeding. Bleeding less than 200 mL/h frequently stops without additional therapy as the effects of cardiopulmonary bypass and anticoagulation resolve. Bleeding greater than 300 mL/h only rarely resolves spontaneously. Severe bleeding (>400 mL/h) frequently requires operation. If the patient is hemodynamically stable, evaluation for a nonsurgical

cause of bleeding may be undertaken provided that preparation for mediastinal exploration is begun and sufficient blood products are available.

If patients can be stabilized and bleeding is less than massive, a check for residual heparin can be performed with an ACT in a few minutes. Protamine then should be administered if the ACT is elevated above baseline. A platelet count should be checked, although an adequate number does not equate with adequate function. Thromboelastography can provide an overview of the level of coagulation, and if it is normal, one should suspect a surgical cause for the bleeding. Routine coagulation tests can be obtained to guide specific factor therapy and to rule out ongoing fibrinolysis.

B. Transfusion—Transfusion therapy is guided by the hemostatic laboratory profile, which should be easily and rapidly obtained. Usually, platelets are the initial therapy because they augment platelet function, supply fresh-frozen plasma, and provide a source of fibrinogen with the same number of donor exposures. If platelet concentrate fails to correct the deficit or severe factor deficiencies are documented, an elevated INR is usually treated with fresh-frozen plasma, and a diminished fibrinogen is treated with cryoprecipitate.

C. Other Agents—Antifibrinolytics such as aminocaproic acid (4–5 g in 250 mL of diluent over 1 hour intravenously, followed by 1 g/h as a continuous infusion) can be added if fibrinolysis is significant; however, most agents should be given preoperatively for full effect. Patients felt to be at high risk for bleeding should be treated prophylactically. Desmopressin acetate (0.3 µg/kg intravenously over 15–30 minutes) is particularly effective in the treatment of patients with platelet deficiency owing to uremia or von Willebrand's disease, but it may cause increased graft thrombosis. Conjugated estrogens and serine protease inhibitors also may be helpful in treatment of uremic bleeding, although consideration always must be given to the risks and benefits of these pharmacologic therapies. Recently, recombinant factor V11a has become available to assist with hemorrhagic complications following cardiac surgery. Although it has been used with success in both the adult and the pediatric population, an evidence-based approach guiding its use is not yet available. Similar to published reports, we have found it useful in the setting of continuing hemorrhage and coagulopathy despite ongoing transfusion of usual products in the absence of surgical bleeding.

If correction of the clotting mechanism does not stop the hemorrhage, immediate surgical exploration is mandatory irrespective of the patient's hemodynamic status.

D. Thrombosis—Clinical (eg, chest pain and hemodynamic changes) and electrocardiographic (eg, ST-segment changes) evidence for coronary graft thrombosis is not infrequently due to graft spasm, particularly with arterial conduits (mammary arteries). In unresolved cases, echocardiography should be obtained to evaluate wall motion in the suspect arterial

territory. Antispasmodics should be instituted (eg, calcium channel blocking agents, nitroglycerin, or phosphodiesterase inhibitors) while diagnostic evaluation continues. Many centers give antispasmodics (eg, calcium channel blockers) prophylactically in an attempt to avoid spasm. If wall motion abnormalities are documented and persist with antispasmodics, angiography may be indicated to confirm graft patency. Reexploration of grafts then is considered on an individual basis.

Peripheral thromboembolism is not uncommon in open-heart surgery and occurs in the presence of a left ventricular thrombus, preexisting vascular disease, and injuries from prior angiography. Additionally, peripheral emboli and thrombosis are frequent in patients with intravascular prostheses or devices, particularly intraaortic balloon pumps and prosthetic valves. All unnecessary foreign bodies should be removed as soon as possible. Patients should be stratified according to risk of thrombosis, and those who subsequently have a thromboembolism despite one level of anticoagulation should be increased to the next level of anticoagulation, and a thorough evaluation of why they failed should be undertaken. Patients with a high risk of thrombosis, delayed onset of long-acting anticoagulants (eg, warfarin), or evidence of current thromboembolism should be treated with rapid-onset anticoagulants (eg, heparin) with appropriate consideration of the risk of bleeding in the perioperative period.

All patients with unexplained or recurrent thrombotic episodes should be evaluated for acquired or inherited thrombophilias, including (at least) resistance to activated protein C (eg, factor V Leiden or HR₂ haplotype), heterozygosity or homozygosity for factor V Leiden or G20210A prothrombin mutation, hyperhomocysteinemia, factor VIII levels, and the presence of lupus anticoagulant. If HIT is suspected, all heparin should be eliminated. If ongoing anticoagulation is needed, then direct thrombin inhibitors or platelet inhibitors can be used until warfarin levels are adequate. Antithrombin III deficiency can be treated temporarily with fresh-frozen plasma and long term with warfarin. The treatment of protein A, C, or S deficiency is approached on an individual basis. Hyperhomocysteinemia is treated indefinitely with folic acid, supplemented with vitamins B₆ and B₁₂ if homocysteine levels do not normalize on folic acid alone.

▶ Cardiopulmonary Bypass, Hypothermia, Circulatory Arrest, & Ventricular Assistance

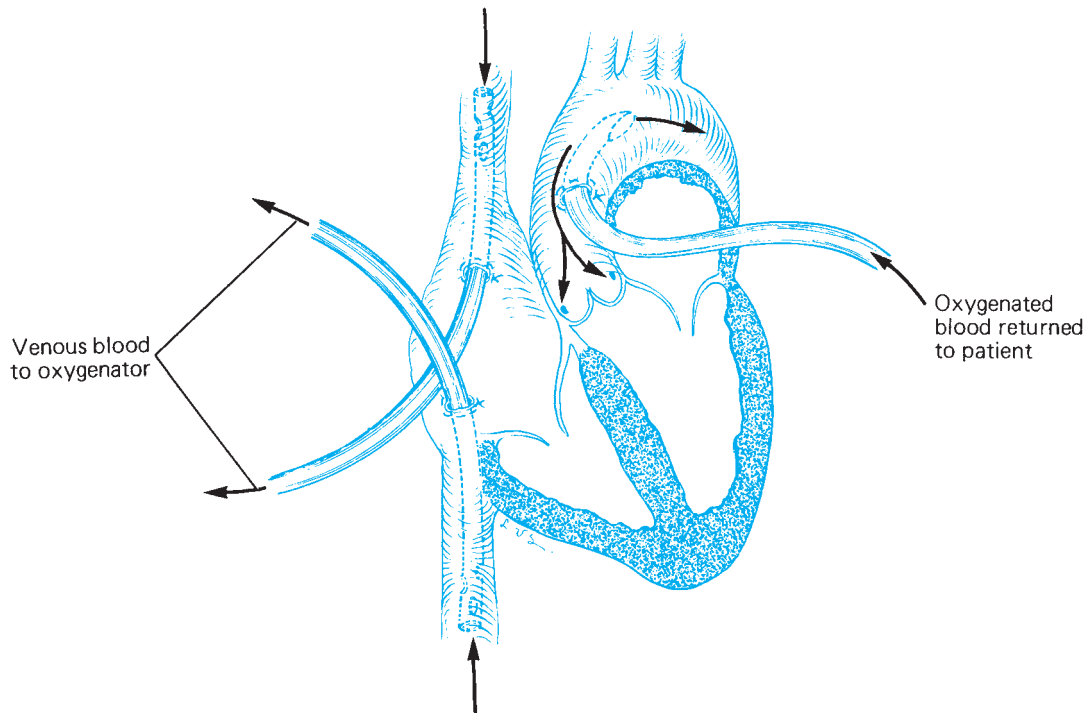

ESSENTIALS OF DIAGNOSIS

- ▶ Decreased peripheral perfusion.
- ▶ Altered end-organ function.
- ▶ Hypothermia.
- ▶ Coagulopathy.
- ▶ Hemolysis.
- ▶ Edema, localized or generalized.

General Considerations

More than 30 years ago, the introduction of cardiopulmonary bypass—and therefore the ability to interrupt and alter the circulation locally and systemically—revolutionized the approach to cardiothoracic and other major surgery of vascular structures. Continued advances in technique have made cardiopulmonary bypass well tolerated, but untoward effects still occur, particularly at the extremes of age. Despite the recent popularity of minimally invasive and off-pump techniques in cardiac surgery, full cardiopulmonary bypass is still used for the majority of cardiac surgical procedures in the United States. An understanding of the pitfalls of cardiopulmonary bypass are crucial to realizing its benefits.

Both total and partial bypass circuits are used on a routine basis and are primed with crystalloid, colloid, or blood if estimated hemodilution will be severe. Total cardiopulmonary bypass begins with drainage of systemic venous blood into a reservoir via a venous cannula. A separate pump-driven cardiotomy suction device can be added to return shed blood from the operative field to the same reservoir. Blood then is actively pumped through an oxygenator/heat exchanger and back to the systemic circulation via the arterial cannula. A number of additional specialized circuits deliver cardioplegia, provide pulmonary venous and collateral drainage (vents), or perfuse localized areas. Arterial and venous cannulas are usually placed in the ascending aorta and right atrium, but a number of locations are used on an individual basis (Figure 23–3). Partial bypass circuits include venovenous bypass (usually with oxygenator), left atrioarterial or right atriopulmonary bypass or ventricular assist (usually without oxygenator), and simple arterioarterial and venovenous shunts, with or without pumps

▲ Figure 23-3. Cannulation sites used commonly in connecting the extracorporeal circuit. Venous blood is drained through tubes introduced into both venae cavae. Oxygenated blood is returned to the arterial system through a tube in the aorta. (Reproduced, with permission, from Way LW (ed), *Current Surgical Diagnosis & Treatment*, 10th ed. Originally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

or oxygenators. Severe adverse effects of cardiopulmonary bypass strictly owing to the circuit itself are rare but include massive air embolism, aortic dissection from cannulas or clamps, general or localized venous congestion from kinked or misplaced return lines; severe hypoxia from oxygenator dysfunction; and a number of unusual but significant events. One or more lesser effects of the cardiopulmonary bypass circuit are nearly universal. Microscopic air, platelet, and cholesterol emboli; direct blood cell trauma; and endothelial injury may occur secondary to mechanical pump or cannulation injury.

Blood contact with the artificial surfaces of the circuit causes a variety of undesirable effects, including systemic inflammation (ie, elaboration of cytokines and leukocyte activation), complement activation, coagulation abnormalities, and endothelial cell activation. Indeed, these changes contribute to the morbidity and mortality of cardiac surgery. Full anticoagulation with heparin (300 units/kg) is required in all circuits to prevent widespread coagulation, although lower anticoagulation protocols may prove equally efficacious as the biocompatibility of the circuits improves (ie, heparin bonding). Partial-bypass circuits—and some full-bypass circuits with heparin-bonded components—

frequently can be maintained with little or no systemic anticoagulation depending on flow, component surfaces, and the effects of the pump, filters, and special devices. Circuit priming solutions and added fluids cause hemodilution, which is frequently helpful in diminishing blood cell loss but may be excessive in patients with low blood volumes. In selected patients with generous prebypass blood cell volumes, whole blood or blood components may be removed prior to bypass for retransfusion postoperatively. This restores coagulation factor activity and reduces homologous blood product utilization.

Perfusion during total cardiopulmonary bypass is almost always nonpulsatile, and flow is maintained at a level to ensure adequate end-organ perfusion based on metabolic demands. Perfusion during partial bypass or ventricular support may be pulsatile or nonpulsatile depending on the circuit and device. Flows in these local circuits are determined by arterial resistances in the native perfused and mechanically perfused beds, left- and right-sided pressures during ventricular support, inflow limitations, technical considerations, and device capabilities. Measured pump flows are felt to be more crucial than blood pressure in patients without vascular stenoses. Typical flows at normothermia

are 2.4 L/min/m², which sustains systemic blood pressure at greater than 40 mm Hg.

Determinants of tissue metabolic demand include tissue activity (primarily skeletal and cardiac muscle), temperature, tissue mass, and preexisting metabolic debt. Certain organs are intrinsically more susceptible to inadequate flows. Brain and spinal cord, heart, liver, kidneys, GI tract, skeletal muscle, and skin tolerate warm ischemia for periods varying between a few minutes and many hours. Metabolic activity of cardiac muscle can be markedly decreased with hyperkalemic or other forms of arrest. Skeletal muscle relaxants vastly decrease the metabolic demands of skeletal muscle. Barbiturates may decrease CNS metabolic demands. In addition to minimizing contraction of cardiac and skeletal muscle, hypothermia is often added to extend the period of safe hypoperfusion. Systemic hypothermia further attenuates metabolic demands and may be used during certain cardiac surgical procedures (eg, coronary artery bypass grafting) to minimize the sequelae of bypass or circulation arrest. The routine use of systemic hypothermia during cardiac surgery remains controversial. The length of time that decreased or arrested circulation is tolerated varies inversely with temperature, with CNS protection being the limiting factor. At core temperatures near or below 18°C, circulatory arrest may be well tolerated for periods exceeding 1 hour in extreme circumstances. However, the safety of the CNS is not guaranteed owing to temperature variations and undesirable metabolic activity.

Following cardiopulmonary bypass, patients usually are anemic because they have gained significant extracellular and intracellular fluid. The combined effects of anesthesia, surgery, and cardiopulmonary bypass produce hypothermia and coagulopathy. The latter is caused by factor loss and activation, hemodilution, and residual heparin and protamine. Ongoing effects are due to reperfusion of tissues inadequately protected or congested during cardiopulmonary bypass. In addition, a number of drugs, anesthetics, blood products, and ongoing insults from cardiac instability make the period immediately following cardiopulmonary bypass unique.

All organs are potential sites of dysfunction, and each should be examined as it becomes accessible to evaluation. Cardiovascular and renal complications are evident almost immediately. Neurologic function frequently is slow to return secondary to anesthetics, particularly in the elderly, but is probably the most sensitive measure of the adverse effects of cardiopulmonary bypass. Indeed, much of the impetus for off-pump techniques was directed toward minimizing the neurologic sequelae that occur frequently after bypass. Short-term memory loss, focal defects, choreoathetoid motions, paraplegia, confusion, worsening of previous neurologic deficits, seizures, and visual changes occur frequently and are presumably due to edema, microemboli, hypoperfusion, residual anesthetics, and drugs and the systemic effects of cardiopulmonary bypass. GI function usually returns within 24 hours, and persistent GI complaints are rare. The extremities may be hypoperfused individually or in concert and occasionally are sufficiently ischemic to result in tissue (usually muscle) loss.

A. Circuit-Related Complications—Circuit-related complications are infrequent following cardiac surgery but are serious when they occur. Full knowledge of the type, location, and variations of the cannulas used during bypass or ventricular support is essential to evaluate subsequent problems. Complications include aortic dissection from ascending aortic cannulation; arterial occlusion from peripheral cannulation; congestion of the upper body, lower body, or both from venous cannulation mishaps; and obstruction, leakage, and cavitation of indwelling cannulas owing to kinking, disrupted connections, or excessive pump flows. Monitoring lines are frequently placed in unusual locations, particularly in patients with congenital disease and in those with ventricular assist devices. Familiarity with their care and use is essential.

Certain bypass components are related more frequently than others to adverse effects. Oxygenators are either of the membrane or bubble type, with a trend nowadays toward membrane oxygenators because of a perception that they are associated with fewer deleterious effects because a “membrane” separates blood from air. Roller pumps or centrifugal pumps are used for total cardiopulmonary bypass. Centrifugal pumps are used more commonly because there is less blood component trauma and less chance of massive air embolism. Care providers of patients with ventricular assist devices should familiarize themselves with the anatomy, connections, components, and monitoring associated with individual patient situations. The complications in these patients secondary to circuit failure are characteristically immediate and severe. A familiarity with typical operative circuits also provides excellent background for diagnosis of related problems.

B. Coagulation Parameters—Profound heparin anticoagulation is required for cardiopulmonary bypass. Protamine is used intraoperatively to reverse the heparin effect. Inadequate anticoagulation results in consumption coagulopathy; with inadequate protamine, rebound heparinization may occur. Significant protamine reactions are infrequent but may result in hypotension, coagulopathy, pulmonary hypertension, and massive pulmonary edema.

C. Crossclamp Time and Hypothermia—Crossclamp time primarily applies to cardiac procedures, but any organ that was isolated from systemic cardiopulmonary bypass support should be considered at special risk. With current organ protection techniques, crossclamp time does not always represent ischemia and may in fact be beneficial, but the circumstances and length of altered organ perfusion should be considered.

The degree of hypothermia and the length of decreased or absent systemic perfusion should be established to raise the index of suspicion for complications of these interventions. At the extremes of age, systemic effects are common, as outlined below. The extent of rewarming is variable, and ongoing temperature changes have significant effects.

D. Fluid and Drug Administration—To monitor the course of the operation and to assist with postoperative fluid management, both perfusion and anesthesia records should be evaluated. Intake and output fluids—including blood loss, hemoconcentrators, urine output, red blood cell scavenger, acute blood donations, cardioplegia, chest tube autotransfusion, rapid infusers, and priming solutions—should be considered carefully.

Inotropes, pressors, vasodilators, inhaled and intravenous anesthetics, paralyzing agents, antiarrhythmics, anticoagulants, and antibiotics are a routine part of cardiopulmonary bypass and have altered effects, kinetics, and distribution volumes in the bypass circuit itself and in cold, artificially perfused organs. As in all critically ill patients, effects of current and past drugs should be considered as the cause of a variety of complications.

E. Surgical Details—The specifics of the operative procedure, particularly in unusual cases, are essential to understanding ongoing problems. Complex aortic procedures, congenital disease, valvular disease, and noncardiac surgery requiring cardiopulmonary bypass frequently have unique complications secondary to old and new anatomy and physiology.

Diagnosis

A. Peripheral Perfusion—Alterations in generalized or local perfusion can result from prior cardiopulmonary bypass or ongoing cardiac support with assist devices. Peripheral pulses should be examined immediately following operation or device placement so that the severity of subsequent changes can be appreciated fully. Peripheral perfusion is frequently decreased immediately following cardiopulmonary bypass owing to vasoconstriction from hypothermia but should return to normal when normothermia is reached.

A general evaluation of all major tissue beds should be performed early. Examination of the circulation, including peripheral pulses, ankle/brachial pressure indices, duplex examinations of vascular beds with abnormal perfusion, ophthalmologic examination, and angiography, should be pursued early when localized changes are noted. Cardiovascular parameters, including filling pressures, outputs, vascular resistances, and oxygen saturations, should be reviewed. Pulmonary function may change dramatically with reperfusion, and blood gases—particularly PaCO₂ levels—increase rapidly with rewarming and inactivation of muscle relaxants. Renal function is normally quite brisk owing to excess fluid and mannitol administration surrounding the period of cardiopulmonary bypass. Low urine output may indicate renal hypoperfusion. Neurologic dysfunction is present in almost all patients to a mild degree when evaluated by psychometric testing. Single and multifocal CNS defects result most commonly from thromboembolism and hemorrhage. Watershed defects frequently are due to inadequate local or generalized flows. More severe psychometric defects, seizures, blindness, and choreoathetoid movements

may result from air embolus, microparticulate emboli, hypoxia, profound anemia, or hypoperfusion. Paraplegia from regional hypoperfusion, aortic dissection, or embolism is rarely seen with full cardiopulmonary bypass but may occur in up to 40% of patients with complex thoracoabdominal procedures with or without artificial support. GI and hepatic symptoms, including abdominal pain, ileus, ascites, and GI bleeding, may represent prior or ongoing venous congestion or arterial hypoperfusion.

B. Hypothermia—Numerous local temperatures are measured during bypass. Core temperature should be evaluated postoperatively, and other localized temperatures (ie, axillary and rectal) should be correlated.

C. Coagulopathy—Coagulopathy and hemolysis usually are most evident during or immediately after cardiopulmonary bypass, respectively, and both may herald a complicated post-cardiopulmonary bypass course. Examine for diffuse bleeding, blood-tinged urine, evidence of abnormal thrombosis, or abnormal laboratory values.

D. Edema—Differential edema and severe generalized edema should be noted and potential reversible mechanical causes (venous obstruction) evaluated. Accurate pre- and postoperative weights are essential for evaluating fluid accumulations and losses, which may represent 10–20 L in extreme cases.

E. Laboratory Studies—Coagulation studies, free hemoglobin, amylase, liver function tests, and arterial blood gases may delineate secondary adverse effects of cardiopulmonary bypass on tissue beds.

F. Imaging Studies—A chest x-ray should be examined postoperatively for retained foreign bodies, catheter position, ventricular support cannula positions, chest tubes, valves, pulmonary parenchymal and pleural abnormalities, mediastinal contour, aortic calcification and evidence of displacement, endotracheal tube position, and if applicable, intraaortic balloon pump placement.

G. Mechanical Problems—In patients with ongoing ventricular support, erratic pump flows or increased tubing motion may herald cannula obstruction or pump failure. Air in the circuit is always an emergency, and although rare, it should be excluded. Left- and right-sided chamber pressures are vitally interdependent in patients being maintained on ventricular assist devices because the normal physiologic homeostatic mechanisms do not apply. Filling, arterial, and line pressures require constant vigilance.

Differential Diagnosis

Secondary organ changes owing to congenital, valvular, and coronary disease are frequently superimposed on—and magnified by—the effects of cardiopulmonary bypass. An appreciation of the preexisting and subsequent anatomy and physiology is essential. Sepsis, either preexisting or new,

mimics almost all the inflammatory, organ failure, and embolic effects of cardiopulmonary bypass, as do many anaphylactic or cardiovascular drug reactions and hemolysis. Superimposed myocardial infarction during cardiopulmonary bypass may have profound systemic effects.

Treatment

A. Minimize Support Period—Decreasing the level and time of artificial circulation is the most direct treatment but is rarely feasible. Changing the type of support device will be possible occasionally, and many available pulsatile support devices are tolerated for long periods of time. As mentioned earlier, improvements in the biocompatibility of the bypass circuit blunt the systemic coagulation and inflammation abnormalities and may improve clinical endpoints. Despite these “equipment” improvements, they are only partially effective, and optimal therapy in the future probably will combine multiple strategies for optimal outcomes.

B. Restore Perfusion—Organs with documented inadequate flow should have perfusion restored by moving cannulas, administering vasodilators locally, performing peripheral bypass grafts where appropriate, or performing thromboembolectomy.

C. Correct Hypothermia—Correction of hypothermia should be ongoing with warmed intravenous fluids, radiant heat, and heated ventilatory gases. However, the efficacy of all these maneuvers is very limited, and in cases of extreme hypothermia, consideration should be given to direct blood rewarming with a partial bypass circuit and heat exchanger.

During rewarming, fluid requirements may be substantial secondary to vasodilation and ongoing losses. The significant cellular and extracellular edema that accumulates demands vigorous diuresis as soon as feasible to prevent the increased cardiovascular burden of increasing preload as fluid is mobilized. Robust urine output of 300–500 mL/h may be necessary to keep pace with fluid administration and mobilization.

D. Correct Coagulopathies—Coagulopathies frequently correct spontaneously with rewarming, but the occasional patient with ongoing fibrinolysis, significant factor deficits, or ongoing bleeding needs specific therapy as outlined in the section on coagulation.

E. Organ Dysfunction—Patients who develop myocardial dysfunction, neurologic or ophthalmologic deficits, acute respiratory distress syndrome (ARDS), pancreatitis, generalized inflammatory states, renal failure, and extremity ischemia temporally related to cardiopulmonary bypass are treated in fashion similar to what is available for these maladies caused by other insults. Cardiopulmonary bypass should not be assumed to be the cause of these deficits until other primary causes are excluded.

▶ Postoperative Low-Output States

ESSENTIALS OF DIAGNOSIS

- ▶ Diaphoresis.
- ▶ Cyanosis or pallor.
- ▶ Poor peripheral perfusion.
- ▶ Thready pulse; tachycardia or bradycardia.
- ▶ Tachypnea.
- ▶ Venous congestion.
- ▶ Pulmonary rales.
- ▶ New or increased murmurs.
- ▶ Mental status changes.
- ▶ Anxiety.
- ▶ Low urine output.

General Considerations

Cardiac insufficiency may complicate the course of postoperative cardiac surgical patients. Intrinsic myocardial dysfunction, valvular disease, and congenital anomalies frequently coexist with extrinsic cardiac factors and complicate the diagnosis and therapy of shock in this group of patients. Rapid diagnosis and reversal of decreased cardiac output are essential to avoid secondary organ damage.

Etiology

A. Intrinsic Factors—The preoperative cardiac and vascular anatomy, rhythm, ventricular function (diastolic and systolic), vascular resistances, valvular gradients and insufficiencies, coronary anatomy, and prior interventions should be reviewed and correlated. This cannot be overemphasized, particularly in patients with cardiomyopathy, acute coronary insufficiency, valvular heart disease, congenital cardiac lesions, pulmonary hypertension, ventricular outflow obstruction, or ventricular failure.

B. Cardiomyopathy—Cardiomyopathy is conveniently classified by etiology as ischemic or nonischemic and by type as dilated or nondilated. Dilated cardiomyopathy is characterized by loss of muscle mass or function that is compensated

for by moving residual myocardial function farther along the Starling curve, that is, by increasing myofibril length. Resting cardiac output is preserved, but systolic reserve is limited, and compliance is decreased. These cardiomyopathies frequently are associated with ventricular dilatation, areas of dyskinesis, mitral incompetence, cardiac rhythm disturbances, pulmonary hypertension, and secondary right ventricular failure. Hypertrophic disease usually is nondilated and causes decreased diastolic function with small chamber size, increased left ventricular mass, functional outflow obstruction, and elevated filling pressures. Many patients with cardiomyopathy undergo revascularization, arrhythmia surgery, valvular replacement, or eventual transplant.

C. Acute Coronary Insufficiency—Preoperative acute coronary insufficiency frequently necessitates emergent revascularization. This may be complicated by reperfusion injury, residual ischemia, and myocardial infarction with secondary mitral regurgitation, ventricular rupture, or ventricular septal defect. Reperfusion injury results in decreased ventricular compliance, decreased systolic and diastolic function, and rhythm disturbances (eg, atrial fibrillation and flutter, premature atrial contractions, ventricular fibrillation, ventricular tachycardia, and heart block). Residual ischemia causes similar derangements that may fluctuate with the level of ischemia. Acute papillary muscle rupture with severe mitral regurgitation, ventricular free wall rupture, and ischemic ventricular septal defects can occur pre- or postoperatively. These events usually are associated with large transmural infarcts and usually present acutely with severe compromise.

D. Valvular Heart Disease—Valvular heart diseases frequently leave residua that predispose to poor cardiac function despite correction of the valvular lesion. Aortic stenosis leads to left ventricular hypertrophy and severely reduced ventricular compliance early in its course. Ventricular dilatation and reduced systolic function are frequent late consequences. Associated coronary artery disease or left ventricular outflow tract obstruction also may contribute to poor hemodynamics in patients with aortic stenosis. Aortic insufficiency classically evolves into a dilated, hypokinetic left ventricle with decreased compliance. Aortic valve disease of both types is often complicated by pulmonary hypertension and right-sided heart failure. With mitral valve disease, left ventricular dynamics may be near normal (eg, rheumatic mitral stenosis) or severely depressed (eg, ischemic mitral regurgitation). Mitral stenosis frequently coexists with a normally functioning ventricle preoperatively; however, with relief of inflow obstruction, ventricular overload may occur. Mitral regurgitation is often associated with decreased left ventricular function and dilatation preoperatively. Function may worsen in the early postoperative period because of an acute increase in afterload and anatomic changes. Left ventricular function is usually less compromised following mitral valve commissurotomy or repair, but prosthetic mitral valve replacement changes ventricular dynamics significantly and in many cases severely impairs left ventricular

function. Other confounding factors include left ventricular outflow obstruction following mitral valve repair or replacement, pulmonary hypertension, right ventricular failure, and tricuspid regurgitation.

E. Congenital Lesions—Congenital lesions are beyond the scope of this discussion, but an assessment of preoperative and postoperative anatomy and function is essential to treatment. Specifically, both the systemic status and the pulmonary (if present) ventricle's functional state should be assessed, preoperative and residual shunts quantitated, vascular resistances determined, outflow and inflow obstructions documented, and associated pulmonary and vascular changes considered. Ventricular function may be compromised for a variety of reasons. Patients with a right ventricle as a systemic chamber have minimal reserve function and are a subset of the cardiomyopathies mentioned earlier. Congenital lesions may be associated with coronary compromise and secondary loss of ventricular function (eg, tricuspid atresia with intact ventricular septum). In patients without a pulmonary ventricle (eg, postoperative Fontan patients), supranormal systemic ventricular function, low systemic-sided filling pressures, and low pulmonary vascular resistance all must be maintained to promote passive pulmonary flow. Patients with left ventricular outflow obstruction (eg, coarctation or aortic stenosis) frequently have significant left ventricular hypertrophy and dysfunction. Shunts at multiple levels are also common. Residual shunts following correction of congenital anomalies may be beneficial by permitting decompression of high filling pressures and maintenance of cardiac output (eg, following Fontan repair) or may cause significant compromise owing to ventricular overload or arterial desaturation. In view of these complexities and their interrelationships, a detailed understanding of the function of each ventricle, the volume load presented to each chamber, and the configuration of outflow and inflow is essential to proper management.

F. Arrhythmias—Arrhythmias may complicate the postoperative course and produce low-output states. Supraventricular rhythms, including atrial fibrillation and flutter, occur in up to 30% of open-heart surgery patients and are particularly detrimental in the presence of decreased ventricular compliance or marginal functional reserve. Metabolic derangements, atrial ischemia, atrial dilatation, and sympathetic activity all contribute to supraventricular arrhythmias. Similarly, ventricular arrhythmias are common, particularly in dilated cardiomyopathies, hypertrophic disease, and ischemia. Finally, bradycardias and conduction disturbances are common, particularly at the extremes of age.

G. Pulmonary Disease—Pulmonary and pulmonary vascular disease may be superimposed on any of the preceding lesions. Chronic left ventricular failure compromises lung compliance, airflow, and oxygenation. Pulmonary vascular resistance is frequently elevated and may or may not be reversible. Vascular rings and slings may directly compromise

pulmonary blood flow or gas exchange. Additionally, some conditions may be associated with decreased lung parenchyma or vasculature (eg, endocardial cushion defects, tetralogy of Fallot, and pulmonary atresia).

H. Extrinsic Factors—Pericardial tamponade, tension pneumothorax, inadequate or excessive resuscitation, and circulating myocardial depressants all should be considered during evaluation of inadequate cardiac output. Resuscitation is frequently inadequate during the early postoperative course. Patients with ongoing blood loss, decreased ventricular compliance, perioperative infarcts, significant organ damage, or complicated cardiopulmonary bypass courses have particularly high fluid requirements, as do those who are rewarming following hypothermic bypass or circulatory arrest. Overzealous fluid administration also can result in acute cardiac insufficiency, especially in patients with exceptionally low ejection fractions. This delicate balance between inadequate and excessive fluid administration provides the basis for invasive hemodynamic monitoring in patients with complex problems.

1. TAMPONADE—Tamponade may result from both early bleeding and late pericardial fluid accumulation. Localized collections can result in atypical but equally dangerous presentations. The causes of tamponade are reviewed in the sections on postoperative hemorrhage and postpericardiotomy syndrome.

2. TENSION PNEUMOTHORAX—Tension pneumothorax should be excluded in any patient with hemodynamic compromise. Myocardial depressants are frequently active perioperatively. Calcium channel blockers, β -blockers, antiarrhythmics, and anesthetic agents all contribute to decreased myocardial performance. Endogenous substances such as interleukin 6 (IL-6) also may play a role in patients with long cardiopulmonary bypass runs or systemic injury from prolonged hypoperfusion.

Clinical Features

A. Symptoms and Signs—Invasive hemodynamic monitoring with pulmonary artery catheters is valuable to assess cardiopulmonary physiology and guide therapy. Confounding problems specific to cardiac surgery patients are due to the frequent presence of endotracheal tubes, residual anesthetic agents, and continued “normal” residual effects of cardiopulmonary bypass. Ongoing hemorrhage, pulmonary insufficiency, metabolic derangements, volume shifts, and temperature changes all contribute to variable cardiac performance.

B. Imaging Studies—Chest radiographs should be obtained early and evaluated for evidence of enlarging cardiac silhouette (eg, tamponade), pulmonary venous congestion (eg, congestive heart failure and tamponade), pleural fluid (eg, ongoing bleeding), mediastinal shift, and extrapulmonary air (eg, tension pneumothorax). Chest radiographs

need to be evaluated in comparison with previously obtained films to highlight changes and permit correlation with a changing clinical course.

C. Echocardiography—Surface or transesophageal echocardiography can be invaluable in specific clinical circumstances. Surface echo is usually performed initially. If necessary, transesophageal studies can be added to provide additional information about posterior structures, particularly the mitral valve and thoracic aorta. Echocardiography is useful in the evaluation of tamponade because it can display diffuse or localized fluid collections as well as shift and paradoxical motion of the ventricular septum, which suggest hemodynamic compromise. In addition, echo can confirm poor ventricular function, which occurs with cardiomyopathy or global ischemia. It visualizes localized wall motion abnormalities owing to new or recurrent local ischemia. Ventricular filling and insufficient or excess volume resuscitation also can be evaluated. Echo is also helpful in evaluating left ventricular outflow obstruction, seen frequently present in patients with hypertrophic cardiomyopathies and after mitral or aortic valve repair or replacement. New or residual valvular disease, dissection of the aorta, and septal defects also can be visualized.

D. Electrocardiography—Electrocardiographic tracings should be compared with preoperative and earlier postoperative examinations for evidence of ischemia, rhythm and rate disturbances, or diffuse changes sometimes seen with pericardial hematoma and pericarditis.

E. Hemodynamic Monitoring—Cardiac output, central venous pressure, and pulmonary artery and pulmonary wedge pressures, as determined with a thermodilution pulmonary artery catheter, are invaluable for assessment of cardiovascular status at the bedside. Indeed, these data are often the earliest and easiest to obtain, further underscoring their importance. A cardiac index of less than 2.0 L/min/m² always requires prompt evaluation and correction. Even higher indices may be inadequate in specific situations. Inaccurate output measurements can occur if incorrect calibration constants are used or tricuspid regurgitation is present. If measured values appear inappropriate to the clinical situation, their validity should be confirmed by venous O₂ saturation measurement or echocardiography (see below). Central pressures should be evaluated early in the course of low-output states.

F. Oxyhemoglobin Saturation—Venous oxyhemoglobin saturation can be measured intermittently by transcatheter aspiration or continuously by fiberoptic pulmonary artery catheters. Central venous (right atrial) oxygen saturations typically are measured, and resting values are usually 75%. Assuming a 100% arterial saturation, this represents unloading of one-fourth of the available oxygen. Venous desaturation usually indicates inadequate tissue perfusion whether or not the cardiac index is depressed. Oxygen content calculations from specific chambers also can be used to determine intracardiac shunts and flows.

Differential Diagnosis

Intravascular volume changes, including hypovolemia, ongoing bleeding, and overload with impaired right or left ventricular function, all can result in acute cardiovascular insufficiency. Extrinsic factors (eg, pericardial tamponade, tension pneumothorax, or hemothorax) and intrinsic cardiac compromise (eg, ventricular free wall rupture, acute ventricular septal defect, papillary muscle rupture, prosthetic valve dehiscence or thrombosis, coronary ischemia, and arrhythmias) also can be confused with low-output syndromes. Systemic hypoxia, hypocalcemia, acidosis, sepsis, and organ ischemia occasionally can present initially as a low-output state in the postoperative period. Malfunctioning arterial catheters and electronic monitors occasionally prompt a search for the cause of hypotension in a normal patient.

Treatment

A. Supportive Measures—As with any critically ill patient, the first objective is to maintain adequate oxygen delivery and pH control by optimizing ventilation. If the cause of the low-output state is not easily identifiable and remedied, then early reintubation, while the patient is still hemodynamically resuscitatable, is preferable to subsequent emergent intervention. If an endotracheal tube is already in place, its function and position should be confirmed rapidly by assessing breath sounds, ventilatory settings and pressures, and inspired O₂. Pulse oximetry and blood gas analysis should be obtained as quickly as possible, as well as electrolytes and hematocrit. Reversible causes (eg, respiratory disorders and electrolyte imbalance) should be corrected promptly.

During evaluation for specific causes, the circulation should be supported aggressively, and this is best accomplished by a systematic approach to appraisal of the hemodynamic status of the patient. As mentioned earlier, adequate oxygenation and ventilation must be ensured. Preload then should be optimized. The virtues of prompt administration of fluids, when appropriate, cannot be overemphasized. Inadequate volume administration is common in patients who are rewarming following a period of hypothermia, who are being treated with vasodilators, or who have poor left or right ventricular compliance. In these circumstances, prompt fluid administration is all that is required for full restoration of cardiovascular stability. In addition, patients with tamponade frequently respond to fluids while preparations for definitive therapy are being made. Conversely, in the patient who has gradually become volume-overloaded, with subsequent impairment of ventricular performance, it is important to treat with inotropes and afterload reduction instead of with additional volume. Patients with very poor ventricular function are prone to both hyper- and hypovolemia. Occasionally, some of the classic signs of hypovolemia, such as increased creatinine and decreased cardiac output, are the result of excessive fluid administration and subsequent ventricular impairment.

Heart rate and rhythm disturbances then should be assessed and treated as outlined in Chapter 22. Contractility may be enhanced with inotropic agents, with particular attention to right ventricular status. Lastly, afterload may be reduced with vasodilators to further improve cardiac output and systemic perfusion. Although most inotropes are described elsewhere in the text, a few warrant further comment.

There are a number of inotropic drugs that are used commonly to support the failing heart—including dopamine, dobutamine, epinephrine, and phosphodiesterase inhibitors (eg, milrinone). While these agents are all effective for improving the contractile state of the myocardium and have variable effects on heart rate and afterload, their effects are exerted primarily on the left ventricle. More recently, the importance of adequate right ventricular function to cardiovascular success has been appreciated, as well as the sensitivity of the right ventricle to increased afterload, which is manifested as cardiovascular failure. Accordingly, pharmacologic agents that provide physiologic benefit to the right ventricle—in the context of perioperative low cardiac output syndrome—including phosphodiesterase III inhibitors (eg, amrinone and milrinone), inhaled nitric oxide (NO), and the increasingly used agent recombinant human B-type natriuretic peptide (BNP, ie, nesiritide [Natrecor]) have received attention.

The phosphodiesterase III inhibitors have been termed *inodilators* because of their ability to improve myocardial contractility while simultaneously causing vascular smooth muscle relaxation. As a result, these agents have consistently been shown to improve cardiac index and decrease systemic vascular resistance (SVR) and pulmonary vascular resistance (PVR). Furthermore, they cause little or no increase in myocardial oxygen consumption and have almost no effect on systemic blood pressure and heart rate. Moreover, these agents may act synergistically with β_1 -adrenergic agonists (eg, epinephrine). Amrinone and its newer derivative, milrinone, are the most common drugs used in this class. As a result of these beneficial effects on the myocardium and the pulmonary and systemic vasculature, these agents are playing an increasing role in the management of perioperative low cardiac output syndrome.

Nitric oxide (NO), formerly known as *endothelium-derived relaxing factor* (EDRF), has emerged as a critical regulator of vascular tone and reactivity in both normal and pathologic processes. Exogenous (ie, inhaled) NO retains the biologic properties of endogenous NO and is the only known agent that specifically dilates the pulmonary vasculature. Accordingly, it has been used with success when pulmonary hypertension is the primary physiologic disturbance. When it is used, continuous monitoring of its lethal by-product (nitrogen dioxide) is necessary. Furthermore, therapy with inhaled NO mandates mechanical ventilation and is very expensive—thus it is infrequently a first-line agent. The role of NO in the treatment of perioperative low cardiac output syndrome is limited at this time, but NO offers specific physiologic benefits that may provide the basis for increased use of NO in this setting.

BNP, or nesiritide, is a promising new agent in cardiovascular medicine. It has been approved for use in heart failure but may assist with management of cardiac surgery patients. Like endogenous BNP, nesiritide has widespread favorable effects, including vasodilatation (thus reducing peripheral and pulmonary vascular resistance), natriuresis, increased glomerular filtration rate, symphathoinhibition, and inhibition of the renin-aldosterone system. Although there is limited experience published to date, these pharmacologic properties make it an attractive adjunct to postoperative management of cardiac surgery patients, particularly, perhaps, those with current congestive heart failure, renal insufficiency, or pulmonary hypertension.

In patients who continue to have low-output states despite these strategies, intraaortic balloon counterpulsation should be added. In appropriate patients who fail to respond to intraaortic balloon counterpulsation, more extensive ventricular support should be considered.

B. Correction of Arrhythmias—Most patients will have continuous electrocardiographic monitoring, and the rate and rhythm should be established and corrected as appropriate. Rate abnormalities may have profound hemodynamic consequences, and a rate of 80–100 beats/min should be the goal. Temporary atrial, ventricular, and ground wires are frequently available and can be used to correct bradycardias with atrial, ventricular, or sequential AV pacing. In emergent settings, simple single-chamber ventricular pacing should be instituted first to restore cardiac function immediately. Then, if atrial wires are available, sequential AV pacing can be instituted to optimize cardiac function. Electrical cardioversion of hemodynamically significant arrhythmias is preferable to long periods of low cardiac output and is performed easily, particularly in intubated and ventilated patients. In extubated patients, brief intravenous anesthesia is sometimes appropriate for cardioversion of atrial fibrillation, atrial flutter, or sustained slow ventricular tachycardia. This is not indicated in patients who are significantly compromised.

C. Surgical Evaluation of Pericardial Tamponade—Ventilation, rhythm, blood pressure, and fluid status should be established within the first few minutes of evaluation. Classically, cardiac tamponade is suggested by hemodynamic

instability in a patient with significant bleeding that recently decreased or stopped. Further evidence includes elevated filling pressures (possibly left-right equilibration), mediastinal widening on serial chest radiographs, and increasing tachycardia (compensatory). If not diagnosed rapidly, pulseless electrical activity may result. Despite full evaluation, tamponade frequently cannot be excluded conclusively, and mediastinal exploration, either in the ICU or in the operating room, is required. If time permits, echocardiography may be performed at the bedside to determine the presence or absence of pericardial tamponade. Any patient with cardiovascular collapse in the early period following cardiac surgery should be considered to have tamponade and should be explored surgically if they are not responding to appropriate therapy—even if other examinations are inconclusive or are negative. Tension pneumothorax can occur in any critically ill patient and should be treated on the basis of ventilator pressure changes, physical examination, and chest x-ray.

D. Other Modalities—Occasional patients will be incompletely revascularized or may have vein or arterial conduit spasm. If serial ECGs are suggestive of ischemia, vascular antispasmodics (ideally calcium channel blockers) should be administered and consideration given to echocardiography to document localized wall motion abnormalities, angiography to definitively establish localized vascular lesions, or early reoperation to treat acute graft occlusion.

Pulmonary Disease

Darryl Y. Sue, MD
Janine R. E. Vintch, MD

► Status Asthmaticus

ESSENTIALS OF DIAGNOSIS

- ▶ Usually unremitting asthma, rapidly increasing in severity, but may present with sudden and severe obstruction without warning.
- ▶ Poor and decreasing response to β -adrenergic agonist therapy.
- ▶ May develop hypercapnic respiratory failure.
- ▶ Severe hyperinflation.
- ▶ Evidence of respiratory (inspiratory) muscle fatigue.

General Considerations

Status asthmaticus is very severe asthma that is unremitting and poorly responsive to usual therapy. Studies have emphasized the differences between chronic stable asthma and status asthmaticus in terms of pathophysiology, prognosis, management, and response to treatment. Importantly, there has been increased awareness of mortality and morbidity from severe asthma, recognition of the key role of inflammation in the mechanism of severe asthma, changes in the mode of delivery of agents for treating asthma, and revised concepts in management of patients requiring mechanical ventilation.

Many patients with asthma will have episodic attacks that are treated easily and rapidly. These mild exacerbations call for changes in management because even episodic asthma is undesirable, but the important feature of such cases is that the patient responds and returns to baseline in a short time. These attacks are distinguished from status asthmaticus, which is characterized by slow and inadequate response to treatment and a poor outlook for resolution of attacks. The recognition of severe acute asthma in some cases may be difficult when the patient is assessed against a background of chronic but stable asthma.

Pathophysiology and Pathogenesis

Asthma prevalence is increasing throughout the world, and asthma mortality is a matter of great concern. Airway obstruction is the major feature of this disorder, and asthma is both an acute reversible obstructive disease and a chronic pulmonary disease leading to permanent airway obstruction. Failure to control asthma symptoms is associated with a more rapidly progressive decline in lung function and loss of reversibility. This is the basis for consensus recommendations for chronic asthma management, which can be summarized as follows: (1) There is a key role for anti-inflammatory therapy (eg, corticosteroids), (2) regular β -adrenergic agonist use as the sole therapy for asthma is ineffective and potentially harmful, and (3) the goal of asthma treatment is to keep the patient completely symptom-free at all times. Despite widespread dissemination of these recommendations, optimal management of asthma is far from an achieved objective, and many asthmatics have moderate to severe exacerbations requiring hospitalization—with some requiring ICU management.

Airway obstruction in asthma results from three mechanisms: enhanced bronchial smooth muscle contraction (increased tone and response to stimuli), bronchial mucosal inflammation and edema, and plugging of the bronchi by secretions and inflammatory debris. The response to therapy depends on the relative contributions of each of these mechanisms. For example, bronchodilators relax bronchial smooth muscles but have little or no effect on reducing airway obstruction caused by inflammation or debris. Corticosteroids have no direct effect on bronchial smooth muscle but reduce inflammation in the bronchial walls.

The baseline amount of inflammation and airway narrowing is a major determinant of the severity of exacerbations once an asthma exacerbation is triggered. Exacerbations may be triggered by allergens in susceptible individuals, by cold air or irritants such as dust, by aspirin, or by respiratory infections, especially viral infections. These insults cause release of mast cell products such as histamine,

inflammatory mediators (eg, leukotrienes and prostaglandins), and substances that attract and activate leukocytes, especially eosinophils. An identifiable precipitating cause for an exacerbation often cannot be identified. Bronchial smooth muscle contraction and bronchospasm usually occur early, with mucosal edema, increased mucous gland secretions, and inflammatory cell infiltration following rapidly. The proportion of airway obstruction owing to bronchospasm and that owing to edema, inflammation, and mucus plugging is highly variable between patients.

Eosinophilic infiltration of the bronchial mucosa in asthma plays a key role, but neutrophils and T-lymphocytes also have been implicated. Eosinophils may be attracted by platelet-activating factor produced by a variety of cells, and there is increased local production of interleukin 5 (IL-5), an activator of eosinophils.

A number of studies have suggested an association between regular use of β -adrenergic agonists and fatal or near-fatal asthma events. Proposed mechanisms are (1) promotion of airway hyperresponsiveness by these drugs because they are so effective that the patients are more apt to undergo prolonged exposure to allergens or irritants, (2) heavy use of β -adrenergic agonists results in hypokalemia and cardiac arrhythmias, and (3) some other effects of β -agonists that remain undetermined. Recent studies have linked long-acting β -adrenergic agonists to worsening asthma and increased mortality, yet there are very clear data demonstrating benefits of these agents. Some studies have shown that concomitant inhaled corticosteroids may protect against adverse effects of long-acting β -agonists, but this has not been settled. Furthermore, it is likely that some patients are more susceptible to adverse effects of β -agonists potentially because of polymorphisms of the β -adrenergic receptor resulting in greater downregulation with repeated stimuli.

Status asthmaticus is characterized by poor responsiveness to bronchodilator therapy; a rapid, unremitting, and often progressive course; and slow recovery to a baseline. Patients who die with status asthmaticus are often found to have severe mucus impaction of airways and marked inflammatory infiltration of the bronchial walls, suggesting a greater role of airway mucosal inflammation over bronchial smooth muscle contraction. In some patients with status asthmaticus, hypoxemia persists much longer than airway narrowing (as measured by peak flow or forced expiratory capacity in 1 second [FEV₁]), suggesting that persistent blockage of small airways with mucus prolongs ventilation-perfusion mismatching. It is not known why an asthmatic with exacerbation sometimes may develop a self-terminated bronchoconstrictor response and at other times generate a persistent unremitting response (status asthmaticus) with airway edema and inflammation.

A small number of patients with fatal or near-fatal asthma appear to have rapid onset of symptoms with little airway inflammation. These patients experience very severe bronchospasm that may lead to death within minute or hours. Identification of such patients before they have a fatal or

near-fatal episode is difficult, but evidence suggests that these patients may have reduced perception of increased airway resistance combined with decreased hypoxic ventilatory drive.

Most patients with asthma exacerbations can be treated successfully before they develop severe respiratory failure. Respiratory failure in status asthmaticus comes about from two major mechanisms. First, the diffuse and variable bronchial obstruction causes ventilation-perfusion mismatching with resulting hypoxemia and, if the patient fails to increase alveolar ventilation appropriately, hypercapnia. Second is respiratory muscle fatigue, which somewhat paradoxically is more marked for the inspiratory than for the expiratory muscles. Because airway obstruction in asthmatics is intrathoracic, airway narrowing is more marked during the expiratory phase, increasing expiratory work of breathing and lengthening the time needed for adequate exhalation. However, because respiratory drive is increased in asthma as a result of hypoxemia, hypercapnia, and other factors, the respiratory rate increases and expiratory time shortens. This combination of greater expiratory airway obstruction and shorter expiratory time results in hyperinflation (air trapping). Hyperinflation puts an additional burden on the inspiratory muscles because these muscles are shorter than normal prior to contraction and thus are unable to generate as much tension for as long a time. Respiratory failure develops because the patient becomes unable to compensate for the pathophysiologic changes. The result is fatigue of inspiratory muscles, worsening hypercapnia and respiratory acidosis, and usually a need for intubation and mechanical ventilation.

Clinical Features

A. Symptoms and Signs—The severity of an asthma exacerbation should be judged in order to make decisions about management. Early (30–60 minutes) response to therapy is the key piece of information, but other information may be helpful including prolonged duration of attacks, history of hospitalization for asthma, prior or current use of systemic corticosteroids, poor response to bronchodilators, increasingly more frequent or increased dosages of medications, recent or repeated emergency room or office visits for acute asthma, and a history of requiring mechanical ventilation for asthma. Increasing severity of asthma may be manifested by less diurnal variation in asthma severity, diminished peak flow both before and after bronchodilators, and inability to sleep. A minority of asthmatics present with status asthmaticus after very short duration of symptoms. Some investigators have suggested that these patients presenting with a hyperacute attack may have a variety of asthma marked by sudden severe airway closure, perhaps from a neural mechanism rather than from airway inflammation. Because pregnancy has a variable effect on women with stable chronic asthma, including causing marked worsening in some individuals, pregnancy in women with childbearing potential should be considered as a factor for asthma worsening.

The physical examination is helpful for identifying signs of severe airway obstruction (eg, absence of wheezing, use of accessory muscles of respiration, intercostal retractions, and pulsus paradoxus) or signs of impending respiratory muscle fatigue (eg, paradoxical abdominal wall movement), but these signs are insensitive or unreliable when used by themselves to assess severity. A number of studies have attempted to assess the value of other signs, such as tachycardia, tachypnea, cyanosis, and hypotension, singly or in combination, but these have not proved to be of discriminating value. A key role of physical examination is to exclude other acute respiratory problems that may be mistaken for asthma, such as pulmonary edema, pulmonary embolism, anaphylaxis or angioedema, pneumothorax, pneumonia, and upper or central airway obstruction owing to tumor, foreign body, or epiglottitis.

B. Laboratory Findings—Ninety percent of patients with acute asthma will have hypoxemia of mild to moderate degree, and hypoxemia is not a particularly discriminating variable for asthma severity. Most asthmatics (80%) presenting with an acute episode have mild respiratory alkalosis. Only a small proportion have normal or elevated PCO_2 , and there is an association between severe airway obstruction and hypercapnia in asthma. Nonetheless, although hypercapnia is of concern in status asthmaticus, hypercapnia is not consistently linked with prolonged severe asthma or the need for mechanical ventilation. Metabolic acidosis owing to an increase in blood lactate in patients presenting with acute asthma, especially in association with hypoxemia, may be seen. Although pulse oximetry gives an estimate of arterial oxygenation, an arterial blood gas determination of pH and PCO_2 is mandatory for any asthmatic admitted from the emergency department or being considered for admission to the ICU.

Serum sodium and potassium should be measured because of the association of hyponatremia with pulmonary diseases and respiratory failure and the observation that aggressive β -adrenergic agonist use can result in severe hypokalemia. Although magnesium has been used as a bronchodilator and hypokalemia and hypomagnesemia are closely related, hypomagnesemia has not been associated with asthma exacerbations.

C. Imaging Studies—Chest radiographs during acute asthma almost always show hyperinflation, with low, flat hemidiaphragms and an increased anteroposterior diameter. They are not helpful in assessment of the severity of asthma, precipitating factors, or complications. However, some investigators have claimed that chest radiographs provide important diagnostic information in asthmatics who are admitted to the hospital in that the choice of therapy is altered by the findings on the radiograph. Features to be sought include the presence of pneumothorax, infiltrates suggestive of bacterial or viral pneumonia, findings suggestive of allergic bronchopulmonary aspergillosis (eg, fleeting infiltrates or cylindrical bronchiectasis), and lobar or segmental atelectasis

suggesting mucous impaction of large airways. Because pulmonary edema may present with acute onset of dyspnea and wheezing, cardiomegaly and features of congestive heart failure should be excluded.

D. Spirometry—Spirometry can be very helpful in the assessment of status asthmaticus both initially and in following treatment. The objective response to therapy after the first 1–2 hours provides much meaningful information. Peak flow or FEV_1 should be measured on initial presentation to the emergency room and then hourly with treatment until a decision is made to hospitalize. The frequency of spirometry thereafter depends on clinical assessment, but the response to additional treatment with bronchodilators and, after sufficient time has elapsed, to corticosteroids may be of additional value in planning treatment and observation. The FEV_1 or peak flow may be compared with predicted values for the patient's age, sex, and size, but improvement in the measured values over time is the most helpful indicator. In one study, good response to treatment at 30 minutes was the single variable most highly correlated with favorable patient outcome.

Differential Diagnosis

Features suggesting status asthmaticus, including acute onset of shortness of breath, cough, wheezing, and progression to respiratory failure, may be seen to varying degrees in congestive heart failure, upper airway obstruction, exacerbation of chronic bronchitis or emphysema, spontaneous pneumothorax, anaphylaxis, acute pulmonary embolism, and foreign-body aspiration. Upper airway obstruction is characterized by inspiratory wheezing or stridor, sometimes loudest over the trachea in the neck. Asthmatics who had prior endotracheal intubation—especially for long duration—or tracheostomy should be suspected of having extrathoracic airway obstruction. A small but significant number of patients mistakenly diagnosed as having asthma instead have vocal cord dysfunction syndrome. In this syndrome, the vocal cords adduct inappropriately during exhalation, increasing expiratory resistance and causing expiratory wheezing and hyperinflation. Vocal cord dysfunction may go unidentified for years until direct visualization of the vocal cords during the respiratory cycle makes the diagnosis. On some occasions, patients who are intubated for severe asthma have sudden and complete relief of obstruction and wheezing, and these patients should be suspected of vocal cord dysfunction syndrome.

Treatment

Status asthmaticus is treated with bronchodilators (titrated to patient response), corticosteroids, and oxygen, with endotracheal intubation and mechanical ventilation if necessary. The aim of treatment is to relieve the airway obstruction by relaxing bronchial smooth muscles and reversing inflammation while supporting respiratory function. Support of respiratory function depends on the severity of the asthma and the

ability of the patient to sustain inspiratory and expiratory muscle work. An important concept in the treatment of status asthmaticus is that the airway obstruction should not be expected to reverse as quickly or completely as in mild asthma exacerbations. Current management focuses on supporting the patient's gas exchange without causing further harm while waiting for anti-inflammatory treatment to take effect.

A. Oxygen—Ninety percent of patients presenting with an asthmatic attack are hypoxemic to some degree. Hypoxemia increases respiratory drive and tachypnea, contributing to increased hyperinflation and possible inspiratory muscle fatigue. In addition to correcting hypoxemia, oxygen may be helpful in attenuating some respiratory drive and prolonging expiratory time, thereby decreasing hyperinflation. Because hypoxemia is usually due to ventilation-perfusion mismatching, hypoxemia in most asthmatics can be treated with low concentrations (30–50%) of supplemental oxygen in sufficient amounts to raise PaO_2 to 80–100 mm Hg. In nonintubated patients, oxygen can be given by nasal cannula or Venturi-type masks.

B. Bronchodilators—Bronchodilators of all types have been used in status asthmaticus, including β -adrenergic agonists (sympathomimetics), methylxanthines (theophylline), anticholinergics, and others (see Chapter 12). β -Adrenergic agonists are the most effective bronchodilator agents in acute asthma exacerbations. Those that are modified to have greater specificity for β_2 receptors, such as albuterol, are preferred because of their decreased effect on heart rate. Aerosolized formulations are much more potent and better tolerated than the same drugs given orally, subcutaneously, or intravenously, having a greater bronchodilator effect and causing less tachycardia and less hypokalemia even in patients who have severe bronchial obstruction. In moderately severe to severe asthma, aerosolized β -adrenergic agonists can be given with equal effectiveness with either a metered-dose inhaler (MDI) with spacer or hand-held nebulizer. Finally, the effective dose of β -adrenergic agonists is often higher than was formerly recommended; the doses should be titrated in individual patients to tolerance, often using clinical response, tachycardia, tremor, or other observations as guides to dosage. Beta-adrenergic agonists may be given in conventional doses as often as hourly or even by continuous nebulization. Continuous nebulization has been found to be variably effective. Hypokalemia as a consequence of β -adrenergic agonist therapy—causing increased transport of potassium into cells—is a known complication when these drugs are given in large doses.

Subcutaneous epinephrine has a long history of effective use in acute asthma, but inhalation of selective β -adrenergic agonists is more effective. The side effects of epinephrine include tachycardia, increased myocardial oxygen requirement, and hypertension. Salmeterol is a long-acting β -adrenergic agonist that is structurally similar to albuterol but has a longer side chain that anchors it near the β_2 -receptor site. This drug has no value in acute severe asthma, and salmeterol should be reserved for use only after resolution of the acute attack.

In severe asthma, aerosolized albuterol is recommended. If given by MDI, a spacer or reservoir is necessary. A starting dosage is 2–4 puffs every 1–2 hours, and the number of puffs can be increased to 6–8 or more, if tolerated. Alternatively, a nebulized solution of 0.5 mL albuterol (0.5%) diluted in 2.5 mL normal saline can be given by gas-powered nebulizer or intermittent positive-pressure breathing every 2–6 hours, but there is no evidence that this is more effective than administration by MDI. The response to bronchodilators should be measured objectively, preferably by peak flow. Tachycardia, tremors, and changes in blood pressure should be monitored carefully, especially when doses given exceed usual recommendations.

Anticholinergic drugs are generally considered more effective in chronic bronchitis than in asthma. Studies support their use in severe asthma in conjunction with optimized β -adrenergic agonist use. The quaternary anticholinergic drug ipratropium bromide is given via MDI or by nebulization. Effective doses of ipratropium bromide may be considerably higher than currently recommended, but its minimal side effects allow it to be well tolerated. Ipratropium should be given to asthmatics with severe exacerbations along with maximal β -adrenergic agonist therapy. By MDI, the starting dosage should be 2–4 puffs every 4–6 hours. For nebulization, an effective dose is 0.5 mg given every 6–8 hours. Even at the highest doses, side effects of ipratropium are minimal, and these doses appear to be safe.

The addition of theophylline to optimized regimens of β -adrenergic agonist therapy confers little or no additional benefit and increased toxicity and side effects. Some of the side effects of theophylline are identical to those of β -adrenergic agonists, and this may limit use of the more beneficial agent. Theophylline should be considered a third-line bronchodilator drug in status asthmaticus, but it might warrant consideration in selected patients who are not responding to other therapy. Theophylline is tolerated only when the serum concentrations are carefully maintained in the therapeutic range, and in some patients toxicity occurs even then.

Intravenous magnesium sulfate (MgSO_4) has been shown to be an effective bronchodilator in some studies of asthma exacerbation. Doses administered have been in the range of 0.5–1 mmol/min over 20 minutes, corresponding to about 3–5 grams of MgSO_4 . Comparison with β -adrenergic agonists has not been carried out in the ideal manner for evaluating the precise role of magnesium sulfate in combination with other drugs. There have been trials of inhaled magnesium sulfate as well.

C. Corticosteroids—Corticosteroids are a key component of treatment of status asthmaticus, but the ideal dosage remains undetermined. In one study, 15 mg methylprednisolone given intravenously every 6 hours did not appear to be as effective as larger doses such as 40 or 125 mg every 6 hours, and most clinicians agree that a dose of 10–15 mg/kg per day of hydrocortisone or equivalent is effective. Larger doses have not resulted in improved outcome or more rapid resolution. These recommendations translate into quite large doses,

such as 120–240 mg prednisone or methylprednisolone per day in divided doses for average-sized adults. Oral administration has been shown to be as effective as intravenous infusion with no difference in time of onset of effect, but intravenous administration is chosen more commonly.

For status asthmaticus, intravenous methylprednisolone at 40–60 mg every 6 hours, or similar dosage of oral prednisone or methylprednisolone is recommended. The dose should be continued, in the absence of acute severe side effects, for several days even if the patient improves. The rate of tapering of systemic corticosteroids depends on clinical response as well as the patient's recent history of asthma severity and previous dosage of corticosteroids.

The beneficial effect of corticosteroids is not clinically apparent until at least 6 hours after administration. Therefore, if corticosteroids are to be optimally effective, they should be given early, as soon as a diagnosis of status asthmaticus is made. Corticosteroids should be continued initially for at least 36–48 hours and then reduced by approximately 25–50% depending on clinical response. Further reduction generally can take place over about a 2-week period. Most investigators do not believe there is a role for aerosolized corticosteroids in status asthmaticus because of concern about delivery to the airways during acute airway obstruction. However, these agents are quite beneficial as the systemic corticosteroids are tapered, and relatively soon (within a few days), highly potent inhaled corticosteroids are effective.

The major concern of corticosteroid therapy is the side effects. The usual side effects of high-dose corticosteroids in critically ill patients include hyperglycemia, altered mental status, metabolic alkalosis, and hypokalemia. In asthmatics, acute myopathy has been reported in association with corticosteroids. Three mechanisms have been proposed to explain this phenomenon. First, hypokalemia may develop, especially with high-dose β -adrenergic agonist use and high-dose corticosteroids. Second, acute steroid myopathy has been reported at the dosages used in status asthmaticus. Finally, there is an association with prolonged muscle weakness when high-dose corticosteroids are given in combination therapy with nondepolarizing muscle relaxants. In the latter syndrome, temporary pharmacologic denervation of muscles appears to potentiate the acute myopathic effects of corticosteroids. This syndrome, seen in asthmatics and others requiring muscle relaxants to help them accept mechanical ventilation, may prolong the need for mechanical ventilation.

Because of the central role of inflammation in status asthmaticus, other agents that interfere with the inflammatory response have been proposed. Although methotrexate has been used in stable steroid-dependent asthmatics, there are no studies of this antimetabolite in status asthmaticus. Leukotriene antagonists and inhibitors of leukotriene synthesis are effective in modifying asthma and perhaps reducing exacerbations. They do not appear to have a role in acute asthma exacerbations but have been used in clinical trials.

D. Asthma in Pregnancy—Asthma is the most commonly encountered pulmonary problem in pregnant women, and asthma may worsen, improve, or remain unchanged in severity (roughly one-third in each group) during pregnancy. Fetal outcome is adversely influenced if the mother's asthma is poorly controlled, and improvement in asthma control is rewarded by a better outcome. Guidelines for treatment developed by the National Asthma Education and Prevention Program emphasize recommendations similar to those for nonpregnant patients. These include close monitoring of lung function, early administration of inhaled corticosteroids or other anti-inflammatory agents, and rapid therapeutic intervention during acute exacerbations to avoid hypoxemia. Clinicians may be reluctant to give medications to pregnant women because of risks to the fetus. Beta-adrenergic agonists are considered safe, as are inhaled corticosteroids, and systemic corticosteroids should not be withheld if needed during acute exacerbations. A more complete discussion of this topic is included in Chapter 39.

E. Mechanical Ventilation—Patients with status asthmaticus who require intubation and mechanical ventilation are identified either by the extreme severity of the airway obstruction or by anticipating failure of the patient to maintain adequate alveolar ventilation. Although most patients who require intubation and mechanical ventilation develop altered mental status, acute CO₂ retention, or both, a poor response to treatment or evidence of impending inspiratory muscle failure implies a high likelihood of a need for ventilatory support.

1. DYNAMIC HYPERINFLATION AND COMPLICATIONS FROM MECHANICAL VENTILATION—Mechanical ventilation in status asthmaticus was at one time associated with a disproportionate complication rate and high mortality. Barotrauma (eg, pneumothorax) and other complications of positive-pressure ventilation and endotracheal intubation were much higher in asthmatics than in patients with other forms of respiratory failure requiring mechanical ventilation. Possible reasons for this include failure to recognize the severity and slow reversibility of status asthmaticus, insufficient attention to the high airway pressure and progressive hyperinflation seen during mechanical ventilation of asthmatics, and failure to understand the importance of hyperinflation or air trapping as a cause of gas-exchange failure. Identified risk factors for barotrauma in one study included significantly higher minute ventilation and degree of estimated hyperinflation compared with those who escaped complications.

Current recommendations for mechanical ventilation reduce complications and mortality in this disorder to rates comparable with other causes of acute respiratory failure. The most important recommendation is limiting the degree of dynamic hyperinflation. Dynamic hyperinflation occurs when end-expiratory lung volume increases because there is insufficient time for the patient to exhale. This increases the risk of barotrauma because the lung is highly stretched at

end expiration and end inspiration. It also results in very inefficient gas exchange with a large increase in the ratio of dead space to tidal volume and in hypercapnia. Finally, because of the high air space pressures it engenders during both inspiration and expiration, dynamic hyperinflation may compromise the circulation.

Dynamic hyperinflation results from a combination of factors. First, expiratory airway resistance is high, and the tidal volume requires more time to be exhaled. Second, patients with asthma may have high ventilatory drive owing to hypoxemia, hypercapnia, or both. High ventilatory drive increases respiratory rate and decreases the time available for exhalation. Third, because of the hypercapnia, clinicians may try to increase minute ventilation by raising tidal volume and increasing respiratory rate during mechanical ventilation. High tidal volume and high respiratory rate during status asthmaticus are predictably associated with high peak airway pressures, high inspiratory plateau pressures, short expiratory times, auto PEEP, and hyperinflation. The magnitude of dynamic hyperinflation can be remarkable. In one study, estimates of the volume of “trapped gas” were as much as 12–20 mL/kg above normal end-expiratory volume.

2. VENTILATOR SETTINGS—All asthmatics who are receiving mechanical ventilation potentially can have severe dynamic hyperinflation, and a trial of reduced tidal volume, respiratory frequency, or both should be initiated with careful monitoring of arterial pH and PCO_2 . Dynamic hyperinflation is especially likely to occur if hypercapnia is worsening in the face of recent increases in tidal volume or respiratory frequency. One key adjustment is to minimize dynamic hyperinflation by maximizing inspiratory flow rate (if volume-cycled ventilation is used). This adjustment shortens inspiratory time and lengthens expiratory time, providing a greater opportunity to exhale the tidal volume. Inspiratory flow should be at least 80–100 L/min (1.3–1.6 L/s). The resulting I:E ratio should be 1:4 or higher.

A second important strategy is to constrain tidal volume and respiratory rate during volume-cycled positive-pressure ventilation to keep inspiratory plateau pressure 30 cm H_2O or less. Tidal volume should be 6–7 mL/kg of ideal body weight, and respiratory rate should be adjusted to minimize estimated auto PEEP (<5 cm H_2O) and inspiratory plateau pressure (<30 cm H_2O). Patients may require sedation but almost never muscle relaxants to achieve these goals.

Dynamic hyperinflation plays a dominant role in determining effective gas exchange. Therefore, although seemingly paradoxical, decreasing tidal volume or respiratory rate (lower minute ventilation) may result in a lower $Paco_2$. However, a more likely consequence of such changes is worsening hypercapnia. Current practice is to allow moderate hypercapnia (pH >7.25) to avoid the consequences of dynamic hyperinflation, a far worse complication. Thus “permissive hypercapnia” is often seen in the management of status asthmaticus.

The decision to increase minute ventilation and reverse hypercapnia generally is made as peak airway pressure and

auto PEEP decline as the patient’s high airway resistance falls with treatment. In one study, a 40–60 seconds apnea period was set for asthmatic patients who were sedated and given muscle relaxants. The total exhaled gas volume was measured; this consisted of the previous tidal volume plus any amount of “trapped gas” that could be exhaled during the prolonged exhalation period. Patients whose total exhaled gas volumes exceeded 20 mL/kg had their respiratory frequency reduced regardless of the measured PCO_2 . However, the respiratory frequency was increased in the other patients as much as possible without exceeding 20 mL/kg total exhaled volume, and these patients did not have worsening of hypercapnia or evidence of barotrauma. Patients were discontinued from mechanical ventilation when a PCO_2 of 40 mm Hg could be obtained and exhaled gas volume was less than 20 mL/kg.

There is limited published experience with administration of intravenous sodium bicarbonate to compensate for the increased PCO_2 , and this treatment should be used judiciously in selected patients. In one study, no complications of bicarbonate therapy were identified, but there is concern for development of paradoxical cerebrospinal fluid acidosis, hyponatremia, and intravascular volume overload. The use of other buffers that do not produce additional CO_2 when they react with acids has been proposed.

Current Controversies and Unresolved Issues

A. General Anesthesia for Refractory Asthma—In patients undergoing mechanical ventilation, halothane and ketamine anesthesia has been used in status asthmaticus that is refractory to conventional management, but this management has not been compared with other forms of therapy. Both agents have bronchodilator properties, but this remains an unproved and potentially risky therapy. Such treatment is used very rarely.

B. Mucolytic Administration by Fiberoptic Bronchoscopy—Recognition that severe refractory airway obstruction in status asthmaticus is often due to plugging of small airways with inspissated mucus led to the use of mucolytic agents such as acetylcysteine. However, aerosolization of this agent sometimes led to bronchospasm, and its effectiveness in the dose and manner administered has been questioned. Bronchoalveolar lavage with acetylcysteine and saline has been performed using the fiberoptic bronchoscope. Because of compromise of the airway with the bronchoscope, this must be done only during mechanical ventilation with sedation, muscle relaxants, or general anesthesia. The usefulness of this technique has not been proved, and because of the high risks to the patient, it should be considered only if other more conventional treatment has failed. Using a strategy to reduce dynamic hyperinflation and waiting for resolution of the underlying asthma in response to corticosteroids is almost always a better option.

C. Helium-Oxygen Inhalation—Helium-oxygen mixtures (21–40% oxygen, balance helium) have less density than

nitrogen-oxygen mixtures. Because a less dense gas is more likely to move through airways under conditions resulting in laminar rather than turbulent flow, helium-oxygen mixtures may improve distribution of ventilation and reduce airway pressures needed for effective ventilation. Helium-oxygen has been used in spontaneously breathing asthmatics to unload the work of the inspiratory and expiratory muscles. This may allow enough time for anti-inflammatory therapy to take effect and avoid intubation and mechanical ventilation. Mechanical ventilation with 60% helium and 40% oxygen mixtures has been used with improved arterial blood gases and markedly decreased airway pressures compared with a nitrogen-oxygen mixture. Although there have been no controlled studies of helium-oxygen mixtures in status asthmaticus, it is reasonable to suppose that this form of treatment may be beneficial in some refractory asthmatics. The problems include obtaining the appropriate gas, adapting the ventilator to use the gas mixture, monitoring tidal volume, and ensuring the adequacy of oxygen in the inspired gas mixture.

D. Noninvasive Ventilation—Non-invasive positive-pressure ventilation (NiPPV) successfully reduces endotracheal intubation and mechanical ventilation in patients with chronic obstructive pulmonary disease (COPD) exacerbation and acute pulmonary edema. Surprisingly, there are numerous studies but limited data supporting its use in status asthmaticus, although it would appear that temporary support by NiPPV of fatiguing inspiratory muscles would be helpful. NiPPV is a potentially useful adjunct but may be successful only in carefully selected patients. One danger is that some patients with status asthmaticus regain lung function very slowly, and NiPPV may not be tolerated long enough to preclude intubation.

▶ Life-Threatening Hemoptysis

ESSENTIALS OF DIAGNOSIS

- ▶ Expectoration of blood or blood-tinged sputum in sufficient quantity to compromise lung function.
- ▶ Either a large volume of hemoptysis in a healthy patient (>600 mL in 24 hours) or a smaller volume (<200 mL in 24 hours) in a patient with preexisting lung or heart disease who is unable to protect their airway, maintain adequate gas exchange, or has altered level of consciousness.

General Considerations

Hemoptysis can be caused by a wide variety of lung conditions. Expectoration of blood sufficient to be acutely life-threatening is not common, occurring in 5–15% of hemoptysis patients. Acute hemoptysis was formerly classified as massive or nonmassive, and the major decision about whether to perform surgical intervention was based on the estimated amount of bleeding. There is now recognition that even large volumes of hemoptysis can be tolerated if the patient is relatively healthy. Conversely, small amounts of bleeding can cause severe complications in patients who have limited cardiopulmonary reserve from COPD, previous lung resection, tuberculosis, or heart disease. Mortality from severe hemoptysis does correlate with the estimated amount of hemoptysis. However, with additional approaches to diagnosis and management now available, one considers both the severity of bleeding and the patient's ability to tolerate accumulation of blood in the lungs and airways.

Pathophysiology and Pathogenesis

A. Mechanisms of Hemoptysis—Bleeding in the airways and lungs can result from several different mechanisms and two major sources, the bronchial arteries (systemic pressure) and the pulmonary arteries (low pressure system). Disorders associated with hemoptysis are listed in [Table 24–1](#). The most common are bronchiectasis, lung cancer, and tuberculosis (including mycetoma).

1. INFLAMMATION OF THE BRONCHI—Inflammation of the tracheobronchial mucosa is the most common cause of hemoptysis but is rarely associated with severe bleeding. In chronic bronchitis, the mucosa develops increased vascularity with engorged and hypertrophied bronchial arteries that readily bleed in the face of increased inflammation or acute viral or bacterial infection.

Table 24-1. Common causes of hemoptysis.*

Airway	
	Tracheobronchitis
	Chronic bronchitis
	Bronchogenic carcinoma
	Benign tracheobronchial tumors
	<i>Bronchiectasis</i>
	Cystic fibrosis
	Suctioning or bronchoscopic trauma
	Post-transbronchial or endobronchial biopsy
	Transthoracic needle aspiration or biopsy
	<i>Trauma</i>
Lung parenchyma	
	Pulmonary infarction (pulmonary embolism)
	Invasive pulmonary infection (<i>Aspergillus</i> , bacteria)
	Necrotizing bacterial or fungal pneumonia
	Lung abscess
	<i>Tuberculosis with or without cavity</i>
	Pulmonary vasculitis
	<i>Goodpasture's syndrome</i>
	<i>Idiopathic pulmonary hemosiderosis</i>
	Trauma
	Thrombocytopenia
Cardiovascular	
	Left-ventricular failure
	<i>Mitral stenosis</i>
	<i>Pulmonary artery rupture (PA catheter balloon)</i>
	<i>Pulmonary artery aneurysm</i>
	<i>Aortic aneurysm</i>
	Hereditary hemorrhagic telangiectasia

*Items in italics are those associated most often with massive hemoptysis.

2. INFECTION—Worldwide, tuberculosis remains an important cause of hemoptysis both during active infection and as a consequence of the scarring and cavitation seen with chronic disease. Active disease may result in hemoptysis from lung necrosis, often with a cavity visible on chest x-ray. Tuberculous cavities may cause hemoptysis whether or not viable mycobacteria are present. Bleeding arises from dilated vessels in the wall of the cavity, most often fed by an elaborately developed network of vessels arising from bronchial arteries with interconnections between these and pulmonary arteries. An important cause of bleeding from tuberculous cavities is the development of a mycetoma, or fungus ball, usually formed by *Aspergillus* species, that seems to further stimulate bronchial artery hypertrophy and blood flow. Rarely, aneurysmal dilation of a vessel in the wall of the cavity has been known to be the cause of severe hemoptysis. In tuberculosis patients without cavities, bleeding can be caused by broncholiths (ie, calcified lymph nodes) adjacent to airways that erode through the bronchial wall and by chronic bronchiectatic changes of the airways. Patients with other forms of bronchiectasis (eg, previous viral infections, bronchopulmonary aspergillosis syndrome, or idiopathic

cases), bacterial lung abscess, and fungal infections with cavitation may present with hemoptysis, and on occasion these patients may have a bout of severe and life-threatening hemoptysis. Bacterial pneumonia sometimes can present with blood-tinged sputum (eg, “rusty” sputum seen with *Streptococcus pneumoniae* or “currant jelly” sputum seen with *Klebsiella pneumoniae*), but significant bleeding is rare.

3. NONINFECTIOUS CAUSES—Infarction of the pulmonary parenchyma can result in hemoptysis by causing death of lung tissue, but most patients with pulmonary embolism do not have pulmonary infarction. Inflammation of lung owing to involvement by Wegener's granulomatosis may be associated with hemoptysis, occasionally severe. Two autoimmune diseases for which hemoptysis is a characteristic feature, Goodpasture's syndrome and idiopathic pulmonary hemosiderosis, are not associated with inflammatory changes in the lung. In the former, bleeding arises from involvement of the alveolar-capillary interface by anti-glomerular basement membrane antibodies. Less frequent causes of hemoptysis include left ventricular failure and mitral stenosis, with bleeding resulting from increased pulmonary venous and capillary pressures. Hemoptysis may be seen with vascular malformations occurring as isolated abnormalities of the pulmonary circulation or in association with hereditary hemorrhagic telangiectasia syndrome (HHT), including Osler-Weber-Rendu syndrome.

Bronchogenic carcinoma and benign tumors of the tracheobronchial tree are other important causes of hemoptysis, with bleeding coming from hypertrophied bronchial arteries supplying the tumor. Finally, thoracic trauma may result in hemoptysis owing to rupture of pulmonary vessels, resulting in bleeding into the lung parenchyma (lung contusion) or laceration of a major airway.

4. HEMOPTYSIS IN ICU PATIENTS—In ICU patients who develop hemoptysis unrelated to their primary problems, some unique mechanisms must be considered. The most common source of hemoptysis is upper airway bleeding, which may result from tracheobronchitis owing to infection or suction catheter trauma. However, other airway problems should be considered, such as trauma from the tip of the endotracheal tube or tracheostomy tube or necrosis of the tracheal mucosa by the tube cuff. Rarely, bleeding can arise from pressure necrosis and erosion of the tube into an innominate or carotid artery or even into the aortic arch. A recognized cause of severe hemoptysis is rupture of a pulmonary artery by a pulmonary artery catheter because of overdistention of the catheter balloon tip, perforation of the vessel by the tip of the catheter, or eccentric balloon placement causing rupture during balloon inflation. Mortality rates with these types of catheter complications are very high.

Regardless of the cause of hemoptysis, bleeding can be made worse in patients with coagulopathy, qualitative platelet dysfunction from uremia or drugs, or thrombocytopenia. Patients with severe thrombocytopenia may have spontaneous alveolar hemorrhage.

B. Massive Hemoptysis—A large volume of hemoptysis, often called *massive hemoptysis*, usually results from a smaller number of common disorders causing hemoptysis (see Table 24–1). The mechanisms are often due to chronic and severe development of enhanced bronchial blood flow (eg, tuberculosis, lung abscess, bronchiectasis, and malignancy), necrosis and destruction of lung parenchyma (eg, abscess, tuberculous cavity, and fungal pneumonia in immunocompromised host), or disruption of a pulmonary artery (eg, trauma, rupture by pulmonary artery catheter balloon). In major series of patients with massive hemoptysis, tuberculosis and bronchiectasis are found in a large majority of patients, whereas bronchogenic carcinoma is quite unusual as a cause of massive hemoptysis.

Clinical Features

A. Symptoms—Patients, especially those with chronic sputum production (eg, chronic bronchitis or bronchiectasis), may complain of coughing up blood-tinged sputum. Others will note expectoration of bright or dark red material only. The degree of coughing is highly variable, with some patients having intractable coughing and others noting only that the blood wells up into the mouth with little stimulation of cough. Occasionally, patients actually can describe the approximate location of the intrathoracic source by pointing to the area of the sensation within their chest. The relationship of prior hemoptysis to massive or life-threatening hemoptysis is also highly variable. Some patients have prolonged minor hemoptysis, whereas others have no premonitory blood in the sputum prior to a life-threatening event. The degree of dyspnea accompanying hemoptysis is determined by the volume of blood expectorated and by the patient's underlying cardiopulmonary reserve. Patients with moderate to severe obstructive lung disease, those with extensive lung destruction from tuberculosis, and those with other heart or lung disorders will be most likely to have respiratory compromise. Fever, night sweats, and weight loss suggest active tuberculosis, but other infections also should be considered. A history of cigarette smoking or other risks for bronchogenic carcinoma should be sought.

An important part of the medical history is to estimate the amount of bleeding. While this cannot always be measured accurately, the patient should be asked to provide an estimate in cups, tablespoons, or other convenient measures and over as precise a time frame as possible. If admitted to the hospital, they should be given a cup to collect all their expectorated sputum over a 24-hour period for a more accurate determination of the amount of bleeding.

B. Signs—Physical examination may not be helpful in evaluating the severity of hemoptysis. The upper airway, including the nasopharynx and upper larynx, should be carefully examined to exclude these sites as the source of bleeding. Localization to the right or left lower respiratory tract by physical examination alone is often inaccurate. The presence of blood in the airways may lead to generalized or focal

wheezing, crackles, and dullness to percussion if there is sufficient bleeding to fill a portion of the lungs. In patients with chest trauma, rib fractures, superficial injury, and other findings may be helpful in assessing the likelihood of lung contusion, but these indicators are insensitive and nonspecific. Features of heart failure, such as a third heart sound, rales, and lower extremity edema, may be helpful in the differential diagnosis, as well as a diastolic murmur suggesting mitral stenosis. Osler-Weber-Rendu syndrome is suggested by finding single or multiple telangiectases on the skin or mucosal membranes. The physical examination is most useful in determining the severity of respiratory and nonrespiratory diseases that contribute to mortality and complications from hemoptysis.

C. Laboratory Findings—Sputum should be examined by acid-fast stain for mycobacteria, by Gram stain for bacteria, and by cytology for malignant cells. The presence of a large number of red blood cells often makes these examinations difficult. Cultures should be obtained from sputum and blood if bacterial pneumonia is suspected. Coagulation times, bleeding time, platelet count, and hematocrit should be determined. Blood for transfusion should be arranged for but often is not needed to correct a low hematocrit until operative treatment is indicated. The presence of a coagulopathy or thrombocytopenia, however, should trigger the administration of replacement of coagulation factors or platelets to help to control the bleeding process. Arterial blood gases are helpful in evaluating the adequacy of gas exchange and the ability to tolerate further aspiration of blood into the lungs.

The presence of renal insufficiency changes the differential diagnosis of hemoptysis to include pulmonary-renal syndromes including Goodpasture's syndrome and Wegener's granulomatosis. Therefore, it is important to evaluate the urine for the presence of hematuria and to determine renal function. Unfortunately, despite a rigorous evaluation, the investigators in one study were unable to identify a cause of hemoptysis in 41% of patients with a serum creatinine level greater than 1.5 mg/dL and hemoptysis, and the yield of fiberoptic bronchoscopy was very low.

D. Imaging Studies—Usual procedures such as chest x-rays and CT scans may show an infiltrate, cavity, atelectasis, or other features that suggest a lesion from which bleeding is arising. These findings should be interpreted with caution, however, because another unsuspected source may be present. For example, aspirated blood may cause atelectasis and infiltrates remote from the actual bleeding site. Lung cavities are often multiple, bilateral, and involve several lobes, but the cavity from which blood is coming may not be readily identified. Cavitory lung disease, especially in the upper lung zones, may suggest tuberculosis, but active tuberculosis cannot be diagnosed accurately from imaging studies. Furthermore, cavities are seen in fungal infection, sarcoidosis, necrotizing pneumonia, and other diseases. A mycetoma

within a cavity may be identified on chest x-rays or CT scan—especially if taken with the patient in several positions. High-resolution CT scans without intravascular contrast agents are helpful in establishing the cause and location of hemoptysis. Localization of bleeding, however, may require bronchial or, rarely, pulmonary angiography (see below).

Treatment

In life-threatening hemoptysis, maintenance of the airway and removal of blood from the airway take precedence. Diagnostic measures must be deferred until it is established that the patient can maintain adequate gas exchange with or without an artificial airway, oxygen, and other measures to reverse coagulopathies or other bleeding tendencies. After the patient is stabilized, efforts are directed toward determining the site of bleeding as rapidly as possible so that definitive control of the bleeding site can be achieved.

The outcome of patients with large-volume hemoptysis is said to be poor, and this has strongly influenced recommended treatment options. However, much of these data comes from older studies in which tuberculosis caused the hemoptysis from severe chronic destruction of the lung parenchyma. For example, a series of patients from the 1950s and 1960s demonstrated that patients who coughed up more than 600 mL of blood within 16 hours had a 75% mortality rate, whereas those who produced less than 600 mL over 16–48 hours had a mortality rate of only 5%. About three-fourths of these patients had active or inactive tuberculosis, with the remainder having lung abscess, bronchiectasis, or bronchogenic cancer. Another study of patients who expectorated more than 600 mL of blood within 24 hours reported a 22% overall mortality rate.

The term *life-threatening hemoptysis* is preferred over *massive hemoptysis*. Although the volume of expectorated blood does relate to outcome, asphyxiation rather than exsanguination is the most common cause of death. Therefore, the most important risk factors for mortality are the *rapidity* of blood loss and the severity of preexisting cardiopulmonary disease. Other prognostic signs are listed in [Table 24–2](#), and most reflect the ability to control blood loss, maintain a patent airway, and provide for adequate gas

exchange. Some studies have pointed out that spontaneous cessation of bleeding in those who have had massive hemoptysis does not necessarily predict a good short- or long-term outcome. Rebleeding is very common without definitive treatment and may occur soon after the patient has been judged to be stable or greatly improved.

A. Localization of Bleeding—Severe hemoptysis occasionally may be misidentified as upper GI bleeding or bleeding from the nose, nasopharynx, mouth, or upper airway, but the history and examination should confirm or absolve these structures as possible sites of bleeding. The evaluation of the bloody material produced by the patient occasionally can be helpful in distinguishing between a GI source and a lung source. The presence of alveolar macrophages or an alkalotic pH in the absence of acid-suppressing medications is more likely to represent a respiratory tract specimen, whereas food particles or an acidic pH is more suggestive of a stomach source. Once the lungs are suspected, the next step is to establish whether bleeding is from the trachea or the right or left lung. Although it is tempting to conclude that an infiltrate or cavity on chest x-ray or chest CT scan indicates the site of bleeding, bilateral disease in tuberculosis, infection, and inflammatory disorders is common. The infiltrate also may represent a collection of blood brought up from the contralateral side or from a different lobe or segment.

Bronchoscopy is the procedure of choice for identification of a bleeding site in the tracheobronchial tree, and flexible fiberoptic bronchoscopy generally is preferred over rigid bronchoscopy. Bronchoscopy performed early in the course of massive hemoptysis increases the likelihood of localization. The advantages of fiberoptic bronchoscopy are patient comfort and the ability to explore further generations of bronchi. The fiberoptic bronchoscope may be of limited use in severe hemoptysis because the view is easily obscured by small amounts of blood, and its suctioning ability is limited by the small-diameter channel. Although the fiberoptic bronchoscope can be passed through a large enough endotracheal tube (usually >8 mm), maintenance of a patent airway may be very difficult if the patient is actively bleeding. The fiberoptic bronchoscope provides limited treatment options, including lavage, suctioning, and balloon tamponade. New techniques have shown value, including direct application of thrombin or thrombin-fibrinogen. Bronchoscopy-guided topical hemostatic tamponade therapy (THT) using an oxidized regenerated cellulose (ORC) mesh recently has been shown to be helpful. On the other hand, the rigid bronchoscope can be used even during large-volume hemoptysis because of its better ability to suction blood, maintain the airway, and provide adequate ventilation. In general, if hemoptysis subsides and the patient is stable, bronchoscopy can be delayed for several days so that the fiberoptic instrument can be used for careful inspection of the tracheobronchial tree. In more emergent situations, rigid bronchoscopy is the preferred bronchoscopic technique. Isolation of a bleeding lobe or segment by endobronchial balloon tamponade using the

Table 24–2. Factors contributing to life-threatening hemoptysis.

Massive hemoptysis (estimated >600 mL blood over 24 hours)
Decreased pulmonary function (obstructive or restrictive disease)
Altered mental status or level of consciousness
Poor cough due to advanced age, sedation, neuromuscular weakness
Coagulopathy or thrombocytopenia
Mechanism of hemoptysis
Underlying disease

fiberoptic or rigid bronchoscope and lavage of the bleeding site with iced saline or vasoconstrictor agents such as epinephrine should be regarded as minor adjuncts to control of hemoptysis. Lastly, these procedures may be difficult to perform in the face of severe hemoptysis.

Bronchial arteriography may be useful for localization of bleeding, and bronchial artery embolization (see below) is used widely for control of severe hemoptysis. The angiographic characteristics of potentially involved bronchial arteries include hypervascularity, hypertrophy, aneurysms, and bronchopulmonary anastomoses. Occasionally, no abnormalities are identified. In tuberculosis and other disorders, these changes may be seen in several locations, including bilaterally, suggesting that findings do not establish the site of bleeding with complete confidence. Because extravasation of contrast material injected into a bronchial artery is rarely, if ever, seen except with rapid blood loss, exact localization of a bleeding site is often not confirmed until after successful embolization. If there is no evidence of potential bronchial artery abnormalities, some investigators suggest that pulmonary arteriography should be performed to examine the pulmonary circulation as a source of bleeding.

B. Medical Treatment—Supportive care consists of maintaining an adequate airway and introducing measures to control bleeding. Patients should be at bed rest with the suspected or known side of bleeding dependent to protect less involved parts of the lungs from filling with blood. Cough suppressants such as codeine and sedative drugs should be used cautiously, with a balance between decreasing irritation of the airway from coughing and losing the effectiveness of cough in keeping the airways clear. Vitamin K, fresh-frozen plasma, and platelet transfusions should be given if coagulopathy or thrombocytopenia is present. Significant anemia is not usually due to acute hemoptysis, so erythrocyte transfusions are needed only if the patient has symptomatic anemia or other sources of blood loss. Oxygen generally is administered to all hospitalized patients. Antibiotics are often given to decrease any inflammatory component owing to acute bacterial bronchitis. If active tuberculosis is suspected, antituberculosis therapy should be instituted.

The best means of maintaining an adequate airway is the patient's own cough. The decision to place an endotracheal tube implies that the rate and volume of hemoptysis exceed the patient's ability to cough up blood to keep the airway clear. A cuffed endotracheal tube can be introduced into the trachea and the patient suctioned to see if this treatment is adequate to keep the airway clear. A sufficiently large endotracheal tube—preferably at least 8 mm—is usually needed. If extensive bleeding continues, selective endobronchial intubation of the *nonbleeding* lung for ventilation can be performed by advancing the endotracheal tube into a main bronchus to protect the nonbleeding lung. For uncontrolled right-sided bleeding, the endotracheal tube should be

inserted into the left main bronchus under fluoroscopic or bronchoscopic guidance. The left lung is selectively ventilated, and blood is allowed to come up the trachea around the tube. For left-sided bleeding, however, the endotracheal tube cuff should be placed in the trachea, and a balloon-tipped catheter (eg, Fogarty-type 14F balloon) is used to seal the left main bronchus while the right lung is selectively ventilated. This method permits ventilation of the entire right lung, including the right upper lobe, because its opening is usually close to the carina and is frequently blocked by the insertion of an endotracheal tube into the right mainstem bronchus. Placement of the balloon-tipped catheter may be difficult while there is active bleeding.

Although the use of double-lumen endobronchial tubes for split lung ventilation during thoracic surgery has been advocated to separate the bleeding lung from the nonbleeding lung, these tubes are not placed easily by inexperienced persons and are subject to displacement even if situated properly. In addition, the two lumens are small, which limits the amount of blood that can be suctioned. Both Carlens-type double-lumen tubes and newer plastic double-lumen tubes with soft low-pressure tracheal and bronchial cuffs have been used to achieve lung separation in hemoptysis, but only experienced personnel familiar with these devices should be asked to insert them. To maintain the position of these tubes, patients generally require heavy sedation and sometimes even paralysis.

C. Bronchial Artery Embolization—Bronchial arteriography and selective bronchial artery embolization with artificial material (eg, polyvinyl alcohol, steel coils, and gelatin sponge) have greatly changed the management of severe hemoptysis. Control of bleeding is achieved with a high degree of success in patients with a variety of causes of hemoptysis. Bronchial artery embolization is performed by identifying bronchial arteries leading to the affected side, the usual patterns consisting of one or two bronchial arteries on each side arising from the aorta between the fifth and sixth thoracic vertebrae. Branches of these arteries also may supply anterior spinal arteries and intercostal arteries. Complications of this procedure include distal arterial embolization if the catheter is not placed far enough into the selected artery and spinal cord damage if embolization is performed into a branch supplying both the bronchial artery and the spinal cord. If performed with proper care, this procedure is highly effective and may lead to long-term resolution of hemoptysis as well as short-term control prior to definitive therapy. Estimates of immediate control of bleeding by bronchial arterial embolization range as high as 90% of patients. Recurrent bleeding after successful embolization may suggest the need for repeat embolization in the same or other areas. In some patients with chronic inflammatory lung disease, identification of collateral arterial vessels may be important. In one study, lasting control of hemoptysis was achieved in 82% of patients during follow-up for as long as 24 months. Recurrent bleeding was seen with significantly

greater frequency in patients with residual pulmonary disease and mycetomas.

D. Surgical Treatment—Surgical resection of the bleeding lobe or segment in patients who can tolerate the procedure removes the threat of recurrent bleeding. Earlier reports of mortality rates higher than 30% from resectional surgery in massive hemoptysis are now considered to be due to ongoing bleeding, poor pulmonary function, and failure of preoperative localization of the bleeding site. Local control of bleeding by airway management or bronchial artery embolization allows surgery to be performed under more controlled conditions, and emergency surgery is now quite rare, with a corresponding decrease in surgical deaths.

On the other hand, many patients with severe hemoptysis will not be surgical candidates because of extensive bilateral lung disease and severe reduction of lung function. Of the remainder, medical management is usually adequate to control bleeding, and early surgical therapy is reserved for those with progressive aspiration of blood or inability to control bleeding.

There is debate about prophylactic surgical resection after severe hemoptysis has resolved. Recurrent bleeding is common after medical management in some series (25–40%), and death from hemoptysis has occurred during the initial bout of hemoptysis without warning or during a recurrent bout after bleeding had apparently ceased. This risk of recurrent life-threatening hemoptysis has prompted some to perform elective resectional surgery in all patients with hemoptysis in whom surgery is deemed tolerable. However, while there is nearly universal agreement that surgery is indicated for recurrent hemoptysis from a tuberculous or other cavity in which a mycetoma is identified, prophylactic surgery is not universally recommended. Potential candidates for resection include those with well-localized disease, adequate pulmonary function, minimal pleuropulmonary adhesions, and a high likelihood of recurrence. Results of surgical resection should be compared with the increasingly long-term experience with arterial embolization (nonsurgical management) for hemoptysis.

▶ Deep Venous Thrombosis & Pulmonary Thromboembolism

ESSENTIALS OF DIAGNOSIS

Deep venous thrombosis:

- ▶ Risk factors include a chronic or acute illness, immobilization, recent surgery or orthopedic injury, hypercoagulable state.
- ▶ Asymmetric calf or thigh pain or tenderness but may be asymptomatic.
- ▶ Confirmation by contrast venography or duplex compression ultrasonography.

Pulmonary thromboembolism:

- ▶ Dyspnea, tachycardia, pleuritic chest pain, and tachypnea; if severe, hypotension, syncope, cyanosis, or shock.
- ▶ May have evidence of deep venous thrombosis.
- ▶ Mild to moderate hypoxemia, increased $P(A-a)_{O_2}$, and mildly reduced $Paco_2$.
- ▶ Suggested by a clinical syndrome consistent with pulmonary embolism in the presence of a confirmed deep vein thrombosis
- ▶ Confirmation by ventilation-perfusion radionuclide scan, pulmonary angiogram, or CT angiography (helical CT scan).

General Considerations

Venous thromboembolism is a disease thought to affect approximately 1 in every 1000 hospitalized patients in the United States and Europe. Some studies suggest that this process accounts for or contributes to over 200,000 deaths annually in the United States. Because of the difficulty in recognizing and diagnosing this syndrome, this figure may be an underestimate of its true prevalence.

Deep venous thrombosis and pulmonary thromboembolism present three primary problems in the ICU. First, patients with pulmonary thromboembolism may present with severe respiratory failure or hemodynamic instability. Second, critically ill patients with a variety of medical and surgical disorders can develop pulmonary thromboembolism complicating their underlying conditions. The diagnosis of venous thromboembolism in these ICU patients is often especially difficult to make or confirm. The usual method of treatment with anticoagulation is hazardous and may be contraindicated in some of these patients. Finally, there is increased emphasis on the prevention of deep venous thrombosis and pulmonary thromboembolism in ICU patients given that they tend to have multiple risk factors for this disease. The causative relationship between the two disorders means that the diagnosis, treatment, and prevention of both must be considered together.

Pathophysiology and Pathogenesis

A. Deep Venous Thrombosis—The pathophysiology of deep venous thrombosis centers around Virchow's triad of stasis of blood flow, intimal vascular injury, and a hypercoagulable state. It is often the failure of mechanisms that prevent the normally circulating blood from clotting in the intravascular space, which leads to clot formation. A systemic hypercoagulable state can be either inherited or acquired and is identified in only a small fraction of patients with venous thromboembolism. In general, these thrombophilic states do not cause a clinical thrombotic event without the presence of a second acquired risk factor or precipitating circumstance. Factor V Leiden or activated protein C resistance has been identified in up to 5% of the Caucasian population in the United States. Other hypercoagulable states include congenital or acquired deficiency of circulating anticoagulants (eg, deficiency of protein C, protein S, or antithrombin III), prothrombin gene mutation (ie, G20210A), abnormalities in fibrinolysis, the presence of a lupus-associated anticoagulant, and increased procoagulant activity such as occurs in some malignant diseases and severe generalized trauma. Assessment for the presence of one of these thrombophilic states can only in part be performed at the time of the acute thromboembolic event because the clotting process itself can contribute to low of protein C and S levels. These low protein C or S levels during the acute phase may not represent a true deficiency of these factors, but may actually represent consumption of these factors. Factor V Leiden and anticardiolipin, and antiphospholipid antibodies, on the other hand, are not affected by the acute clotting process. More often, however, patients with deep venous thrombosis have a combination of venous stasis plus local damage to the venous endothelium, exposing subendothelial procoagulant tissue factor to the blood. Obstruction of venous flow leads to edema and pain in the area drained by the affected veins. On occasion, the intravenous clot is palpable on examination as a cord. Destruction of venous valves and persistent venous occlusion by this process may lead to venous

insufficiency or permanent localized discomfort, edema, and pain known as the *postphlebitic syndrome*.

Risk factors for deep venous thrombosis include prolonged immobilization, trauma to the extremity or pelvis, generalized trauma, preexisting venous insufficiency, peripheral arterial disease, recent surgery, pregnancy or recent delivery, obesity, nephrotic syndrome, congestive heart failure, acute myocardial infarction, malignancy, estrogen therapy, and advanced age. Another important risk group consists of patients with neurologic diseases leading to immobility including strokes and spinal cord injury with subsequent paralysis. Severe acute illness necessitating hospital admission is also associated with an increased incidence of deep venous thrombosis. Lastly, the increasing use of central venous catheters in the ICU setting has led to an increasing incidence of upper as well as lower extremity deep venous thromboses.

Deep venous thrombosis develops most frequently in the posterior tibial vein, the popliteal vein just above the knee, and the common femoral vein in the thigh. A smaller number of patients with deep venous thrombosis have thrombi in the pelvic veins. While the calf vein is probably the most common site of deep venous thrombosis, only about 15–20% of these lesions will extend proximally into deep veins above the knee. In addition, it appears that upper extremity deep venous thrombosis may occur more frequently than previously speculated owing to the use of short- and long-term central venous catheters inserted into the internal jugular or subclavian veins in ICU patients. Thrombi also may be found in the right atrium in patients with chronic atrial fibrillation and in the ventricles of patients with dilated cardiomyopathy or ventricular aneurysms. Hypercoagulable states may cause clots to form in the superior and inferior vena cava, the renal veins (especially in nephrotic syndrome), and the hepatic veins (in Budd-Chiari syndrome).

B. Pulmonary Thromboembolism—As many as 90% of patients with pulmonary thromboembolism have blood clots arising from proximal veins of the lower extremities (deep femoral veins), with the remainder having thrombi coming predominantly from pelvic veins. In a study of patients with deep venous thrombosis, perfusion lung scans were uniformly negative in those with thrombosis limited to calf veins only. This emphasizes the importance of identifying high-risk thrombi located in popliteal and thigh veins or extension of clot from calf to proximal veins. Thrombosis of superficial veins is rarely associated with significant pulmonary embolism. With increasing use of central venous catheters and transvenous pacemakers, there has been a reported rise in venous thrombosis and subsequent pulmonary thromboembolism from the upper extremity. A 7–20% risk of embolization has been cited in patients with symptomatic upper extremity thromboses.

The finding of lower extremity proximal deep venous thrombosis has become part of several algorithms for the diagnosis of pulmonary embolism because of the association between proximal leg deep venous thrombosis and pulmonary embolism. These data are obtained from the overall population

of patients with pulmonary embolism but may not reflect findings in patients already in the ICU. Nevertheless, deep venous thrombosis of the proximal leg veins remains the most frequent source of pulmonary thromboemboli.

The clinical manifestations of pulmonary thromboembolism reflect two pathologic processes: obstruction of the pulmonary circulation resulting in hemodynamic compromise and gas-exchange abnormalities. The degree of circulatory compromise depends on the size and number of thromboemboli and the preembolic state of the right side of the heart and pulmonary circulation. Some authors have used the term *massive pulmonary embolism* to describe the angiographic occlusion of two or more lobar pulmonary arteries or greater than 50% of the pulmonary circulation, while others reserve this label for patients who have hemodynamic instability directly related to the embolic event. The use of this radiographic description of a “massive pulmonary embolism” has started to fall out of favor as these large or multiple emboli may or may not be associated with circulatory collapse and shock. Patients with a previously normal pulmonary circulation and right ventricular function generally can tolerate occlusion of even a large pulmonary artery with maintenance of sufficient cardiac output to avoid shock. However, acute pulmonary thromboembolism in a patient with preexisting pulmonary hypertension or heart failure with minimal reserve may lead to acute right-sided heart failure and subsequent circulatory collapse. The same may happen to a previously normal patient in whom a very large embolus lodges in the main pulmonary artery or who has multiple moderately sized emboli in several major branches.

Occlusion of pulmonary arteries results in decreased regional perfusion of the lungs. If ventilation to these areas is maintained, then high \dot{V}/\dot{Q} areas contribute to increased dead space ventilation. Minute ventilation requirements increase to maintain PaCO_2 within normal range. Arterial hypoxemia is much more common. Although the mechanism of hypoxemia is not completely understood, it probably results from a combination of ventilation-perfusion mismatching from atelectasis, redistribution of pulmonary blood flow, and increased blood transit time. Occasionally, acute pulmonary hypertension leads to the opening of a patent foramen ovale with intraatrial right-to-left shunting and severe refractory hypoxemia.

The manifestations of pulmonary thromboembolism often appear to be greater than can be explained by the degree of vascular occlusion by thrombi. Although this is often due to a lack of cardiopulmonary reserve in patients with chronic illness, it is probable that vasoactive and bronchoactive substances play a role as well as normal compensatory processes within the lung circulation and parenchyma. Among potential candidates for participation in this response are products released by platelets and endothelial cells. In addition, occlusion of a pulmonary artery is associated with a decreased amount and effectiveness of surfactant in the region of lung supplied by that vessel contributing to atelectasis.

Pulmonary infarction is another potential manifestation of pulmonary thromboembolism. However, this diagnosis does not seem to alter outcome or management other than

causing different abnormalities on chest x-ray and somewhat different clinical manifestations. Pulmonary infarction is uncommon in pulmonary embolism because of the dual systemic and pulmonary artery blood supply to the lung. Patients who present with pulmonary infarction are more frequently those with congestive heart failure, in whom both pulmonary venous congestion and systemic perfusion may be compromised at baseline.

Because the lungs receive the total cardiac output, a number of other emboli can make their way into the pulmonary arterial circulation. These include pieces of tumor, including adenocarcinomas that have eroded into the systemic veins; foreign bodies such as broken intravenous catheters or particulate matter accidentally or deliberately injected into veins; fat and tissue emboli from orthopedic injury, operative procedures, or bone marrow infarction as seen in acute chest syndrome in patients with sickle cell disease; air introduced through intravenous lines, lung rupture, or decompression during ascent from underwater diving; and amniotic fluid introduced into the systemic circulation during a tumultuous obstetric delivery. The pathophysiologic consequences of these emboli depend somewhat on the clinical situation, the size and number of emboli, and concomitant medical problems. Of note, fat emboli may result in a distinct syndrome with systemic manifestations as a result of the breakdown of free fatty acids within the microcirculation.

Clinical Features

The clinical features of deep venous thrombosis and pulmonary thromboembolism are intertwined, and both can present diagnostic difficulties. Deep venous thrombosis causes nonspecific clinical findings and is sometimes found in patients with pulmonary embolism in whom thrombosis was previously unsuspected. The diagnosis of pulmonary thromboembolism can be difficult because it too presents with nonspecific symptoms, signs, and laboratory tests that suggest other acute lung and heart diseases. In the critically ill patient with preexisting cardiac or respiratory failure, pneumonia, atelectasis, pleural effusion, or infection, diagnosing superimposed pulmonary thromboembolism may be even more difficult. It is often suspected when a critically ill patient undergoes acute deterioration from previous baseline findings manifested by tachypnea, tachycardia, and impaired gas exchange.

A. Deep Venous Thrombosis—

1. SYMPTOMS AND SIGNS—Obstruction of the deep venous system of the leg may result in edema of the lower part or the entire leg, pain, tenderness, redness, and other nonspecific features. Findings are notoriously unreliable and insensitive, with as many as 50% of patients with deep venous thrombosis being asymptomatic or lacking abnormal physical findings. Clinically significant venous thrombi may not completely occlude the vascular lumen, or collateral veins and lymphatics may prevent swelling. Most blood clots do

not elicit an inflammatory response unless there is additional vascular injury, so redness and warmth are most often not present in uncomplicated deep venous thrombosis. Importantly, patients with proximal deep venous thrombosis may have a somewhat greater tendency to have silent disease compared with those who have calf vein involvement. However, swelling above or below the knee, recent immobility, cancer, and fever were found to have diagnostic value in proximal acute deep venous thrombosis. Only 5% of 95 patients had none of these five findings, whereas 42% had between two and five of these features.

The differential diagnosis of deep venous thrombosis in symptomatic patients includes cellulitis and other soft tissue infections, popliteal cysts with below-the-knee swelling, septic or inflammatory arthritis, lymphatic obstruction or inflammation, external compression of deep veins, trauma, and hematomas. The finding of unilateral leg swelling does not rule out primary disease in pelvic iliac veins.

2. DIAGNOSTIC WORKUP—Imaging studies for deep venous thrombosis include contrast venography, duplex compression ultrasonography, impedance plethysmography, radiofibrinogen uptake scans, CT venography, and MRI. Contrast venography uses injection of radiopaque material into peripheral veins of the legs to identify obstructing thrombi in the deep venous system. Between 20% and 50% of proximal venous thrombi usually can be identified as intraluminal filling defects. Costs and complications make this test less desirable.

Duplex ultrasound uses a combination of real-time ultrasound imaging to demonstrate normal venous collapse with direct compression and Doppler venous flow assessment. Because collapse with compression is the most important feature, a more accurate name for this technique is *compression ultrasonography*. Failure to collapse or demonstration of intraluminal echoes is indirect evidence of deep venous thrombosis. Compression ultrasonography is practical for the popliteal vein, the common femoral vein, and often the superficial femoral vein. It is generally regarded as having as high as 89–98% sensitivity for proximal deep venous thrombosis and comparable specificity. It is less reliable in imaging the venous plexus in the calf, and it cannot detect thrombi limited to iliac or pelvic veins. As discussed below, compression ultrasonography has been incorporated into numerous diagnostic algorithms for the diagnosis of pulmonary thromboembolism.

Impedance plethysmography uses the change in electrical impedance of the lower extremity when blood flows out of the leg venous system after release of a pressure cuff. Failure to change impedance is presumptive evidence of proximal deep venous thrombosis. This test has been reported to be highly accurate for diagnosing proximal deep venous thrombosis, although other forms of venous obstruction and congestive heart failure can give false-positive results. In addition, the accuracy of the test is likely to be hospital-dependent or operator-dependent. It has been recommended

that each facility establish the accuracy of impedance plethysmography compared with contrast venography. Impedance plethysmography must be performed with the leg held immobile and cannot be used if there is a plaster cast on the suspected leg. In a comparison trial of compression ultrasonography and impedance plethysmography, the predictive value of compression ultrasonography was significantly higher in symptomatic outpatients.

Radiofibrinogen leg scans demonstrate the inclusion of radiolabeled fibrinogen into actively forming thrombi. This test is useful primarily for identifying calf and lower-thigh deep venous thrombosis. Only clots that are actively forming can be located with this method. It is poor in detecting proximal deep venous thrombosis. This test is used rarely today except in research protocols.

MRI and CT pulmonary angiography accompanied by venography are currently being investigated for their role in the workup of thromboembolic disease. The advantage of these studies would be evaluation of the pulmonary vascular system for emboli combined with evaluation of the pelvis and lower extremity venous system for their source in a single study.

Owing to its invasive nature, contrast venography is obviously not appropriate for screening patients at risk for deep venous thrombosis. Both impedance plethysmography and compression ultrasonography can be used effectively for this purpose. In patients at high risk for deep venous thrombosis, such as those with pelvic or hip trauma and those with critical medical illness, compression ultrasonography is probably most sensitive and specific for proximal vein thrombosis, even though there has been greater experience with impedance plethysmography. In patients with deep venous thrombosis limited to the calf, serial compression ultrasonography of patients is needed to identify the 15–20% of patients who extend their thrombi into the proximal veins. Most clots have been found to extend proximally within the first 7 days. Thus studies have recommended follow-up examinations within 2–3 days and again in 7–10 days if clinical suspicion for deep venous thrombosis remains high.

B. Pulmonary Embolism

1. SYMPTOMS AND SIGNS—The clinical features of pulmonary embolism have been accurately described, and review of these findings demonstrates their nonspecificity. Table 24–3 summarizes data from a series of 500 patients comparing the clinical signs and symptoms in patients with proven pulmonary emboli by pulmonary angiography (202 patients) versus those without pulmonary embolism. Dyspnea and chest pain were the most common complaints; tachycardia, tachypnea, rales, and an increased intensity of the pulmonic component of the second heart sound were the most frequent findings on physical examination. The classic findings of hemoptysis, chest pain, and dyspnea were uncommon as a triad. Fewer than one-third of the total group had symptoms or signs suggesting deep venous thrombosis. While it is correct that these clinical findings do

not distinguish patients with pulmonary embolism from those with other severe heart and lung diseases, patients suspected of pulmonary embolism who have cyanosis, hypotension, shock, or syncope deserve particular consideration.

Symptoms and signs can establish meaningful probabilities for pulmonary embolism. Several clinical models for estimating probability have been developed and validated. Patients suspected of pulmonary embolism were stratified into low, moderate, and high probability, and these classifications were confirmed by subsequent testing (Table 24-4). This clinical estimate of pulmonary embolism likelihood is

Table 24-4. Estimating clinical probability of pulmonary embolism (PE).

	Points
Risk factors

High (74%)	Total ≥11

Modified from Le Gal G et al: Prediction of pulmonary embolism in the emergency department: The revised Geneva score. *Ann Intern Med* 2006;144:165-71.

the first step in diagnosis, followed by laboratory and imaging studies. Objectively derived clinical prediction rules should be used for judging “pretest” probability of pulmonary embolism. These have been derived for nonhospitalized patients suspected of pulmonary embolism and may not be valid in hospitalized or ICU patients.

2. LABORATORY FINDINGS—Arterial blood gases most often show mild to moderate hypoxemia, increased $P(A-a)O_2$, and mildly reduced $Paco_2$. Almost all patients with pulmonary embolism have a PaO_2 of less than 80 mm Hg, but no absolute level of PaO_2 can be used to exclude the diagnosis. Diagnostic accuracy may be improved somewhat by using the $P(A-a)O_2$ difference rather than the PaO_2 , but again, a clear distinction between those with and those without pulmonary embolism cannot always be made. In the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study, 7% of patients with angiographically documented pulmonary emboli had completely normal arterial blood gas measurements. Conversely, another study found that patients suspected of having a venous thromboembolic event who had a normal $P(A-a)O_2$ had only a 1.8% chance of having a pulmonary embolism. Severe hypoxemia refractory to oxygen administration may indicate the opening of a patent foramen ovale. Hypercapnia is unusual and suggests the presence of underlying lung disease.

Sinus tachycardia is a frequent and nonspecific finding in acute pulmonary embolism. Supraventricular tachycardia and atrial fibrillation are sometimes present. Features suggesting acute right-sided heart strain on the ECG occur relatively infrequently; these include acute right-axis deviation, P pulmonale, right bundle branch block, and inverted T waves and ST-segment changes in right-sided leads. Electrocardiographic patterns such as an S wave in lead I, a Q wave in lead III, and an inverted T wave in lead III (“S1Q3T3”) and S waves in leads I, II, and III (“S1S2S3”) were considered highly predictive of pulmonary embolism. These observations were found in fewer than 12% of patients with pulmonary emboli. In the differential diagnosis of pulmonary embolism, the ECG is particularly useful to assess the presence of myocardial ischemia and infarction.

D-dimer, a fibrin degradation product, is found in the plasma of patients with deep venous thrombosis and pulmonary embolism. D-dimer is the result of plasmin action (thrombolysis) on fibrin monomers that have undergone cross-linking by factor XIII to form fibrin polymers. Various methodologies are available to measure D-dimer levels. ELISA D-dimer assays have a higher sensitivity and negative predictive value (91–100%) when compared with latex agglutination techniques. However, the older ELISAs were more labor-intensive, required skilled personnel, and took hours to complete, making them less useful clinically in an emergent situation, whereas the semiquantitative latex agglutination studies can be performed at the bedside. A D-dimer level of less than 500 µg/L by ELISA is considered the cutoff for excluding venous thromboemboli. Newer latex whole blood agglutination techniques have demonstrated consistently high negative predictive values in patients with low pretest probability of disease. Current recommendations are to combine this laboratory finding with the pretest clinical probability as well as some other noninvasive evaluation to guide decision making for diagnosis and management. The one exception would be in the face of a low clinical pretest probability, when the finding of a low D-dimer may be enough to exclude venous thromboembolic disease. Lastly, D-dimer is of limited use in a number of clinical scenarios, which are associated with elevated D-dimer levels as part of the disease state including surgery or trauma in the past 3 months, underlying malignancy, sepsis with or without disseminated intravascular coagulation (DIC), inflammatory states, pregnancy, or abnormal liver function.

Elevation in cardiac troponins in the setting of an acute pulmonary embolism has been described. In patients with either a moderate or large pulmonary embolism, troponin T (TnT) levels greater than 0.1 ng/mL were seen in 32% of patients in one trial. None of the patients with small emboli had an elevation of this cardiac marker. In another study, troponin I (TnI) levels greater than 0.4 ng/mL were seen in 21% of patients with pulmonary embolism, with levels exceeding 2.3 ng/mL in 4% of patients. It is thought that the strain on the right ventricle from the increased pulmonary arterial resistance in the face of an acute embolism leads to the right ventricular myocardial ischemia in these patients and is associated with a poorer prognosis.

3. IMAGING STUDIES—Radiographic studies include nonspecific tests such as chest x-rays, examinations of the pulmonary circulation such as perfusion lung scans, CT pulmonary angiography (spiral or helical CT scans), MRI, and pulmonary angiograms, as well as studies directed at finding deep venous thrombosis.

a. Chest x-ray—The chest x-ray is most useful in identifying coexisting problems such as pneumonia, lung mass, lymphadenopathy, pulmonary edema, atelectasis, or pleural effusion. The most common findings in pulmonary embolism without coexisting disease are nonspecific, including no visible abnormality, enlarged cardiac silhouette, elevated hemidiaphragm, atelectasis, or small pleural effusion. A normal chest x-ray in a patient with shortness of breath and hypoxemia should prompt a further evaluation for pulmonary embolism. Findings suggestive of pulmonary vascular occlusion, such as an apparent cutoff of a segmental or lobar pulmonary artery, regional hyperlucency of the lung parenchyma or oligemia (Westermarck’s sign), or a wedge-shaped density consistent with pulmonary infarction (Hampton’s hump if located in the periphery), may suggest pulmonary embolism but are insensitive and lack specificity.

b. Radionuclide ventilation-perfusion scan—The ventilation-perfusion lung scan was previously the test used most frequently to diagnose pulmonary embolism. Newer imaging studies have replaced this nuclear medicine study in many centers. In addition, scan results must be considered carefully because these tests do not have perfect diagnostic accuracy, and over 70% of patients undergoing this radiographic evaluation have indeterminate results. To perform the perfusion scan, radionuclide-labeled macroaggregated albumin is injected into a peripheral vein, after which the labeled particles become trapped in the pulmonary capillary bed. Uniform distribution of the radionuclide throughout the lung fields implies the absence of significant localized pulmonary arterial obstruction, whereas a pulmonary embolism occluding a pulmonary artery will result in a perfusion defect. Unfortunately, perfusion defects commonly result from other causes, including focal vasoconstriction accompanying atelectasis, pneumonia, or bronchospasm.

To improve diagnostic value, uniformity of ventilation is assessed using a ventilation scan, performed by inhalation of either radioactive Xenon or an aerosol containing a radiolabeled solute. The perfusion and ventilation scans are then compared. A sufficiently large perfusion defect *without* a corresponding ventilation defect in the same area (ie, mismatched defect) generally is considered supportive of the diagnosis of pulmonary embolism. On the other hand, a matched ventilation-perfusion defect generally is considered indeterminate and not helpful in making the diagnosis of pulmonary embolism or other kinds of heart or lung disease such as pneumonia or bronchospasm.

By convention, ventilation-perfusion lung scans are interpreted as normal (no perfusion defects), low or high probability for pulmonary embolism, or intermediate probability (sometimes called *indeterminate*) for pulmonary embolism. Prospective studies have led to accepted diagnostic strategies

Table 24-5. PIOPED lung scan interpretation criteria (modified).

High probability
≥ 2 large (>75% of the segment), OR
≥ 2 moderate (25-75% of the segment) plus one large, OR
≥ 4 moderate mismatched perfusion lung scan defects
Low probability
Nonsegmental perfusion defects only, OR
One moderate mismatched segmental perfusion defect with normal chest x-ray, OR
Any perfusion defect with a larger chest x-ray abnormality, OR
Limited number of large or moderate perfusion defects with matching ventilation defects (with normal or mildly abnormal chest x-ray)
Intermediate probability
Not falling into normal, low-, or high-probability categories
Borderline high or borderline low
Difficult to categorize as high or low
Normal
No perfusion defects, OR
Perfusion outlines exactly the shape of lungs seen on chest x-ray (chest x-ray or ventilation lung scan may be abnormal)

for pulmonary embolism. The PIOPED multicenter study compared lung scan results with pulmonary angiography in patients with suspected pulmonary embolism. Table 24-5 is a modified summary of lung scan categories and criteria used in 931 patients included in this study.

Of patients with suspected pulmonary embolism, lung scans indicated a high probability of pulmonary embolism in 13% and were normal or nearly normal in 14%. Intermediate or low probability was the conclusion in 73%. The sensitivity, specificity, and likelihood ratios of lung scan interpretations for angiographically diagnosed pulmonary emboli are shown in Table 24-6. The likelihood of pulmonary embolism parallels the interpretation of the lung scans, especially when used in conjunction with the pretest clinical likelihood of pulmonary embolism. A reading of *any* probability (low, intermediate, or high) of pulmonary embolism on lung scan resulted in 98% sensitivity but low specificity. Unfortunately, only 41% of cases of pulmonary embolism had high-probability lung scans, whereas 42% had intermediate-probability scans and 17% had low-probability scans. It is emphasized that patients with low-probability lung scans are found to have pulmonary emboli about 15–30% of the time.

These and other data show that ventilation-perfusion lung scans are of greatest utility when they show high probability for pulmonary embolism (87% likelihood of pulmonary embolism in all patients suspected of pulmonary embolism; 96% if clinical suspicion is high) or when they are normal (nil to 4% likelihood of pulmonary embolism during long-term follow-up even if clinical suspicion was high). Thus high-probability lung scans effectively predict pulmonary embolism, whereas a normal scan (no perfusion defects) effectively excludes pulmonary embolism. Treatment or withholding therapy can be guided by this rule with considerable confidence. Unfortunately, the majority of patients suspected of having pulmonary embolism fall into intermediate or low probability, and substantial numbers within each

Table 24-6. Sensitivity, specificity, likelihood ratios, and posttest probabilities of ventilation-perfusion radionuclide lung scans and CT pulmonary angiograms for pulmonary embolism.

For a patient with suspected pulmonary embolism, estimate pretest probability (clinical information or clinical information plus results of prior tests). Look up posttest probability at intersection of pretest probability (column) and test result (row).

				Pretest Probability*			
				8%	28%	50%	74%
Ventilation-Perfusion Radionuclide Scan							
Scan Result	Sensitivity	Specificity	Likelihood Ratio	Posttest Probability			
High probability	41%	97%	17.1	60%	87%	94%	98%
Indeterminate	41%	62%	1.1	9%	30%	52%	76%
Low probability	16%	60%	0.4	3%	13%	29%	53%
Near-normal or normal	2%	81%	0-0.1	0-1%	0-4%	0-9%	0-22%
CT Pulmonary Angiogram							
Positive	78-97%	53-100%	3.5-32	23-74%	58-93%	78-97%	91-99%
Negative			0.05-0.48	0-4%	2-16%	5-32%	12-58%

*Using the revised Geneva Score (see Table 24-4).

category will or will not actually have the disease. It should be emphasized that these studies have characterized mostly patients who were not critically ill, in whom the appropriate studies could be performed and compared. The predictive value of lung scans may not be comparable in patients in the ICU.

c. Combination imaging—Multiple approaches for improving diagnostic accuracy when lung ventilation-perfusion scanning is nondiagnostic have been described (Figure 24–1). The traditionally used strategy is to perform pulmonary angiography for all suspected patients in whom intermediate probability lung scans are found (pulmonary embolism present by angiography in 16–66% depending on clinical suspicion) or in whom a low-probability lung scan is associated with high or uncertain clinical suspicion (pulmonary embolism found in 16–40%). A normal pulmonary angiogram is quite accurate in excluding pulmonary embolism, with fewer than 1% of patients with negative pulmonary angiograms subsequently proving to have pulmonary

embolism *without treatment* during long-term follow-up or at autopsy. This approach would be ideal if it were not for problems encountered with obtaining pulmonary angiography, including limited availability, uncertain reliability in all hospitals, and risks of vascular catheterization and radiographic contrast agents. Small amounts of contrast material, selective pulmonary angiography, nonionic contrast material, and careful preinjection measurement of pulmonary artery pressure reduce the frequency of complications from pulmonary angiography. Pulmonary hypertension is a relative contraindication because of reported morbidity and mortality from injecting additional volume into a system already under high pressure. Other complications, including death, respiratory distress leading to intubation, renal failure, and hematoma requiring transfusion, are reported to occur in up to 4% of critically ill patients undergoing pulmonary angiography. Pulmonary angiography used to be performed in all patients being considered for thrombolytic

¹If CT is contraindicated due to iodine allergy or creatinine clearance is prohibitive, consider starting with V/Q scan or compression ultrasonography

▲ Figure 24–1. One suggested approach to a patient with suspected pulmonary embolism. After estimation of clinical probability (see Table 24–4), most patients should have CT pulmonary angiogram performed unless a contraindication exists. If the cumulative probability of clinical estimation plus CT angiogram results is sufficient to begin or withhold treatment, diagnostic studies are completed. If not, further studies are required (eg, compression ultrasonography or pulmonary angiography) until a decision can be reached. Any decision to begin or withhold treatment must take into account the risk of treatment compared with the potential benefits of treatment.

therapy, but this recommendation is being questioned because of the subsequent risk of bleeding (as high as 20%). The major disadvantage of this approach is that a large number of patients would require pulmonary angiography because of abnormal but nondiagnostic lung scans. In some studies, patients making up this group comprise 40–60% of the total enrolled.

A second approach recognizes the close relationship between pulmonary thromboembolism and deep venous thrombosis. Proximal vein deep venous thrombosis is found on initial testing in about 50% of patients with pulmonary embolism. In patients with low- or intermediate-probability ventilation-perfusion lung scans but with high or uncertain clinical probability of pulmonary embolism, compression ultrasonography or impedance plethysmography may be performed. A combination of high or uncertain clinical suspicion, abnormal (but not high-probability) lung scan, and positive noninvasive test for deep venous thrombosis strongly supports the diagnosis of pulmonary embolism. Treatment should be initiated on the basis of this result. The absence of evidence of deep venous thrombosis, however, should not rule out pulmonary embolism because the false-negative rate of a single noninvasive test for deep venous thrombosis ranges from as low as 3% to as high as 30%. Therefore, these patients must undergo pulmonary angiography or serial duplex ultrasonography if the initial ultrasound is negative (see below). The combination of lung scan and noninvasive deep venous thrombosis studies decreases the number of pulmonary angiograms needed in these patients from about 72% to 33%. Completely noninvasive strategies for selected patients also have been proposed. In patients suspected of pulmonary embolism who have abnormal but nondiagnostic lung scans (ie, low or intermediate probability) and adequate cardiopulmonary reserve (eg, lack of respiratory failure, hypotension, severe underlying lung disease, and severe tachycardia), *serial* noninvasive tests for proximal lower extremity deep venous thrombosis are performed (eg, impedance plethysmography or compression ultrasonography). If evidence of deep venous thrombosis is found initially or subsequently, treatment is started. However, if no evidence of deep venous thrombosis is found, anticoagulation is withheld while noninvasive deep venous thrombosis studies are repeated at least twice over the next 10–14 days. In a study of 627 untreated patients with suspected pulmonary embolism with nondiagnostic lung scans and negative serial impedance plethysmographic studies over 2 weeks, pulmonary thromboembolism occurred in only 1.9% over the next 3 months. Treatment therefore can be withheld in this group of patients with acceptable results. In fact, this approach clarifies the natural history of pulmonary thromboembolism in that extension of the pulmonary embolus itself rarely occurs without treatment, and treatment is directed solely at prevention of extension of the venous thrombus. This noninvasive approach can be used to avoid pulmonary angiography in some patients with nondiagnostic lung scans. For critically ill patients, however, this

strategy may not be feasible because of concomitant heart and lung disease and lack of cardiopulmonary reserve. In addition, patients being considered for therapy other than anticoagulation, such as thrombolytic therapy, cannot be evaluated appropriately using this method.

Another completely noninvasive strategy included the combined use of CT angiography, a ventilation-perfusion scan, plasma D-dimer measurements, and in some patients compression ultrasonography of the lower extremities. In 247 patients evaluated using this strategy, the 3-month risk of developing an embolic event without therapy if none of these studies revealed venous thromboembolism was only 1.7%. In general, the diagnostic protocols that combine these noninvasive studies either have obtained all studies during the initial assessment and made treatment decisions based on all study results altogether or have obtained a single study at a time and continue to obtain additional diagnostic data if the results are not conclusive until a definitive diagnosis is obtained or excluded.

d. CT pulmonary angiography—Imaging studies that attempt to assess the pulmonary vasculature bed directly have been evaluated for their role in the diagnostic workup of pulmonary thromboembolism. The development of helical (spiral) and electron-beam CT pulmonary angiography has nearly replaced the ventilation-perfusion scan in many centers with its reported sensitivities in most studies of greater than 80% and specificities of greater than 90% for diagnosing pulmonary emboli in the main, lobar, and segmental pulmonary arteries. The lower sensitivity of this imaging study results in part from the poor performance in the diagnosis of subsegmental emboli. The clinical impact of emboli in these subsegmental arteries is unclear, and they may not pose the same morbidity and mortality risks as emboli in larger segments. However, in patients with a limited cardiopulmonary reserve, emboli in subsegmental arteries potentially could be devastating. Newer imaging techniques that are available today, including thin collimation (1–3-mm instead of 5-mm slices) and faster acquisition timing have improved the evaluation of these subsegmental vessels. An additional advantage of these imaging studies is their ability to provide additional information with regard to other disease processes within the thorax that may be responsible for the patient's clinical presentation, such as pneumonic infiltrates, pleural disease, mediastinal lymphadenopathy, or parenchymal masses. CT imaging requires the administration of intravenous contrast material and a degree of patient cooperation with the ability to lie still and breath-hold for approximately 25 seconds in some protocols to obtain good-quality pictures of the vasculature. In a small but important proportion of studies, the results are not acceptable because of movement artifacts or inadequate concentration of contrast material in the pulmonary arteries.

The exact role of these CT imaging techniques with the diagnosis of pulmonary thromboembolic disease is continuing to evolve, and these techniques are included in a number of combined-strategy models. In fact, some investigators have adopted CT imaging as the key starting diagnostic test for all patients considered likely to have a pulmonary

embolism. A meta-analysis evaluated the 3-month clinical outcome in patients with suspected pulmonary embolism managed solely based on the results of CT pulmonary angiography. The rate of subsequent venous thromboembolism after a negative CT result in untreated patients was 1.4%, which is similar to the rate seen in previous studies with negative pulmonary angiograms. Because concern still exists among many physicians about the overall sensitivity of CT imaging but with acceptable specificity, the helical CT can be used to diagnose pulmonary thromboembolism if a thrombus is seen but may not be able to exclude significant pulmonary artery thrombi if clots are not visualized in patients with a high pretest probability of having this disease state. Nevertheless, a diagnostic strategy based on clinical probability, D-dimer, and CT pulmonary angiography proved highly effective. In those in whom pulmonary embolism was “excluded,” only 1.3% of untreated patients had recurrent venous thromboembolism.

CT pulmonary angiography combined with CT venography of the pelvis and lower extremities to evaluate the venous system for the source of the embolus during the same study (ie, CTA-CTV) was investigated in the PIOPED II trial. While the addition of venography increased the sensitivity of this combined CT imaging study, the authors concluded that both CT angiography alone or combined with CT venography had high predictive values when concordant with the pretest probability of disease. However, when these imaging studies were discordant with the pretest probability, additional studies were needed before excluding venous thromboembolic disease from the differential diagnosis for the patient’s clinical signs and symptoms. Therefore, the addition of CT venography to diagnostic algorithms has not been strongly recommended based on the little it adds to predictive value of CT angiography and clinical probability. MRI of both the pulmonary vasculature and the venous system of the pelvis and lower extremity also may have a future role in the workup of this disease. The advantage MRI studies of the vasculature would be the avoidance of iodine-based contrast material and its associated risks, including anaphylactic reactions and renal impairment.

4. DIAGNOSTIC APPROACH TO PULMONARY THROMBOEMBOLISM—Many algorithms optimizing diagnostic strategies have been proposed. A logical approach is to assess clinical pretest probability based on symptoms and signs and then apply tests that increase or decrease the probability of disease (posttest probability). In this way, the likelihood of pulmonary embolism can be estimated and the risks of treatment compared. Table 24–5 assigns low, moderate, and high clinical estimates for disease based on clinical findings for patients evaluated in an emergency department setting. Validation of these data confirmed that these groups had 8%, 28%, and 74% likelihood of pulmonary embolism.

The clinician must decide whether these probabilities are a sufficient basis for decisions about whether or not to treat a patient. If a more certain diagnosis is warranted—and this is almost always the case with clinical information alone—

another diagnostic test is applied. The first diagnostic study in many algorithms in the past was the ventilation-perfusion radionuclide scan, but this has now been replaced in many centers by CT pulmonary angiography, especially in patients with preexisting obstructive or parenchymal lung disease likely to result in uninterpretable scans. Table 24–6 compares posttest probability using typical sensitivity and specificity values for various imaging results for selected clinical pretest probabilities. If posttest probability is sufficiently high to justify starting treatment or sufficiently low to justify withholding treatment, further diagnostic tests are not indicated. If more diagnostic certainty is desired, then noninvasive studies—compression ultrasonography or pulmonary angiography—can be performed. For decision-making purposes, the pulmonary angiogram is assumed to have 100% specificity; that is, a negative study excludes pulmonary embolism. The probabilities of pulmonary embolism when assessed by compression ultrasonography, D-dimer, and other diagnostic tests are shown in Table 24–7. These tests can be applied sequentially to support the diagnosis or to exclude the diagnosis; although to be certain, these estimates are derived from a number of studies of different populations. While they are not strictly independent estimates, the combined probabilities are still likely to have value. Any decision to begin or withhold treatment must take into account the risk of treatment compared with its potential benefit especially in the ICU patient population.

Treatment

A. Anticoagulation—Anticoagulation is the major therapy for deep venous thrombosis and pulmonary embolism. Heparin, either unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH), is most often given for 4–5 days, overlapping with oral anticoagulant therapy beginning on day 1. Oral anticoagulant agents, mainly in the form of vitamin K antagonists such as warfarin, are given for a minimum of 3 months. There are a number of other treatment schedules depending on the underlying cause of the event, the history of previous thromboembolic events, and the patient’s underlying medical history. Heparin therapy should be started immediately before any definitive tests are performed if there is a strong clinical suspicion and no contraindications exist. Heparin also should be started once a diagnosis of deep venous thrombosis or pulmonary embolism is confirmed, if not started prior to the diagnosis. Anticoagulants do not directly affect existing thrombi, but if given in sufficient amounts, they can prevent further clot propagation until the patient’s inherent fibrinolytic system can begin to break down the thrombus or embolism.

In the absence of contraindications, initial treatment should be with heparin in the form of continuous intravenous infusion of UFH or subcutaneous LMWH. To begin therapy with continuous UFH, an infusion of heparin is given at a dose that achieves and maintains a stable activated partial thromboplastin time (aPTT) of 1.5–2.5 times control when measured at 6-hour intervals. The aPTT then can be

Table 24-7. Sensitivity, specificity, likelihood ratios, and posttest probabilities of pulmonary embolism from selected studies of compression ultrasonography and D-dimer.

Instructions: For a patient with suspected pulmonary embolism, estimate pretest probability and find posttest probability at intersection of pretest probability (columns) and test results (rows).

				Pretest Probability

measured at approximately daily intervals once this goal range has been achieved. Failure to achieve an aPTT at least in the lower level of this range within the first 24 hours of therapy has been associated with recurrent venous thromboembolism in patients with deep venous thrombosis.

Standard heparin dose-adjustment protocols or nomograms for deep venous thrombosis and pulmonary

thromboembolism are highly desirable and have been shown to increase therapeutic efficacy and reduce bleeding complications. One weight-based nomogram is shown in Table 24–8. A bolus of UFH at 80 units/kg of body weight is given, followed by 18 units/kg per hour. For a 60-kg adult, this corresponds to 4800 units as a bolus followed by 1080 units/h or about 26,000 units/day. Concern has been expressed that

Table 24-8. Body weight-based dosing of intravenous unfractionated heparin.

Initial dosing

Loading: 80 units/kg

Maintenance infusion: 18 units/kg/h using 25,000 units in 250 mL D₅W (100 units/mL)

Obtain aPTT before and 6 hours after starting heparin

Subsequent dose adjustments based on aPTT measured at 6-hour intervals*

aPTT (s)	Rate Change (units/kg/h)	Additional Action	Next aPTT
<35 (<1.2 × normal)	+4	Rebolus with 80 units/kg	6 hours
35–45 (1.2–1.5 × normal)	+2	Rebolus with 40 units/kg	6 hours
46–70 (1.5–2.3 × normal)	0	None	6 hours
71–90 (2.3–3.0 × normal)	-2	None	6 hours
>80 (>3 × normal)	-3	Stop infusion for 1 hour	6 hours

*During the first 24 hours, repeat aPTT every 6 hours. Thereafter, obtain aPTT every morning unless it is outside the therapeutic range.

Modified from Hyers TM: Venous thromboembolism. Am J Respir Crit Care Med 1999;159:1–14.

the maintenance dose of heparin is frequently underestimated, resulting in recurrent deep venous thrombosis or pulmonary thromboemboli. The mean heparin requirement in several studies was approximately 1300 units/h (about 31,000 units/24 h) compared with older studies suggesting that 1000 units/h usually was adequate. The dose is adjusted upward or downward as needed based on the aPTT. Although this nomogram should be strictly used only when the same reagent is employed as in the development of the nomogram, it should prove useful as a guide in all hospitals.

LMWH differs from standard UFH in its pharmacokinetics, bioavailability, and anticoagulant activity and has found a role in the treatment of both deep venous thrombosis and pulmonary embolism. These heparin fractions have greater bioavailability when given subcutaneously, longer duration of action, allowing for once- or twice-daily dosing, and predictable anti-factor Xa activity. The anticoagulation effects of LMWH can be correlated with body weight for dosing purposes, and this diminishes the need for following laboratory parameters to ensure adequate anticoagulation. In direct comparisons, LMWH has been associated with fewer major bleeding complications, less thrombocytopenia, and a lower incidence of osteoporosis than UFH. All LMWH formulations crossreact with UFHs and cannot be used as an alternative form of anticoagulation in patients with heparin-induced thrombocytopenia syndrome. Dosage adjustments may be necessary in patients with morbid obesity and renal insufficiency. Each LMWH formulation has its own distinct pharmacokinetic profile, so data on one form cannot be readily extrapolated to another form in the same class. In the treatment of deep venous thrombosis and pulmonary thromboembolism, the 2004 American College of Chest Physicians (ACCP) consensus recommendations are as follows: LMWH treatment administered subcutaneously in doses adjusted to body weight or dose-titrated intravenous UFH for at least the first 5 days of therapy; LMWH is preferred over UFH in patients with “nonmassive” pulmonary emboli, whereas UFH is preferred in patients with severe renal impairment.

In addition to heparin, warfarin can be started on day 1 unless there are contraindications to its use. Warfarin, an oral anticoagulant that inhibits synthesis of vitamin K–dependent coagulation factors, becomes an effective anticoagulant only after disappearance of previously synthesized circulating coagulation factors. Thus several days are needed for warfarin to have an antithrombotic effect, whereas its anticoagulant effect occurs sooner. In the past, concern has been raised about a potential hypercoagulable state induced by warfarin because synthesis of proteins C and S, naturally occurring anticoagulants, is also inhibited by this agent. This problem is encountered very rarely.

Almost all patients can be started with a single oral dose of warfarin at 5 mg/day. The goal is to achieve an international normalized ratio (INR) of 2.5 (range 2.0–3.0). This corresponds roughly to a prolongation of the prothrombin time to 1.3–1.5 times normal (using the usual tissue

thromboplastin assay employed in laboratories in North America). Nomograms for warfarin dosing suggest that the INR measured at least 15 hours after the first dose is helpful in deciding on subsequent doses. If the first INR is greater than 1.5, a very low maintenance dose (1 mg) is probably sufficient; an INR of between 1.2 and 1.3 calls for a dose of 2–3 mg/day. All other patients should receive a second oral dose of 5 mg and should be monitored by continued daily INR measurements. Heparin can be discontinued after 4–5 days if the INR is greater than 2.0 for two consecutive days.

The dose of warfarin should be adjusted according to the prothrombin time. Initially, the prothrombin time should be measured daily until a stable INR is achieved. Thereafter, twice-weekly measurements followed by weekly measurements should be adequate. A number of drugs interact with warfarin, both increasing and decreasing its effectiveness. Antibiotics in particular may decrease bacterial flora of the gut that are responsible for a significant amount of vitamin K synthesis. In the ICU, other drugs that may prolong the prothrombin time by potentiating the action of warfarin include aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), omeprazole, and amiodarone, as well as antimicrobial agents such as most cephalosporins, erythromycin, fluconazole, and metronidazole. On the other hand, barbiturates, rifampin, and carbamazepine may reduce the effect of warfarin on the prothrombin time by increasing the rate of its metabolism in the liver. Warfarin and other oral vitamin K antagonists are contraindicated during pregnancy because of the potential for abnormal fetal development.

The optimal duration of anticoagulation therapy for deep venous thrombosis and pulmonary embolism has not been determined for all clinical situations and depends on underlying predisposing risk factors. Studies have shown that heparin followed by 3 months of warfarin results in an acceptably low (<5%) frequency of recurrent deep venous thrombosis in patients who have a transient and identifiable risk factor. This applies to patients with a first event whose predisposing risk factor, such as immobilization from a broken bone, surgery, or trauma, has resolved. For patients with a first episode of idiopathic venous thromboembolism (no identifiable risk factor), at least 6 months of anticoagulation therapy is recommended. On the other hand, patients in whom risk factors are long term and poorly reversible, such as those with chronic congestive heart failure or hypercoagulable states, should receive a longer period of anticoagulation therapy on the order of 12 months or even indefinitely. In patients with a hypercoagulable state associated with malignancy, the effectiveness of anticoagulation is highly variable. Patients unable to receive warfarin should be given either subcutaneous UFH at a dosage sufficient to prolong the aPTT more than 1.5 times control (adjusted-dose subcutaneous heparin) or daily LMWH.

The major complication of UFH therapy is bleeding, occurring in approximately 5% of patients (ranges from 1% in those with low risk for bleeding to 10% in those with high risk). LMWH has imposed a lower risk of major bleeding events

when used in the setting of venous thromboembolism. Bleeding is usually not spontaneous but due to some underlying cause. Heparin-induced thrombocytopenia may contribute to bleeding, as may simultaneous administration of antiplatelet agents such as aspirin or dextran. Warfarin and other oral anticoagulant agents are also associated with bleeding complications. Bleeding has been demonstrated to be less common when excessively prolonged coagulation times are avoided.

The effect of UFH can be quickly counteracted by discontinuing its infusion and administering protamine sulfate. Approximately 1 mg of protamine will neutralize 100 units of circulating heparin. The reversal of subcutaneously administered UFH may require a prolonged infusion of protamine. Patients who use a protamine-based insulin preparation, have undergone a vasectomy, or have known hypersensitivity to fish are at increased risk of developing adverse allergic reactions to protamine, including anaphylaxis. The effects of LMWH are only in part reversed by the administration of protamine. Nonbleeding patients on warfarin with an elevated INR but in the less than 5.0 range can safely have warfarin withheld until the INR falls into the therapeutic range. For INR values between 5.0 and 9.0, low-dose vitamin K (<5 mg oral phytonadione) is indicated if there is bleeding, high risk of bleeding, or need for performing an invasive procedure. If the INR is greater than 9.0 and associated with bleeding, oral vitamin K in larger doses (5–10 mg) is necessary. For serious bleeding at any elevation of INR, treatment is a 10 mg slow intravenous infusion of vitamin K supplemented with factor replacement (eg, fresh-frozen plasma or prothrombin complex concentrate). Restoration of the desired anticoagulated state may be difficult and prolonged if too much vitamin K is administered. Reversal of the effects of warfarin with oral or intravenous vitamin K can take several hours to correct the INR, whereas fresh-frozen plasma, which contains the vitamin K–dependent factors inhibited by warfarin, can be given to reverse the prothrombin time relatively quickly.

An important complication of heparin use is heparin-induced thrombocytopenia syndrome, an immune-mediated disease that is associated with both bleeding and venous and arterial thrombotic complications. This syndrome should be suspected when the platelet count falls precipitously in a patient receiving any form of heparin. It is seen in approximately 3–4% of patients receiving UFH and fewer patients receiving LMWH. Treatment of this syndrome includes immediate discontinuation of all forms of heparin administration, including intravenous flushes. If anticoagulation is still necessary for the patient's primary disease process, direct thrombin inhibitors (eg, lepirudin, bivalirudin, and argatroban) or heparinoids (eg, danaparoid) can be used. Case reports of using fondaparinux, a synthetic pentasaccharide anticoagulant, in cases of heparin-induced thrombocytopenia are also in the literature. However, this drug is not currently FDA approved for this indication, but may play a role in the future as more evidence becomes available. Warfarin should not be used alone.

B. Thrombolytic Therapy—Thrombolytic agents currently approved for use in venous thromboembolic disease in the United States are urokinase, streptokinase, and alteplase (ie, recombinant tissue plasminogen activator [tPA]). Deep venous thrombosis, especially in patients with extensive iliofemoral thrombosis with limb threat owing to vascular occlusion, is an approved indication for the use of thrombolytic agents according to the 2004 American College of Chest Physician guidelines. In studies in which thrombolytic therapy was given for pulmonary embolism the associated deep vein thrombosis resolved more rapidly, and there was evidence that destruction of venous valves was lessened, decreasing the pain, swelling, and potential for postphlebotic venous insufficiency. However, thrombolytic therapy should be individualized and is not currently recommended as routine therapy for deep vein thrombosis.

In short-term studies of pulmonary embolism, thrombolytic therapy was associated with faster clot lysis than heparin, decreased pulmonary hypertension, improved pulmonary perfusion, and subsequent higher pulmonary capillary blood volume, as assessed by carbon monoxide diffusing capacity. A trend toward lower death rates in patients with pulmonary embolism treated with urokinase followed by heparin compared with those given heparin alone was seen in one trial; in the first 2 weeks of treatment, 7% died in the urokinase group compared with 9% in the heparin group. Lower numbers of recurrent pulmonary emboli in the urokinase-treated group also were found. Despite these results, many physicians believe that the benefits of thrombolytic therapy over anticoagulation alone are not clear for patients with pulmonary embolism. Thus the vast majority of patients are treated with heparin and oral anticoagulation alone.

Thrombolytic therapy has been considered most often in the setting of “massive” pulmonary embolism, described in earlier studies based on the radiographic finding of a clot occupying over 50% of the pulmonary vascular bed. Occlusion of much smaller amount of the pulmonary vascular bed may be considered “massive” in a patient with significant underlying cardiopulmonary disease. Rather than the size of the radiographic occlusion itself defining a massive pulmonary embolism, this syndrome is now defined by the presence of severe hemodynamic compromise with hypotension, shock, syncope, or severe gas-exchange abnormalities. Several small clinical trials of patients with severe large pulmonary emboli have shown faster lysis of clot in the pulmonary circulation, reduction of pulmonary artery pressure, and improved cardiac output with the combination of thrombolytic agent and heparin compared with heparin alone. However, a survival benefit has not been clearly established with this therapy and the risk of bleeding is higher than when heparin is used alone.

At present, thrombolytic therapy should be considered in patients with acute massive embolism who are hemodynamically unstable and who appear to be able to tolerate thrombolysis. It may also be a consideration in patients with “submassive” embolism who show evidence of right ventricular (RV) dysfunction, but this area remains controversial.

RV dysfunction appears to identify normotensive patients who have a significantly higher risk of recurrent pulmonary embolism and death, and therefore, thrombolysis may benefit this subgroup of patients. Mortality rates between 4.3% and 12.8% have been seen in patients with an acute pulmonary embolism with evidence of RV dysfunction as compared with rates between 0% and 0.9% in patients with normal right-sided heart function. Echocardiography has become a key tool used to evaluate right-sided heart function in these patients. Echocardiographic findings suggestive of RV dysfunction acutely related to a pulmonary embolism include qualitative findings such as RV hypokinesis and quantitative finding such as enlarged RV to LV end-diastolic diameter greater than 1 mm, RV end-diastolic diameter greater than 30 mm, and pulmonary artery systolic pressure greater than 30 mm Hg. Another echocardiographic finding that has been found to have a high specificity in the diagnosis of an acute pulmonary embolism is the McConnell sign in which the RV free wall is hypokinetic in the face of preserved contractility of the apical segment.

Most investigators previously recommended that pulmonary angiography be used to confirm the diagnosis of pulmonary embolism prior to the administration of thrombolytic therapy. However, one analysis found that the frequency of major bleeding averaged 14% in patients who received tissue plasminogen activator after pulmonary angiography, whereas it was estimated from thrombolytic trials in acute myocardial infarction patients that a noninvasive diagnosis of pulmonary embolism would be associated with only a 4.2% risk of bleeding. These authors suggested that it would be safer to avoid pulmonary angiography for patients chosen to receive thrombolytics who have positive findings on a CT pulmonary angiogram, a high-probability lung scan, an intermediate-probability scan plus high clinical suspicion, or evidence of significant RV dysfunction by echocardiography. A comparison of relative risks may prove useful in making decisions about pulmonary angiography and thrombolytic therapy.

Contraindications to thrombolytic therapy include surgery in the past 10 days, recent puncture or invasion of non-compressible vessels, recent intracerebral hemorrhage or stroke, uncontrolled hypertension, recent trauma, pregnancy, hemorrhagic retinopathy, other sites of potential bleeding, and infective endocarditis. In addition, streptokinase has been associated with allergic reactions given its antigenic properties and cannot be administered more than once in a 6-month period. Customary invasive vascular procedures such as arterial blood gas measurements and catheterization sites where bleeding cannot be easily controlled should be avoided. Pulmonary angiography, if done, should be approached from the brachial vein rather than from the femoral vein. Heparin should be discontinued before starting thrombolytic agents; antiplatelet agents should not be given simultaneously.

Streptokinase, urokinase, and alteplase have been used in pulmonary embolism. Urokinase and streptokinase are

given as a loading dose (streptokinase: 250,000 units over 30 minutes; urokinase: 4400 units/kg over 10 minutes), followed by continuous infusion (streptokinase: 100,000 units/h for 24 hours; urokinase: 4400 units/kg per hour for 12–24 hours). Alteplase usually has been administered as a continuous peripheral infusion of 100 mg over 2 hours.

After completion of thrombolytic therapy with any of these agents, the continuous infusion of heparin is reinstated once the measured aPTT is less than 2.5 times control. Streptokinase and urokinase activate plasminogen bound to both fibrinogen and fibrin, but alteplase or tissue plasminogen activator, a genetic recombinant product, is somewhat more specific for activation of plasminogen bound to fibrin. This difference suggests that alteplase may be associated with fewer bleeding complications than urokinase or streptokinase, but clinical bleeding so far has been found to be similar for all three agents.

C. Inferior Vena Cava Interruption—There are no data supporting the routine use of inferior vena cava (IVC) interruption with a filter in patients with deep venous thrombosis or pulmonary emboli. A study comparing anticoagulation with anticoagulation plus placement of an IVC filter demonstrated a slight reduction in early symptomatic or asymptomatic pulmonary embolism. There was no effect on mortality. After 3 years, a significant increase in recurrent deep venous thrombosis was found in the IVC filter group.

These data, however, support the effectiveness of IVC interruption in reducing early embolization. Therefore, three main indications have evolved for interruption of the inferior vena cava in patients with deep venous thrombosis and pulmonary embolism. First, patients who are at high risk for pulmonary embolism (proximal deep venous thrombosis) in whom heparin is contraindicated should be strongly considered for the procedure. The contraindication may be a strong likelihood of bleeding prior to anticoagulation or moderate to severe bleeding during heparin therapy. For example, in trauma patients admitted to the ICU who were treated for deep venous thrombosis or pulmonary embolism with heparin, 36% developed complications requiring termination of the drug, whereas no serious complications or deaths were reported in 34 other patients who underwent placement of an IVC filter. A second indication is failure of anticoagulation to prevent recurrent pulmonary embolism despite an adequate dose and duration of therapy. However, early embolism after initiation of heparin generally should not be considered as necessitating IVC interruption because poorly organized thrombi may detach themselves from the venous wall or from other parts of the clot regardless of heparin therapy. Finally, a clinical indication for IVC interruption is identified in the rare patient whose cardiac and pulmonary reserves are so low that even a single small pulmonary thromboembolus may be life-threatening.

The decision to proceed with interruption of the IVC should be based on evidence that the thromboemboli are coming from deep veins that flow into that vessel. The right

atrium and ventricle and the upper extremities should be excluded as sources. If an upper extremity is identified as the continued source of emboli, some centers are capable of placing superior vena cava filters. Contrast venography or other proof of existing clot below the site of planned interruption should be obtained.

The Greenfield filter or other types of intravenous devices is used most often, while surgical ligation of the IVC is rarely needed. The filter can be placed via percutaneous venous access under fluoroscopic guidance either from an internal jugular vein or from a femoral vein. The filter usually is positioned below the level of the renal veins, but there are reports of its being placed above the renal veins in patients with IVC and renal vein thrombosis. If the filter is placed because of recurrent pulmonary emboli during anticoagulation, anticoagulation usually is continued to prevent additional thrombi from forming on the filter and elsewhere. If the filter is placed because of a contraindication for or adverse reaction to anticoagulation, anticoagulation therapy is not given. The risk of recurrent pulmonary emboli after interruption of the vena cava with this device is low (2–3%). Other reported problems include procedural complications, filter malposition and migration, caval occlusion, and sepsis owing to device infection.

D. Other Treatment—In some centers, emergent pulmonary embolectomy can be performed in selected patients. Mortality is high (up to 30% in some series), and special experience and expertise are needed. Other modalities currently being investigated include local instillation of thrombolytics directly into the embolus; intravascular catheter disruption systems, including fragmentation, rotor devices, and rheolytic therapy that break the clot into smaller pieces that then can be removed; suction catheter removal of the clot; and balloon angioplasty of the embolus.

E. Supportive Care—Abnormal pulmonary gas exchange may require supplemental oxygen. Severe respiratory distress, because of involvement of large portions of the lungs or because of underlying heart or lung disease, may necessitate mechanical ventilatory support. Some patients may have bronchospasm that benefits from bronchodilators. Hemodynamic compromise in pulmonary embolism usually indicates severe obstruction of the pulmonary circulation with failure of the right ventricle. Volume loading of the right ventricle may be helpful. However, volume overexpansion can lead to increasing right ventricular myocardial oxygen consumption and subsequent ischemia and deterioration of function. Inotropic and vasoactive drugs generally are of little value in severe hemodynamic compromise, but dopamine, dobutamine, and norepinephrine may be tried.

Prevention

Prevention of deep venous thrombosis and thereby of pulmonary embolism has become a major goal in the management of critically ill patients who are at high risk of

development of deep venous thrombosis as a consequence of bed rest, immobility, central venous catheterization, critical illness, or trauma. It has been pointed out, however, that many ICU patients are not receiving thromboembolism prophylaxis despite this high risk.

The risk of developing a deep vein thrombosis varies with the clinical scenario and the patient's underlying medical condition. Patients with hip fracture, total hip replacement, or total knee replacement have a 40–70% chance of developing deep venous thrombosis. Other surgical and medical patients have approximately a 15–50% risk. It is estimated that patients with myocardial infarction have about a 24% overall incidence of deep venous thrombosis, and patients with stroke may have up to a 55% risk.

Prevention of deep venous thrombosis depends on reversal of predisposing conditions (eg, the local hypercoagulable state and venous stasis). Antithrombotic therapy can interfere with thrombus formation either by preventing the platelet nidus from forming or by preventing activation of the coagulation cascade. The type of preventive therapy is closely linked to the underlying condition and the bleeding risk. For example, patients at moderate risk (eg, minor surgery with additional risk factors or aged 40 to 60 years with no additional risks) will benefit from low-dose UFH, LMWH, or intermittent pneumatic compression of the legs. On the other hand, high-risk patients including hip fracture or total knee replacement patients must be treated with LMWH, fondaparinux (2.5 mg started 6–8 hours after surgery), or adjusted-dose warfarin with a target INR of 2.5. A summary of recommendations is presented in [Table 24–9](#).

Low-dose UFH, 5000–7500 units subcutaneously every 8–12 hours, has been shown to be effective and safe in several groups of patients, including those immediately postoperative from general or gynecologic surgery and medical patients with heart failure, myocardial infarction, respiratory failure, and stroke. At these doses, the aPTT is not usually prolonged, and there is little increased risk of bleeding. LMWH also has been shown to have reliably favorable dose-response properties and turns out to be superior for prophylaxis of deep venous thrombosis in a number of clinical settings. Warfarin is effective in certain clinical situations and, for example, is one of the choices for prophylactic treatment for patients with hip fractures as well as elective hip and knee replacement surgeries. Fondaparinux, a synthetic pentasaccharide that selectively inhibits factor Xa activity, has been shown to be highly efficacious in the prevention of deep vein thrombosis primarily in large orthopedic surgical trials. Finally, mechanical methods of prophylaxis with graduated compression stockings or external compression of the legs can be provided by rhythmic intermittent pneumatic compression devices and have been shown to have comparable effectiveness in preventing deep venous thrombosis with no risk of hemorrhage. These devices can be combined with pharmacologic means of prophylaxis in very high-risk patients or used alone in patients at risk of bleeding complications from medical therapy.

Table 24-9. Prophylaxis of deep vein thrombosis and pulmonary embolism for patients.

Medical Conditions	
Critically ill patients with high bleeding risk	Mechanical prophylaxis (ES or IPC) until risk diminishes
Critically ill patients without high bleeding risk	LDUH or LMWH with or without mechanical prophylaxis
General Surgery	
Low risk (minor procedure, age <40, no risk factors)	Early and persistent ambulation
Moderate risk (40–60 years, major procedure and <40 years with no risk factors)	LDUH, 5000 units bid or LMWH <3400 units once/day
High risk (not low or moderate risk) and highest risk (multiple risk factors)	LDUH, 5000 units tid or LMWH >3400 units once/day or LMWH with mechanical prophylaxis (higher risk)
High risk of bleeding	Mechanical prophylaxis (ES or IPC) until risk diminishes
Vascular Surgery	
Low-risk procedure	No routine prophylaxis
High-risk procedure	LDUH or LMWH
Gynecologic Surgery	
Procedure <30 min for benign disease	Early and persistent ambulation
Laparoscopic procedure, risk factors present	LDUH, LMWH, and/or mechanical prophylaxis
Major surgery for benign disease	LDUH, 5000 units bid; LDUH, 5000 units tid if VTE risk factors; continue until discharge; if age >60, continue for 2–4 weeks after discharge
Extensive surgery for malignancy	LDUH 5000 units tid or LMWH >3400 units/day; continue for 2–4 weeks after discharge
Urologic Surgery	
Minor, transurethral procedure	Early and persistent ambulation
Major open procedure	LDUH twice or three times daily; with multiple risk factors, add mechanical prophylaxis
Bleeding or high risk of bleeding	Mechanical prophylaxis (ES or IPC) until risk diminishes
Laparoscopic Surgery	
Laparoscopic surgery	Early and persistent ambulation, unless risk factors present, then LDUH, LMWH, and/or mechanical prophylaxis
Orthopedic Surgery	
Elective total hip replacement	LMWH at high-risk dose, 12 h before surgery or 12–24 h after surgery, or 4–6 h after surgery at half the high-risk dose; increase to high-risk dose the next day or fondaparinux 2.5 mg beginning 6–8 h after surgery or adjusted-dose warfarin started the evening after surgery (INR target 2.5) Continue prophylaxis for 28–35 days after surgery
Elective total knee replacement	LMWH at high-risk dose, fondaparinux, or adjusted-dose warfarin (INR target 2.5)
Hip fracture surgery	Fondaparinux, LMWH at high-risk dose, adjusted-dose warfarin (INR target 2.5), or LDUH; continue for 28–35 days after surgery
Neurosurgery, Trauma, Spinal Cord Injury	
Elective spine procedure (elderly, malignancy, neurologic deficit, prior to VTE, or anterior surgical approach)	Postoperative LDUH, LMWH, or IPC alone; if multiple risk factors, combine LDUH or LMWH with mechanical prophylaxis
Trauma, identifiable risk factor	LMWH, when safe; mechanical prophylaxis if LMWH is delayed or contraindicated because of high bleeding risk; consider screening with ultrasound for those at highest risk; continue LMWH or warfarin (INR target 2.5) after discharge if impaired mobility
Acute spinal cord injury	Mechanical prophylaxis; add LDUH or LMWH started when safe (hemostasis achieved)

However, in patients with trauma—especially to the brain or spinal cord—or those undergoing surgical procedures of the eye, brain, or spinal cord, even low-dose heparin may be contraindicated because of the increased risk of bleeding at these operative sites. External pneumatic compression of the legs is effective in these patients. Neurosurgical patients and patients with heparin-induced thrombocytopenia also should be considered for prevention of deep venous thrombosis by pneumatic compression devices. This therapy generally is well tolerated, but patients may require sedation owing to discomfort from the cyclic compression or heat generated by the apparatus.

Hip fractures, major orthopedic surgery, and some types of urologic surgery enhance the thrombogenic state, probably by increased contact with and release of tissue thromboplastin. While low-dose UFH does decrease the risk of deep venous thrombosis in some of these patients, it is less effective than LMWH and the newer anticoagulant fondaparinux. Current guidelines recommend the use of LMWH, fondaparinux, or adjusted-dose warfarin (goal INR 2.5) in these high-risk orthopedic patients. Adjunctive prophylaxis with mechanical devices such as elastic stockings and intermittent pneumatic compression devices can add additional benefit with little risk. The duration of prophylaxis, especially in this orthopedic patient population, is being investigated. There is some evidence that extending the period of prophylaxis to 28–35 days postoperatively has reduced the incidence of deep venous thrombosis and subsequent pulmonary embolism. The 2004 ACCP consensus guidelines recommend extending prophylaxis into the outpatient setting with LMWH, fondaparinux, or warfarin for a total of 4–5 weeks after surgery for these high-risk postoperative patients.

IVC filters also have been studied for their use in the prevention of complications from deep venous thrombosis, primarily in the surgical population. Four studies evaluating high-risk surgical patients without current evidence of deep venous thrombosis using historical controls found a decreased incidence of pulmonary emboli in the following patients who had an IVC filter placed: those with high injury severity scores, head or spinal cord trauma, pelvic or lower extremity fractures, prolonged immobility, and mechanical ventilatory support. This means of prophylaxis has not been studied in direct comparison with heparin or mechanical devices. Other patient populations that may benefit from prophylactic filter placement include patients with advanced malignancy, orthopedic surgical patients, and patients with limited cardiopulmonary reserve such as those with severe COPD. The use of these filters as prophylaxis remains controversial and requires larger studies to determine their exact role.

Current Controversies and Unresolved Issues

The diagnosis of pulmonary embolism in the critically ill patient with multiple preexisting diseases can be very difficult. The incidence of pulmonary embolism complicating critical

illness is unknown, but 5–10% of deaths may be associated with unsuspected pulmonary emboli. In a study of patients with COPD exacerbation, 25% of those without obvious precipitating cause had pulmonary embolism. Risk was associated with malignancy, prior venous thromboembolic disease, and decrease in PaCO₂ of at least 5 mm Hg. Abnormal pulmonary gas exchange and hemodynamic compromise resulting from new pulmonary emboli may not be identified in patients who already have underlying lung or heart disease. Defects on perfusion lung scans may or may not represent pulmonary emboli in patients with abnormal chest x-rays, and ventilation scans cannot be performed without special arrangements for patients receiving mechanical ventilation. The helical or spiral CT scan requires administration of contrast material and a degree of patient cooperation and breathing to achieve adequate imaging. Again, this may be difficult for critically ill patients to perform. Finally, treatment issues are complex, with some patients having relative contraindications to anticoagulation and others having diseases in which adequate anticoagulation is difficult to achieve.

Patients with worsening hypoxemia or increased physiologic dead space, increased pulmonary artery pressure (in the absence of other causes), unexplained tachycardia or hypotension, or other features of unclear cardiopulmonary insufficiency should be suspected of having pulmonary thromboembolic disease until proven otherwise. The use of end-tidal CO₂ monitors in the ICU may be a noninvasive means for detecting an acute change in dead space ventilation that may be an early clue for pulmonary embolism.

Ventilation-perfusion scans in patients with COPD generally are considered to be of limited value because airway obstruction causes falsely positive perfusion defects. A study of such patients suspected of having a pulmonary embolism found that high-probability scans were rare but had a high predictive value for pulmonary embolism; similarly, a normal perfusion scan was highly predictive of a normal pulmonary angiogram. However, 90% of the group had *intermediate-probability* (60%) or *low-probability* (30%) scans, of which only 17% had pulmonary embolism confirmed by angiography. The authors of the study concluded that ventilation-perfusion lung scans were helpful only if they were high-probability or normal. In all others, they concluded, sufficient clinical suspicion should lead to pulmonary angiography.

▶ Anaphylaxis

ESSENTIALS OF DIAGNOSIS

- ▶ Follows reexposure to foreign antigens such as food, drug, nonhuman protein, or other substances.
- ▶ Respiratory tract: rhinitis, edema, laryngeal edema, asthma.
- ▶ Hypotension, lightheadedness, collapse.
- ▶ Generalized erythema, pruritus, and urticarial skin lesions with or without angioedema.

General Considerations

Anaphylaxis is a severe allergic reaction that occurs after reexposure to a foreign substance such as food, a drug, serum, venoms, or nonhuman proteins but also occurs occasionally after exercise. Approximately 72 hours after initial exposure to a foreign antigen, IgE antibody synthesis begins. Reexposure to the antigen promotes cross-linking of mast cell and basophil-bound IgE molecules and causes the subsequent release of stored mediators of anaphylaxis such as histamine and other substances. These factors cause increases in capillary permeability, mucosal edema, and smooth muscle contraction; activate the classic complement pathway and components of the clotting cascade; and cause the release of other mediators.

Anaphylactoid (ie, anaphylaxis-like) reactions are clinically similar to anaphylaxis but are not mediated by antigen-antibody interactions. Many of the same mediators are involved, so treatment is identical to that for anaphylaxis. Mechanisms include (1) activation of the complement cascade by immune complexes or other substances that cause release of anaphylatoxins (eg, C3a and C5a), resulting in mediator release from mast cells and basophils, and (2) direct activation by certain agents of mast cells and basophils resulting in mediator release (eg, effect of hyperosmolar solutions such as mannitol and radiocontrast media).

Patients with anaphylaxis may be admitted to the ICU because of severe respiratory or cardiovascular compromise, or they may develop anaphylaxis in the ICU from exposure to blood products or drugs.

Clinical Features

The onset of a systemic anaphylactic reaction, which may develop over minutes to 1–2 hours, depends on the sensitivity of the person as well as the route, rate, and quantity of the precipitating agent. The clinical signs and symptoms can differ greatly depending on the severity of the anaphylactic reaction, and clinical findings may be present in various combinations. Severe systemic reactions are characterized by respiratory failure and cardiovascular collapse. Recurrence of symptoms can occur 2–24 hours after onset despite initial stabilization and treatment.

A. History—A history of recent use of medication, ingestion of new or unusual foods (notably peanuts and other nuts and shellfish), and exposure to toxic products such as venoms or insect bites should be sought, but treatment should be initiated immediately if necessary. An increasingly recognized cause of allergy and anaphylaxis is exposure to latex rubber. About half of patients will have a history of atopy, and only about 70% of patients who develop anaphylaxis outside the hospital will have an identifiable precipitating cause. In the ICU, intravenous contrast agents, antibiotics, NSAIDs, aspirin, and other drugs are the most likely causes.

B. Symptoms and Signs—Anaphylaxis is often associated with severe anxiety and apprehension. Patients may experience any combination of the following symptoms: itching of skin and mucosal surfaces, swelling of the lips and tongue, hoarseness, coughing, shortness of breath, wheezing, vomiting, abdominal cramps, diarrhea, and palpitations.

Physical findings in severe systemic reactions include hypotension, upper airway obstruction resulting in stridor, and bronchospasm with impaired gas exchange, hypercapnia, and wheezing. Loss of consciousness may result from poor cerebral perfusion. Urticaria may be present, and there may be evidence of angioedema.

Allergens injected systemically—for example, insect stings, intravenous drugs, blood products, and allergy desensitization treatments—often cause a predominantly

cardiovascular reaction with hypotension. Food and inhaled allergens may cause more facial and respiratory edema, associated with respiratory problems.

Differential Diagnosis

Anaphylaxis may be confused with syncopal episodes associated with metabolic or vascular disturbances, acute respiratory failure secondary to epiglottitis, status asthmaticus, obstruction owing to foreign-body aspiration, and pulmonary embolism. Similar disorders with cutaneous and respiratory manifestations—for example, mastocytosis, carcinoid syndrome, hereditary angioedema, and other specific adverse pharmacologic (allergic and nonallergic) reactions to drugs—should be considered if appropriate.

Treatment

Treatment is based on early recognition of features of anaphylaxis combined with a history of exposure to an inciting agent. The suspected agent should be discontinued if possible (eg, a drug, blood products, or contact with latex rubber), the extent and severity of the reaction should be assessed, and treatment should be initiated as soon as anaphylaxis is suspected.

A. General Measures—The patient should be positioned supine or head down with the feet elevated. The airway must be maintained by proper positioning. If necessary, endotracheal intubation, tracheostomy, or cricothyroidotomy should be performed. Because of the need for intravenous fluid infusion and medications, a large-bore intravenous catheter should be inserted.

B. Initial Treatment—Epinephrine should be given first in a dosage of 0.3–0.5 mL of 1:1000 dilution (0.3–0.5 mg) intramuscularly deep into the thigh every 10–20 minutes as needed. The subcutaneous route is no longer recommended. In severe anaphylaxis with suspicion of poor perfusion, slow intravenous injection (5 mL of 1:10,000 dilution) should be considered. Other initial treatment includes oxygen, inhaled β -adrenergic agonists for bronchospasm, and airway management.

C. Other Medications—Medications are directed toward blocking further mediator action on target organs, preventing further release of mediators, reversing the physiologic effects of the mediators, and supporting vital functions. Antihistamines (histamine H1-antagonists) such as diphenhydramine hydrochloride, 25–50 mg intravenously every 6 hours, are useful. Some studies show additional benefit of histamine H2-receptor antagonists, so cimetidine or ranitidine may be given as well. Excessive antihistamine dosages may cause impaired CNS function, anticholinergic symptoms (eg, dry mouth or urinary retention), and drowsiness, especially in elderly patients. Hydrocortisone, 100 mg intravenously every 8 hours for

several doses, is recommended, especially if there is bronchospasm or airway compromise. Patients who are receiving β -blockers may have a poor response to treatment directed at hypotension. These patients may have some response to glucagon, which has both inotropic and chronotropic effects on the heart.

D. Intravenous Fluids—Adults should receive 0.9% NaCl solution, 0.5–1 L intravenously over 30 minutes, if hypotensive. Additional fluid therapy depends on blood pressure, heart rate, urine output, and clinical response.

E. Prevention of Anaphylaxis—The patient should be instructed to avoid the offending agent in future, if possible. For patients who have a likelihood of reexposure to an identified antigen, a kit containing epinephrine for self-administration should be considered.

▶ Angioedema

ESSENTIALS OF DIAGNOSIS

- ▶ Subcutaneous swelling of skin or mucous membranes, possibly with laryngeal or lower airway compromise.
- ▶ May present with urticaria.
- ▶ Acute angioedema: may have history of ACE inhibitor, aspirin, or NSAID therapy or a history of allergies.
- ▶ History of recurrent transient episodes of swelling may be present in allergic or hereditary forms.

General Considerations

Angioedema is produced by mechanisms similar to those that cause anaphylaxis and anaphylactoid reactions. In addition, these mechanisms can be triggered by various physical forces, exercise, and other medical conditions such as endocrine disorders, infections, malignancies, allergic phenomena, and collagen vascular diseases. Severe angioedema involving the upper or lower airways is a medical emergency similar to anaphylaxis.

Acute angioedema, which may occur once or on multiple occasions, is often idiopathic or associated with allergic phenomena. Among identified causes, the most common are related to ACE inhibitor therapy, aspirin, and NSAIDs.

Hereditary angioedema is caused by an autosomal dominant inherited deficiency or functional abnormality of C1 esterase inhibitor. Without this inhibitor, the complement cascade is activated, and a kinin-like fragment and other mediators are released that produce the angioedema.

Acquired C1 esterase inhibitor deficiency is very rare and seen in adults with autoimmune or lymphoproliferative disorders. Patients have unexplained recurrent angioedema,

and the diagnosis is confirmed by low levels of C1q and low C1 esterase inhibitor activity.

Clinical Features

A. Symptoms and Signs—Angioedema is characterized by the presence of nonpruritic subcutaneous swelling of the skin and mucous membranes. Lesions of the skin are poorly demarcated and reddish. These may occur in conjunction with urticarial lesions. Involvement of the upper airway can result in hoarseness, stridor, shortness of breath, and even death. Likewise, GI involvement is associated with abdominal pain, nausea, and diarrhea. Patients may or may not have associated urticaria, characterized by evanescent pruritic lesions.

Because of widespread use of ACE inhibitors for hypertension, diabetic proteinuria, and congestive heart failure, these agents are a common cause of acute angioedema. This disorder may present after recent initiation of ACE inhibitor therapy but may occur even after prolonged use. It is said that urticaria is unusual in ACE inhibitor-induced angioedema. Angiotensin-receptor blockers, sometimes given to patients instead of or in addition to an ACE inhibitor, rarely have been associated with angioedema, but some experts have cautioned against use of these agents in patients with ACE inhibitor-induced angioedema. Hereditary or acquired angioedema has been precipitated by ACE inhibitors.

In hereditary angioedema, episodes can be precipitated by trauma, emotional upset, infections, and exposure to sudden temperature changes. The disorder usually is apparent in childhood, and attacks tend to be recurrent and usually are of 2–4 days duration. The physical findings are similar to those described earlier. Similar features are present in acquired forms of angioedema.

B. Laboratory Findings—In patients with angioedema or urticaria, investigation should include a complete blood count, erythrocyte sedimentation rate, and urinalysis. Other laboratory tests should be ordered depending on the underlying medical condition. In patients with abdominal symptoms, edema of the bowel wall may be seen on CT scan.

When hereditary angioedema is suspected, C4, C3, CH50 or total complement, and C1 esterase inhibitor (by immunochemical and functional assay) should be measured. Levels of C4 and C2 are always low, and CH50 is usually diminished or absent during an attack. C1 esterase will be reduced but may be normal in persons with a functional abnormality. Acquired angioedema (acquired C1 inhibitor deficiency) is due to increased catabolism of C1 esterase inhibitor and C1q. Laboratory findings in allergic angioedema and that induced by ACE inhibitors and NSAIDs are rarely specific or helpful.

Treatment

Patients may require long-term treatment and should avoid precipitating conditions and situations. In some patients, the underlying cause may not be identifiable.

A. General Measures—Acute angioedema is treated initially much the same way as anaphylaxis. The underlying cause should be treated or removed, especially if ACE inhibitors have been implicated. Hypotension and shock should be treated with intravenous fluids. The airway should be protected, and endotracheal intubation may become necessary. If there is severe upper airway obstruction, tracheostomy should be considered.

B. Specific Treatment

1. EPINEPHRINE—Epinephrine is indicated for patients with severe acute urticaria or angioedema with airway involvement. It can be given subcutaneously or intravenously. One recommendation is to give 0.3–0.5 mL of 1:1000 solution subcutaneously and repeat every 10–20 minutes as necessary. Epinephrine may be lifesaving in angioedema, but it should be noted that many patients with ACE inhibitor–induced angioedema are elderly or have heart disease or hypertension. Epinephrine may cause excessive tachycardia, may increase myocardial oxygen demand, may provoke myocardial ischemia, and may raise blood pressure excessively.

2. ANTIHISTAMINES—Antihistamines usually are effective against urticaria and can be helpful for some forms of angioedema. H1-blockers such as diphenhydramine, 50 mg orally or intravenously every 6 hours, are helpful for an acute episode of urticaria. Patients may have dry mouth, drowsiness, and excessive sedation with these agents. In patients with angioedema, in addition to H1-blockers, an H2-blocker such as ranitidine, 50 mg intravenously two or three times daily or 150 mg orally twice daily, or cimetidine, 300 mg orally or intravenously every 6 hours, may be helpful.

3. CORTICOSTEROIDS—Corticosteroids usually are not necessary for acute urticaria alone but can be very helpful in refractory acute urticaria or chronic urticaria. A recommended initial dosage is prednisone, 2 mg/kg per day orally, or methylprednisolone, 60 mg intravenously every 6 hours.

C. Hereditary Angioedema—Clinical trials of recombinant C1 inhibitor concentrate for acute hereditary angioedema are under way. C1 inhibitor concentrates from pooled plasma are available in Europe but not in the United States. Fresh frozen plasma may be given (2 units) as treatment to prevent angioedema or in preparation for surgery. Long-term preventive treatment of angioedema can be tried using androgen derivatives such as danazol, 200 mg orally three times daily, or stanozolol, 2–4 mg/day.

Endocrine Problems in the Critically Ill Patient*

Shalender Bhasin, MD
Piya Ballani, MD
Ricky Phong Mac, MD

Several endocrine problems may require management in the ICU, including severe thyroid disease, acute adrenal insufficiency, and diabetic ketoacidosis. While these problems usually are encountered in patients in whom a diagnosis of endocrine dysfunction has already been made, they are occasionally the presenting manifestation in an undiagnosed patient. If these endocrine disorders are not identified, specific treatment such as endocrine replacement therapy may be delayed, and significant complications or death may ensue.

In this chapter, severe thyrotoxicosis (eg, thyroid storm or decompensated hyperthyroidism), severe hypothyroidism (eg, myxedema coma), and acute and chronic adrenal insufficiency are discussed. Diabetic ketoacidosis and other manifestations of severe diabetes mellitus are covered in Chapter 26. In this chapter we also discuss the problem of assessing thyroid function in severe nonthyroidal illness (ie, sick euthyroid syndrome).

▶ Thyroid Storm

ESSENTIALS OF DIAGNOSIS

- ▶ Long-standing hyperthyroidism, uncontrolled or poorly controlled.
- ▶ Breakdown of the body's thermoregulatory mechanisms, resulting in hyperpyrexia.
- ▶ Altered mental status.
- ▶ Precipitating illnesses or events such as thyroid surgery, infection, trauma, acute abdominal problems, or anesthesia.
- ▶ Signs and symptoms of severe hyperthyroidism—usually marked wasting.

*Shalender Bhasin, MD, Laurie K. S. Tom, MD, and Phong Mac, MD, were the authors of this chapter in the second edition.

General Considerations

Thyroid storm—or thyrotoxic crisis—results from the eventual failure of the body's compensatory mechanisms in severe hyperthyroidism. Clinically, *thyroid storm* has been defined as “a life-threatening augmentation of the manifestations of hyperthyroidism.” There are no pathognomonic laboratory markers of thyroid storm. However, because of its high mortality rate, one should be vigilant for its diagnosis and provide aggressive and prompt management. This is especially true because the features of thyroid storm are common findings in other critically ill patients.

A. Incidence—The incidence of thyroid storm has decreased markedly since the advent of antithyroid drugs. Some studies suggest that the incidence is 2–8% of all patients admitted to the hospital for management of hyperthyroidism. However, a recent evaluation at a major teaching hospital revealed that severe complicated thyrotoxicosis is a rare syndrome, accounting for only 0.01% of hospital admissions over a 14-year period. Thyroid storm occurs nine to ten times more commonly in women than in men, probably a reflection of the higher incidence of thyroid diseases in women in general. No race- or age-related differences in incidence have been reported. An association between thyroid storm and medically underserved, socially disadvantaged populations has been suggested. In one study, patients admitted because of complicated thyrotoxicosis were more likely to be uninsured, poorer, unmarried, and African-American than uncomplicated thyrotoxic controls. One explanation is that control of chronic hyperthyroidism with antithyroid drugs is very effective in preventing decompensation, but poorer populations may be less likely to receive adequate treatment.

Pathophysiology

The pathophysiology of thyrotoxic crisis is not well understood. Indices of thyroid gland overactivity (levels of total and free thyroxine or triiodothyronine) are not significantly higher than in usual cases of hyperthyroidism.

Although the signs and symptoms of hyperthyroidism suggest sympathetic overactivity, plasma levels and secretion rates of epinephrine and norepinephrine are actually normal in patients with thyroid storm. Because of this, increased sensitivity to catecholamines has been suggested, and elevated cAMP levels in these patients have been cited as evidence of increased adrenergic activity.

The mechanisms that lead to the decompensated state characteristic of thyroid storm have not been well studied. Higher levels of cytokines and immune dysregulation have been implicated, but without conclusive data. The basal metabolic rate and thermogenesis are increased, and there is a net degradation of proteins. Although both protein synthesis and degradation are increased, hyperthyroidism results in negative nitrogen balance, muscle wasting, and reduced albumin concentrations. Although cortisol clearance is increased, its production rates are also increased, so the cortisol levels remain essentially unchanged. Thyroid hormones have direct cardiostimulatory effects, resulting in tachycardia and increased contractility. Increased thermogenesis results in vasodilatation as part of the compensatory response to increased body temperature.

Clinical Features

Thyroid storm is usually seen in patients with known hyperthyroidism but may be the presenting feature in a patient with previously undiagnosed thyrotoxicosis. Thyroid storm is seen often in association with one of a long list of precipitating conditions, but the two most common conditions are surgical procedures of any kind—but particularly thyroid surgery in an uncontrolled or poorly prepared hyperthyroid patient—and infections. Thyroid storm is now quite uncommon following thyroid surgery because of preoperative preparation and control of hyperthyroidism with antithyroid drugs.

Other potential precipitating factors include cardiovascular disease (including acute myocardial infarction), systemic illness, trauma, diabetic ketoacidosis, vigorous palpation of an untreated hyperthyroid gland, administration of iodinated contrast material, stroke, and preeclampsia or eclampsia. Rare cases of thyroid storm have been seen after amiodarone administration. Exacerbation of hyperthyroidism may occur following radioactive iodine treatment of Graves' disease, but thyroid storm is unusual because most hyperthyroid patients are well controlled by antithyroid drug therapy. In contrast, thyroid storm may occur in hyperthyroid patients who discontinue antithyroid medications prematurely or inadvertently. Patients who accidentally or deliberately ingest an excessive amount of thyroid hormone may present with severe hyperthyroidism but usually without the complete picture seen in thyroid storm.

A. Symptoms and Signs—Thyroid storm is characterized by clinical features of severe thyrotoxicosis with fever and altered mental status. In one series of patients hospitalized for complicated thyrotoxicosis, cardiovascular complications and neuropsychiatric syndromes were the two most frequent

indications for admission. Mental status changes may include confusion, agitation, overt psychosis, and in extreme cases, even coma. Common cardiovascular manifestations include tachycardia that is out of proportion to fever, cardiac arrhythmias (sinus or supraventricular tachycardia, including atrial fibrillation), and congestive heart failure. Patients presenting with congestive heart failure are usually elderly and have an underlying history of heart disease. However, it is well documented that hyperthyroidism can cause congestive heart failure even in the absence of underlying heart disease. Hypotension and shock may be late manifestations. GI manifestations include nausea, vomiting, diarrhea, and abdominal pain. Weight loss and cachexia are common.

Goiter is almost always present and may be diffuse or multinodular. Since many of these patients have Graves' disease, the goiter is more often diffuse and nontender. Patients often have marked muscle weakness owing to proximal myopathy and generalized cachexia. Tremor is present. The skin is warm, moist, flushed, soft, and "velvety." The reflexes may be brisk. Graves' disease patients also may have ophthalmopathy and dermopathy. Burch and Wartofsky have proposed a point scale to facilitate the diagnosis of thyroid storm, assigning points based on the severity of thermoregulatory dysfunction (temperature), cardiovascular dysfunction, CNS effects, GI-hepatic dysfunction, and precipitating factors. That is, thyrotoxic patients with fever and dysfunction of one or more organ systems, particularly cardiovascular and CNS, are more likely to have severe thyrotoxicosis and need hospitalization for aggressive treatment.

B. Laboratory Findings—Elevated aminotransferases, hyperbilirubinemia, and hepatomegaly are common. Alkaline phosphatase levels are also increased, but this usually represents an increase in the bone fraction rather than the liver fraction. Serum calcium may be elevated as a reflection of increased bone resorption. Other laboratory abnormalities observed in patients hospitalized for complicated thyrotoxicosis include hypo- or hypernatremia, hyperglycemia, and anemia.

The diagnosis of thyroid storm is essentially a clinical one. The presence of high fever and altered mental status in a severely ill patient with hyperthyroidism should warrant aggressive treatment for thyrotoxic crisis. Laboratory tests of thyroid function confirm the presence of hyperthyroidism, that is, high total and free thyroxine (T_4) and triiodothyronine (T_3) and a reduced and nearly undetectable thyrotropin (TSH) level. However, T_3 and T_4 levels may be decreased by concurrent nonthyroidal illness. Therefore, levels of T_4 and T_3 may not correlate with the patient's clinical picture.

Treatment

The management of thyroid storm can be discussed under three broad categories: (1) control of hyperthyroidism, (2) treatment of the precipitating illness, and (3) other supportive measures. Treatment is summarized in [Table 25-1](#).

Table 25-1. Treatment of thyroid storm.

Mechanism of Action	Treatment
Measures to reduce thyroid hormone synthesis or peripheral conversion of T_4 to T_3	Propylthiouracil,* 200–300 mg orally or through a nasogastric tube every 6 hours. <i>or</i> Propylthiouracil, 600 mg loading dose orally, followed by 200–300 mg every 8 hours. <i>or</i> Methimazole, 20–30 mg orally or through a nasogastric tube every 6 hours. <i>plus</i> Iodate, [†] 1–1.5 g/d for the first 24 hours, then 500 mg twice daily.
Measures to inhibit the release of thyroid hormones	Lugol's solution, 5–10 drops three times daily, or saturated solution of sodium iodide, 3 drops three times daily, after antithyroid therapy (above) has been instituted. Lithium carbonate, 300 mg every 8 hours, may be used in patients with iodine allergy.
Sympathetic blockade	Propranolol, 0.5–1 mg IV slowly over 5–10 minutes. Repeat every 3–4 hours as indicated. Contraindicated in COPD and asthma; should be very carefully administered in patients with congestive heart failure.
Glucocorticoids	Dexamethasone, 2–4 mg IV every 6–8 hours.
Supportive measures	Identify and treat the precipitating event. Provide fluid and electrolyte replacement as needed. Hyperpyrexia: Cooling blankets, ice, or cool sponges as necessary. Other supportive measures.

*Both propylthiouracil and methimazole may be administered rectally.

[†]If the patient is allergic to iodine, lithium may be used: lithium carbonate, 300–400 mg every 8 hours. Serum lithium levels to be maintained at approximately 1 meq/L.

A. Control of Hyperthyroidism—Several therapeutic agents that act by different mechanisms to block the synthesis, secretion, activation, or action of thyroid hormones can be used together for rapid control of hyperthyroidism.

1. THIOUREAS—Propylthiouracil, methimazole, and carbimazole inhibit thyroid hormone synthesis primarily by inhibiting reactions catalyzed by the thyroid peroxidase

enzyme. These reactions include oxidation, organification, and iodotyrosine coupling. Propylthiouracil is also a weak inhibitor of peripheral conversion of T_4 to T_3 . Methimazole is generally considered to be more potent than propylthiouracil. In comatose patients with thyroid storm, propylthiouracil or methimazole may be given through a nasogastric tube because these drugs are not available in parenteral formulations.

There is no agreement about the optimal dosage of antithyroid drugs. One regimen is to start propylthiouracil at an initial dose of 600–1200 mg/day in four divided doses. Alternatively, 60–120 mg/day methimazole can be given in four divided doses. Should the patient be unable to take medication orally, these medications can be administered rectally. Others have advocated giving a loading dose of 600–1200 mg propylthiouracil followed by 200–300 mg every 8 hours. However, some investigators have questioned whether additional inhibition of thyroperoxidase is achievable at dosages of propylthiouracil in excess of 300 mg daily. Methimazole is given at one-tenth the preceding dosage. The serum half-life of propylthiouracil is 75 minutes; of methimazole, 240–360 minutes. However, the intrathyroidal residence time of methimazole is 20 hours, and its duration of action is believed to be as long as 40 hours. These data have been used to support once-daily administration of methimazole. However, in the life-threatening situation of thyroid storm, it may be preferable to give methimazole three or four times daily. Propylthiouracil is also a weak inhibitor of 5'-deiodinase, the enzyme that converts T_4 to T_3 , and this may be a minor advantage over methimazole—although the two drugs have never been compared directly. Propylthiouracil has been rarely associated with pulmonary capillaritis and alveolar hemorrhage.

Resistance to the effects of antithyroid drugs is extremely uncommon. Most cases of apparent resistance turn out to be problems of noncompliance. Acute side effects of these drugs are uncommon, but allergic reactions, leukopenia, and hepatotoxicity may occur.

2. IPODATE SODIUM—Iodate sodium is an iodine-containing radiocontrast agent used for gallbladder imaging. It is one of the most potent inhibitors of 5'-deiodinase. Clinical studies with ipodate in hyperthyroidism have shown that the drug has an extremely rapid onset of action, resulting in marked lowering of serum T_3 levels within 4–6 hours and normalization of serum T_3 levels within 24–48 hours. The mechanism of antithyroid effect of ipodate is complex. Besides inhibiting conversion of T_4 to T_3 , ipodate also lowers serum T_4 levels, albeit to a lesser degree, indicating additional direct effects on thyroid hormone synthesis. Reverse T_3 levels are higher in ipodate-treated patients, an observation consistent with drug-induced inhibition of 5'-deiodinase. Although ipodate is an iodine-containing contrast agent, radioiodine uptake studies in patients with Graves' disease treated with ipodate for more than a year revealed normal uptake a week after discontinuation of ipodate therapy.

Iodate sodium is administered orally as capsules containing 500 mg. Recommended dosages range from 1–3 g/day. In obtunded patients, ipodate can be administered via

the intragastric route. It has been recommended that propylthiouracil or methimazole be given prior to administration of iodine-containing medications to prevent an iodide-mediated exacerbation of hyperthyroidism.

3. LITHIUM—Lithium can be used in patients unable to tolerate iodine. Lithium is concentrated by the thyroid and inhibits iodine uptake by the thyroid. It also inhibits thyroid hormone release. A dosage of 300–400 mg every 8 hours can be used temporarily to control the thyrotoxic patient who is allergic to iodine. The dose should be adjusted as necessary to maintain a serum lithium level of approximately 1 meq/L.

4. IODIDE—Iodide blocks the release of thyroid hormones from the gland. Iodide also has an inhibitory effect on thyroid hormone synthesis. High doses of inorganic iodide decrease the yield of organic iodine within the thyroid gland—a phenomenon referred to as the *Wolff-Chaikoff effect*. However, this inhibitory effect on thyroid hormone synthesis is transient, and in most patients, an escape from this inhibition occurs with time.

Iodide should be administered only after synthesis of thyroid hormones has been inhibited by prior administration of thioureas. Intravenous sodium iodide can be administered at a dosage of 0.25 g every 6 hours. Alternatively, if the patient is able to take medication orally, Lugol's solution at a dosage of 5–10 drops three times a day or saturated potassium iodide solution at a dose of 3 drops three times daily can be used.

Administration of a large dose of inorganic iodide predictably will reduce radioiodine uptake by the thyroid gland for several weeks. Therefore, prior administration of inorganic iodide will preclude subsequent treatment with radioactive iodine for several weeks.

5. PROPRANOLOL— β -adrenergic blockers attenuate many of the peripheral manifestations of hyperthyroidism. Thus these agents can reverse the thyroid hormone-induced increases in heart rate, cardiac output, and tremor. However, weight loss is not affected by β -blockers. Propranolol, in addition to its antiadrenergic properties, is a weak inhibitor of 5'-deiodinase and thus lowers T_3 levels. The advantage of the 5'-deiodinase inhibition property of propranolol is unclear given the similar action of propylthiouracil and ipodate sodium. Other β -adrenergic blocking agents such as esmolol and labetalol also have been used successfully.

The response to propranolol varies from patient to patient, and dosages should be titrated to the clinical response. The initial dose usually is 0.5–1 mg intravenously given slowly over 5–10 minutes for a total of up to 10 mg. This can be followed by 40–60 mg orally every 6 hours. If the patient is unable to take medication orally, propranolol can be administered intravenously in doses of 1–2 mg every 3–4 hours. These dosage recommendations are only general guidelines to be used initially. Subsequent dosage adjustments should be dictated by the clinical response. Propranolol blood levels in the range of 50–100 $\mu\text{g/mL}$ have been shown to provide effective beta blockade. However, blood levels of propranolol have not been used extensively in

clinical practice; it is much simpler to follow the heart rate and blood pressure responses. Side effects of β -adrenergic blockade in patients with thyroid storm include heart failure, bradycardia, hypotension, and increased airway resistance.

6. GLUCOCORTICOIDS—The older literature warned that adrenal insufficiency might ensue in patients with thyroid storm because of accelerated cortisol degradation. However, this hypothesis has never been validated, and the routine use of glucocorticoid replacement has declined. Glucocorticoids do, however, have several salutary effects on thyroid function in thyroid storm. In patients receiving thyroxine replacement, glucocorticoids lower serum T_3 concentrations, probably by inhibition of peripheral 5'-deiodinase. In addition, glucocorticoids lower serum T_4 levels in patients with Graves' disease. Finally, glucocorticoids in pharmacologic doses inhibit TSH secretion. One recommended regimen is 2–4 mg dexamethasone every 6 hours intravenously. Patients suspected of having adrenal insufficiency should be treated accordingly with higher doses of hydrocortisone (see below).

7. EXTRACORPOREAL THERAPY—Exchange transfusion and plasmapheresis have been advocated as ways of removing large amounts of thyroid hormones from the circulation. Experience with these techniques is limited. Furthermore, with the availability of potent antithyroid drugs, they are not likely to be needed.

B. General Supportive Measures—General measures include fluid and electrolyte replacement and control of hyperpyrexia. The latter may require the use of cooling blankets. Salicylates should be avoided because these drugs can inhibit T_4 and T_3 binding to the binding proteins and increase the concentrations of the free T_4 and T_3 . In addition, specific measures for prompt treatment of the precipitating illness, cardiac arrhythmias, and congestive heart failure should be initiated if indicated.

Prognosis

Most data on mortality statistics in thyroid storm are old, and there are no recent series. Survival figures vary from 24–66% in older series. The precipitating illness is clearly an important determinant of prognosis. Many of these patients may require admission to the ICU, and most require an extended hospital stay; in one study, the median hospital stay was 12 days.

▶ Myxedema Coma

ESSENTIALS OF DIAGNOSIS

- ▶ Features of severe hypothyroidism (myxedema): dry, rough, cold skin, nonpitting doughy edema, loss of eyebrows and scalp hair, and delayed relaxation phase of deep tendon reflexes.
- ▶ Hypothermia.
- ▶ Altered mental status or coma.
- ▶ Hypercapnic respiratory failure.

General Considerations

Myxedema coma represents a breakdown of the body's compensatory mechanisms during the course of long-standing severe hypothyroidism. Development of an intercurrent illness such as an infection on top of the underlying severe hypothyroidism usually leads to this decompensation. Myxedema coma is primarily a clinical diagnosis. While laboratory tests confirm hypothyroidism, the diagnosis is based on the constellation of clinical findings of myxedema, altered mental status, and hypothermia. The physician must remain alert for the possibility of myxedema coma because the consequences of missing the diagnosis can be devastating. In addition, the usual clinical signs of infection such as fever and leukocytosis may be masked in patients with severe hypothyroidism. Therefore, one also must actively search for infection or other precipitating factors and treat these illnesses aggressively.

Pathophysiology

Hypothyroidism is a common endocrinopathy, but myxedema coma is encountered much less commonly because of thyroid hormone replacement therapy. Myxedema coma is associated with poor outcome. Patients with myxedema most often have a history of hypothyroidism, but the precipitating condition is almost always a combination of failure to take an adequate amount of thyroid replacement therapy and the presence of some comorbid condition. Because the serum half-life of T_4 is quite long, hypothyroidism is a subacute condition characterized by decreased metabolic rate, accumulation of edema fluid, deterioration of cardiac function from structural and physiologic changes, hyperlipidemia, and inability to manifest an appropriate response to hypothermia. Ventilatory drive is diminished from central mechanisms and, because of respiratory muscle weakness and pleural effusions and ascites, can result in hypercapnia. Hyponatremia is common and results from the inability to dilute urine maximally.

Clinical Features

Myxedema coma almost always occurs in patients with known hypothyroidism but rarely can present as the initial

finding in hypothyroidism. A precipitating event usually can be identified along with absent or inadequate thyroid replacement therapy. The majority of cases of myxedema coma are reported in winter months in regions with cold climates. Thus cold exposure appears to be an important antecedent factor. Other precipitating factors include sedative or anesthetic drugs, congestive heart failure, cerebrovascular accidents, trauma, infections, and a variety of other illnesses.

A. Symptoms and Signs—Most patients with myxedema are elderly women. The classic signs of myxedema are present, including puffy, expressionless face; dry, rough, and cold skin; nonpitting, doughy edema; loss of eyebrows and scalp hair; delayed relaxation phase of the tendon reflexes; and enlarged tongue. Hypothermia is a hallmark of myxedema coma, with core body temperatures as low as 21°C but more often in the range of 32–35°C. Severe hypothermia (temperature <32°C) is associated with a poor prognosis. However, hypothermia can be easily overlooked if a thermometer that can register temperatures below the usual range is not used. Blood pressure may be normal, high, or low. The heart rate is classically slow. Respirations may be slow and shallow depending on the level of ventilatory drive and respiratory muscle weakness. Mental status changes may include confusion, somnolence, hallucinations, or coma. The thyroid gland may not be palpable because of idiopathic atrophy, prior radiation, or surgery.

Drug metabolism is significantly reduced in hypothyroidism, and administration of the usual doses of sedatives may depress ventilation significantly and compromise mental status. In critically ill patients, the diagnosis of hypothyroidism sometimes may be hard to make on clinical grounds.

B. Laboratory Findings—Hyponatremia is often present. Arterial blood gases may reveal respiratory acidosis, hypercapnia, and hypoxemia. Hypoglycemia may occur, particularly if there is deficiency of pituitary hormones as well. Chest x-ray may reveal an enlarged cardiac silhouette and pleural and pericardial effusions. The ECG may demonstrate low voltage, sinus bradycardia, diffuse T-wave depression, nonspecific ST-segment changes, and prolonged QT and PR intervals. There may be conduction blocks as well. Cerebrospinal fluid (CSF) pressure and protein concentrations may be increased.

Although myxedema coma is a clinical diagnosis, thyroid function tests reveal low thyroxine (T_4), low T_3 resin uptake, and a high thyrotropin (TSH) level. It may be difficult at times to distinguish sick euthyroid syndrome from primary hypothyroidism by thyroid function tests. Very high serum TSH levels (>20 $\mu\text{U}/\text{mL}$) favor the diagnosis of primary hypothyroidism. Moderately elevated TSH levels (up to 20 $\mu\text{U}/\text{mL}$) may be seen occasionally in the course of sick euthyroid syndrome. Severe nonthyroidal illness decreases the TSH response, and inappropriately low TSH is seen in secondary hypothyroidism owing to hypothalamic or pituitary disorders.

C. Adrenal Insufficiency—In patients with hypothyroidism, the manifestations of adrenal insufficiency may be masked. This is important because adrenal insufficiency can coexist

with hypothyroidism in two clinical situations. First, in patients with autoimmune thyroid disease, there is a higher incidence of autoimmune adrenalitis and adrenal insufficiency than in the general population. Second, patients with panhypopituitarism may have absence of both TSH and adrenocorticotropic (ACTH). These patients with secondary adrenal insufficiency lack the skin and mucosal hyperpigmentation that is characteristic of primary adrenal insufficiency. For these reasons, it is easy to miss adrenal insufficiency in this setting, and the clinician must keep alert to the possibility of concomitant adrenal insufficiency. A rapid ACTH stimulation test should be performed in patients with myxedema. However, it should be recognized that the cortisol response to ACTH may be attenuated by hypothyroidism.

Treatment

Treatment consists of thyroid hormone replacement, replacement of other necessary hormones, and supportive measures (Table 25-2), including treatment of hypothermia and of the precipitating illness.

A. Thyroid Hormone Replacement—While all commentators assert the need for prompt thyroid hormone replacement in myxedema coma, there is disagreement about what constitutes an optimal regimen. The major controversy relates to which regimen of thyroid hormone replacement to use: T_4 alone, T_3 alone, or a combination of T_4 and T_3 . The use of T_3 alone has been advocated by some on physiologic grounds. This is so because the activity of 5'-deiodinase is diminished in hypothyroidism, and the conversion of T_4 to T_3 may be

limited. On the other hand, a rapid increase in T_3 may be detrimental to the patient because of cardiac arrhythmias and too rapid an increase in myocardial oxygen demand. Large doses of T_3 ($>75 \mu\text{g}$) have been associated with increased mortality. Because of its potential adverse effects, the use of this regimen has been discouraged by some.

Intravenous administration of T_4 is considered safe and has been the standard for the past three decades. One traditional regimen consists of 500 μg of levothyroxine (T_4) given slowly intravenously, followed by 100–150 μg every 24 hours. The rationale for the large initial dose is that it restores the total thyroxine pool. However, it is not clear if this regimen is any better than 150 μg given intravenously daily. The rate of fall in serum TSH levels is not significantly different between the two regimens. In fact, a dose of 100–150 μg levothyroxine given intravenously daily would correct the thermoregulatory, respiratory, cardiac, and mental status changes over 24–48 hours.

A third regimen consists of a combination of both T_4 and T_3 . It is suggested that 200–300 μg T_4 be given simultaneously with 25 μg T_3 intravenously. This is followed by administration of another 25 μg T_3 12 hours later and 100 μg T_4 at 24 hours. Starting the third day, 100 μg T_4 is given daily until the patient regains consciousness.

Recent literature has witnessed conflicting reports on the effectiveness of combined regimens of levothyroxine and triiodothyronine. The rates of conversion of thyroxine to triiodothyronine do vary in different tissues; animal studies suggest that T_3 concentrations in some tissues of thyroidectomized rats replaced with levothyroxine alone are lower than those observed in euthyroid animals. Similarly, circulating levels of T_3 in hypothyroid patients treated with levothyroxine alone are lower than those in euthyroid individuals. Objective differences between thyroxine replacement compared with combined thyroxine plus triiodothyronine replacement have not been found.

There is no strong basis for advocating any one regimen. The rapid restoration of thyroid hormone levels is desirable. Most authorities agree that expeditious thyroid hormone replacement is a more important objective than the exact regimen of thyroid hormone replacement and that high-dose levothyroxine administered intravenously is a reasonable and safe choice.

B. Glucocorticoids—As discussed earlier, signs of adrenal insufficiency may be masked in hypothyroid patients. On the other hand, initiation of levothyroxine therapy without concomitant glucocorticoid replacement may precipitate adrenal crisis if the patient has adrenal insufficiency. Therefore, one must be on guard against the possibility of adrenal insufficiency in appropriate patients. If in doubt, it is better to err on the side of treatment with corticosteroids (see “Adrenal Insufficiency” next) because the consequences of delayed or no replacement can be serious.

C. Supportive Measures—Patients with myxedema coma may need transient endotracheal intubation and mechanical ventilation for hypercapnic respiratory failure. Intravenous

Table 25-2. Treatment of myxedema coma.

Mechanism of Action	Treatment
Thyroid hormone replacement	Levothyroxine (T_4), 500 μg by slow intravenous infusion, followed by 100–150 μg every 24 hours. <i>or</i> T_4 , 200–300 μg , and triiodothyronine (T_3), 25 μg IV; 25 μg of T_3 12 hours later; and 100 μg of T_4 at 24 hours.
Glucocorticoid	Hydrocortisone, 100 mg IV every 8 hours.
Supportive measures	Maintain adequate ventilation. Institute endotracheal intubation and mechanical ventilation if necessary. Identify and treat the precipitating event. Provide fluid and electrolyte replacement as needed. Correct core body temperature.

fluids, electrolytes, and vasopressors may be needed to maintain blood pressure. Rapid rewarming through the use of heating blankets is not generally recommended because it may provoke or worsen peripheral vasodilation and hypotension. However, in patients with severe hypothermia, thermogenic shivering mechanisms may become impaired, and these patients may not be able to raise their body temperatures. Therefore, gradual but active rewarming may be required in some patients. In most patients with mild hypothermia, wrapping the patient in blankets in a warm room is sufficient to restore body temperature, provided that thyroid replacement therapy has been initiated. Treatment of hypothermia is discussed in Chapter 38. A search for infection or other precipitating factors should be mounted. In many instances, empirical antibiotic therapy may be justified. Because of decreased metabolic rate, many drugs are cleared more slowly in patients with severe hypothyroidism.

Prognosis

Myxedema coma may be fatal if unrecognized and left untreated. Poor prognostic indicators include severe hypercapnia and hypothermia. If infection or other precipitating illness is present, outcome depends on treatment and response to these problems. Complications of thyroxine (T_4) and triiodothyronine (T_3) replacement therapy may include serious cardiac morbidities, such as acute coronary syndrome and cardiac arrhythmias.

▶ Acute Adrenal Insufficiency

ESSENTIALS OF DIAGNOSIS

- ▶ Hypotension, volume depletion, hypovolemic shock.
- ▶ Hyperkalemia, hyponatremia.
- ▶ Weakness, abdominal pain, nausea, vomiting, fever.
- ▶ Acute infectious illness or trauma, recent cessation of corticosteroid therapy, or inadequate replacement in chronic adrenal insufficiency.
- ▶ Abnormal ACTH stimulation test.

General Considerations

Critical illness, whether from sepsis, trauma, surgery, or any condition associated with hemodynamic compromise, stimulates the hypothalamic-pituitary-adrenal axis causing an increased production of cortisol. This hormone, synthesized in the adrenal cortex under the influence of ACTH, maintains vascular integrity and tone, stimulates neoglucogenesis and free water clearance, and influences fluid and electrolyte balance. Lack of aldosterone—a mineralocorticoid—is associated with inability to conserve sodium in the face of hypovolemia and hyperkalemia. Deficiency of cortisol—a glucocorticoid—on the other hand, is associated with inability to clear free water and with hemodynamic compromise mimicking hypovolemic or septic shock. Hyponatremia, a hallmark of adrenal insufficiency, is typically due to the inability of these patients to clear free water owing to cortisol deficiency and dysregulated antidiuretic hormone (ADH) secretion. Patients with adrenal insufficiency become hypotensive owing to a combination of factors, including hypovolemia and impaired vascular response to catecholamines and also to loss of a direct inotropic effect of cortisol. Cortisol stimulates hepatic neoglucogenesis, and it is therefore not surprising that patients with adrenal insufficiency may present with hypoglycemia. Serum cortisol levels in acutely ill patients are usually increased.

Acute adrenal insufficiency is the result of inadequate cortisol production with life-threatening cardiovascular collapse and potentially severe electrolyte and fluid abnormalities. Acute insufficiency can occur as a result of an acute insult to the adrenal glands from infection or trauma or may be seen in a patient with chronic adrenal insufficiency who develops critical illness. Patients who receive corticosteroids for treatment of inflammatory diseases will have chronic suppression of pituitary-adrenal function, and abrupt cessation of therapy may precipitate acute adrenal insufficiency, especially if there is intercurrent illness. A high index of suspicion for the diagnosis of adrenal crisis is the key. Because delay in instituting treatment can be fatal, acute adrenal insufficiency should be suspected in any patient presenting with hypotension, fever, abdominal pain, hyponatremia, or hyperkalemia, especially if hyperpigmentation is present. In many clinical situations, empirical therapy may be appropriate, even before a definitive diagnosis has been made.

Pathophysiology

Idiopathic or autoimmune adrenalitis accounts for about 80% of cases of chronic adrenal insufficiency in outpatients. Tuberculosis used to be a major cause of adrenal insufficiency, but that disease is relatively uncommon now in developed countries. Other less common causes include adrenal hemorrhage; fungal infections such as histoplasmosis, coccidioidomycosis, blastomycosis, and candidiasis; hemochromatosis; irradiation; surgical removal of the adrenal glands; drug toxicity; and congenital disorders such as synthetic

enzyme deficiencies. Patients with HIV infection often have abnormalities in the adrenal glands at autopsy but appear to have only a slightly increased incidence of adrenal insufficiency (about 5–10%). The impaired immune status resulting from HIV infection increases the likelihood of adrenal involvement with cytomegalovirus (the most common finding), fungi (eg, *Cryptococcus* and *Histoplasma*), or mycobacteria (both tuberculous and nontuberculous). HIV, however, directly affects the adrenal glands only in a small number of patients. Secondary adrenal insufficiency can occur in HIV-infected patients because of direct involvement of the hypothalamus or the pituitary gland, opportunistic infections (eg, tuberculoma or histoplasmosis), or lymphoma.

Other causes of adrenal insufficiency include metastatic cancer and hemorrhage. Although metastases to the adrenal gland are relatively common, adrenal insufficiency as a result of metastatic disease is uncommon. Adrenal hemorrhage may occur during the course of sepsis, excessive anticoagulation, trauma, pregnancy, or surgery. Adrenal infarction may occur as a result of thrombosis, embolism, or arteritis. Infiltrative disorders include amyloidosis, sarcoidosis, and hemochromatosis. Congenital disorders leading to adrenal insufficiency include congenital adrenal hyperplasia. This is due to a genetic defect in one of the steroidogenic enzymes or hypoplasia.

A number of drugs directly inhibit the enzymes involved in steroidogenesis. Etomidate is frequently used during endotracheal intubation; it suppresses adrenocortical function for up to 24 hours. Metyrapone inhibits β -hydroxylase, aminoglutethimide inhibits side-chain cleavage enzymes, ketoconazole inhibits a number of cytochrome P450-linked steroidogenic enzymes, and mitotane is an adrenolytic cytotoxic agent. Fluconazole also has been implicated. Relatively common medications such as rifampin and seizure medications (eg, phenytoin and carbamazepine) increase hepatic cytochrome P450 activity, thus increasing cortisol metabolism. These medications should be used with caution in patients with limited adrenal reserve.

In patients with autoimmune adrenalitis, there is an increased incidence of other endocrinopathies. For example, Hashimoto's thyroiditis, Graves' disease, pernicious anemia, hypoparathyroidism, premature ovarian or testicular failure, and type 1 diabetes occur with a greater frequency than in the general population. It is now clear that multiple endocrine organs may be affected by organ-specific autoimmune disease. These polyendocrine autoimmune syndromes are classified into two major groups: type I and type II. Type I patients usually present in early childhood with hypoparathyroidism and mucocutaneous candidiasis; adrenal insufficiency may develop later. Disease is usually limited to one generation of siblings. Genetic analyses of families are consistent with an autosomal recessive inheritance in a single gene. Mutations in an autoimmune regulator gene (*AIRE*) have been described in association with polyendocrine autoimmune syndrome type I. In contrast, type II patients usually present with adrenal insufficiency in the third or fourth decade. Type 1 diabetes mellitus occurs in almost

half of patients. There is a strong association with HLA-DR3 or -DR4 haplotypes. Hyperthyroidism (Graves' disease), Hashimoto's thyroiditis, primary ovarian failure, myasthenia gravis, celiac disease, and pernicious anemia occur much more commonly in patients with type II polyendocrine autoimmune syndrome than in the general population. Multiple generations in the same family are usually affected. The genetic analyses of families suggest that it is a polygenic disorder with autosomal dominant inheritance. Autoantibodies against at least three cytochrome P450 enzymes that are involved in cortisol synthesis have been reported in association with Addison's disease as part of both type I and type II syndromes.

Acute Adrenal Crisis

Acute adrenal crisis refers to the collapse and shock syndrome that occurs in a patient with inadequate adrenal cortical function. This can occur in chronic adrenal insufficiency because of stress imposed by a serious illness such as infection, trauma, or surgery without adequate replacement. In other patients, acute bilateral adrenal hemorrhage (ie, Waterhouse-Friderichsen syndrome), originally described in association with meningococcemia, is the cause of acute adrenal insufficiency. Acute adrenal hemorrhage can complicate the course of systemic sepsis from other pathogens as well. In fact, *Pseudomonas aeruginosa* is a common organism in children dying with sepsis and adrenal hemorrhage. Other common acute antecedent factors include anticoagulant therapy, disseminated intravascular coagulation, and the perioperative state.

Clinical Features

The clinical manifestations of adrenal insufficiency depend (1) on whether the patient has primary or secondary adrenal failure, (2) on the presence or absence of other endocrinopathies (eg, coexistence of hypothyroidism may significantly attenuate the manifestations of adrenal insufficiency), and (3) on the presence of superimposed nonendocrinologic illness or stress. In the ICU, symptoms and signs of the acute illness may overshadow the features of concomitant adrenal insufficiency, making clinical suspicion the key to diagnosis.

A. Symptoms and Signs—Patients with chronic adrenal insufficiency may not come to medical attention for some time because of the nonspecific nature of symptoms, such as fatigue, anorexia, weight loss, nausea, and vomiting. Other manifestations include weakness, salt craving, and postural dizziness. Patients with primary adrenal insufficiency usually have hyperpigmentation of the skin and mucous membranes because of increased ACTH production by the pituitary. Patients often develop a "tan" in both sun-exposed and non-exposed parts, especially in areas that suffer chronic friction and trauma, such as elbows, knees, knuckles, and the belt-line. The buccal mucosa may show hyperpigmentation, especially along sites of dental occlusion. The "tan" appearance of these patients often conveys a misleading impression of good health. Scars acquired during the course of adrenal

insufficiency also become hyperpigmented, whereas those acquired before or after remain unpigmented.

The hallmarks of acute adrenal insufficiency (ie, adrenal crisis) include severe hypotension and vascular collapse, nausea, vomiting, abdominal pain, and fever. Hypotension is due largely to volume depletion, and there may be other evidence of volume depletion. Abdominal symptoms may lead to an erroneous diagnosis of acute abdomen, resulting in unwarranted and potentially catastrophic surgical exploration. Confusion and altered mental status also may occur. Petechiae may be found if meningococemia is the cause of acute adrenal hemorrhage. Hyperpigmentation, if present, indicates chronic primary adrenal insufficiency. Infection, surgical stress, and trauma may precipitate acute adrenal crisis in patients with chronic adrenal insufficiency. Patients should be questioned about receiving chronic corticosteroid therapy, especially if they have a history of asthma, interstitial lung disease, rheumatologic diseases such as systemic lupus erythematosus, or lymphoproliferative disorders. Patients with HIV infection and autoimmune endocrinopathies should be suspected of adrenal insufficiency if they present with intractable hypotension and hyponatremia.

A degree of clinical suspicion may be necessary in evaluating critically ill patients who may present in atypical fashion. Patients with hemodynamic instability that cannot be explained easily—in association with fever with no identified source and alteration in mental status—should be considered for adrenal insufficiency. These patients may benefit from empirical adrenal replacement therapy.

B. Laboratory Findings—Laboratory data may reveal hyponatremia, hyperkalemia, and azotemia. Hypoglycemia occurs more often in children but may be seen in adults as well, especially in those who have been vomiting. Corticosteroids play an important role in regulating gluconeogenesis and have potent anti-insulin actions. Hypercalcemia and eosinophilia also may be found. Hyponatremia is usually multifactorial. Patients with primary adrenal insufficiency are unable to conserve sodium because of mineralocorticoid deficiency. However, these patients become hyponatremic even in the face of positive sodium balance. This is so mainly because of inability to clear free water due to glucocorticoid deficiency. The exact pathophysiology of the defect in free water clearance in primary adrenal insufficiency is not known, but there is lack of adequate suppression of ADH levels in the face of hyponatremia. In addition, glucocorticoids also exert a permissive effect of ADH directly at the kidney level. In the evaluation of volume depletion and hyponatremia, low urinary sodium and fractional excretion of sodium usually reflect volume depletion; in adrenal insufficiency, however, both urinary indices may be elevated because of the inability of the kidneys to conserve sodium maximally in the absence of cortisol and aldosterone.

C. Adrenal Function Tests—A patient in whom acute adrenal insufficiency is suspected should be treated immediately.

However, diagnosis can be made rapidly and reliably by an ACTH stimulation test. In addition, a random serum cortisol level greater than 20 $\mu\text{g}/\text{dL}$ makes the diagnosis of adrenal insufficiency unlikely.

The traditional protocol for the rapid ACTH stimulation test is as follows: 250 μg cosyntropin (containing amino acids 1–24 of ACTH) is administered intravenously, and plasma samples are obtained at 0, 30, and 60 minutes for measurement of cortisol. In addition, it is helpful to save contingency samples for plasma aldosterone measurement. Earlier studies had suggested that an increment of more than 7 $\mu\text{g}/\text{dL}$ after cosyntropin administration or peak levels greater than 17 $\mu\text{g}/\text{dL}$ would exclude adrenal insufficiency. However, other data indicate that any cortisol value greater than or equal to 20 $\mu\text{g}/\text{dL}$ before or after the cosyntropin test is consistent with normal adrenal function. A normal response excludes primary adrenal insufficiency. Concern about adrenal insufficiency should be raised if any of these criteria are not met. A small incremental increase in plasma cortisol after cosyntropin despite a baseline value in the normal range may be associated with a poor outcome and increased mortality.

Some studies have suggested that the supraphysiologic dose of corticotropin used may cause false-negative readings in patients with partial or secondary adrenal insufficiency. This is so because patients with adrenal insufficiency may have some reserves left, and using the relatively large dose of corticotropin might lead to a normal response. Some have advocated using instead a low-dose ACTH stimulation test with 1 μg corticotropin. A normal response is a rise in cortisol level to 20 $\mu\text{g}/\text{dL}$ or more at 30 or 60 minutes.

If the cortisol response to cosyntropin is subnormal, the contingency samples can be used to measure aldosterone and endogenous ACTH to distinguish primary from secondary adrenal insufficiency. Aldosterone responses to cosyntropin are impaired in primary adrenal insufficiency but are preserved in secondary adrenal insufficiency (due to decreased endogenous ACTH secretion). ACTH is elevated in primary adrenal insufficiency and low normal or below normal in secondary adrenal insufficiency. Certain clinical features also can be useful in distinguishing primary from secondary adrenal insufficiency. For example, hyperpigmentation and hyperkalemia are observed in primary but not in secondary adrenal insufficiency. The presence of other endocrine hormone deficiencies does not necessarily indicate panhypopituitarism because these also could be a consequence of autoimmune polyendocrinopathy.

Treatment

Once the diagnosis of adrenal insufficiency has been made, treatment is relatively straightforward (Table 25–3).

A. Corticosteroid Replacement—Promptness in instituting corticosteroid therapy is very important. Corticosteroid replacement can be given as hydrocortisone sodium succinate, 75–100 mg intravenously every 6–8 hours. If the patient is

Table 25-3. Management of acute adrenal insufficiency (adrenal crisis).

Diagnostic testing	If you are considering a diagnosis of acute adrenal insufficiency, perform a rapid ACTH test (see text) immediately and initiate treatment pending return of laboratory results. If a patient is highly likely to have adrenal insufficiency, give dexamethasone immediately while the ACTH test is being conducted.
Glucocorticoid	Hydrocortisone sodium succinate, 75–100 mg IV immediately and then every 6–8 hours. <i>or</i> Dexamethasone, 3–4 mg IV every 6–8 hours.
Mineralocorticoid	Not required when large doses of hydrocortisone (>50–60 mg/d) are used. Consider adding fludrocortisone acetate, 0.05–0.1 mg orally daily if dexamethasone is used.
Supportive measures	Identify and treat the precipitating illness. Correct fluid and electrolyte abnormalities. Intravenous NaCl 0.9% is usually given initially. Monitor blood glucose and electrolytes and administer glucose if necessary.

hypotensive, performance of the diagnostic ACTH stimulation test may unduly delay institution of therapy. Under these circumstances, an equivalent dose of dexamethasone (3–4 mg every 6–8 hours) can be given intravenously contemporaneously with ACTH administration. Dexamethasone does not crossreact in the cortisol assay, and the diagnostic procedure therefore can be done without concern about the delay in instituting replacement therapy. The dose of hydrocortisone sodium succinate can be reduced to the replacement level (10–20 mg in the morning and 5–10 mg in the evening) as the patient's condition improves.

Some studies cast doubt on the need for large pharmacologic doses of corticosteroids during surgery. Studies in adrenalectomized monkeys suggest that physiologic replacement doses of corticosteroids are sufficient in this primate model to tolerate the stress of surgical laparotomy. Supraphysiologic doses of corticosteroids conferred no survival advantage on these adrenalectomized monkeys over physiologic replacement doses during the period of surgical stress. Other studies have shown that patients receiving steroids prior to undergoing surgery did not require additional glucocorticoids during the perioperative period.

Empirical recommendations for glucocorticoid administration in surgical patients are to estimate the degree of stress and give 25 mg/day of hydrocortisone for mild stress, 50–75 mg/day for 2–3 days for moderate stress, and 100–150 mg/day for 2–3 days for severe stress. After recovery from acute illness, patients with adrenal insufficiency should be placed on chronic replacement therapy with hydrocortisone. Traditionally, a dose of 30 mg hydrocortisone administered in two divided doses—20 mg in the morning and 10 mg in the evening—has been used widely. However, recent assessments using more accurate isotope dilution and mass spectrometric methods suggest that daily cortisol production rates are 5–6 mg/m² of body surface area rather than the 12–15 mg/m² of body surface area, as was thought previously.

Therefore, the traditional regimen of 30 mg hydrocortisone daily possibly represents excessive glucocorticoid replacement and may increase the risk of osteoporosis. A more appropriate regimen may be 15 mg hydrocortisone administered in two divided doses: 10 mg in the morning and 5 mg in the afternoon. Although hydrocortisone traditionally has been administered in a twice-daily regimen, some authors have suggested that a thrice-daily regimen (10, 5, and 5 mg) might provide more physiologic cortisol levels.

B. Mineralocorticoid Replacement—Most patients with primary adrenal insufficiency require mineralocorticoid replacement. In chronic adrenal insufficiency, this can be administered as fludrocortisone acetate. The usual starting dosage is 0.05–0.1 mg by mouth daily. Some patients may develop leg edema on initiation of therapy. This usually will abate if the dose is reduced. Hydrocortisone by itself has some mineralocorticoid activity, so when patients are receiving more than 50–60 mg/day of hydrocortisone, no additional mineralocorticoid replacement is necessary. However, if dexamethasone, which has little or no mineralocorticoid activity, is used instead of hydrocortisone, a mineralocorticoid should be added.

C. Fluid and Electrolytes—Patients with adrenal insufficiency often have an enormous salt and water deficit. It is important to correct these deficits aggressively by administration of 0.9% NaCl solution intravenously. However, patients with adrenal insufficiency may continue to be hypotensive even after adequate fluid and electrolyte replacement. Blood pressure may be restored only by corticosteroid administration. It is often not recognized that corticosteroids have an inotropic effect on the myocardium. Patients with adrenal insufficiency may present with hyperkalemia; therefore, routine potassium replacement should be postponed until serum potassium measurements are obtained.

D. Glucose—Corticosteroids are important regulators of gluconeogenesis. Although in adults, unlike children, hypoglycemia is not a common manifestation of adrenal insufficiency, patients who have been vomiting for a few days may present with hypoglycemia or develop hypoglycemia during the course of evaluation or treatment. Therefore, plasma glucose levels should be monitored and glucose given intravenously to correct or prevent hypoglycemia.

E. Other Treatment—It is crucial to identify and treat the antecedent illness precipitating acute adrenal insufficiency. This may include administration of antibiotics to treat an infection. Many patients with adrenal insufficiency have one or more endocrinopathies. It is important to recognize and treat these when identified.

Current Controversies and Unresolved Issues

Serum cortisol is measured as the total rather than free cortisol, and more than 90% of cortisol is protein-bound. In critically ill patients, low serum albumin and serum proteins may cause lower serum total cortisol but normal free cortisol. Therefore, some patients might be labeled incorrectly as having cortisol deficiency. In a recently published study, baseline and postcosyntropin total cortisol were lower in patients with serum albumin levels of less than 2.5 g/dL compared with those with higher serum albumin levels. Despite this finding, baseline and postcosyntropin free cortisol measurements were often not different. Thus, in this study, almost 40% of patients with low serum albumin levels had low total cortisol levels, but all had normal adrenal function. Because free cortisol measurements are not widely available, it is not clear how to interpret low serum total cortisol in the face of hypoproteinemia. The safest course would be to continue to give these patients glucocorticoid replacement but recognize that some of the patients may be treated unnecessarily.

Another controversial issue has been the use of corticosteroids in patients with septic shock. Some studies suggest that hydrocortisone at dosages similar to replacement for adrenal insufficiency improves outcome in septic shock. Benefit was seen almost exclusively in those with an increase in serum cortisol level of less than 9 µg/dL in response to corticotropin, despite some patients having supraphysiologic baseline serum cortisol levels. A cytokine-induced “relative” adrenal insufficiency has been postulated, but it is not clear that patients with high cortisol levels require replacement. However, a recent study did not find that corticosteroids benefit septic shock patients, and one recommendation is to use corticosteroids only if baseline cortisol levels are very low or if etomidate had been given within 24 hours.

▶ Sick Euthyroid Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Low T_3 and/or low total T_4 suggestive of hypothyroidism in a patient with acute or chronic nonthyroidal illness.
- ▶ But patient is euthyroid, as shown by clinical appearance, normal TSH, usually normal TSH response to thyrotropin-releasing hormone (TRH), and normal free T_4 by equilibrium dialysis.
- ▶ In extremely ill patients, free T_4 may fall to subnormal levels.

General Considerations

Alterations in thyroid function occurring with nonthyroidal illness are usually associated with changes in other hormonal systems and can be thought of as part of a complex and multifaceted response of the endocrine system to illness. A number of nonthyroidal illnesses produce alterations in thyroid function in patients in whom no intrinsic thyroid disease is present and the patient is judged to be euthyroid. These low T_3 and low T_3 - T_4 syndromes seen with nonthyroidal illness represent a continuum probably reflecting severity of the disease process rather than discrete conditions. The syndromes must be distinguished from hypothyroidism because their treatment requires correction of the underlying disorder rather than thyroid hormone replacement.

Pathophysiology

The sick euthyroid syndrome is essentially a laboratory diagnosis (Table 25–4). Patients are clinically euthyroid, but because they have acute or chronic nonthyroidal illness, the underlying disease may make assessment of thyroid status difficult or unclear. The syndrome may be divided into three

Table 25-4. Profile of thyroid hormone indices during different phases of acute illness.

Phases of Illness	T ₃	T ₄	FT ₄	rT ₃	TSH
Mild, early	D	N	N	I	N
Moderate	D	N, D	N	I	N
Severe	D	D	D	I	N, D
Early recovery	D	D, N	D, N	I	N, I

D = decreased; I = increased; N = normal.

patterns: low T₃, low T₃ and T₄, and low thyroid-stimulating hormone (TSH).

A. Low T₃—This is the most common presentation. In the early stages of nonthyroidal illness, serum T₃ (bound and free) decreases, and reverse T₃ (rT₃) is increased. T₄ and TSH levels are within the normal range. The low T₃ state results in part from decreased conversion of T₄ to T₃ because of the inhibition of peripheral tissue 5′-monodeiodinase activity and reduced T₃ production. Contrary to earlier belief that the elevated rT₃ resulted from increased conversion of T₄ to rT₃, the elevated rT₃ results from decreased rT₃ clearance secondary to decreased 5′-monodeiodinase activity. Circulating T₃ levels can fall below normal within 24 hours of onset of any systemic illness, major trauma, surgery, or caloric deprivation, and T₃ concentrations generally become normal as the underlying illness resolves. It has been postulated that decreased T₃ may be a protective mechanism during acute illness because it is associated with decreased urine urea nitrogen excretion and decreased protein breakdown. Tissue T₃ levels fall proportionate to serum levels.

In the early recovery phases from illness, there may be a transient increase in serum TSH concentrations to levels seen in patients with primary hypothyroidism. Although these levels rarely exceed 20 μU/L, there have been several case reports of sick euthyroid patients having TSH values exceeding this commonly used cutoff value. This elevation of TSH has been proposed to stimulate the thyroid gland to increase its secretion of T₄. Nonetheless, a TSH level greater than 20 μU/mL is suggestive of primary hypothyroidism.

In one study of unselected ICU patients, 44% had low free T₃ levels on admission, indicating nonthyroidal illness, 24% of these had normal TSH and 21% had low TSH levels.

B. Low T₃ and T₄—Free T₄ (FT₄) is almost always normal early in the course of nonthyroidal illness. In more severe illness of longer duration, the decreased serum T₃ levels are accompanied by a reduction in serum T₄. This portends a poor prognosis: The greater the reduction in T₄, the worse is the outcome. This condition may occur in 25–50% of

medical patients admitted to an ICU. In patients with T₄ concentrations less than 3 μg/dL, the mortality rate may reach 80%. The fall in FT₄ to subnormal levels is multifactorial; decreased TSH resulting in decreased T₄ secretion from the thyroid, alterations in T₄ binding to plasma proteins, and alterations in binding protein concentrations all contribute to low T₄ concentrations. Despite the finding of very low T₄, these patients are not considered as having hypothyroidism, and replacement of thyroid hormone does not improve outcome.

C. Low TSH—Low T₃ or low T₃ and T₄ are also seen in hypothyroidism, but a euthyroid state in these patients with nonthyroidal illness is suggested by the clinical appearance, the normal TSH concentration, and the normal free T₄ level by equilibrium dialysis. Also, the TSH response may be blunted to thyrotropin-releasing hormone (TRH) stimulation.

Not uncommonly, low TSH values (<0.1 μU/mL) rather than normal TSH values are encountered in euthyroid hospitalized patients, although most patients will have only marginally depressed values of more than 0.1 μU/mL. The availability of more sensitive third-generation TSH assays has made it possible to distinguish between marginally depressed TSH concentrations in euthyroid patients and the highly suppressed levels seen with hyperthyroidism (<0.01 μU/mL). If necessary, a TRH stimulation test can be used to confirm the result. Euthyroid patients with nonthyroidal illness and depressed TSH will show detectable responses of TSH (>0.1 μU/mL) to TRH stimulation, whereas hyperthyroid patients will show the expected absence of response to TRH stimulation.

Diagnosis

A. Laboratory Findings—When assessing thyroid dysfunction in the critically ill, perhaps the best initial screening tests are total T₄, T₃ resin uptake, T₃, and sensitive TSH levels. Low T₃ is always seen in sick euthyroid syndrome and can fall from normal values within 24 hours of onset of acute illness. The rT₃ level may be increased. The euthyroid state is confirmed if total T₄ and T₃ resin uptake are normal or if free T₄ by equilibrium dialysis is normal, along with normal TSH values.

As described earlier, a more difficult situation arises when both T₃ and total T₄ are reduced in more severe or prolonged illness. Free T₄ by equilibrium dialysis is often normal but may be misleadingly low despite the patient being clinically euthyroid. A normal or low TSH generally confirms the finding of a euthyroid state, whereas TSH greater than 20 μU/L makes hypothyroidism a strong possibility. If there is any doubt about the TSH response, then evaluation of pituitary function may be helpful.

B. Disorders Associated with Altered Thyroid Function Tests—A number of conditions can produce alterations in thyroid function tests suggesting thyroid hormone deficiency (Table 25-5).

Table 25-5. Conditions that produce thyroid function test patterns suggesting thyroid hormone deficiency (sick euthyroid syndrome).

Malnutrition, caloric deprivation
Chronic liver disease
Renal disease
Diabetes mellitus
Infection
Acute myocardial infarction
Cancer
Surgery
Medications
AIDS

1. MALNUTRITION OR CALORIC DEPRIVATION—Caloric deprivation such as that seen during fasting can produce a significant fall in serum T_3 concentrations and a rise in serum rT_3 within 24 hours. Hypocaloric diets containing as few as 600 kcal/day can produce these same changes. T_4 concentrations are usually normal, but the TSH response to TRH is blunted. Free T_4 may rise transiently and then stabilize. It has been suggested that caloric deprivation causes the starving body to conserve energy by reducing the amount of metabolically active T_3 . Administering T_3 to starving subjects induces greater muscle catabolism. Refeeding with as little as 50 g carbohydrate (200 kcal) normalizes serum T_3 and rT_3 . However, the TSH response to TRH may remain reduced, suggesting a difference in recovery time between peripheral 5'-monodeiodination and pituitary responsiveness.

2. CHRONIC LIVER DISEASE—Liver disease may have profound effects on thyroid function. The liver is the main organ for thyroid hormone metabolism and the major site for extrathyroidal (peripheral) conversion of T_4 to T_3 . Serum T_3 levels are low, rT_3 is elevated, and TSH is normal in patients with liver disease. The serum T_4 is usually normal, although low levels are found in the most severely ill. Very low T_3 predicts a poor outcome.

3. RENAL DISEASE—Patients with chronic renal failure tend to have multiple factors that may affect thyroid function tests. These include poor nutrition, metabolic disturbances, medications, and hemodialysis. A reduced serum T_3 is found in many patients, and T_3 does not increase with thyroxine replacement. However, rT_3 is normal rather than elevated because of increased uptake in tissues. Secondary hyperparathyroidism, which often accompanies renal failure, also may be partly responsible for this pattern of thyroid function tests because a low T_3 and normal rT_3 also are seen in states of elevated parathyroid hormone. Free T_4 may be elevated transiently during hemodialysis, probably representing a heparin effect. TSH levels are usually normal. Extensive metabolic studies of patients with renal failure and low serum T_3 concentrations indicate that they are euthyroid.

Patients with nephrotic syndrome may lose significant amounts of thyroxine-binding globulin (TBG) from urinary protein losses, resulting in decreased serum T_4 levels. The T_3 resin uptake is increased in proportion to the lowered TBG levels, and the free T_4 index is usually normal. A number of other conditions are associated with increased and decreased TBG levels (Table 25-6).

4. DIABETES MELLITUS—Diabetes and thyroid disorders are linked at several levels. The association of autoimmune thyroid disease with type 1 diabetes mellitus as part of the autoimmune polyendocrinopathy syndrome is well recognized. Diabetic ketoacidosis produces a similar pattern of altered thyroid function tests seen in other severe illnesses. With treatment, most patients normalize thyroid function tests within a few days. Insulin deficiency mimics a fasting state because carbohydrate is not used properly. Poorly controlled diabetes causes a marked reduction in conversion of T_4 to T_3 ; T_3 levels increase with improved glycemic control.

5. INFECTION—Infection also produces changes in thyroid hormone parameters similar to those seen in sick euthyroid patients. These alterations are corrected by successful treatment of the infection. Because malnutrition often accompanies severe infection, it is thought to play a role in the changes observed. Fever alone also may be a factor in altering thyroid function tests. A negative correlation between temperature and serum T_3 has been observed.

6. ACUTE MYOCARDIAL INFARCTION—A consistent pattern of thyroid function abnormalities has been observed in acute myocardial infarction. Serum T_3 concentrations fall after an

Table 25-6. Conditions associated with altered thyroxine binding globulin (TBG) concentrations.

Increased TBG	Decreased TBG

Familial disorders	

acute myocardial infarction, reaching a nadir at 1–3 days with a reciprocal increase in rT_3 . Serum TSH levels increase at day 4–5, followed by a rise in T_4 . The severity and size of the infarct are correlated with the degree of fall in T_3 and increase in rT_3 . The same pattern is seen with unstable angina. Low T_3 is a powerful prognostic marker of death in all forms of cardiac disease, including congestive heart failure.

7. CANCER—Most cancer patients show a pattern of thyroid studies similar to other nonthyroidal illness. Malnutrition and cachexia are contributing factors. Some antitumor chemotherapeutic agents such as fluorouracil and asparaginase alter TBG levels.

8. SURGERY—Elective and emergency surgeries typically cause significant changes in thyroid hormone levels. Serum T_3 concentrations fall during surgery and may take up to a week to recover. This is accompanied by a reciprocal rise in rT_3 . Serum T_4 levels usually remain stable unless there is a prolonged recovery period. TSH may be unchanged or reduced intraoperatively but returns to normal within a couple of days.

9. MEDICATIONS—The patient in the ICU is commonly taking multiple medications, some of which may have profound effects on thyroid function parameters. Some common drugs and their effects are listed in Table 25–7. Patients in the ICU commonly receive dopamine for blood pressure support or high-dose corticosteroids for various reasons. These drugs suppress TSH secretion, but not usually to the levels seen in hyperthyroidism. However, in patients with primary hypothyroidism, dopamine may suppress an elevated TSH into the normal range, confounding diagnosis.

Other drugs likely to be encountered in the ICU that may confuse interpretation of thyroid function tests include octreotide, amiodarone, and β -adrenergic antagonists. Octreotide decreases TSH secretion at high doses. Amiodarone, an antiarrhythmic drug containing iodide, may induce hypothyroidism or hyperthyroidism but more commonly results in low serum T_3 and normal or high T_4 . Amiodarone inhibits 5'-deiodinase. Large doses of propranolol, atenolol, and metoprolol decrease serum T_3 levels but do not result in hypothyroidism.

10. AIDS—In patients with AIDS, direct infection of the thyroid gland by opportunistic organisms such as cytomegalovirus, *Cryptococcus*, and *Pneumocystis jirovecii* may occur rarely in addition to infiltration by Kaposi's sarcoma. Patients with *P. jirovecii* thyroiditis may have hypo- or hyperthyroidism depending on the degree of involvement and disruption of the gland. Cytomegalovirus thyroiditis usually is associated with sick euthyroid syndrome rather than hypothyroidism. Some of the medications used for treating patients with AIDS may alter thyroid function. For example, rifampin increases T_4 clearance by hepatic microsomal enzyme induction. Hypothyroidism has been reported after ketoconazole treatment. One would expect to see a sick euthyroid pattern with AIDS, but this occurs infrequently

and usually at later stages of HIV infection owing to decreased extrathyroidal conversion to T_3 .

A unique pattern of thyroid function tests in AIDS has been observed that includes a progressive elevation in TBG, decreased rT_3 , and normal T_3 levels. These alterations are felt to be part of the abnormal immunoregulation in HIV-infected individuals and may be mediated by tumor necrosis factor or other cytokines. The normal T_3 level is felt to be a failure of the normal adaptive response to illness, but whether this causes the cachexia associated with AIDS remains to be proved. The prevalence of hypothyroidism, both clinical and subclinical, in AIDS is higher than in the general population and has been correlated with CD_4 cell count.

Treatment

It is important to distinguish the sick euthyroid state from intrinsic thyroid disease because the former does not require thyroid hormone replacement therapy. Studies show that treating patients with the low T_3 - T_4 syndromes with T_4 was not beneficial and had no effect on mortality rates. In fact, there was no increase in T_3 levels, suggesting that peripheral conversion was not enhanced. To exclude inhibition of peripheral conversion as a factor in nonthyroidal illness,

some investigators have administered T_3 , but once again these studies have not demonstrated a beneficial effect on outcome. Supportive measures such as adequate nutrition and specific and successful treatment of the underlying illness should result in eventual normalization of the thyroid function alterations.

Current Controversies and Unresolved Issues

Two major issues related to sick euthyroid syndrome are the subject of some controversy. First, the pathogenesis of the syndrome remains unclear. The only thing that appears certain is that the mechanisms are complex, multifactorial, and involve changes at multiple levels of the thyroid loop, including changes in TSH and thyroid hormone secretion, 5'-deiodinase, and thyroid hormone binding to proteins owing to a variety of inhibitors.

Second, the physiologic significance of these changes in the thyroid function tests remains unclear. We do not know whether these abnormalities signal a functionally hypothyroid state or are part of the body's adaptation to the stress of acute illness. The answer to this question will determine whether these patients should receive thyroid hormone replacement therapy. Unfortunately, there are no clinically practical markers that reflect the biologic action of thyroid hormones in tissues rather than their levels in the blood. Several studies in small numbers of patients have failed to reveal any benefit of thyroid hormone replacement therapy. On the contrary, in patients with burns, T_3 replacement increased urinary nitrogen excretion. Furthermore, thyroid hormone replacement therapy may inhibit TSH secretion and thereby delay recovery of thyroid function as the acute underlying illness abates. Only a large prospective study randomizing administration of thyroid hormone can answer this question.

Low T_3 levels are found in the vast majority of heart donors, in potential heart transplant recipients, and in patients who have undergone cardiopulmonary bypass. Because cardiac dysfunction is a major problem after

transplantation, T_3 supplementation has been proposed for both donor and recipient. There are limited data demonstrating that T_3 supplementation in brain-dead donors decreases both the amount and duration of inotropic support. Recently, combined administration of growth hormone-releasing peptide 2 (GHRP-2), TRH, and gonadotropin-releasing hormone (GnRH) was shown to reactivate the growth hormone, TSH, and luteinizing hormone (LH) axes in men with prolonged critical illness. Combined administration of these secretagogues evoked beneficial metabolic effects, including reduction in urea production and an increase in osteocalcin levels, which were not observed with GHRP-2 infusion alone. The clinical efficacy of such an approach should be further tested.

Diabetes Mellitus, Hyperglycemia, & the Critically Ill Patient*

Eli Ipp, MD
Chuck Huang, MD

26

Patients with diabetes mellitus are seen frequently in the ICU because of complications of poorly controlled disease, including diabetic ketoacidosis, hyperglycemic hyperosmolar nonketotic diabetic coma, and hypoglycemia. In addition, diabetic patients with critical illness often will exhibit instability and poor control of blood glucose, including hyper- and hypoglycemia. Recent studies have demonstrated that hyperglycemia in nondiabetic patients in the ICU also can have a significant impact on morbidity and mortality. This chapter also will cover new approaches to management of hyperglycemia in the ICU.

▶ Diabetic Ketoacidosis

ESSENTIALS OF DIAGNOSIS

- ▶ Acute illness in a patient with known type 1 (insulin-dependent) diabetes mellitus, especially if the patient is vomiting.
- ▶ Evidence of precipitating illness, including infection.
- ▶ Clinical symptoms and signs of volume depletion.
- ▶ Clinical features of metabolic acidosis.
- ▶ Laboratory features: hyperglycemia, anion gap acidosis, ketonemia, and acidemia.

General Considerations

Diabetic ketoacidosis is the most serious metabolic complication of type 1 (insulin-dependent) and, to a smaller extent, type 2 (non-insulin-dependent) diabetes mellitus. There has been little change in the mortality rate associated with diabetic ketoacidosis in recent decades despite great

improvements in our understanding of its pathophysiology and treatment. The most effective means of reducing deaths owing to diabetic ketoacidosis consists of teaching patients to recognize its early signs. Close clinical and biochemical observation of every patient during treatment of diabetic ketoacidosis remains the cornerstone of effective management.

A. Pathophysiology—The pathophysiology of diabetic ketoacidosis is based primarily on an abnormal hormonal setting: insulin deficiency combined with an excess of hormones that increase the blood glucose level. This situation is similar to the physiologic state seen during normal fasting and is probably best considered as an abnormal and extreme expression of the fasting state. During the fed state, insulin is the predominant hormone, required for disposal and storage of ingested nutrients. During fasting, the body converts to a state in which endogenous sources of fuels need to be tapped for ongoing support of metabolism in the brain and in muscle tissue, and the hormonal milieu therefore begins to change. Plasma insulin concentrations fall, and glucagon concentrations rise. This change in the insulin:glucagon ratio permits the liver to become the major source for glucose during fasting. At the same time, decreased insulin concentrations lead to lipolysis in fat depots, providing a source of free fatty acids as a fuel for muscle and thus sparing glucose for use by the brain. Furthermore, free fatty acids are converted by the liver to ketones under the influence of glucagon. Ketones constitute another alternative (nonglucose) energy source for brain and muscle tissues. Glycerol released by lipolysis and alanine from protein catabolism in muscle provide substrates for gluconeogenesis in the liver.

In diabetic ketoacidosis, this picture is greatly exaggerated because of severe insulin deficiency. This is typical of patients with type 1 diabetes, all of whom have sustained autoimmune beta cell destruction. However, insulin deficiency is now also recognized as the major contributor to ketoacidosis in type 2 diabetes, an increasingly reported entity, once thought to be exceedingly rare. The effectiveness of circulating insulin is also reduced because patients with diabetic

*Eli Ipp, MD, and Tricia L. Westhoff, MD, were the authors of this chapter in the second edition.

Table 26–1. Mechanisms of insulin resistance in diabetic ketoacidosis.

Glucose toxicity

ketoacidosis also have considerable insulin resistance. Historically, this resistance to insulin action was thought to require massive doses of insulin during treatment of diabetic ketoacidosis. Although since the 1970s “low dose” continuous insulin infusion has replaced the large intermittent doses used previously, a high level of resistance to insulin action remains an important feature of diabetic ketoacidosis. Some of the known causes of insulin resistance in diabetic ketoacidosis are listed in [Table 26–1](#).

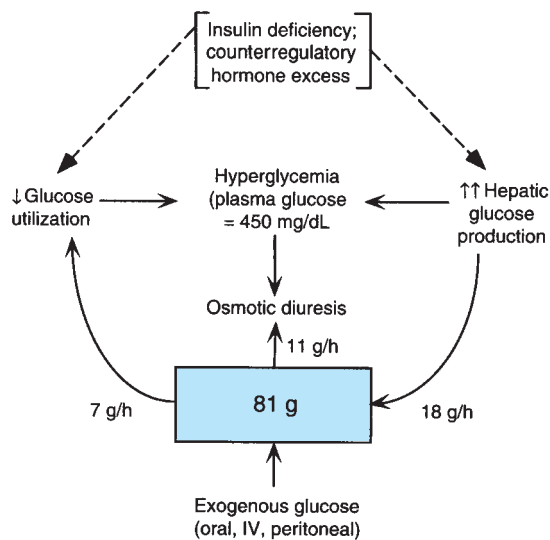

In contrast to the low levels of insulin, glucagon concentration is markedly elevated, with a high glucagon:insulin ratio more striking than that seen during fasting. In addition, diabetic ketoacidosis is characterized by large increases in the levels of stress hormones, including the glucose counterregulatory hormones cortisol, growth hormone, and catecholamines. These hormones help to define diabetic ketoacidosis and are responsible for its two major features: hyperglycemia and ketonemia. Glucagon has its predominant effects on the liver, enhancing long-chain fatty acid transport into mitochondria by decreasing levels of malonyl-CoA and increasing activity of carnitine acyltransferase I. Cortisol enhances gluconeogenesis by increasing delivery of gluconeogenic substrates to and transamination in the liver. Prolonged hypersecretion of cortisol also decreases sensitivity to insulin. Catecholamines enhance lipolysis, providing substrate for ketogenesis, and accelerate glycogenolysis and gluconeogenesis. Finally, growth hormone also contributes to increased lipolysis and insulin resistance.

Ketoacidosis in a pregnant diabetic is a rare example that highlights these pathophysiologic components. This serious complication is caused by insulin deficiency in a setting of three factors unique to all pregnancies: accelerated starvation, severe insulin resistance, and net lowered buffering capacity owing to increased renal excretion of bicarbonate, a consequence of increased minute ventilation and respiratory alkalosis in pregnancy.

B. Hyperglycemia—Hyperglycemia in diabetic ketoacidosis results from several mechanisms involving a variety of hormones as well as their different target organs. Using glucose turnover studies, it has been shown that the major physiologic aberration that results from the combination of mechanisms just described is excessive hepatic glucose

production. This, in turn, is responsible primarily for hyperglycemia in patients with diabetic ketoacidosis. Glucose clearance by insulin-sensitive tissues is also reduced, although some increase in glucose utilization is associated with the mass-action effect of high blood glucose levels. An important factor that determines the degree of hyperglycemia in diabetic ketoacidosis is the extent of renal glucose losses. As long as the kidneys are well perfused, they act as a continuing source of glucose leak from the extracellular space and thereby prevent severe hyperglycemia.

[Figure 26–1](#) illustrates mechanisms for hyperglycemia, with emphasis on a quantitative estimate of their contributions in diabetic ketoacidosis. The numbers presented in this diagram are drawn from mean values reported in patients with diabetic ketoacidosis. Insulin deficiency associated with glucose counterregulatory hormone excess gives rise to highly exaggerated hepatic glucose production. Although some increase in glucose utilization owing to severe hyperglycemia may occur, glucose clearance remains low, and utilization is insufficient to match the rise in glucose production by the liver. In an average 70-kg patient in diabetic ketoacidosis with a hypothetical stable glucose concentration of 450 mg/dL, hepatic glucose production is approximately 18 g/h. Average glucose utilization is estimated

▲ Figure 26–1. Mechanisms contributing to hyperglycemia in a 70-kg patient with a plasma glucose level of 450 mg/dL. Values are from mean values obtained in patients with diabetic ketoacidosis. The box represents the extracellular glucose compartment. Lack of insulin and increased counterregulatory hormones result in decreased glucose utilization (7 g/h) and increased hepatic glucose production (18 g/h). Renal glucose losses may delay development of severe hyperglycemia.

to be about 7 g/h. The square in the diagram represents the extracellular space, in which there is a total of 81 g glucose at this time. Considering that the input into the system (hepatic glucose production) exceeds the output (glucose utilization), stable glucose concentrations can persist only if there is another source of glucose loss. Thus renal losses of glucose are an important component of the protection from severe hyperglycemia afforded patients with developing diabetic ketoacidosis. The average amount of glucose lost through the kidneys in this example is estimated to be approximately 11 g/h.

If, without any increase in hepatic glucose production, the leak of glucose in the urine were diminished by only one-fifth—for example, as a result of diminished perfusion of the kidney owing to volume depletion—considerable net accumulation of glucose would occur rapidly in the extracellular space. In this example, a reduction of about 2 g/h of urinary glucose losses would result in a further accumulation of about 50 g glucose added to the 81 g in the extracellular space over 24 hours. If the rate of glucose utilization were unchanged—and with contraction of the extracellular space owing to fluid losses—this could result in a doubling of serum glucose concentrations within a 24-hour period. The features of this diagram accentuate the important role of the kidneys and the liver in the generation of hyperglycemia in diabetic ketoacidosis. Although not demonstrated in this diagram, these factors will be discussed later as an important mechanism for reduction of hyperglycemia once treatment begins.

The degree of volume depletion has an important effect on the development of hyperglycemia. In a study of insulin withdrawal in type 1 diabetes, volume depletion (>3% of weight) increased plasma glucose concentrations compared with control subjects. Glucose production and disposal were increased during the volume-depletion study compared with the control study. Although the study did not evaluate renal perfusion, a likely explanation of the increased glycemia is a reduction of glucose excreted owing to reduced glomerular filtration during volume depletion. Much of the variability of glycemia in ketoacidosis may be the result of lack of fluid or energy intake prior to or during metabolic decompensation. Given the common occurrence of volume depletion in patients who present with diabetic ketoacidosis, it is probable that the variability in severity of this factor—as well as the severity of insulin deficiency and underlying illness—explains much of the glycemic variability observed in diabetic ketoacidosis.

C. Ketosis and Metabolic Acidosis—Ketosis is the second major manifestation of diabetic ketoacidosis and results from the accumulation of keto acids generated by the liver. Ketosis is predominantly a disorder of increased synthesis of ketones, although inability of peripheral tissues to use the excess ketones probably plays a small role. The keto acid measured in the blood during diabetic ketoacidosis is predominantly β -hydroxybutyrate rather than acetoacetate. This reflects an altered redox state in the liver.

The increase in keto acids results in an increase in the serum anion gap that develops because of buffering by bicarbonate of hydrogen ion. If the acidosis in diabetic ketoacidosis is due only to ketosis, the fall in serum bicarbonate is equal to the increase in anion gap. It is evident, however, that acidosis in diabetic ketoacidosis may have additional mechanisms. Many patients have a reduction in serum bicarbonate concentration that is greater than the increase in anion gap, indicating, in addition, the presence of a non-anion gap hyperchloremic acidosis. Previously, hyperchloremic acidosis was recognized as a common manifestation of the later treatment stages in diabetic ketoacidosis. It is now appreciated that it also may be present at initial presentation, where it appears to occur in patients who are less severely volume-depleted. Recognition of hyperchloremic acidosis is important because hyperchloremic acidosis takes longer to resolve during treatment than ketoacidosis. This is so because keto acids are metabolized to generate bicarbonate in equimolar amounts, whereas hyperchloremic acidosis depends for its correction on regeneration of bicarbonate by the kidneys. Another cause of acidosis in diabetic ketoacidosis is lactic acidosis. Lactic acidosis also contributes to the increase in the anion gap, with a corresponding further decrease in serum bicarbonate.

D. Fluid and Electrolyte Imbalance—Extensive losses of fluids and electrolytes comprise the third important feature of diabetic ketoacidosis and are a consequence of the foregoing abnormalities. Fluid and electrolytes are lost in the osmotic diuresis caused by glycosuria that occurs as a result of marked hyperglycemia in diabetic ketoacidosis. Fluid losses are generally about 5–8 L in a 70-kg person, and depletion of sodium, potassium, and chloride may be 300–500 mmol or more at presentation (Table 26–2). Magnesium and phosphate are also lost, but in smaller quantities. While water losses are usually easily appreciated clinically, serum electrolyte concentrations do not generally reflect the large losses that occur in these patients. This is especially true for potassium because, despite large urinary losses, normal or even high serum levels are seen at presentation as a result of a shift of potassium from the intracellular to the extracellular fluid—a consequence of acidosis and the loss of water from

Table 26–2. Approximate fluid and electrolyte deficits in patients with diabetic ketoacidosis.

Water	5–8 L
Sodium	400–700 mmol
Chloride	300–500 mmol
Potassium	300–1000 mmol
Calcium	100 mmol
Magnesium	50 mmol
Phosphate	50 mmol
Bicarbonate	350–400 mmol

the extracellular space. The water shift is in response to the hyperosmolar extracellular space brought on by hyperglycemia; intracellular potassium accompanies the water shift. This fluid shift also plays a role in determining serum sodium concentration. Because osmotic diuresis is associated with greater water loss than sodium or chloride, hypernatremia might be expected to occur, but this is not seen commonly because of the fluid shift from the intracellular space. This mechanism explains the mild hyponatremia often found at diagnosis. In contrast, normal serum chloride concentrations are the rule, for the reason that chloride losses are less than sodium losses. This is so because sodium is also lost as the cation accompanying ketones excreted in the urine.

E. Altered Mental Status—The altered state of consciousness observed in diabetic ketoacidosis has not been explained. The closest correlation with impaired consciousness is the serum osmolality. There appears to be an almost linear relationship between the degree of mental obtundation and the level of serum osmolality, and most patients with mental impairment have been found to have serum osmolality greater than 350 mOsm/Kg (Figure 26-2). If a patient has altered consciousness in association with a serum osmolality of less than 340 mOsm/Kg, another cause for the neurologic problems should be considered.

F. Precipitating Disease—Although diabetic ketoacidosis can occur in the absence of any coexisting disease, in all patients with diabetic ketoacidosis (or even milder metabolic decompensation in diabetes mellitus), a precipitating factor should be looked for. The most commonly identified precipitating factors are withdrawal of insulin, infection, and

undiagnosed diabetes during the initial presentation of the disease. Intercurrent illnesses increase the requirements for insulin by increasing insulin resistance, a consequence of the hormonal mechanisms outlined earlier. In the absence of an appropriate increase in the dose of insulin, patients become acutely insulin-deficient; the effects of stress increase the counterregulatory hormones; and the stage is set for the development of diabetic ketoacidosis.

Clinical Features

A. Symptoms and Signs—Most patients present with a history of polyuria and polydipsia, weakness, and weight loss. Duration is often as short as 24 hours, but the history usually extends over several days, and in newly diagnosed diabetes, symptoms often go on for weeks. Patients are usually anorexic and may have vomiting and abdominal pain. Abdominal pain associated with ketosis is most common in children, although it may occur in adults as well, and occasionally has features of an acute abdomen. Fatigue and muscle cramps are also presenting features of diabetic ketoacidosis.

Signs of volume depletion are characteristic. Decreased skin turgor, dry mucous membranes, sunken eyeballs, tachycardia, orthostatic hypotension, and even supine hypotension may be present. If severe acidosis is present, deep and slow Kussmaul respirations may be noted as well as the characteristic odor of ketones on the breath. Additional findings include alteration in CNS function ranging from drowsiness to coma. Only about 10% of patients who present with diabetic ketoacidosis are actually in coma, and about 20% have clear mentation. The rest have various degrees of altered consciousness. Abdominal tenderness may be noted. Hypothermia may be present, but fever is not associated with diabetic ketoacidosis alone. The features of an associated precipitating illness often dominate the clinical picture.

Precipitating factors for diabetic ketoacidosis are listed in Table 26-3. The most commonly recognized causes fall into three groups: (1) undiagnosed type 1 diabetes mellitus, (2) reduction of insulin dose in association with intercurrent illness (particularly patients who have anorexia and vomiting and reduce the insulin dose for fear of hypoglycemia) or non-compliance (in recent times, interruption of nonconventional, nondepot insulin delivery—for example, insulin infusion pumps—also may be responsible for an unintended reduction in insulin dose), and (3) infection, where two important and potentially confounding features of diabetic ketoacidosis should be recognized: Fever is not caused by diabetic ketoacidosis alone and therefore suggests the presence of infection, and a white blood cell count of 15,000–40,000/ μL may be seen in the absence of any infection. In some patients, precipitating factors cannot be identified.

Unusual presentations of patients with diabetic ketoacidosis must be recognized in order to make the correct diagnosis and provide appropriate therapy (Table 26-4). Diabetic ketoacidosis should be considered in any patient

Table 26-4. Typical and atypical features of diabetic ketoacidosis.

Typical	Exceptions
Acute illness in a patient with (suspected) type 1 diabetes	Diagnosis of diabetic ketoacidosis may be delayed in older patients with new-onset type 2 diabetes.
Clinical symptoms and signs of volume depletion	Absence of volume depletion in patient with diabetic ketoacidosis and oliguric renal failure.
Laboratory features	
Hyperglycemia	Less severe hyperglycemia in pregnancy or after alcohol intake.
Increased anion gap	Hypertriglyceridemia may mask increase in anion gap by interfering with serum Cl^- and HCO_3^- measurements.
Metabolic acidemia	Vomiting may cause concurrent metabolic alkalosis, decreasing severity of metabolic acidosis.
Ketonemia	Beta-hydroxybutyrate is not detected by nitroprusside reaction. If this ketone predominates, ketonemia may be underestimated or absent.

with type 1 diabetes who develops an acute illness. The need to rule out diabetic ketoacidosis in a patient with type 1 diabetes who is becoming ill applies equally in the outpatient or inpatient setting. When patients are at home, ketosis can be tested easily by checking urine ketones. The possibility of developing diabetic ketoacidosis provides a rationale for teaching patients to test their urine for glucose and ketones even though urine glucose measurement is no longer used to monitor glycemic control. In inpatients, urine or serum ketones will help to exclude diabetic ketoacidosis as the cause of a change in a patient's condition. Effective bedside methods for measurement of serum β -hydroxybutyrate now have been developed, and this should contribute to more rapid diagnosis of ketosis in hospitalized patients.

B. Laboratory Findings (See Table 26-5)—

1. HYPERGLYCEMIA—Serum glucose usually ranges from 500–800 mg/dL in patients with diabetic ketoacidosis. Although it is often the blood glucose measurement that alerts the staff to the possibility of diabetic ketoacidosis in an undiagnosed patient, it is important to keep in mind that severe hyperglycemia does not always occur. The diagnosis should be suspected even if serum glucose levels are not greatly elevated. This is particularly important in patients who are fasting and may have imbibed alcohol recently (which inhibits gluconeogenesis) or in pregnant women, whose serum glucose levels can be normal or only slightly elevated during severe diabetic ketoacidosis.

2. METABOLIC ACIDOSIS—Total keto acids average 10–20 mmol/L; lactate is often elevated. As shown in Table 26-5, however, less severe acidosis may be seen, based on the bicarbonate and pH measurements, at initial presentation. This may be a result in part of possible earlier access to medical care, but it also may be due to a shift in the strictness of the criteria used to classify acute metabolic decompensation in diabetes.

Absence of acidemia or only mild acidemia in diabetic ketoacidosis may occur if the patient has had vomiting severe enough to result in a mixed metabolic alkalosis and acidosis. Absence of ketones in a patient with acidosis, hyperglycemia, and volume depletion should make one suspect a predominance of the β -hydroxybutyrate component of the serum ketones. With an altered redox state—in particular, in the presence lactic acidosis—acetoacetate is converted to β -hydroxybutyrate. The nitroprusside reagent that is used to measure ketones semiquantitatively in most laboratories recognizes only acetoacetate. A predominantly β -hydroxybutyrate acidosis therefore may be missed because it will not be picked up by this method. Use of bedside methodology for β -hydroxybutyrate measurement should help to eliminate this factor as a source of confusion in the diagnosis of diabetic ketoacidosis.

3. SERUM ELECTROLYTES—Table 26-6 summarizes electrolyte abnormalities seen at the time of presentation in diabetic

‡Unpublished results.

ketoacidosis. Mild hyponatremia is the most common abnormal finding and is due to a shift of water from the intracellular compartment into the hypertonic extracellular fluid. In addition, a total sodium deficit occurs as a result of the osmotic diuresis and the obligate cations accompanying ketones excreted in the urine. Hypochloremia is less common because chloride is not lost with urinary ketones and because of the high incidence of hyperchloremic acidosis mentioned earlier. Despite total body losses of other electrolytes, serum chloride concentrations usually are normal or low normal at presentation. Most patients have normokalemia or hyperkalemia at

presentation, but it is important to recognize that up to 20% will be hypokalemic at that time. Ten percent of patients have hypophosphatemia at diagnosis, and less than 10% of patients present with hypomagnesemia. Hypocalcemia occurs in almost 30% of patients. Serum osmolality is rarely measured directly but instead is calculated from the electrolytes. Hyperosmolality of varying degrees is a typical feature.

4. INTERFERENCE WITH OTHER LABORATORY TESTS—Abnormalities observed in diabetic ketoacidosis may contribute to artifactual interference with other laboratory tests.

Table 26-6. Serum electrolyte concentrations in patients with diabetic ketoacidosis at presentation (% of patients).

	Low	Normal	High	Comment
Sodium	67	26	7	Body stores depleted; serum [Na ⁺] depends on [glucose] and relative water loss.
Chloride	33	45	22	
Potassium	18	43	39	Body stores depleted.
Magnesium	7	25	68	
Phosphate	11	18	71	Decreases with insulin treatment.
Calcium	28	68	4	

Acetoacetate crossreacts in some automated methods for measuring creatinine and thus may artificially elevate creatinine concentrations; if owing to this mechanism, elevated serum creatinine concentrations diminish rapidly as acetoacetate levels are cleared with therapy.

Hypertriglyceridemia occurs quite frequently in diabetic ketoacidosis. This is of importance not only because of the clinical manifestations of hypertriglyceridemia (eg, acute pancreatitis) but also because high triglyceride levels interfere with accurate measurement of sodium, chloride, and bicarbonate. When hypertriglyceridemia is present, pseudohyponatremia may be seen (serum is composed of a sodium-containing water phase and a large lipid-triglyceride phase that contributes non-sodium-containing volume). What is less well recognized is that hypertriglyceridemia can interfere with the colorimetric measurement of chloride and bicarbonate, although there is no interference with more commonly used ion-specific electrode assays. The effect is to report falsely high serum chloride and bicarbonate concentrations that may mask the increase in anion gap expected in ketoacidosis and lead to incorrect evaluation of the patient. This possibility should be considered whenever the anion gap is not elevated in an otherwise typical clinical situation suggestive of diabetic ketoacidosis.

Differential Diagnosis

Clinical manifestations of diabetic ketoacidosis, such as dyspnea, nausea, vomiting, or abdominal pain, may mimic non-diabetic acute disease. In known diabetic patients with coma or altered mental status, ketoacidosis must be distinguished from hypoglycemia. This is usually not difficult clinically because the circumstances and clinical findings are usually quite different. The patient with diabetic ketoacidosis is volume-depleted and may be acidotic, whereas the hypoglycemic patient is usually cold and clammy. In either case, bedside diagnosis of these conditions by direct measurement of blood glucose can be made quickly, so clinical differentiation is less relevant. In comatose patients with diabetic ketoacidosis in whom serum osmolality is less than 340 mOsm/Kg, another cause of coma should be considered.

A common difficulty arises when differentiating alcoholic ketosis from diabetic ketoacidosis in a patient with diabetes who has ingested alcohol. In such situations, whatever the cause of ketosis, the management is that of diabetic ketoacidosis. Severe abdominal pain from diabetic ketoacidosis, often accompanied by vomiting, may mimic an acute abdomen. Acute pancreatitis is often in the differential diagnosis, and its diagnosis is complicated by the fact that serum amylase levels are often elevated in diabetic ketoacidosis as a result of an increase in serum amylase from the salivary isoenzymes.

Treatment

The principles of management of diabetic ketoacidosis are to replace losses of water and electrolytes, give sufficient insulin

Table 26-7. Initial diagnosis and management of diabetic ketoacidosis.

<p>Rapid clinical examination. Bedside blood glucose and urine ketone determinations. Obtain blood for laboratory determination of glucose, ketones, electrolytes, urea nitrogen, creatinine, phosphorus, magnesium. Obtain arterial blood for blood gases. Chest x-ray. ECG (also to monitor K⁺ levels). Search for precipitating factor. Monitoring: Hourly bedside glucose and two-hourly measurement of anion gap, serum electrolytes, serum ketones, serum phosphorus. Obtain arterial blood gases as needed.</p>

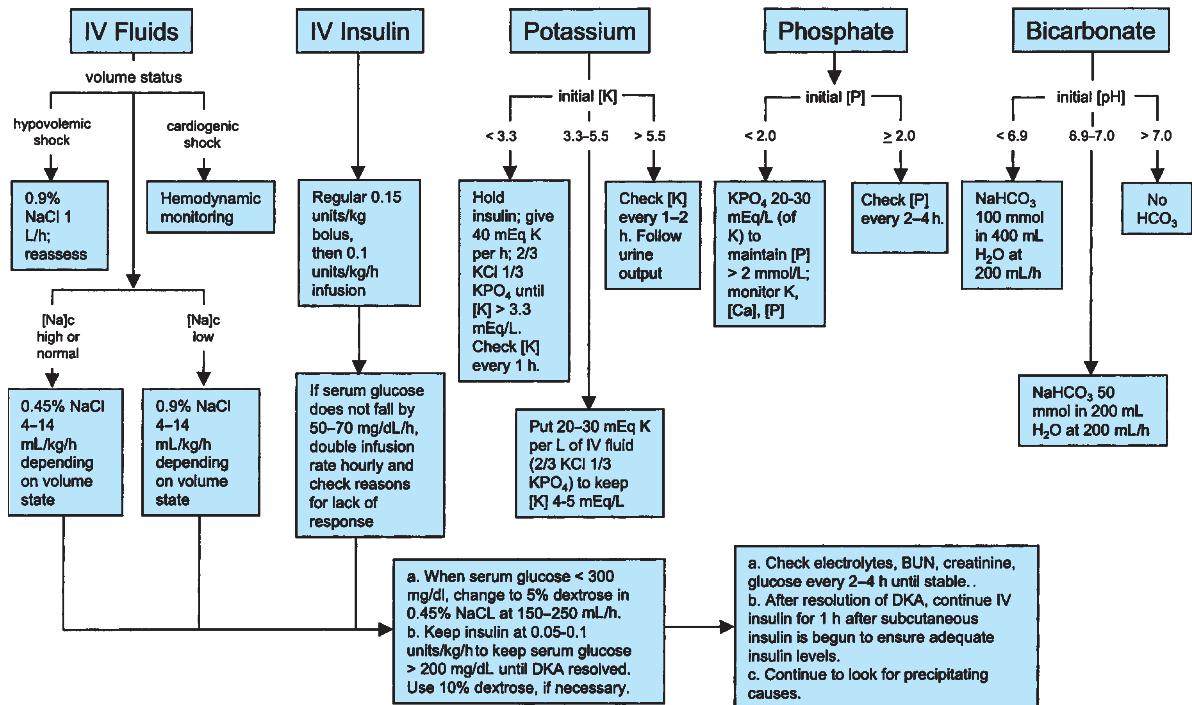

(ie, stop ketogenesis, lipolysis, and gluconeogenesis), correct blood pH, closely monitor the patient through all stages of management, and eliminate or treat precipitating causes. Rapid initial evaluation takes place in the emergency room in most patients with diabetic ketoacidosis, although at times diabetic ketoacidosis does develop in the hospital. Table 26-7 sets forth the initial steps in management when diabetic ketoacidosis is suspected. Figure 26-3 provides an overview of management.

A. Monitoring—Close monitoring is the key to successful management of diabetic ketoacidosis. Most management decisions are fairly straightforward if the data are available in timely fashion. Errors in management occur most often when there is a lapse in monitoring so that a “catch-up” situation develops or the effects of overtreatment need to be corrected.

Blood glucose should be monitored hourly at the bedside. This provides information about whether the insulin dose is adequate to cause a fall in blood glucose at the expected rate of about 100 mg/dL per hour. Later, glucose measurement prevents overshooting the target serum glucose level of 250–300 mg/dL, at which time infusion of dextrose should be started. Serum electrolytes and ketones should be monitored every 2 hours, and this should include measurement of serum phosphorus as well. Arterial blood gases should be repeated as necessary if progress in the clearing of acidosis is slow or if there are associated pulmonary problems. If phosphate therapy is used, serum calcium should be measured at least once (after an initial measurement) during the first 12 hours to detect any large decrease in serum calcium. All the data obtained, including fluid balance measurements, should be maintained on a flowchart for easy review and evaluation.

1. CORRECTION OF HYPERGLYCEMIA—Correction of hyperglycemia occurs by four different mechanisms (Table 26-8). First, the concentration of the extracellular glucose is diluted by fluid replacement, expanding the extracellular space. The second is by continuing—and usually increased—urinary

Complete initial evaluation. Start 0.9% NaCl 1 L/h (15–20 mL/kg/h); recheck glucose, electrolytes 2 h after insulin begun.

▲ **Figure 26-3.** Management of adult patients with diabetic ketoacidosis. $[Na]_c$ = corrected serum sodium concentration (for each 100 mg/dL glucose > 100 mg/dL, add 1.6 meq/L to measured serum sodium.) (Modified from American Diabetes Association. Hyperglycemic crises in diabetes. *Diabetes Care* 2004;27:S94–102.)

loss of glucose that occurs with improved renal perfusion following expansion of the intravascular space. Third is the effect of insulin to diminish the hepatic glucose production rate. Considering that this is one of the important pathophysiologic mechanisms producing hyperglycemia in diabetic ketoacidosis, inhibition of this process must be one of the management goals. Indeed, it has been demonstrated that insulin infused at the routine doses is very effective in reducing glucose production by the liver during recovery from diabetic ketoacidosis. Increased glucose utilization is the fourth mechanism and is also an insulin-dependent process.

2. CORRECTION OF KETOSIS—Ketosis is corrected more slowly than hyperglycemia, so while serum glucose levels usually will reach 250–300 mg/dL within an average of 6–8 hours, it can take up to 12 hours or more for ketosis to clear. It is particularly important to continue insulin infusion during this period despite the fact that one major goal of therapy (reduction of hyperglycemia) has been attained. Intravenous insulin therefore should be stopped only when ketosis has cleared.

It is not always easy to decide when a patient is no longer in a state of ketoacidosis. Serum ketone measurements do not provide the entire answer because they can remain positive for many hours after the acidosis is resolved, probably because acetone is cleared much more slowly than the two keto acids. Acetone, however, is also measured by the nitroprusside reaction and can give rise to persistently positive serum ketone measurements even though it does not alter acid-base balance. For this reason, monitoring the anion gap is a better way of determining when ketosis has cleared. Serum bicarbonate concentrations are useful for monitoring progress of therapy but less useful when used alone to determine

Table 26-8. Correction of hyperglycemia: Mechanisms.

Dilution by expansion of extracellular volume
 Urinary losses
 Diminished glucose production rates
 Increased glucose utilization

that ketoacidosis has cleared because bicarbonate is slow to normalize completely. This is so because hyperchloremic acidosis accompanies saline therapy in almost all patients and because hyperventilation persists after the patient is no longer acidotic. Arterial blood pH measurement can be useful when it is difficult to decide whether ketosis has cleared—particularly if the anion gap has normalized and hyperglycemia is resolved, yet the patient still appears to be ill. The overall clinical picture is useful—in a patient whose appetite has returned and is able to eat and retain a meal, this generally signals resolution of ketoacidosis.

B. Fluid Replacement—Fluid losses in an adult with diabetic ketoacidosis average 5–7 L and may be as much as 10–15% of body weight. Fluid replacement should be initiated immediately after diagnosis to prevent further deterioration of hemodynamic status. Fluid therapy is begun with intravenous 0.9% NaCl solution. A rough guide to volume replacement is as follows: (1) 2 L can be given over the first 2 hours, (2) this can be followed by 2 L over the next 4 hours using 0.9% or 0.45% NaCl solution, and (3) over the next 8 hours, another 2 L can be given using either 0.9% or 0.45% NaCl. This schedule should be modified according to ongoing assessment of volume replacement needs and serum sodium levels. In hemodynamically compromised patients and the elderly, close monitoring of volume status may be necessary, and consideration should be given to use of a central venous pressure or pulmonary artery catheter. If severe hypotension is present, maintaining intravascular volume with albumin or other plasma expanders also should be considered.

When the plasma glucose concentration reaches 250–300 mg/dL, 5% dextrose solution should be started with an appropriate amount of NaCl according to the needs of the patient at that time.

There is disagreement about the best approach when serum sodium exceeds 150 meq/L at presentation. When 0.45% NaCl is given at the outset, some patients have developed hypotension during treatment. This is likely due to the insulin effect to drive glucose intracellularly; water follows, and the intravascular space is depleted. When hypotonic saline is used, there is less addition of solute that will remain in the intravascular and extracellular spaces. Therefore, a greater proportion of the infused fluid will be ineffective in expanding the intravascular volume.

Administering 0.9% NaCl solution provides a greater osmotic load, and thus it is more likely to protect intravascular volume in the face of fluid shifts in diabetic ketoacidosis patients who are strikingly volume-depleted. The concern with infusing 0.9% NaCl (normal saline) is that hyperosmolality will not be corrected. However, this approach conforms to the physiologic principle that during states of severe volume depletion, volume maintenance takes precedence over maintaining normal serum osmolality. Thus 0.9% NaCl is recommended as the volume replacement fluid of first choice even when the patient is initially hypernatremic: 0.9% NaCl is hypo-osmolar relative to serum when serum osmolality is

greater than 308 mOsm/Kg. Once volume depletion has been corrected, administration of 0.45% NaCl or 5% dextrose in water to correct hypernatremia is indicated.

Fluid replacement has been given without insulin therapy to test its effects in the absence of insulin. In a few studies there has been considerable improvement in hyperglycemia but with no consistent effect on serum ketones. The improvement in serum glucose concentrations in the absence of insulin is probably the result of increased renal glucose losses and a dilution effect (see Table 26–8).

C. Insulin

1. INITIAL THERAPY—Insulin is started at the time of diagnosis at a rate of 0.1 unit/kg per hour by continuous intravenous infusion. A bolus dose of 0.15 unit/kg may be administered initially. Blood glucose levels should be checked at hourly intervals using bedside (glucometer) measurements, and laboratory serum glucose determinations can be obtained every 2 hours, along with serum electrolytes, to provide confirmation of the glucometer measurements.

In most patients, the recommended starting dose is sufficient to treat diabetic ketoacidosis because the serum-free insulin levels achieved with this infusion rate are 7 to 10 times normal basal concentrations. However, some patients do require even faster infusion rates. Therefore, if serum glucose concentrations have not begun to fall after the first hour, the rate of insulin infusion should be doubled—and doubled once again if the same should happen during continuing therapy. The insulin infusion should cause blood glucose to fall at a rate of about 75 mg/dL per hour. The rate of insulin infusion should be continued—if glucose is falling appropriately—until serum glucose has reached 230–300 mg/dL. At that time, a 5% dextrose infusion should be started, but the insulin infusion must continue until ketosis clears. Because considerable insulin resistance remains even though some of the factors described in Table 26–1 have normalized, insulin infusion should be maintained at the same rate and 10% dextrose infused, if necessary, to maintain serum glucose levels while awaiting clearance of ketones. Decreasing insulin infusion rates at this time may result in slower resolution of ketosis. Clearing of ketosis should be monitored using a combination of the anion gap, bicarbonate, and serum ketone measurements and, if necessary, arterial blood gas pH measurement.

2. AFTER RESOLUTION OF KETOSIS—Once ketosis has cleared—and if the patient is eating—a subcutaneous insulin regimen can be started. The patient should be given a subcutaneous injection of regular insulin about 30 minutes before stopping the insulin infusion. This allows some of the subcutaneously injected insulin to be absorbed before the insulin infusion is halted. Because intravenous insulin has a half-life of only 5–6 minutes, stopping the intravenous insulin prior to giving subcutaneous insulin can result in temporarily inadequate serum insulin concentrations. Low serum insulin levels, in turn, can cause a rebound into diabetic ketoacidosis,

particularly if there is significant delay in delivering the subcutaneous regular insulin injection. Subcutaneous rapid-acting (regular or analogue) insulin is also best injected before a meal, and the insulin infusion can be halted once the meal begins. The bolus of regular insulin thus will be delivered at a physiologically appropriate time, and the meal will help to compensate for any error of excess in estimating the regular insulin dosage at that time.

Split-dose insulin therapy with a combination of regular and NPH insulin before breakfast and dinner can be started as soon as the diabetic ketoacidosis has resolved and the patient is able to eat. The total daily dose can be similar to prehospital doses in patients with known diabetes; in newly diagnosed patients, regular insulin can be given before meals and at 12 midnight using a sliding scale for 24 hours. The total dose required then can be used to calculate split-dose therapy, giving two-thirds of the total dose in the morning and one-third in the evening. NPH insulin usually constitutes two-thirds of the morning dose and three-fourths of the evening dose, with the remainder in each case being regular insulin.

D. Potassium Replacement—Usual potassium deficits in diabetic ketoacidosis have been estimated to be approximately 300 meq, but the deficit may be as much as 1000 meq. This total body potassium deficit is the result of combined renal losses owing to osmotic diuresis and potassium shifts from intracellular to extracellular fluid that lead to further loss through the kidneys.

If the patient is normokalemic or hypokalemic at presentation, potassium replacement should be started when insulin therapy is initiated. If the serum potassium level is high, potassium therapy should be started only after insulin therapy is begun and with the second liter of fluid replacement. If treatment is necessary before the serum potassium level is reported, epidemiologic data provide a basis for determining the frequency of serum potassium abnormalities (see Tables 26–5 and 26–6). Most patients initially have either normal or high serum potassium levels; however, up to 20% of patients will have hypokalemia at the outset. In this last group of patients, insulin infusion alone (without potassium replacement) will exacerbate the hypokalemia, with potentially severe consequences. In contrast, the fear of giving potassium to normokalemic or hyperkalemic patients is mitigated by the effects of the concomitant insulin infusion, intracellular rehydration, and rise in pH. Thus, if the serum potassium concentration is unknown, the ECG does not demonstrate hyperkalemic changes, and the patient is producing adequate amounts of urine, potassium infusion should be started at the same time insulin therapy is begun.

Potassium replacement is started by the addition of potassium chloride 20–40 meq/L to the fluid replacement solution. Potassium phosphate also may be given (alternating with potassium chloride) if phosphate repletion is necessary. Subsequent potassium replacement depends on the results of serum potassium determinations, which should be done at 2-hour intervals throughout the period of management of

diabetic ketoacidosis. In addition, electrocardiographic follow-up with single-lead measurement is a useful way of monitoring serum potassium for gross hyperkalemia or hypokalemia so that emergency treatment can be initiated if necessary. It should be kept in mind that even while replacement of potassium is taking place, continuing potassium losses occur in the kidney throughout the period of management of diabetic ketoacidosis. For this reason, serum potassium measurements also should be obtained daily once the patient is no longer ketotic. A total body deficit of potassium may persist despite initial correction of serum potassium, and oral potassium replacement therapy should be given to patients who continue to be hypokalemic.

E. Bicarbonate—Acidosis generally resolves with insulin therapy and metabolism of keto acids. In most cases of diabetic ketoacidosis, it is not necessary to treat acidemia with bicarbonate. Recent studies have demonstrated that bicarbonate therapy does not alter the eventual outcome of diabetic ketoacidosis, nor does it increase the rate at which pH is corrected. In fact, some have found a counterproductive effect of sodium bicarbonate in the treatment of diabetic ketoacidosis. Clinical and animal studies have shown that bicarbonate administration actually may increase ketone production. Recent data suggest also that in children with diabetic ketoacidosis, the mean duration of hospitalization for those receiving bicarbonate was 23% longer than that of children who did not receive bicarbonate. Lastly, a multicenter retrospective study of the risk factors associated with cerebral edema in children with diabetic ketoacidosis found that the relative risk of cerebral edema was 4.2 in children treated with bicarbonate compared with a matched control group that did not receive bicarbonate. Bicarbonate therapy also has been associated with hypocalcemic tetany, decreased tissue oxygen delivery, a paradoxical fall in pH of the cerebrospinal fluid, rebound alkalosis, greater potassium needs, and sodium overload.

However, when pH values are extremely low, concern about the hazards of acidemia begin to outweigh the concerns with alkali therapy. Therefore, at a pH of less than 7.0, particularly in a patient who is very ill, many clinicians will administer bicarbonate. The effects of low pH are a negative inotropic effect on the heart, vasodilatation, cerebral depression, insulin resistance, and depression of enzyme activity. If treatment with bicarbonate is begun, the American Diabetes Association (ADA) recommends that 100 mmol of sodium bicarbonate should be added to 400 mL of sterile water and given at a rate of 200 mL/h in severe acidosis (pH <6.9). In patients with a pH of 6.9–7.0, 50 mmol of sodium bicarbonate should be diluted in 200 mL of sterile water and infused at a rate of 200 mL/h.

In general, taking into account the hazards of treatment, the hazards of acidemia, and the probable benefits of bicarbonate administration, it is not necessary to treat routinely with bicarbonate.

F. Phosphate Replacement—The routine administration of phosphate in the management of diabetic ketoacidosis remains

controversial. Although there are theoretical reasons for replacing phosphate during treatment, most studies have not demonstrated any beneficial effect. Despite depletion of erythrocyte 2,3-diphosphoglycerate and the concern about decreased oxygen delivery to the tissues resulting from a leftward shift in the oxyhemoglobin dissociation curve, there are no deleterious clinical consequences of a mildly low serum phosphorus concentration. For most patients with diabetic ketoacidosis, routine administration of phosphate is unnecessary.

However, it is important to separate out one group of patients in whom phosphate therapy is essential—those with low serum phosphorus levels at presentation, which includes about 10% of patients (see Table 26–6). Serum phosphorus decreases in all patients, sometimes dramatically, after institution of insulin therapy. If the initial serum phosphorus concentration is 1.5 mg/dL, however, it may fall with treatment into the range of concentrations that are associated with the hypophosphatemia syndrome (Table 26–9). This syndrome may include decreased myocardial contractility, respiratory muscle weakness and respiratory failure, hemolysis, and rhabdomyolysis. It is important to note that none of the studies evaluating the efficacy of phosphate therapy in diabetic ketoacidosis included patients with severely depressed serum levels at presentation, so the conventional wisdom that phosphate therapy is unnecessary should not be extended to include the group with low serum phosphate levels at diagnosis.

Severe hypophosphatemia may not be recognized unless frequent serum phosphorus measurements are made. These should be obtained every 2 hours during treatment of diabetic ketoacidosis in all patients whose serum phosphorus level is less than 2.5 mg/dL at presentation. Patients with hypophosphatemia should be given supplemental phosphorus in the form of potassium phosphate.

Potassium phosphate can be added to the fluid replacement solution, alternating with potassium chloride. Hypophosphatemic patients generally will require 500–1000 mg elemental phosphorus given over 12–24 hours depending on the severity of phosphorus depletion. This is equivalent to

about 15–30 mmol of phosphate, or a total of 5–10 mL of potassium phosphate solution (3 mmol/mL) to be added to the fluid replacement solutions (1–4 mL potassium phosphate solution per liter of replacement fluid). A concern about phosphate administration in patients with diabetic ketoacidosis is hypocalcemic tetany, which has been described in some patients who receive phosphate therapy. It should be kept in mind that calcium levels may fall during the management of diabetic ketoacidosis. Small decreases in serum calcium therefore may not be a contraindication to continued phosphate repletion in patients who are phosphorus-depleted, but they do require more frequent monitoring of serum calcium to prevent hypocalcemia.

Patients with normal or high serum phosphorus levels at diagnosis will have a decrease in serum phosphorus during therapy, but only to levels that do not usually require treatment.

Complications of Diabetic Ketoacidosis

A number of complications of diabetic ketoacidosis may occur during treatment. Hypocalcemia, hypokalemia or hyperkalemia, hypophosphatemia, and hypoglycemia need to be watched for during continuous monitoring of patients with diabetic ketoacidosis (Table 26–10). Another recognized complication is thromboembolism that occurs as a result of

Table 26–9. Hazards of hypophosphatemia and phosphorus repletion in diabetic ketoacidosis.

Hypophosphatemia
Decreased red cell 2,3-diphosphoglycerate with decreased O ₂ delivery
Muscle weakness
Hypophosphatemia syndrome ([P] <1.0 mg/dL) with respiratory insufficiency, decreased myocardial contractility, rhabdomyolysis, hemolysis
Phosphorus administration
Hypocalcemia and tetany

Table 26–10. Complications of diabetic ketoacidosis.

Complication	Possible Mechanism
Hypokalemia	Bicarbonate therapy, inadequate replacement, insulin
Hyperkalemia	Anuria, excessive replacement
Hypophosphatemia	Insulin therapy (if [P] starts out <1.5 mg/dL)
Hypoglycemia	Inadequate glucose infusion with insulin therapy
Other	
Thromboembolism	Increased platelet adhesiveness, hyperviscosity, poor perfusion
Aspiration	Gastric stasis, vomiting; lack of nasogastric suction
ARDS	Use of hypotonic replacement fluids or excess crystalloid infusion or increased pulmonary epithelial permeability
Cerebral edema	Excessive correction of hyperglycemia
Mucormycosis	Use of hypotonic replacement fluids(?) Acidemia

increased platelet adhesiveness and hyperviscosity. Aspiration of gastric contents is associated with gastroparesis and vomiting. Nasogastric suction should be initiated in all patients who have altered consciousness to prevent this complication. Cerebral edema and acute respiratory distress syndrome are other complications that will be discussed below.

One of the rare but significant conditions that should be kept in mind in the management of diabetic ketoacidosis is mucormycosis. This rare condition associated with ketoacidosis is a treatable yet severe infection by the fungus *Rhizopus*. Early diagnosis is essential so that therapy can be instituted to prevent the severe morbidity associated with this rapidly invasive infectious process. The hallmark of mucormycosis is the finding of black necrotic debris in the area of the eye, nose, or nasal cavity and histologic evidence of vascular thrombosis or tissue infarction on biopsy. These findings result from the propensity for invasion by mucormycosis into the vascular system. This diagnosis is considered to be a medical emergency that requires urgent surgical and antifungal therapy.

Current Controversies and Unresolved Issues

A. Fluid Replacement—Fluid replacement remains a controversial issue from two different points of view. The first is volume replacement. A study comparing the effects of providing 3 L of volume replacement over the first 8-hour period of treatment versus giving 6 L over the same period of time showed very little difference in outcomes in the two groups of patients. The conclusion is that smaller volumes of fluid may be administered safely to some patients with diabetic ketoacidosis. It needs to be emphasized that patients with severe volume deficits were excluded from this study, but patients with moderate fluid deficits may do well with slower replacement of their losses. One approach provides a more flexible regimen for fluid replacement that recognizes the unique requirements of each patient but consequently requires careful monitoring. Fluid is replaced at a rate of 15–20 mL/kg per hour for 1 hour and then at 4–14 mL/kg per hour thereafter according to need, as determined by careful monitoring of fluid balance.

The type of fluid replacement also has been an issue of controversy. Some investigators feel that colloid therapy is better than crystalloid infusion in the management of diabetic ketoacidosis. Their concern is that insufficient fluid is maintained in the intravascular space during therapy and that much of the fluid, when given as crystalloid, finds its way into the interstitial space, where edema is the result. It has been suggested that the syndromes of cerebral edema and pulmonary edema may be a consequence in part of the sequestration of fluid outside the intravascular space. However, no controlled studies of colloid infusion have been performed. Colloid solutions should be considered in the management of hypotension in patients who present with diabetic ketoacidosis, but at this time, crystalloid infusion remains the management of choice.

B. Cerebral Edema—This serious complication is fortunately quite rare. Cerebral edema manifests as a deteriorating level of consciousness at a time when other parameters of diabetic ketoacidosis are improving in response to treatment. Clinical evidence for this complication generally appears early in the course of treatment; almost two-thirds of patients who develop neurologic deterioration begin to do so within 12 hours of initiation of therapy. Cerebral edema occurs mainly in children and young adults and is associated with a greater than 90% mortality. However, despite its rarity, this complication has influenced one of the basic aspects in our management of diabetic ketoacidosis because of its catastrophic consequences. As mentioned earlier, it is accepted practice to start glucose infusion to prevent serum glucose concentrations from falling below 250–300 mg/dL. This recommendation derives from studies of experimentally induced cerebral edema in diabetic dogs that demonstrated an association of cerebral edema with greater decrements in plasma glucose concentrations during treatment.

In an observational study of children who developed cerebral edema with ketoacidosis, only treatment with bicarbonate was associated with cerebral edema. Neither the initial serum glucose concentration nor the rate of change in the serum glucose concentration during therapy was associated with the development of cerebral edema. Symptomatic cerebral edema has developed in a few children with diabetic ketoacidosis before the initiation of therapy, suggesting that it may not necessarily be caused by therapy. Children with diabetic ketoacidosis who have low partial pressures of arterial carbon dioxide (relative risk 2.7 per decrease of 7.8 mm Hg) and high serum urea nitrogen concentrations (relative risk 1.8 per increase of 9 mg/dL) at presentation were at increased risk for cerebral edema. This supports the hypothesis that cerebral edema in children with diabetic ketoacidosis is related to decreased perfusion of the brain. Both hypocapnia, which causes cerebral vasoconstriction, and extreme dehydration would be expected to decrease brain perfusion. Furthermore, because the developing brains of children are more sensitive to hypoxia, this may explain the greater incidence of cerebral edema in children than in adults.

Subclinical cerebral edema appears to be quite common in patients with diabetic ketoacidosis because compression of the subarachnoid and ventricular spaces during treatment has been observed by CT scan without any obvious clinical manifestations. The high frequency of subclinical edema has raised questions about the rate and composition of fluid replacement discussed earlier in this section. Mannitol is used in therapy of symptomatic cerebral edema.

C. Acute Respiratory Distress Syndrome (ARDS)—Another unusual but serious complication of ketoacidosis is ARDS. Patients present with progressive dyspnea and hypoxemia; the earliest sign appears to be an increased $P(A-a)O_2$, and pulmonary edema is found on chest x-ray. ARDS in diabetic ketoacidosis tends to occur most often in patients under 50 years of age, and the mortality rate associated with

this syndrome is extremely high. The pathogenesis of ARDS in diabetic ketoacidosis is unknown, but it also has been suggested that the syndrome may be associated with crystalloid infusion and perhaps with excess volume replacement. It is unlikely that either of these factors is the sole cause of ARDS because it is too unusual a complication of diabetic ketoacidosis to be simply fluid-dependent given the wide range of replacement regimens used. However, it is possible that there is an association with excessive fluid replacement in patients who have some underlying pulmonary disease process associated with increased pulmonary epithelial permeability.

▶ Hyperglycemic Hyperosmolar Nonketotic Coma

This disorder is probably not a distinct entity but rather a variant of the diabetic ketoacidosis syndrome because a large overlap exists in the clinical presentation and pathogenesis of diabetic ketoacidosis and nonketotic coma. Management of the two conditions is essentially identical. However, there are clearly major differences in clinical presentation between typical patients with nonketotic coma and diabetic ketoacidosis, who probably represent opposite extremes of this metabolic syndrome.

The patient with nonketotic coma typically is an elderly person who presents with diabetes for the first time, is severely dehydrated, is more often in coma, and has severe associated diseases and a poor outcome. In contrast, the common first presentation of diabetic ketoacidosis is in a teenager who is otherwise healthy, not often in coma, and has an excellent chance of recovery. Biochemically, the typical patient with hyperglycemic hyperosmolar nonketotic coma has more severe hyperglycemia (eg, serum glucose often > 1000 mg/dL) and hyperosmolarity, more pronounced electrolyte abnormalities, and no ketosis. Between these two extremes are a large number of patients in whom the clinical syndromes overlap, so some degree of ketosis is often present in a patient who otherwise would be classified as having typical nonketotic coma; on the other hand, hyperosmolarity and severe hyperglycemia occur in what otherwise appears to be typical diabetic ketoacidosis.

The pathogenesis of hyperglycemic hyperosmolar nonketotic coma is not well understood. The severity of the hyperosmolarity can be ascribed to a greater degree of volume

depletion. Indeed, severe volume depletion is the most important common feature and can best be explained by the degree of hyperglycemia. Figure 26–1 provides an explanation for this severe hyperglycemia. Since volume depletion is a characteristic feature, renal blood flow and the glomerular filtration rate are reduced, thus diminishing the urinary escape of glucose. However, the hormonal setting ensures a continuing high rate of hepatic glucose production (see above for further discussion of Figure 26–1), and this has the capacity to rapidly increase blood glucose levels. If this sequence of events is not halted, severe hyperglycemia and hyperosmolarity ensue.

The other major feature of nonketotic coma—the relatively low level of serum keto acids—also may play an important role in the development of severe hyperglycemia. Ketoacidosis makes the patients feel more ill and thus prevents the syndrome from going undiagnosed for prolonged periods. The lack of ketosis in hyperglycemic hyperosmolar nonketotic coma may delay presentation, resulting in ongoing osmotic diuresis that results in more severe volume depletion. The mechanism for the lower levels of ketosis is unexplained. The hormonal picture at presentation is not helpful because concentrations of circulating counterregulatory hormones do not appear to be different from those seen in diabetic ketoacidosis, nor do insulin levels seem to differ. Nevertheless, it is thought that a restraining effect on lipolysis by small increases of circulating insulin—and, as a result, less availability of substrate for ketogenesis—may explain low ketone concentrations in this syndrome. It also appears that hyperosmolarity may itself play a role in diminishing ketosis; this is based on *in vitro* studies in which hyperosmolarity was shown to suppress lipolysis.

Management is not different from that of diabetic ketoacidosis. Plasma glucose concentrations should be allowed to decrease at a rate of about 100 mg/dL per hour, and fluid replacement should begin with normal saline as discussed earlier. Early aggressive volume replacement is important to prevent hypotension that may result from fluid shifts that accompany insulin-mediated glucose transport into the intracellular compartment. Many of these patients are elderly, and monitoring fluid balance with central venous catheters therefore is advised. Because of the massive osmotic diuresis that precedes presentation in these patients, electrolyte losses may be severe. It is particularly important to monitor serum potassium concentration carefully during early management and in subsequent days so as to provide potassium supplements if they become necessary. The mortality rate is high, with deaths often due to concurrent illnesses or thrombotic and infectious complications.

MANAGEMENT OF THE ACUTELY ILL PATIENT WITH HYPERGLYCEMIA OR DIABETES MELLITUS

Management of patients in the ICU setting has undergone a strategic change in a matter of a few years since the publication of a landmark work known as the *Leuven study* in 2001. This study demonstrated unequivocally that management of hyperglycemia is of fundamental importance in critically ill patients and has changed the way in which hyperglycemia and diabetes are managed in the ICU.

For many years it was thought that moderate control of blood glucose in inpatients and the critically ill was appropriate care. This was a result of the prevailing interpretation of the hyperglycemia of injury as a benign adaptive process that contributes to survival. Mild or moderate hyperglycemia is common in critically ill patients, even in those not previously known to have diabetes. Hyperglycemia is due to a combination of physiologic changes including insulin resistance and increased hepatic glucose production despite increased secretion of insulin and was seen as necessary to provide glucose as fuel during severe injury. The Leuven study challenged these concepts after demonstrating that tight glucose control (<110 mg/dL) improved mortality and morbidity in critically ill patients and thereby changed not only the practice of medicine in the ICU but also how we think about glucose regulation in acute illness.

► Hyperglycemia

Pathophysiology

The most frequent pathophysiologic abnormality of glucose metabolism induced by acute illness is an increase in insulin resistance. The molecular mechanisms are not well understood, but a number of associated abnormalities contribute to the development of insulin resistance. Increased secretion of glucose counterregulatory hormones occurs in the acutely ill patient. Increased concentrations of cortisol, catecholamines, growth hormone, and glucagon lead to increased hepatic glucose production by gluconeogenesis and glycogenolysis, as well as insulin resistance at the level of muscle and adipose tissue. Although insulin secretion increases in response to rising glucose concentrations, it is insufficient to prevent hyperglycemia, which is usually mild in nondiabetic patients. Catecholamines may play a role in restraining an adequate insulin secretory response by their action to suppress beta cell function.

The ability to continue to secrete increasing (although inadequate) amounts of insulin in response to elevated serum glucose is probably what prevents the development of ketoacidosis in most patients with type 2 diabetes when acute illness supervenes, although insufficient to prevent hyperglycemia. The presence of even low levels of insulin may be sufficient to inhibit lipolysis in adipose tissue and thereby suppress ketogenesis in the liver. Indeed, it is unusual for patients with type 2 diabetes to develop diabetic ketoacidosis even though they have the same pattern of glucose counter-regulatory hormone

release. If diabetic ketoacidosis occurs in type 2 diabetes, it is due to more severe insulin deficiency than in equally ill type 2 patients without ketosis.

Clinical Benefits of Intensive Insulin Therapy in the Critically Ill

A brief outline of the Leuven study will be provided to illustrate the benefits of the use of insulin-mediated tight glycemic control in the ICU. Critically ill patients, almost all post-cardiac surgery and most not previously known to have diabetes, were studied with the intention of testing the role of maintaining strict normoglycemia (<110 mg/dL) in the ICU. Those patients randomized to the control group also were treated with insulin if the blood glucose level exceeded 200 mg/dL, so average blood glucose concentrations were 150–160 mg/dL, previously thought to be adequate glycemic control in this setting. Mortality was reduced dramatically in the intensive insulin therapy group, especially among patients with prolonged critical illness in the ICU. In those requiring intensive care for more than 5 days, mortality was reduced from 20% to about 10%. Time in the ICU was decreased significantly. Morbidity also was reduced significantly, including prevention of severe complications such as acute renal failure, nosocomial infections, liver dysfunction, critical illness neuropathy, muscle weakness, and anemia. Other recent reports confirm the findings in this landmark study, including medical ICU patients, although less strikingly in this population. Carefully monitored intravenous insulin titration regimens are recommended to induce normoglycemia without the risk of significant hypoglycemia.

This approach is also applied to patients with diabetes, although in known diabetic patients hyperglycemia may be more severe to begin with. Patients who have inadequate insulin secretory reserve but who are not frankly diabetic are at great risk for severe metabolic decompensation owing to intercurrent disease. These patients are unable to respond to increasing insulin needs, but unlike in previously diagnosed diabetes, they may not necessarily recognize the symptom complex associated with hyperglycemia. This can be exacerbated if large quantities of glucose are infused or ingested. For example, in patients who ingest a large amount of sucrose from sugar-containing soft drinks because of extreme thirst induced by diuresis or diarrhea, ensuing osmotic diuresis can make this a self-perpetuating disorder. Similarly, peritoneal dialysis using solutions with high glucose concentrations, used in an attempt to remove excess extracellular fluid, may be associated with hyperglycemia and even hyperosmolar diabetic coma.

An example of how control of diabetes influences the management of another disorder is when diabetes insipidus and diabetes mellitus coexist. In diabetes insipidus, large volumes of free water are lost in the urine because of an inability to concentrate urine. During treatment, equally large quantities of electrolyte-poor solutions—usually 5% dextrose—are infused to match urine output. If the urine output is large, 6–10 L of 5% dextrose may be given within a

24-hour period, representing a load of 300–500 g of glucose into the extracellular pool (compared with about 20 g in the extracellular pool in a patient with normal serum glucose concentration; see Figure 26–1). Nondiabetic subjects handle this glucose load by increasing the secretion of insulin. However, in patients who have underlying or overt diabetes and a poor insulin secretory response, serum glucose increases, and glycosuria and an osmotic diuresis develop unresponsive to the effect of vasopressin. Continuing urine volume losses result in the administration of even larger volumes of dextrose, perpetuating a vicious circle. Proper management consists of preventing glycosuria by tightly controlling blood glucose concentration. This can be achieved using an intravenous insulin infusion in the ICU while simultaneously treating the diabetes insipidus with vasopressin.

▶ Hypoglycemia

Some diabetic patients appear to have decreased insulin requirements or a decreasing need for oral hypoglycemic agents when acute illness supervenes. A decrease in insulin requirements may result from a number of different mechanisms.

Pathophysiology

A. Decreased Insulin Resistance—Weight loss may occur prior to or during the acute illness. It is well known that weight loss reduces insulin resistance in diabetes mellitus, and small decreases in weight often are sufficient to produce a substantially decreased requirement for insulin or other hypoglycemic agents. Another cause of decreased insulin resistance is a deficiency of one of the glucose counterregulatory hormones. Adrenal or pituitary insufficiency may occur as part of an intercurrent disease process. Decreased growth hormone or cortisol can diminish the need for hypoglycemic agents by enhancing peripheral insulin sensitivity and decreasing gluconeogenesis.

B. Decreased Clearance of Insulin or Oral Hypoglycemic Agents—Because the liver and the kidneys are the primary organs involved in metabolism of insulin and the sulfonylurea drugs, development of renal or hepatic failure may delay drug clearance and result in hypoglycemia. In the case of the sulfonylureas, this may be associated with severe, prolonged hypoglycemia and coma. Concomitant use of other drugs also may influence the metabolism of sulfonylurea agents (Table 26–11). A relatively common cause of unexpected hypoglycemia occurs during acute episodes of congestive heart failure in insulin-treated patients. As a result of liver congestion and possibly decreased insulin clearance with reduced hepatic blood flow, insulin requirements are transiently diminished. If the insulin dose is not reduced, hypoglycemia may occur.

C. Drug Interactions—Drug interactions are of particular importance with the first generation of oral hypoglycemic agents that are tightly protein-bound and may be displaced

Table 26–11. Pharmacokinetic and pharmacodynamic interactions that augment the hypoglycemic actions of sulfonylurea drugs.

Interaction	Drug
Displacement of sulfonylureas from plasma proteins	Clofibrate, phenylbutazone, salicylates, sulfonamides
Reduced hepatic sulfonylurea metabolism	Dicumarol, chloramphenicol, monoamine oxidase inhibitors, phenylbutazone
Decreased urinary excretion of sulfonylureas or metabolites	Allopurinol, probenecid, phenylbutazone, salicylates, sulfonamides
Intrinsic hypoglycemic activity	Insulin, alcohol, beta-adrenergic agonists, salicylates, guanethidine, monoamine oxidase inhibitors

by other protein-bound drugs. Table 26–11 summarizes possible interactions between drugs used in management of diabetes and therapeutic agents that may affect glucose control. Because multiple drugs are used often in acutely ill patients, particularly the elderly, the possibility of drug interactions giving rise to hypoglycemia always needs to be considered.

Clinical Features

Hypoglycemia in hospitalized patients occurs most commonly in patients with diabetes, and this is usually due to a decrease in caloric intake related to illness or hospital routine with continued administration of hypoglycemic drugs. Some of the causes of hypoglycemia observed in hospitalized patients with diabetes are presented in Table 26–12. Concomitant diseases play an important role in increasing the risk of hypoglycemia in patients with diabetes, for example, renal insufficiency, malnutrition, and sepsis—three disorders known to be associated with hypoglycemia even in nondiabetic hospitalized patients—as well as alcohol ingestion, liver disease, shock, pregnancy, and malignancy. A high mortality rate has been reported in nondiabetic critically ill patients who develop hypoglycemia, and in some, this may represent a terminal phenomenon associated with malnutrition or kidney and liver disease.

Pentamidine, used for treatment for *Pneumocystis carinii* infection, is associated with hypoglycemia probably owing to destruction of pancreatic beta cells with acute insulin release.

Treatment

Several factors determine appropriate management for patients with diabetes mellitus and acute illness to avoid the consequences of hyperglycemia and hypoglycemia.

Table 26–12. Proximate causes of hypoglycemia in 42 diabetic patients receiving insulin (60 episodes) or oral hypoglycemia drugs (four episodes).

Cause	% Episodes
Decreased intake of calories	45
Nausea, vomiting, anorexia, lethargy	23
NPO because of diagnostic test or surgical procedures	14
Enteral tube feedings held for measurement of residual	5
Meals not delivered	3
Adjustment of insulin dosage	39
Treatment of diabetic ketoacidosis or nonketotic coma	17
Attempt at tighter metabolic control	9
Sliding scale insulin doses too high for patient with renal insufficiency	6
Failure to reduce insulin dose after one hypoglycemia episode	5
Less insulin needed as infection resolved	2
Incorrect dose of insulin given	8
No cause identified	8

A. Goal for Serum Glucose—Based on the data of the Leuven study, target glucose concentrations in acutely ill patients have been changed to attempt to achieve normoglycemia, defined as concentrations of less than 110 mg/dL. In medical patients, a target of 130–140 mg/dL may be more appropriate. This is best achieved using continuous intravenous insulin infusion with a titration algorithm. Once patients are out of the critical care setting, other regimens may be appropriate.

B. Fasting Patients—Patients who for any reason are not being fed do not need bolus injections of rapid-acting insulin to maintain glucose homeostasis postprandially; a continuous intravenous insulin infusion is more appropriate. Intravenous insulin is given routinely if a patient is receiving total parenteral nutrition because of the large load of calories given to patients during this therapy. However, even in the absence of an exogenous source of glucose, such as total parenteral nutrition, it is important to recognize that hyperglycemia in patients with diabetes is the result of a continuous delivery of large amounts of glucose from an endogenous source, that is, the liver. It is logical, therefore, that serum glucose concentration be controlled by continuous levels of insulin, and this can be done with intravenous insulin infusion. The response should be evaluated by monitoring blood glucose level at the bedside at 2–3-hour intervals. An alternative to the use of intravenous infusion of insulin for patients who are no longer critical is the use of long-acting subcutaneous insulin (eg, glargine insulin or insulin-detemir).

These insulins analogues provide the equivalent of a basal infusion rate, but because they do not provide the possibility of hour-to-hour titration, they are unsuitable for anyone but very stable patients, in whom day-to-day titration of insulin is often sufficient.

C. Patients with Intermittent Food Intake—Patients who are acutely ill, are vomiting, or have decreased food intake can be managed somewhat differently. Under these circumstances, longer-acting insulins may be inappropriate because it is difficult to predict insulin needs for more than a few hours in advance. Thus, even if NPH insulin were administered in an appropriate dose, inability to eat a meal hours later could put the patient at risk for hypoglycemia. Rapid-acting insulin given before each meal and at midnight is preferable.

Rapid-acting insulin can be given to patients four times a day using a variable insulin dosage (2–10 units) based on the bedside blood glucose determination (sliding scale). Glucose is measured preprandially, immediately before each insulin dose is to be administered, and at midnight. This provides insulin coverage for the expected glucose excursion with each meal, and the dose can be reduced if the patient is not going to eat the next meal. As soon as the patient begins to stabilize and is able to eat consistently, an attempt should be made to convert the patient to morning and evening split-dose insulin injections using a combination of NPH and regular insulin or multiple-dose insulin using a combination of premeal rapid-acting analogues and a basal insulin (eg, glargine or detemir).

D. Patients Eating Regularly—Patients who are eating meals or receiving feeding in bolus fashion in reasonably consistent manner can be treated with a split-dose regimen of NPH and rapid-acting insulin. Alternatively, basal insulin (eg, glargine or detemir) with premeal rapid-acting analogues can be used. If necessary, a sliding scale of supplementary preprandial rapid-acting insulin doses can be added to provide good glycemic control. There is no need for prolonged use of sliding scales in this situation because with the sliding-scale approach the doses of insulin are variable from day to day, and more stable patients will do better if managed with a more constant regimen.

Once patients have stabilized, in addition to preprandial glucose measurements, which are the basis for the sliding scale, blood glucose measurements also should be performed 2 hours after meals to evaluate whether the dose of rapid-acting insulin given prior to those meals is appropriate for adequate glucose control. These 2-hour postprandial glucose measurements are most useful for determining the required dose of rapid-acting insulin. Rapid-acting insulin dosages can be increased or decreased depending on the change in glucose concentration from that obtained immediately prior to the meal (keeping in mind that there is a normal rise in blood glucose levels of about 40–50 mg/dL after a meal).

► Other Complications of Diabetes Mellitus

In addition to disordered glucose control, it is important to consider the interaction between the complications of diabetes and unrelated acute illness. Some of the complications are clinically obvious, such as renal failure or nephrotic syndrome with hypoalbuminemia. Others are less obvious, such as defects in vision (short of total blindness), which may make it difficult for the patient to be totally compliant with management.

Renal and retinal complications should be looked for routinely if the patient is known to have diabetes. However, the consequences of autonomic neuropathy often are not addressed in clinical evaluation. In patients with long-standing diabetes, there may be devastating effects. For example, orthostatic hypotension is usually not symptomatic in most patients with autonomic neuropathy yet may become dramatically important when other causes of hypotension are present, such as volume depletion, cardiac disease, or drug-related causes. Another overlooked problem that can interfere with management is gastroparesis, which should be considered in patients who are vomiting or have diabetes that is difficult to control. With this disorder, poor glucose control results from a lack of coordination between insulin injection and absorption of meals owing to delay in food exiting the stomach. Recurrent urinary tract infections may result from a neurogenic bladder. Lastly, patients with symptomatic autonomic neuropathy are also at increased risk for sudden death from cardiorespiratory arrest.

Another not uncommon phenomenon that can cause an acute problem in patients with long-standing diabetes is the syndrome of hyporeninemic hypoaldosteronism. This disorder is seen commonly in older patients with type 2 diabetes and mild renal insufficiency. With administration of ACE inhibitors or in the presence of other acute illness, severe hyperkalemia may be seen. Hyperkalemia may occur in patients whose serum potassium concentration may be only mildly elevated or at the upper limit of normal under usual circumstances owing to hyporeninemic hypoaldosteronism.

HIV Infection in the Critically Ill Patient

Mallory D. Witt, MD
Darryl Y. Sue, MD

Since acquired immunodeficiency syndrome (AIDS) was first described in 1981, much has been learned about the spectrum of diseases associated with the progressive immunosuppression caused by the human immune deficiency virus (HIV). Malignancies and opportunistic infections are common sequelae of advanced HIV disease, but HIV also can directly and indirectly affect the pulmonary circulation, kidneys, heart, brain, and adrenal glands. Sepsis, respiratory failure, and neurologic complications are common problems that often require management in the ICU. The advent of highly active antiretroviral therapy (HAART) and the success of prophylaxis strategies against several common opportunistic infections have led to prolonged survival and improved quality of life of patients with HIV infection. In turn, the characteristics of patients with HIV who are admitted to the ICU are changing, with concomitant reconsideration of the benefits of ICU care. However, widespread use of HAART has led to new problems and complications of treatment, some of which are serious enough to warrant ICU admission. The benefits of ICU care for HIV-infected patients were questioned early in the epidemic because of studies reporting poor outcomes for patients with respiratory failure owing to *Pneumocystis pneumonia* (PCP). In the early stages of the HIV epidemic, respiratory failure owing to PCP was responsible for up to one-half of ICU admissions for patients with HIV infection, with a mortality approaching 80–90%. By the mid-1990s, the incidence of PCP with respiratory failure declined significantly, accounting for only 18% of ICU admissions, and mortality rates were considerably lower (50–60%). A recent study at a single institution documented improved survival of HIV-infected patients admitted to the ICU in the current era, with an overall survival rate to hospital discharge of 71% compared with 31% in the pre-HAART era. However, other institutions report survival rates in the range of 44–61%. Differences in patient populations, ICU admission standards, and clinical practices may limit our ability to draw comparisons across institutions.

With the decline in ICU admissions owing to PCP, the most common present-day indications for admission of patients with HIV infection are respiratory failure (42%, including PCP), sepsis (12%), cardiac causes (10%), and neurologic disease (12%), followed by smaller percentages of patients requiring postoperative care and those with GI bleeding, metabolic derangements, trauma, and drug overdoses. End-stage liver disease is an increasingly common cause of death in HIV-infected patients as deaths from opportunistic infections decline and the complications of chronic hepatitis C and B coinfection are seen. Patients may present with complications of HAART, such as lactic acidosis, impaired glucose tolerance, hyperlipidemia, adverse drug reactions, and non-salutary drug interactions leading to toxicities. Thus patients with HIV infection are admitted to the ICU for a number of reasons. Below we review the most common conditions necessitating ICU hospitalization among HIV-infected patients.

COMPLICATIONS OF HIV DISEASE: AN OVERVIEW

The primary cause of immunosuppression in HIV disease is a progressive decline in the number and percentage of CD4 lymphocytes, resulting in decreased cellular immunity as well as impairment of B-lymphocyte function. Increased likelihood of infections caused by bacterial, protozoal, mycobacterial, fungal, and viral pathogens can occur throughout the entire course of HIV infection. However, opportunistic infections and malignancies, certain neurologic disorders, and severe wasting are associated with advanced HIV infection.

The use of HAART has greatly modified the course of HIV disease, with substantial declines in HIV-associated morbidity and mortality. However, HAART regimens are often complex, consisting of multiple drugs from up to four different classes of antiretroviral agents; their success depends on strict compliance with regimens, careful attention to the effects of food on absorption of antiretroviral

drugs, the presence of resistant virus, drug interactions, and patients' ability to tolerate adverse effects of the medications. Side effects and toxicities of HAART drugs are relatively common, and changes in doses and/or components of regimens may be necessary. As described below, a number of antiretroviral agents preclude prescription of other commonly used medications, and certain drug-drug interactions necessitate dose modifications of either or both drugs.

Although the presentation of HIV infection can be highly variable, a number of general principles can be applied to all patients. First, the level of immunosuppression must be considered when evaluating any disorder in an HIV-infected patient. The likelihood of opportunistic infections and malignancies increases as the number of CD4+ T-lymphocytes decreases.

In the presence of waning cellular and humoral immunity, reactivation of latent infections may occur. For example, in the absence of appropriate prophylaxis, one-third of HIV-infected patients with prior exposure to *Toxoplasma* (ie, a positive serum titer of IgG antibody to *Toxoplasma*) may develop cerebral toxoplasmosis if they reach a sufficient level of immunosuppression. In the absence of appropriate antituberculous prophylaxis, an HIV-infected individual with a positive tuberculin skin test has a 7–10% chance per year of developing active tuberculosis compared with an individual without HIV infection with a positive skin test, who has less than a 10% lifetime risk. Endemic fungal infections such as histoplasmosis and coccidioidomycosis may reactivate with declining immune status, presenting as disseminated infection. However, the most common infectious agents encountered in patients with HIV are traditional bacterial pathogens, leading to pneumonia, bacteremia, and sepsis.

Patients with severe immunosuppression marked by low CD4 T-lymphocyte counts benefit substantially from prophylaxis against infections with *P. jiroveci* and *Mycobacterium avium* complex (MAC). Appropriate prophylaxis should be given to selected patients, including those with positive purified protein derivative (PPD) skin tests for tuberculosis and those with antitoxoplasma antibodies.

▶ Severe Complications of Antiretroviral Therapy

Beginning with zidovudine (azidothymidine [AZT]), antiretroviral therapy has been used to slow the progression of HIV infection. In the mid-1990s, protease inhibitors in combination with other antiretroviral therapy demonstrated potent effects on HIV, termed *highly active antiretroviral therapy* (HAART). Increased availability of new HIV therapies has led to an attendant increase in drug-drug interactions as well as adverse effects of these therapies. Below we review the serious complications of antiretroviral therapy that, in some cases, may necessitate ICU admission.

Antiretroviral therapy can be divided into four drug classes: nucleoside analogue reverse-transcriptase inhibitors (NRTIs), nonnucleoside reverse-transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), and fusion inhibitors. These drugs demonstrate both class and individual adverse drug reactions as well as important interactions with each other and with other drugs used to treat heart failure, anxiety, infection, depression, and hyperlipidemia. Patients admitted to the ICU with underlying HIV disease may be receiving antiretroviral therapy that can complicate current management or may present with unique adverse reactions to the medications.

Lactic Acidosis and Hepatic Steatosis

Hyperlactatemia is an uncommon complication of NRTI use and can be associated with fatal lactic acidosis. Its presentation may mimic septic or cardiogenic shock, hepatitis, or drug-induced liver failure. Clinical features include hepatomegaly, abnormal liver function tests, pancreatitis, mild to severe lactic acidosis, and evidence of fatty liver on ultrasound or CT scanning. Many NRTIs have been associated with this disorder, although stavudine and didanosine, alone or in combination, are implicated most commonly. The likely mechanism is inhibition of mitochondrial DNA synthesis leading to impaired oxidative phosphorylation with ensuing lactic acidosis and evidence of dysfunction in the liver as well as other organs.

Hyperglycemia and Other Metabolic Complications

Glucose intolerance, including hyperglycemia, frank diabetes, and even ketoacidosis may occur in some patients, necessitating ICU admissions. Glucose dysregulation has been associated with PI use and resulting insulin resistance after a median of 60 days from initiation of therapy. In some cases, substitution of an alternative antiretroviral agent leads to resolution of hyperglycemia.

Lipid disorders are a growing concern in the setting of HAART, with elevations in triglycerides, low-density lipoprotein (LDL), and total cholesterol described. While hyperlipidemia itself rarely leads to ICU admission, the potential for accelerated atherosclerosis and coronary artery disease associated with these lipid disorders is of concern. The increased risk of cardiovascular disease in HAART-associated hyperlipidemia is small but measurable. A recent report from the Data Collection on Adverse Events of Anti-HIV Drugs study indicated that the incidence of myocardial infarction increased by an average of 26% per year of exposure to HAART. A subsequent analysis revealed that over a period of 36,145 person-years of follow-up, 207 patients experienced at least one cardio- or cerebrovascular event (CCVE). The incidence of the first CCVE was 5.7 per 1000 person-years, with a relative risk of 1.26 per year of exposure to HAART. The impact of HAART on atherosclerotic disease is less than that of hypertension, smoking, and other traditional risk factors; emphasis on modification of risk factors remains paramount in patients with HIV disease on HAART.

Pancreatitis can occur in the setting of HIV infection as a result of antiretroviral and other HIV-related medications and sometimes can be severe enough to necessitate ICU admission. Didanosine, stavudine, or a combination of didanosine, stavudine, and hydroxyurea have been implicated most commonly, but lamivudine, ritonavir, isoniazid, lopinavir/ritonavir, trimethoprim-sulfamethoxazole, sulfonamides, corticosteroids, and pentamidine rarely have been associated with pancreatitis. Alcohol use as well as gallstones must be considered in the HIV-infected person presenting with pancreatitis.

► Pulmonary Complications of HIV Infection

The most common cause of respiratory failure in the presence of HIV infection is *P. jiroveci* pneumonia, discussed below. Other infectious etiologies that may present with

respiratory failure include bacterial pneumonia, endemic fungal infections such as coccidioidomycosis and histoplasmosis, and sepsis.

The likelihood of specific pathogens being responsible for pulmonary infection depends on several factors, including the degree of immunosuppression, relevant exposure history, and receipt of appropriate prophylaxis. For example, pneumococcal pneumonia and tuberculosis may infect patients irrespective of CD4 count, whereas *P. jiroveci* is uncommon with a CD4 count above 200/μL. Second, prophylaxis with trimethoprim-sulfamethoxazole significantly decreases the likelihood of PCP as well as cerebral toxoplasmosis. Third, a history of prior or latent infection may be important, such as the presence of a positive tuberculin skin test, a history of exposure to endemic fungi, or prior bacterial pneumonia. Finally, the pattern on the chest x-ray may provide important clues, including evidence of localized infection or findings consistent with disseminated infection.

A. Symptoms and Signs—Important clues to the underlying cause of respiratory failure include the duration of symptoms; the quantity and quality of sputum; the presence of hemoptysis, dyspnea, and cyanosis; recent travel; geographic place of residence; history of tuberculin skin testing results; and recent adherence to prophylaxis.

B. Laboratory and Imaging Studies—Evaluation should include chest x-ray, sputum Gram stain, sputum acid-fast stain, complete blood count, blood cultures for bacteria, liver function tests, serum lactate dehydrogenase (LDH), creatinine, and arterial blood gases. In some cases, additional studies may be warranted, including serum cryptococcal antigen, fungal and mycobacterial blood cultures, and CD4 count (if not known). Chest CT scan may be helpful to identify additional foci of infection, verify the presence or absence of hilar or mediastinal adenopathy or parenchymal cavitary lesions, or demonstrate a miliary pattern suggestive of disseminated tuberculosis or coccidioidomycosis. Urinary *Histoplasma* antigen should be measured in patients from endemic areas or with known or potential exposure. In the appropriate geographic area or with known or suspected prior exposure, the presence of antibody to *Coccidioides immitis* should be determined, but antibody is absent in up to 25% of patients with advanced HIV infection and disseminated coccidioidomycosis.

C. Fiberoptic Bronchoscopy—For patients with PCP (see next), fiberoptic bronchoscopy with bronchoalveolar lavage is diagnostic, and lavage may be useful for the diagnosis of tuberculosis and nontuberculous mycobacterial infections.

D. Empirical Therapy—If the patient is critically ill, empirical therapy is indicated before results of laboratory studies are available. Because bacterial pneumonia caused by *Streptococcus pneumoniae* is the most common infection leading to focal or diffuse infiltrates, antibacterial antibiotics

should be initiated. For ICU patients, recommended treatment includes a third-generation cephalosporin plus a macrolide such as azithromycin. Antipseudomonal therapy should be initiated in the at-risk patient.

The decision to start empirical treatment for PCP depends on clinical suspicion. Patients likely to have PCP have more severe hypoxemia, may have diffuse lung disease (although x-ray abnormalities vary widely), often have elevated serum LDH, and have a CD4 lymphocyte count under 200/ μ L. Treatment should consist of trimethoprim-sulfamethoxazole unless contraindicated; high-dose corticosteroids are indicated if severe hypoxemia is present (see below).

▶ *P. jiroveci* Pneumonia

ESSENTIALS OF DIAGNOSIS

- ▶ Nonproductive cough, fever, anorexia, progressive dyspnea.
- ▶ Hypoxemia with increased $P(A-a)O_2$.
- ▶ Focal, diffuse, or patchy infiltrates on chest x-ray; on occasion, the chest x-ray appears normal.
- ▶ Finding of *P. jiroveci* on bronchoalveolar lavage.

General Considerations

Despite the widespread use of primary and secondary prophylaxis, PCP remains the most common pulmonary infection associated with respiratory failure in persons with AIDS, usually occurring in patients with previously undiagnosed HIV infection or in patients who are nonadherent to prophylaxis and HAART. Early recognition and treatment, as well as the use of adjunctive corticosteroid therapy, have resulted in improved survival and less morbidity for patients with moderate to severe disease.

Decreased survival of patients with PCP and respiratory failure has been associated with severity of illness at hospital admission and prior use of PCP prophylaxis. The paradox of decreased survival in the setting of PCP prophylaxis has been attributed to more severe immunosuppression leading to failure of prophylaxis or potential resistance to antibiotics.

Clinical Features

A. Symptoms and Signs—Common symptoms include nonproductive cough, fever, anorexia, and progressive dyspnea. Physical examination may reveal fever, tachypnea, cyanosis, and oral thrush, with rales and decreased basilar breath sounds on lung examination.

B. Laboratory Findings—The white blood cell count is typically low or normal. The CD4 lymphocyte count is typically less than 200/ μ L. Patients have moderate to severe hypoxemia

with increased $P(A-a)O_2$. Serum LDH is elevated in nearly all patients.

C. Imaging Studies—The chest radiograph typically demonstrates bilateral interstitial or alveolar infiltrates, although virtually every radiographic pattern has been described. Pleural effusions and mediastinal or hilar adenopathy typically are absent unless a second pulmonary process is present.

D. Fiberoptic Bronchoscopy with Bronchoalveolar Lavage—The diagnosis is confirmed by identifying the organism using modified Giemsa or methenamine silver stains or immunofluorescent antibody. In most patients, the diagnosis is made by bronchoalveolar lavage using fiberoptic bronchoscopy, which has a sensitivity of 95–98%. Some patients may be too hypoxemic to undergo fiberoptic bronchoscopy; in such cases, sputum obtained by suctioning from the endotracheal tube or by expectoration may be stained and examined for *P. jiroveci*, but the sensitivity is considerably lower.

Differential Diagnosis

In a patient with known or suspected HIV infection and respiratory failure with pulmonary infiltrates consistent with PCP, the differential diagnosis includes bacterial and viral pneumonia, tuberculosis, other opportunistic infections (including fungal pneumonia), congestive heart failure with pulmonary edema, and acute respiratory distress syndrome (ARDS).

Treatment

Patients with hypoxemic respiratory failure from PCP generally are managed in the same way as patients with ARDS. Patients will require oxygen supplementation and may require endotracheal intubation and mechanical ventilation.

A. Antipneumocystis Therapy—

1. TRIMETHOPRIM-SULFAMETHOXAZOLE (TMP-SMX)—This agent remains the treatment of choice for patients with PCP. It is given as a fixed combination that delivers 15 mg/kg per day of trimethoprim in divided doses every 8 hours intravenously or orally for 21 days. Side effects include fever, a spectrum of exfoliative skin eruptions, eosinophilia, leukopenia, thrombocytopenia, nausea, vomiting, and hepatitis. The dose must be decreased if the creatinine clearance is less than 40 mL/min.

2. PENTAMIDINE ISETHIONATE—This drug may be given to patients with moderate to severe PCP who are unable to take TMP-SMX because of serious allergic reactions. It is administered a dose of 4 mg/kg per day intravenously for 21 days. However, serious side effects including renal insufficiency, pancreatitis, and orthostatic hypotension limit its utility. Hypoglycemia may occur during or after treatment

and is exacerbated by renal insufficiency. Serum glucose should be monitored at least every 8 hours. In some patients, hypoglycemia may be followed by protracted hyperglycemia requiring insulin. If any of these side effects occur, an alternative treatment must be chosen.

3. CLINDAMYCIN AND PRIMAQUINE—Clindamycin, 600 mg intravenously or 300–450 mg orally every 6 hours, can be given with primaquine, 30 mg base orally once daily, for 21 days. Side effects include pseudomembranous (*Clostridium difficile*) colitis, rash, hemolytic anemia in persons deficient in glucose-6-phosphate dehydrogenase, liver function test abnormalities, and methemoglobinemia.

4. DAPSONE AND TRIMETHOPRIM—Dapsone is given in a dosage of 100 mg orally once daily along with trimethoprim, 15 mg/kg per day in three or four divided doses, for 21 days. Side effects include hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency, methemoglobinemia, liver function test abnormalities, rash, fever, leukopenia, and thrombocytopenia.

5. ATOVAQUONE—Atovaquone may be administered in patients allergic to or unable to tolerate the preceding regimens. It is given as a suspension of 750 mg twice daily by oral administration for 21 days.

B. Corticosteroids—In patients with PCP who present with respiratory failure of moderate to severe degree, adjunctive therapy with corticosteroids is indicated. Corticosteroids reduce the incidence of severe respiratory failure and decrease mortality in patients with severe hypoxemia. Candidates for corticosteroids have a $P(A-a)O_2$ greater than 35 mm Hg or a PaO_2 less than 70 mm Hg. Such patients should be given prednisone, 40 mg orally twice daily for 5 days, 40 mg orally once daily for 5 days, and then 20 mg orally once daily for the remainder of the 21-day course of treatment. To achieve maximum benefit, prednisone should be started within 72 hours of beginning therapy. In patients unable to take oral medications, intravenous methylprednisolone can be substituted using the same dosage regimen.

C. Follow-up Care—Response to therapy typically occurs within 2–7 days, marked by improvement in gas exchange and decrease in fever. For patients who initially respond to therapy and then develop fever, a search for another source of infection should be undertaken. Drug fever, often caused by TMP-SMX, should be considered when no other pathogens are recovered and the patient is improving clinically.

Twenty-one days of antipneumocystis therapy should be followed by secondary prophylaxis with TMP-SMX, one tablet (double-strength) orally three times per week. In patients unable to tolerate TMP-SMZ, acceptable alternative prophylactic regimens include dapsone, atovaquone, and other agents.

► Pulmonary Infection with *Mycobacterium Tuberculosis*

ESSENTIALS OF DIAGNOSIS

- Fever, night sweats, weight loss, cough, hemoptysis.
- Chest radiograph showing focal infiltrates with cavitation (CD4 lymphocytes $>500/\mu\text{L}$); focal or generalized infiltrates (CD4 lymphocytes $<500/\mu\text{L}$); hilar and mediastinal lymphadenopathy.
- Positive sputum for acid-fast bacilli or positive culture for *M. tuberculosis*. Positive acid-fast stain or culture from nonpulmonary site.

General Considerations

Tuberculosis (TB) is common in HIV-infected individuals and in some cases may be associated with respiratory failure or multiorgan dysfunction severe enough to warrant ICU admission. TB occurs at all stages of HIV disease, even when cell-mediated immunity is relatively intact, as measured by CD4 count. Both primary infection and reactivation occur with great frequency in this highly susceptible population. The clinical presentation of tuberculosis in the presence of underlying HIV infection may be atypical. Rather than the cavitary lesions or upper lobe and apical disease usually seen in immunocompetent, HIV-negative hosts, chest x-ray findings may include infiltrates located in the middle and lower lung zones, interstitial infiltrates, and hilar adenopathy; up to 25% of patients may have a normal chest x-ray. Disseminated tuberculosis with lymphatic, bone marrow, and liver involvement is significantly more common in persons with HIV infection than in those with normal immune function. Mycobacterial blood cultures are positive much more frequently in HIV-infected patients. The tuberculin skin test (PPD) is unreliable as a marker of tuberculous infection because of its low sensitivity in HIV-infected patients.

Clinical Features

A. Symptoms and Signs—Patients with tuberculosis and HIV infection may present with fever, productive cough, shortness of breath, night sweats, lymphadenopathy, and weight loss similar to that observed in non-HIV-infected patients. Alternatively, symptoms may be minimal. Physical examination findings include fever, loss of lean body mass, and abnormal lung findings; some patients may have lymphadenopathy and/or hepatosplenomegaly.

B. Laboratory Findings—Liver function tests may be abnormal in patients with tuberculosis, especially with disseminated disease; elevated alkaline phosphatase, LDH, and γ -glutamyl transpeptidase suggest granulomatous hepatitis. Anemia is frequently present, and pancytopenia may be present if there is bone marrow involvement.

Smears for acid-fast bacilli from sputum and culture of sputum for mycobacteria are the key to diagnosis. Three or more sputum samples should be submitted for stain and culture. If the patient is unable to produce adequate sputum for sampling, sputum can be induced by administering aerosolized hypertonic saline. Negative acid-fast smears do not exclude tuberculosis; in select patients, empirical treatment should be continued until cultures are negative. In patients undergoing fiberoptic bronchoscopy with bronchoalveolar lavage for diagnosis of PCP, fluid also should be sent for acid-fast staining and mycobacterial culture, even if prior sputum specimens have been negative. Urine cultures and blood isolators for mycobacteria may be positive. Drug susceptibility studies should be done on all *M. tuberculosis* isolates because drug-resistant strains are not uncommon in many areas.

In patients suspected of having disseminated tuberculosis, bone marrow or liver biopsy, punch biopsy of suspicious skin lesions, and in some cases lumbar puncture may assist in making the diagnosis.

C. Imaging Studies—Virtually any chest x-ray pattern can be seen in tuberculosis with HIV infection, from classic apical fibronodular infiltrates with cavitation to normal lung parenchyma. A radiographic pattern consistent with primary tuberculous infection is seen more often with HIV infection, consisting of middle to lower lung field infiltrates, sometimes with hilar adenopathy. Disseminated tuberculous infection may be accompanied by a miliary pattern on chest x-ray.

Treatment

Patients with HIV infection and tuberculosis with susceptible strains of *M. tuberculosis* usually are treated successfully with conventional antituberculous drug regimens. The ideal duration of therapy is not known. The initial use of rifampin, isoniazid, ethambutol, and pyrazinamide is recommended if organisms are likely to be sensitive. If multidrug-resistant tuberculosis is suspected, five- and six-drug regimens should be considered. Absorption of antituberculous drugs may be impaired in critically ill patients, and administration of parenteral agents may be necessary. Liver aminotransferase levels should be monitored because isoniazid, rifampin, and pyrazinamide are hepatotoxic. Tuberculosis and HIV coinfection is an indication for instituting directly observed therapy (DOT) of tuberculosis.

A. Isoniazid, Rifampin, Pyrazinamide, and Ethambutol—

This combination of drugs is highly effective against susceptible tuberculous organisms. The duration of treatment in the HIV patient consists of 2 months of all four drugs followed by 18 weeks of isoniazid and rifampin. Isoniazid is given in a dosage of 300 mg orally or intramuscularly daily. Common side effects include hepatitis, peripheral neuropathy from pyridoxine deficiency, alteration in sensorium, fever, and rash. Patients receiving isoniazid should be given pyridoxine, 50 mg daily.

The usual dose of rifampin is 600 mg/day orally or intravenously. Side effects include hepatitis, discoloration of urine, rash, fever, and alteration in other drug levels (eg, oral contraceptives, warfarin, corticosteroids, digoxin, and methadone). Pyrazinamide is given as 15 mg/kg orally daily. Elevation of aminotransferases, hepatitis, hyperuricemia, and arthralgias may be seen as side effects of this drug. Ethambutol is given orally at a dosage of 15 mg/kg per day. Ethambutol is generally well tolerated, but loss of color vision or visual acuity may occur.

Rifampin is contraindicated in patients receiving PIs, such as indinavir and ritonavir, and some NNRTIs, such as nevirapine and delavirdine, because of significant drug interactions. Rifabutin may be substituted for rifampin to minimize drug interactions with PIs and NNRTIs. Dose modifications of antiretrovirals and rifabutin may be needed.

B. Other Antituberculous Drugs—Patients in the ICU who cannot tolerate or absorb oral medications may be given intravenous isoniazid and rifampin; intravenous amikacin and a fluoroquinolone should be added to optimize antimycobacterial therapy. The usual dose for amikacin is 7.5 mg/kg every 12 hours intravenously or intramuscularly. Serum levels should be monitored to avoid nephrotoxicity. Side effects may include renal failure, ototoxicity, and rarely, neuromuscular blockade. Dose adjustment for impaired renal function is necessary. Fluoroquinolone dosing varies depending on which agent is selected. Common side effects include GI intolerance, rash, and altered sensorium. The dose is decreased in patients with renal function abnormalities.

▶ Bacterial Pneumonia

At all stages of HIV disease, bacterial pathogens are the most common cause of community-acquired pneumonia. In fact, bacterial pneumonia occurs approximately 25-fold more frequently among HIV-infected adults than in the general community, with an inverse relationship between CD4 counts and incidence. Among the bacterial pathogens, the pneumococcus is particularly important: Infection with *S. pneumoniae* occurs approximately 100 times more frequently than in the HIV-uninfected host, with increased incidence in the setting of smoking and low CD4 counts. Recurrence rates for pneumococcal pneumonia are high, ranging from 6–24%. The presentation of pneumococcal pneumonia in the HIV-infected patient is similar to that in the immunocompetent host, with abrupt onset fever, chills, cough and pleuritic chest pain. *S. pneumoniae* bacteremia in the setting of HIV infection occurs in up to 90% of patients and may be the key to diagnosing a community-acquired pneumonia because the sensitivity of sputum Gram stain and culture is 50% or less. Radiographic findings of pneumococcal pneumonia consist of the characteristic lobar or bronchopneumonia. *Haemophilus influenzae*, *Legionella pneumophila*, and *Mycoplasma pneumoniae* are also seen in the setting of HIV infection. Hospitalized or neutropenic patients are at

increased risk for infection with *Staphylococcus aureus*, including methicillin-resistant *S. aureus* (MRSA), and gram-negative aerobic bacilli, including *Pseudomonas aeruginosa*, especially in the ICU setting. Bacterial infections may occur alone or, less commonly, may complicate an opportunistic infectious process such as PCP. Unusual bacteria may be responsible for pneumonia, including *Rhodococcus equi*, an aerobic intracellular gram-positive coccobacillus causing cavitary lung disease.

For patients admitted to the ICU with community-acquired pneumonia, recommended initial therapy includes a third-generation cephalosporin (eg, ceftriaxone, 2 g intravenously once daily) plus azithromycin, 500 mg intravenously once daily, unless there is suspicion of *Pseudomonas* infection (substitute a β -lactam with antipseudomonal efficacy such as ceftazidime or piperacillin-tazobactam).

OTHER INFECTIOUS CAUSES OF PNEUMONIA AND RESPIRATORY FAILURE

► Fungal Pneumonia

Fungal pneumonias should be considered in patients with pulmonary infiltrates, negative cultures and smears for mycobacteria, negative stains and cultures for bacteria, and clinical progression with antibacterial treatment. Fungal infection also may present as a disseminated process with multiorgan involvement. Tissue biopsies and serologic tests are most helpful because growth of fungal pathogens in culture is slow, sometimes on the order of weeks.

A. Cryptococcal Pneumonia—Since advanced HIV disease is the primary risk factor for cryptococcal infections in most of the world, the incidence of cryptococcal infections has declined significantly in countries with access to HAART. The lung is the most common portal of entry for the organism, after which asymptomatic colonization or life-threatening

pneumonia can occur. In the presence of an advanced immunocompromised state, cryptococcal pneumonia may progress rapidly, with dissemination from the lung to bloodstream, skin, and/or meninges. Most patients with AIDS and cryptococcal pneumonia are symptomatic, with fever, malaise, cough, dyspnea, and weight loss. Radiographic findings include diffuse interstitial opacities, focal infiltrates, alveolar infiltrates, pleural effusions, and cavitary lesions. Diagnosis is made by isolation of *Cryptococcus neoformans* from sputum, bronchoalveolar lavage fluid, or pleural fluid or by the presence of a positive cryptococcal antigen in bronchoalveolar lavage fluid. Lumbar puncture must be performed to rule out CNS cryptococcal infection even if patients are asymptomatic because concomitant CNS involvement is present in approximately 90% of patients with AIDS and cryptococcal pneumonia. The serum cryptococcal antigen is an insensitive test in the absence of disseminated disease and may be negative in the patient with isolated cryptococcal pneumonia. Patients with respiratory failure attributed to cryptococcal pneumonia should undergo evaluation for PCP as well; in some cases, both pathogens may be present. Mortality for those with respiratory failure from cryptococcal pneumonia is very high despite aggressive treatment.

Although mild to moderate cryptococcal pneumonia alone can be treated with fluconazole, HIV-infected patients with severe cryptococcal pneumonia admitted to the ICU should receive amphotericin B, 0.7–1 mg/kg per day intravenously, with or without flucytosine, 100 mg/kg daily, until symptoms are controlled, followed by fluconazole, 200–400 mg/day indefinitely or until immune restoration with HAART has been well established. This regimen is optimal for CNS disease as well, except that amphotericin B and flucytosine are given for at least 2 weeks.

B. Other Fungal Pneumonias—Endemic mycoses caused by such fungi as *Histoplasma capsulatum* and *Coccidioides immitis* usually present in patients with advanced immunodeficiency as a disseminated process of which pulmonary disease is one component. Fever, cough, and progressive dyspnea are common and may be accompanied by signs and symptoms of sepsis or other organ system involvement.

Chronic or subacute pneumonia caused by *C. immitis* can occur in up to 10% of AIDS patients living in endemic areas such as Arizona and the San Joaquin Valley of California. However, use of HAART has been associated with a decline in the incidence of HIV-associated coccidioidomycosis. Any radiographic findings may be present on chest x-ray, including cavities, interstitial or lobar infiltrates, nodules, and pleural effusions. Disseminated coccidioidomycosis is associated with advanced immunosuppression. Sputum, bronchoalveolar lavage fluid, and/or bronchial washings should be sent for fungal stains and culture. Complement fixation titers greater than 1:16 are diagnostic of disseminated coccidioidomycosis but may be insensitive in HIV-infected patients; up to 25% of patients will have no detectable anticoccidioidal antibodies. Intravenous amphotericin B, 0.5–1 mg/kg per day, should be

used for initial treatment of pulmonary disease to a total dose of 30–40 mg/kg, followed by fluconazole at 200 mg/day orally. Patients with suspected dissemination should undergo lumbar puncture to look for meningitis because high-dose fluconazole is the preferred treatment for meningitis caused by *C. immitis*.

Pneumonia owing to *Histoplasma* was seen in up to 15% of AIDS patients living in endemic areas in the pre-HAART era, although it is significantly less common today. Dissemination occurs in patients with advanced disease and low CD4 lymphocyte counts. Chest x-ray findings are non-specific, with diffuse infiltrates, nodules, focal infiltrates, cavities, and hilar adenopathy noted. Urine *Histoplasma* polysaccharide antigen assay is moderately sensitive (50–70%) in cases of pneumonia, with a sensitivity of 90% in the setting of disseminated disease. *Histoplasma* serum and bronchoalveolar lavage antigen, serologic studies, the presence of intracellular organisms on peripheral blood smear (30% sensitivity for disseminated *Histoplasma* infection), and tissue biopsy may be helpful in diagnosis. Cultures of blood, respiratory tract secretions, bone marrow, or biopsy specimens are positive in 85% of patients but require 2–4 weeks to grow. In severe or disseminated disease for patients in the ICU, intravenous amphotericin B should be given initially (for 3–14 days depending on response), followed by itraconazole, 200 mg orally twice daily indefinitely.

Invasive and obstructing aspergillosis has been described rarely in patients with HIV infection and advanced immunodeficiency. Factors predisposing to *Aspergillus* infection include corticosteroid use, neutropenia, pneumonia caused by other pathogens, marijuana smoking, and use of broad-spectrum antibiotics. Chest x-ray abnormalities may include focal infiltrates, cavities, pleural-based densities, or diffuse infiltrates. Because *Aspergillus* organisms may colonize patients without causing infection, sputum culture and staining may be unreliable. A tissue biopsy showing *Aspergillus* in tissue or invading blood vessels is the most reliable diagnostic test. Voriconazole is the treatment of choice for invasive aspergillosis, at a dose of 6 mg/kg intravenous every 12 hours × 2 doses, followed by 4 mg/kg intravenous every 12 hours for at least 1 week, then 200 mg bid. Alternative agents include intravenous amphotericin B, as well as itraconazole for prolonged treatment in milder cases if there has been a good clinical response to initial treatment.

► Kaposi Sarcoma

The incidence of Kaposi sarcoma (KS) has declined dramatically in the HAART era, with a concomitant decline in the incidence of pulmonary KS. Studies from the pre- and early HAART era described an incidence of pulmonary involvement in approximately 35% of patients with HIV-associated KS, with a higher proportion found at autopsy. Clinically symptomatic pulmonary KS is seen most often with advanced HIV disease and can progress to respiratory failure. Most but not all pulmonary KS occurs in the presence of

concomitant mucocutaneous lesions. Patients typically present with nonproductive cough, dyspnea, and sometimes fever, with chest pain and hemoptysis less commonly reported. Chest x-ray abnormalities typically include bilateral middle-lower lung opacities with a central or perihilar distribution; infiltrates may be interstitial or nodular or may appear as linear perihilar densities. Kerley B lines, intrathoracic adenopathy, and pleural effusions are seen less commonly. Abnormal gas exchange, hemoptysis, and superinfection with bacteria may occur. The diagnosis of pulmonary KS is usually established by fiberoptic bronchoscopy. Bronchoalveolar lavage should be performed to rule out other opportunistic pathogens because pulmonary KS is often seen in conjunction with PCP or other opportunistic infections. Response of KS to chemotherapy or radiation therapy generally was poor in the pre-HAART era; however, potent antiretroviral therapy in conjunction with daunorubicin, liposomal doxorubicin, or paclitaxel may arrest or even reverse the course of pulmonary KS.

► Sepsis In HIV-Infected Patients

ESSENTIALS OF DIAGNOSIS

- Fever or hypothermia, hypotension, hyperventilation, change in mental status.
- Complications of organ failure, such as alteration in gas exchange, renal insufficiency or failure, lactic acidosis, disseminated intravascular coagulation, or liver failure.
- Bacteremia, fungemia, or features arousing a high clinical suspicion of infection.
- Previous evidence or suspicion of bacterial, fungal, or mycobacterial infection may be helpful in differential diagnosis.

General Considerations

Sepsis was discussed in Chapter 15. Important considerations in patients with HIV infection include the potential for opportunistic and/or unusual microbial organisms to be involved and differences in diagnostic strategy and empirical therapy.

Because HIV infection is associated with disruption of both cellular and humoral immunity, disseminated infection

occurs in a substantial proportion of patients, with the rate of dissemination proportionate to the degree of immunosuppression. Furthermore, phagocytic cell dysfunction and skin and mucosal membrane disruption increase the likelihood of organism translocation. Compared with age-matched cohorts, bacteremia is more commonly seen in HIV-infected patients with an identified focal bacterial infection. In addition, *M. tuberculosis* is more likely to disseminate to multiple organs and causes active disease more often in patients with HIV infection and immunosuppression. Treatment with various medications used to treat HIV and its complications, including zidovudine, trimethoprim-sulfamethoxazole, pyrimethamine, and valganciclovir—and even HIV itself—may cause neutropenia.

A. Bacterial Sepsis—Most of these infections are associated with an identifiable source, such as the lungs, GI tract, urinary tract, CNS, or an intravascular catheter. Clinically silent sites of bacterial infection include the sinuses, prostate, biliary tract, skin and soft tissues, endocardium, and GI tract. The most common gram-positive organism responsible for bacteremia is *S. pneumoniae*, whereas *Escherichia coli* is the most common gram-negative organism found in blood, suggesting that common infections such as pneumonia and urinary tract infection are still the most likely sources of bacterial infection. Neutropenia should alert one to the possible presence of *P. aeruginosa* and staphylococci, both community- and hospital-acquired. In particular, *P. aeruginosa* infection is reported to be increasing in incidence, with risk factors including neutropenia, antibiotic use, corticosteroid use, and low CD4 lymphocyte count.

Infection with MRSA is increasingly common among patients with HIV infection, typically causing multiple skin and soft tissue abscesses but sometimes with accompanying bacteremia and/or sepsis. Community-acquired strains of MRSA are more susceptible to antibiotics than their nosocomial counterparts, with sensitivity to vancomycin, TMP-SMX, and in some cases clindamycin. Sepsis may be caused by enteric diarrhea-associated pathogens and *Listeria*.

B. Disseminated Mycobacterial Infections—A subacute course of fever, weight loss, night sweats, cough, headache, or lymphadenopathy suggests a fungal or mycobacterial pathogen. The initial symptoms are often nonspecific and the clinical picture benign, but patients may present late, with a clinical picture consistent with sepsis. Findings suggestive of disseminated fungal or mycobacterial infections include hepatosplenomegaly, lymphadenopathy, and the presence of skin or oral lesions. There may be laboratory findings of pancytopenia (bone marrow infiltration) and elevated LDH and alkaline phosphatase levels.

Tuberculosis can present as a widely disseminated process. The clinical picture is characterized by weight loss, anorexia, and fever and sometimes by cough, dyspnea, and night sweats. Disseminated tuberculosis may be associated with tuberculous meningitis, necessitating a lumbar puncture

if clinical suspicion of meningeal involvement exists. Disseminated MAC infection is a late sequela of HIV infection and is seen in patients with CD4 lymphocyte counts of less than 50/ μ L. The clinical picture is similar to that of late-stage tuberculosis and is also associated with severe diarrhea. The course is protracted, and the diagnosis is often made by demonstration of the organisms in the blood using the lysis-centrifugation method or on tissue biopsy. MAC grows in approximately 3–6 weeks and can be identified using a DNA-specific probe.

C. Disseminated Fungal Infections—*C. neoformans*, *C. immitis*, and *H. capsulatum* are primarily acquired through the respiratory tract and are hematogenously disseminated to multiple organs. Because of impaired cellular immunity, infections with these organisms may progress rapidly in HIV-infected persons. Progressive disseminated histoplasmosis is characterized by an initial mild course with minimal symptoms of 4–5 weeks' duration, followed by a syndrome of hypotension, disseminated intravascular coagulation, renal insufficiency, severe pancytopenia, abnormal liver function tests (especially LDH), and respiratory failure. CNS involvement is common. Intracellular organisms may be seen on the peripheral blood smear. Early initiation of amphotericin B therapy is critical while awaiting diagnostic studies. Disseminated coccidioides infection presents in a similar manner. Diagnosis and treatment of coccidioidomycosis are discussed in the section on pulmonary infection in HIV-infected patients.

Although oral and esophageal candidiasis occurs with great frequency in patients with symptomatic HIV infection, disseminated candidiasis is rare except in the usual settings of intravascular catheters, broad-spectrum antibiotics, or intravenous hyperalimentation.

Clinical Features

A. Symptoms and Signs—In addition to features that may localize the primary site of infection, additional information useful for planning empirical therapy include the travel history, tuberculin skin test status, history of exposure to or previous infection with mycobacteria or endemic fungi, and recent use of antibiotics. Besides the primary infection site, examination should focus on potential sites of dissemination, including a careful funduscopic examination, inspection of skin and mucous membranes, and a search for lymphadenopathy and hepatosplenomegaly.

B. Laboratory and Imaging Studies—This should include initially a complete blood count, peripheral blood smear (intracellular *Histoplasma* organisms may be seen occasionally), blood cultures (two sets each for aerobic and anaerobic bacteria); liver function tests: LDH; urinalysis; chest x-ray; and creatine kinase.

Any potential site of infection should be cultured for suspected pathogens. Special culture techniques, such as urine culture after prostatic massage or aspiration of skin

or soft tissue fluid collections, may be indicated. Imaging of specific sites may include CT scan, ultrasonography, MRI, or x-rays.

Septic patients with HIV infection and no obvious site of infection require more generalized investigation. Urine culture for fungi and mycobacteria, blood cultures using the lysis-centrifugation method for mycobacteria and fungi, serum antigen for *C. neoformans*, sputum for acid-fast smear and mycobacterial culture, and urine *Histoplasma* antigen tests should be considered in patients with relevant exposure histories. Patients with sepsis may have subtle CNS, pulmonary, abdominal, soft tissue, or mucosal sources of infection. In these patients, CT scan of the head, abdomen, and pelvis may be indicated. Lumbar puncture should be performed in any HIV patient with unexplained sepsis or fever with or without alteration in mental status or abnormal neurologic findings. Cryptococcal meningitis and fungal and mycobacterial infections of the CNS may be associated with minimal symptoms and physical findings.

Biopsy of suspicious skin or mucosal lesions, lymph nodes, spleen, liver, or bone marrow should be performed expeditiously if results of other studies are unrevealing. Special stains for microorganisms are necessary along with traditional histologic examinations. Cultures from biopsy specimens for many potential organisms may take 4–6 weeks to yield results.

Treatment

Patients with sepsis accompanied by hypotension, altered mental status, severe localized infection, or any organ system dysfunction should receive immediate antimicrobial therapy after appropriate cultures have been obtained. Empirical antibiotic treatment should be directed at possible bacterial pathogens; suspicion of fungal or mycobacterial dissemination should prompt initiation of appropriate targeted therapy. The likelihood of bacterial infection is increased in patients with either leukocytosis or neutropenia, those with acute onset of chills and fever, those who have an identifiable site of infection, and those who have higher CD4 lymphocyte counts. Patients with very low CD4 lymphocyte counts are susceptible to a wide variety of infections, including bacteria, fungi, and mycobacteria. In such patients, antifungal and antimycobacterial agents should be considered early; in addition, these antimicrobial regimens also should be considered in any patient who is deteriorating clinically on antibacterial therapy alone. Filgrastim (G-CSF) is indicated in patients with significant neutropenia (<500–750 cells/ μ L).

Patients with disseminated tuberculosis can be treated initially with regimens used for pulmonary tuberculosis (see above). Treatment of MAC requires administration of a macrolide such as clarithromycin (500 mg orally twice daily) in conjunction with ethambutol (15 mg/kg per day orally) with or without rifampin or rifabutin (600 or 300 mg/day, respectively). If intravenous therapy is necessary, azithromycin plus amikacin or ciprofloxacin should be considered.

► CNS Disorders In HIV-Infected Patients

HIV is a neurotropic virus; as a result, infection of the central and peripheral nervous systems is likely to occur very early in the disease course. However, severe CNS manifestations occur late in the course of HIV disease, when CD4 counts are very low. Neurologic disorders may result from autoimmune phenomena (eg, vasculitis and demyelinating inflammatory polyneuropathy), immunosuppression (eg, opportunistic infections and CNS lymphoma), and direct effects of HIV (eg, meningitis and dementia). In the ICU patient with HIV disease, neurologic problems are the third most common reason for admission. Severe CNS problems leading to ICU admission include delirium and coma, intracranial mass lesions from primary CNS lymphoma or toxoplasmosis, meningitis (eg, bacterial, cryptococcal, tuberculous, aseptic, or viral), status epilepticus, and respiratory failure owing to severe neuropathy or myopathy.

Focal CNS disorders include cerebral toxoplasmosis, primary CNS lymphoma (PCNS-L), and progressive multifocal leukoencephalopathy (PML). Mass lesions can present in a variety of ways, including symptomatic neurologic deficits, altered mental status, or change in personality. In conjunction with the clinical presentation, imaging studies sometimes may be able to distinguish infection, malignancy, or an inflammatory process. If a lumbar puncture can be performed safely, CSF should be submitted for cytology, Epstein-Barr virus (EBV) polymerase chain reaction (PCR), and JC virus PCR, which may assist in the diagnosis of PCNS-L and PML. Empirical therapy for toxoplasmosis should be initiated in critically ill patients with focal ring-enhancing brain lesions pending results of serum *Toxoplasma* titers. Patients with mass lesions and increased intracranial pressure may require endotracheal intubation, ventilatory support, corticosteroids to decrease cerebral edema, antiseizure prophylaxis, and frequent neurologic evaluation.

▶ Cryptococcal Meningitis in HIV-Infected Patients

Meningitis caused by *C. neoformans* is unusual in immunocompetent patients but may occur in the presence of advanced immunosuppression caused by HIV. Patients often present with fever and headache, sometimes in conjunction with nonspecific neurologic findings, including weakness, fatigue, dizziness, lack of alertness, visual changes, and seizures. Importantly, HIV patients with cryptococcal meningitis have little or no meningeal irritation, and meningismus is rare. Thus a lumbar puncture is warranted in the patient with advanced HIV disease and any clinical suspicion of a CNS process. CSF may be completely normal or may reveal slightly elevated protein, decreased glucose, and/or a mild lymphocytic response (up to 100/ μ L). In contrast to these mild abnormalities, India ink preparations are positive in 40–70%; positive cultures are the “gold standard” of diagnosis. CSF cryptococcal antigen is 95–98% sensitive and specific. Opening pressure always should be measured because it has important prognostic significance. For example, elevated opening pressure of the cerebrospinal fluid (>250 mm H₂O) correlates with high cryptococcal polysaccharide antigen, poor clinical response, and decreased short-term survival. With treatment, failure of CSF opening pressure to fall has been associated with poor outcome. Patients with cryptococcal meningitis should be treated with amphotericin B,

0.7–1 mg/kg per day intravenously, with flucytosine, 100 mg/kg daily orally for 2 weeks, followed by fluconazole 400 mg/day orally for 8–10 weeks, and then 200 mg/day as suppressive therapy. Elevated opening pressure should be managed with serial (daily) lumbar punctures to reduce pressure to less than 200 mm H₂O, or 50% of opening pressure.

Dermatologic Problems in the Intensive Care Unit

Kory J. Zipperstein, MD

28

The skin plays an important role in maintaining homeostasis. Thermoregulation, containment of body fluids, and protection of internal organs and structures from environmental insults are some of the vital functions performed by the skin. The skin is readily available for examination, so inspection often provides important clues to underlying diseases. This chapter focuses on the following categories of cutaneous disorders in the critically ill patient: common skin disorders, drug eruptions, purpura, life-threatening dermatoses, and cutaneous manifestations of infections.

COMMON SKIN DISORDERS

Contact dermatitis, miliaria (heat rash), and candidiasis are common in the critically ill patient as well as in the general population. These conditions, as well as graft-versus-host disease, are discussed in this section.

▶ Contact Dermatitis

ESSENTIALS OF DIAGNOSIS

- ▶ Circumscribed vesiculobullous eruptions on a base of erythema, confined to the area of the contact.
- ▶ Linear or sharply angulated pattern suggesting external contact.
- ▶ Pruritus may be a prominent symptom.
- ▶ History of exposure or contact in involved areas.

General Considerations

Contact dermatitis is an eczematous eruption caused by allergens or irritants coming in contact with the skin. The latter type is more common and results from exposure to irritating substances. Allergic contact dermatitis is a delayed

hypersensitivity reaction that affects individuals previously exposed to the antigen. Any substance applied to the skin, including tape, cleansing agents, and topical medications, may be the offender. Even some topical steroids contain sensitizing chemicals. An eruption that appears to improve but subsequently becomes worse may be due to a contact dermatitis from an applied medication. Occasionally, *Candida* or bacteria are a secondary invader.

Clinical Features

The morphology and distribution of the lesions, as well as the history of exposure, are diagnostic. Clinically, a circumscribed vesiculobullous eruption on a base of erythema, confined to the area of the contact, is the hallmark of contact dermatitis. Pruritus may be prominent. Contact dermatitis often has a characteristic configuration—for example, linear or sharply angulated patterns—that suggests that the eruption is caused by external rather than internal stimuli. Marked erythema, often with an eroded surface, suggests an irritant contact dermatitis. Constant exposure to moisture, urine, or fecal matter in areas such as the groin, perineum, the backs of bedridden patients, and around a colostomy site may produce such an eruption. The differential diagnosis of contact dermatitis includes other eczematous eruptions, impetigo, and candidiasis.

Treatment

The suspected irritant or allergen should be removed, and cool tap water compresses can be applied to alleviate discomfort and remove crusts. Apply a high-potency topical steroid such as fluocinonide cream twice daily to the affected area. Eruptions on the face or intertriginous areas should be treated with low- to medium-potency topical steroids. Antihistamines may be administered to control itching. The involved area should be observed for the development of secondary infection.

► Miliaria (Heat Rash)

ESSENTIALS OF DIAGNOSIS

- Seen in bedridden patients with fever.
- *Miliaria crystallina*: small, superficial, sweat-filled vesicles without surrounding inflammation, giving the appearance of clear dewdrops. The vesicles rupture with the slightest frictional trauma.
- *Miliaria rubra* (prickly heat): discrete, pruritic, erythematous papules and vesiculopustules, especially on the back, the antecubital and popliteal fossae, the chest, and other regions prone to sweating and occlusion.

General Considerations

Miliaria is a common disorder characterized by retention of sweat. It is seen in individuals exposed to warm or humid climates and in bedridden patients with fever and increased sweating. Increased moisture causes swelling of the stratum corneum, with resulting occlusion of eccrine sweat ducts and pores and eventual disruption of the sweat gland or duct. Leakage of sweat into the surrounding tissue produces the lesions of miliaria.

Clinical Features

Two forms of miliaria may be seen in the febrile patient. In *miliaria crystallina*, the sweat duct is occluded at the skin surface, producing small and very superficial sweat-filled vesicles without surrounding inflammation, giving the appearance of clear dewdrops. The vesicles rupture with the slightest frictional trauma. The eruption is asymptomatic and self-limited.

A second form, *miliaria rubra* (prickly heat), is due to occlusion of the intraepidermal portion of the sweat duct. The eruption consists of discrete, pruritic, erythematous papules and vesiculopustules. The erythema may be broad and diffuse depending on the degree of inflammation. Areas such as the backs of patients lying in bed, the antecubital and popliteal fossae, the chest, and other regions prone to sweating and occlusions are the sites of predilection; the palms and soles are spared.

Miliaria crystallina is clinically distinct. However, *miliaria rubra* may resemble folliculitis, which usually can be distinguished by its follicular papulopustules with penetrating hair shafts. A Gram stain or culture of the pustular contents may help in distinguishing the two conditions.

Treatment

The patient should be kept cool and dry. The pruritus associated with *miliaria rubra* may respond to oral antihistamines, such as hydroxyzine; medium-potency topical steroids, such as triamcinolone acetonide 0.1%; or a topical antipruritic lotion containing phenol and menthol (eg, Sarna) or pramoxine hydrochloride.

Haas N, Martens F, Henz BM: *Miliaria crystallina* in an intensive care setting. *Clin Exp Dermatol* 2004;29:32–4. [PMID: 14723716]

► Candidiasis (Moniliasis)

ESSENTIALS OF DIAGNOSIS

- Oral candidiasis: white curdlike plaques on the oral mucosa, including the tongue, with a red, macerated base and painful erosions.
- Easily ruptured pustules commonly found in the groin, between the buttocks, under overhanging abdominal folds or pendulous breasts, and in the umbilicus. If ruptured, a bright red base with a fringe of moist scale at the border and satellite pustules. Intense pruritus, irritation, and burning are common.
- In systemic candidiasis, may have acneiform pustules or petechiae that may progress to necrotic ulcerative lesions on the trunk and extremities.

General Considerations

The yeastlike fungus *Candida albicans* may cause infections limited to the skin and mucous membranes in addition to severe disseminated disease. Superficial candidiasis affects warm, moist areas such as the vagina (vulvovaginitis), the mouth (thrush), the uncircumcised penis (balanitis), the intertriginous areas, and sites around fistulas and artificial openings. Other predisposing factors include endocrine abnormalities (especially diabetes), malignancies, and immune-impaired states. Broad-spectrum antibiotics, pregnancy, incontinence, and skin maceration also may allow the yeast to become pathogenic.

Clinical Features

A. Symptoms and Signs—Oral candidiasis, or thrush, commonly consists of white curdlike plaques on the oral mucosa, including the tongue. The base of these plaques is red and macerated, and painful erosions also may be seen. Frequently, the infection will spread to the angles of the mouth (ie, angular cheilitis or perleche), resulting in maceration and fissuring of the oral commissures.

Candidiasis also tends to develop in intertriginous regions, including the groin, between the buttocks, under overhanging abdominal folds or pendulous breasts, and in the umbilicus. In these areas, pustules form but are easily ruptured by the friction of opposing surfaces, leaving a bright red base with a fringe of moist scale at the border. Coalescence of individual lesions results in spreading of the erythema with satellite pustules at the edges. Intense pruritus, irritation, and burning are common.

Oral candidiasis may spread to the esophagus or lungs. Candidal proctitis may develop with or without concurrent perianal infection. Systemic candidiasis is an opportunistic infection that tends to occur in patients with AIDS (rarely), hematologic malignancies, indwelling intravenous catheters, or malnutrition. Widespread dissemination may produce fever and proximal muscle tenderness, but any organ may be affected. Skin findings occur in about 10% of patients with candidal sepsis and consist of acneiform pustules or petechiae that may progress to necrotic ulcerative lesions on the trunk and extremities. Ophthalmoscopy may be helpful to look for candidal endophthalmitis. Concurrent superficial candidiasis may not be present and, by itself, is not helpful in establishing the diagnosis of systemic infection.

Superficial candidiasis is usually distinctive, but it may be confused with eczematous eruptions, dermatophytosis, and pus-producing bacterial skin infections (ie, pyodermas). Systemic candidiasis must be distinguished from other septicemias.

B. Laboratory Findings—For superficial candidiasis, a potassium hydroxide preparation demonstrating budding yeast or spores and pseudohyphae establishes the diagnosis. Culture on Sabouraud's agar shows growth in 3–4 days. The diagnosis of systemic candidiasis is made by discovery of microorganisms in cutaneous biopsy or a positive culture from fluids (eg, blood or cerebrospinal fluid) or tissues normally sterile for *candida* in a patient in whom clinical findings are compatible.

Treatment

A. Superficial Candidiasis—Moist areas should be kept clean and dry. If the skin is weeping, a wet compress should be applied for 10–20 minutes twice daily. Topical anticandidal creams (eg, clotrimazole) applied twice daily are effective. Adding a low-potency topical steroid to the anticandidal agent may reduce the inflammatory component and speed healing. Creams should be rubbed into the area gently but thoroughly. This should be followed with an anticandidal powder (eg, miconazole).

The patient should be evaluated for predisposing factors such as diabetes, fecal and urinary incontinence, and immunosuppression.

B. Systemic Candidiasis—Systemic candidiasis requires more aggressive therapy with systemic agents such as amphotericin B, fluconazole, itraconazole, or an echinocandin.

▶ Graft-Versus-Host Disease

ESSENTIALS OF DIAGNOSIS

- ▶ Prior allogeneic transplant containing immunologically competent cells, particularly bone marrow.
- ▶ Acute (days to weeks after transplant): pruritic macular and papular erythema, frequently progressing to a generalized erythroderma with bullae in severe cases.
- ▶ Chronic (50–100 days after transplant): widespread scaly plaques and desquamation. Cicatricial alopecia and dystrophic nails. In severe forms, sclerodermatous changes supervene.

General Considerations

Graft-versus-host disease occurs when tissues containing immunologically competent cells (eg, blood products, bone marrow, and solid organs) are introduced into an antigenically foreign person who is incapable of mounting an effective response to destroy the transplanted cells. It is the chief complication of allogeneic transplantation. Two forms are recognized: an acute form that can occur within days or as late as 1–2 months after transplantation and a chronic form that typically presents from 50–100 days or more after transplantation. Both forms are associated with significant morbidity and a high mortality rate.

Clinical Features

A. Symptoms and Signs—In acute graft-versus-host disease, the skin is the most commonly affected organ. The cutaneous eruption is characterized by a pruritic macular and papular erythema, often on the palms, soles, ears, and upper trunk, frequently progressing to a generalized erythroderma. In severe cases, bullae may develop, resembling the lesions of toxic epidermal necrolysis. The intestines, liver, and immune system are the other principally involved organs in acute graft-versus-host disease, with manifestations of diarrhea, hepatitis, and delayed immunologic recovery usually appearing after the skin eruption. The incidence of acute graft-versus-host disease ranges from 10–80%.

Chronic graft-versus-host disease may occur with or without preceding acute disease. However, any manifestation of acute graft-versus-host disease increases the chance of developing the chronic form. The incidence ranges from 30–60%. Cutaneous abnormalities occur in about 80% of

patients with chronic graft-versus-host disease and usually resemble lichen planus, with widespread scaly plaques and desquamation. Destruction of skin appendages leads to cicatricial alopecia and dystrophic nails. In severe forms, sclerodermatous changes supervene. This may remain localized but more often is generalized, producing induration, dyspigmentation, atrophy, telangiectases, and chronic skin ulcers. Vitiligo also may occur. Other target organs include the mucosal surfaces, the eyes, the hematopoietic and immune systems, the liver, and the lungs.

B. Laboratory Findings—Skin biopsy may be useful for confirming the diagnosis and grading the severity of acute cutaneous graft-versus-host disease but does not help in differentiating acute graft-versus-host disease from drug eruptions. Laboratory studies are not specific but are important for monitoring other organ system involvement, the severity of illness, and the response to treatment. Key values are total bilirubin and stool output, which, when evaluated with the extent of rash and stage of disease, are prognostic for early acute graft-versus-host disease. Circulating autoantibodies and elevated immunoglobulins may be present in chronic graft-versus-host disease.

Differential Diagnosis

The skin abnormalities in acute graft-versus-host disease may be confused with toxic epidermal necrolysis, drug-induced eruptions, infectious exanthems, and other causes of palmar erythema—including cirrhosis, pregnancy, and other hyperestrogen states—and chemotherapy-related acral erythema. Of these, drug eruptions may be the most difficult to exclude. The skin in chronic graft-versus-host disease may have the appearance of collagen-vascular diseases such as scleroderma, lupus erythematosus, and dermatomyositis. The diagnosis is suspected when a characteristic skin eruption occurs in the presence of typical involvement in other organs.

Treatment

Over the past several years, major efforts have been focused on prophylaxis against graft-versus-host disease using corticosteroids, cyclosporine, tacrolimus, mycophenolate mofetil, and methotrexate. Posttransfusion graft-versus-host disease can be prevented by irradiating blood products prior to transfusion. The immunosuppressive agents used for preventing graft-versus-host disease are also useful in treating established acute disease. Antithymocyte globulins (ATGs), monoclonal antibodies such as anti-interleukin 2 receptor (anti-IL2R), extracorporeal photopheresis, and psoralen with ultraviolet A (PUVA) may be useful in refractory cases.

Patients with localized chronic graft-versus-host disease do well without intervention. In generalized chronic disease, immunosuppressive agents are the mainstays of treatment. In addition, thalidomide, etretinate, extracorporeal photopheresis, PUVA, and hydroxychloroquine are sometimes used.

DRUG REACTIONS

A *drug reaction* is defined as any adverse response temporally related to the administration of a drug. Unwanted drug reactions have been estimated to occur in 15–30% of hospitalized patients. Cutaneous eruptions are among the most common adverse reactions to drugs, affecting 2–3% of hospitalized patients. Patients receiving many different drugs, such as the critically ill, are more likely to develop a drug eruption. The cutaneous manifestations vary in severity from mild and transient to the occasional development of severe systemic disease and even death, and often mimic other dermatoses, both clinically and histologically. In this section, drug eruptions with distinctive morphologic characteristics will be discussed, with emphasis on some common or life-threatening conditions encountered in critically ill patients. Special forms of drug reactions are also discussed in the sections on contact dermatitis, vasculitis, anticoagulant necrosis, and exfoliative erythroderma.

► Morbilliform, Urticarial, & Bullous Drug Eruptions

ESSENTIALS OF DIAGNOSIS

- Exposure to drugs commonly associated with drug eruptions, especially antibiotics, anticonvulsants, and blood products—but may be due to any medication.
- Onset of rash temporally related to drug administration, most often 5–10 days after exposure to a new drug or 1–2 days as a reaction to a drug to which the patient has been previously sensitized.
- Eruptions are usually symmetric and widespread, appear suddenly, and are not associated with systemic symptoms other than pruritus and mild fever.
- Improvement with cessation of drug supports diagnosis.

General Considerations

Adverse reactions that involve immune mechanisms, such as IgE-mediated urticaria and anaphylaxis, and cell-mediated contact reactions are true drug allergies. Reactions involving suspected immune mechanisms of unknown or mixed pathogenesis include the erythematous maculopapular or morbilliform rashes, bullous eruptions, erythema multiforme and Stevens-Johnson syndrome, and exfoliative erythrodermas. Nonimmune mechanisms and idiosyncratic reactions may lead to skin abnormalities via activation of effector pathways, direct toxicity, drug interactions, and overdosage. Drug-induced urticaria can be produced by several mechanisms: IgE-mediated anaphylactic hypersensitivity, immune complex-induced urticaria associated with serum sickness-like reactions (eg, urticaria, fever, hematuria, and arthralgias), non-immunologic release of mast cell mediators, and direct stimulation of the complement cascade. Unfortunately, the pathogenic mechanisms in the majority of drug eruptions remain unknown.

Clinical Features

A. History of Medications—When a drug eruption is suspected, it is important to document each medication currently being given or recently discontinued, the duration of its use, and the timing of drug exposure in relation to onset of the rash. As a rule, a recently started medication is more apt to be responsible for a drug eruption. Rarely will a medication that has been taken regularly for months to years stimulate the immune system to produce an eruption. It typically takes 5–10 days following exposure to a new drug—or 1–2 days after previous sensitization—for a drug eruption to appear. However, the rash may appear suddenly, as seen in urticaria and anaphylaxis. Prior history of an adverse reaction is the only clinically helpful risk factor.

B. Symptoms and Signs—The morphology of the rash and the reported frequency of adverse cutaneous reactions to a given drug may assist in identifying the offending agent. Some drugs are rarely associated with skin eruptions (Table 28–1). In the ICU setting, the most frequently implicated medications are antibiotics (eg, ampicillin, semisynthetic penicillins, and trimethoprim-sulfamethoxazole), anticonvulsants, and blood products. Certain drugs are more commonly associated with specific morphologic patterns, thus helping to identify the causative agent when multiple drug exposures have occurred (Table 28–2).

Morbilliform eruptions, or toxic erythemas, are the most common type of drug-induced rashes. These eruptions are usually symmetric, widespread, and consist of erythematous macules or papules that often become confluent. The rash typically begins on the trunk or in dependent areas; involvement of the palms and soles is variable. Pruritus and mild fever may accompany the reaction. Signs and symptoms usually regress within a few days after treatment is stopped. Exceptionally, the eruption fades despite continued intake of the drug.

Table 28–1. Drugs infrequently associated with adverse skin reactions.

Acetaminophen	Isosorbide dinitrate
Aminophylline	Laxatives
Antacid	Lidocaine
Atropine	Meperidine
Chloral hydrate	Morphine
Chloramphenicol	Multivitamins
Chlorpromazine	Nitroglycerin
Dexamethasone	Potassium iodide
Digoxin	Prednisolone
Diphenhydramine	Prednisone
Ferrous sulfate	Promethazine
Flurazepam	Propranolol
Folic acid	Spirolactone
Hydrochlorothiazide	Tetracycline
Hydroxyzine	Theophylline
Insulin	Thyroid hormones

Urticaria represents the second most common type of drug eruption. Urticaria is a vascular reaction of the skin characterized by wheals, which are pinkish, edematous, pruritic lesions that vary in size and shape. Individual lesions are transient, rarely lasting longer than 24 hours. Angioedema refers to urticarial swelling of deep dermal and subcutaneous tissues. Angioedema may involve the mucous membranes and may be life-threatening. Urticaria may occur alone or in conjunction with angioedema or anaphylaxis. The reaction is usually self-limited, lasting a few days to a few weeks.

Blisters may accompany a variety of drug-induced eruptions, including fixed-drug eruptions, erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis, vasculitis, and anticoagulant necrosis. Some drugs can produce blistering eruptions that are indistinguishable from primary bullous dermatoses such as bullous pemphigoid and porphyria cutanea tarda. Coma bullae—blisters over pressure areas—are seen in patients in coma from various causes, including narcotics, barbiturates, and carbon monoxide poisoning. Some bullous drug eruptions do not fit into any of these diagnostic classes.

C. Laboratory Findings—Laboratory tests are rarely helpful in diagnosis. Morbilliform reactions are occasionally associated with eosinophilia, antinuclear antibody titers are positive in drug-induced lupus, and there may be evidence of liver, kidney, and hematologic abnormalities in the phenytoin hypersensitivity syndrome (see next). Skin biopsy findings are usually nonspecific. Tissue eosinophils may help to differentiate drug eruptions from the dermatoses they mimic. However, a few specific eruptions, including coma bullae, fixed drug eruptions, erythema multiforme, toxic epidermal necrolysis, and vasculitis, may show distinctive histopathologic changes.

Table 28–2. Some morphologic patterns of drug eruptions and commonly incriminated agents.

Maculopapular eruptions	Toxic epidermal necrolysis and Stevens-Johnson syndrome
Oral hypoglycemic agents	Allopurinol
Thiazides	Penicillins
Enalapril	Chlormezanone
Allopurinol	Corticosteroids
Ampicillin	Felbamate
Barbiturates	Lamotrigine
Blood products	Phenylbutazone
Captopril	Valproic acid
Gentamicin	Barbiturates
Isoniazid	Carbamazepine
Phenytoin	Dapsone
Sulfonamides	Phenytoin
Urticaria	Sulfonamides
Azole antifungals	Allopurinol
Cephalosporins	Purpura
Proton pump inhibitors	<i>Thrombocytopenic</i>
Oral hypoglycemic agents	Carbamazepine
Aminoglycosides	NSAIDs
Barbiturates	<i>Vasculitis</i>
Blood products	Allopurinol
Chlorpromazine	Barbiturates
Hydralazine	Clindamycin
Morphine	Furosemide
NSAIDs	Hydralazine
Penicillins	Penicillins
Phenytoin	Phenytoin
Radiographic contrast	Salicylates
Salicylates	Sulfonamides
Sulfonamides	<i>Miscellaneous</i>
Bullous eruptions	Corticosteroids
Barbiturates (coma bullae)	Heparin
Captopril	Warfarin
Heparin	Serum sickness
Pencillamine (pemphigus-like)	Antithymocyte globulin
Piroxicam	Blood products
Phenytoin	Beta-blockers
Sulfonamides	Bupropion
Warfarin	Minocycline
Erythema multiforme major	Cephalosporins
Barbiturates	Penicillins
NSAIDs	Phenytoin
Penicillins	Radiographic contrast
Phenytoin	Sulfonamides
Rifampin	Exfoliative erythroderma
Sulfonamides	Barbiturates
Sulfonyleureas	Captopril
	Carbamazepine
	Cefoxitin
	Cimetidine
	Furosemide
	Isoniazid
	Phenytoin
	Salicylates
	Sulfonamides
	Sulfonyleureas

Differential Diagnosis

Drug eruptions sometimes may be distinguished clinically from the dermatoses they simulate by their sudden appearance, symmetry, widespread distribution, and paucity of associated systemic symptoms. Medication history and improvement of the skin after the medication is stopped may support the diagnosis.

The principal causes of morbilliform eruptions are drug reactions and infections, especially viral exanthems. Occasionally, a morbilliform drug rash may be confused with a bacterial or rickettsial infection or collagen-vascular disease. Although the diagnosis of urticaria is usually apparent because of the presence of evanescent wheals, the cause may be difficult to discern. In addition to drugs, other common causes of urticaria include food allergies, insect bites and stings, and parasitic infections. If the urticarial lesions persist longer than 24–36 hours, are tender, or have a purpuric component, an urticarial vasculitis or serum sickness–like reaction should be considered. Bullous drug eruptions may resemble primary blistering dermatoses.

Treatment

The challenges to the clinician faced with a suspected drug rash are to consider alternative explanations for the rash, identify the offending drug, predict progression to serious or life-threatening eruptions, and decide whether or not to intervene.

A. Review Medications—When feasible, discontinue likely causative agents and substitute chemically unrelated drugs. If the medication is not essential, it may be stopped without substitution. If the eruption is mild and relatively asymptomatic and a particular drug is necessary, the drug may be continued with cautious observation. However, urticaria, erythema multiforme, vasculitis, or generalized erythema (erythroderma) requires a search for alternative therapy.

B. General Measures—Treatment of drug eruptions is usually supportive and symptomatic because most eruptions resolve within 2–5 days of stopping the offending drug. Pruritus can be treated with oral antihistamines, such as hydroxyzine, and a topical antipruritic lotion (eg, Sarna or Pramoxone). Treatment of severe urticarial reactions associated with angioedema or anaphylaxis consists of supportive measures to maintain vital functions, epinephrine, antihistamines, and if all else fails, systemic corticosteroids. Blistering eruptions may require decompression of large bullae, topical antibiotics to denuded areas, and baths or wet compresses to remove exudate or crusts. Drug-induced erythroderma may require systemic corticosteroid therapy.

▶ Erythema Multiforme

ESSENTIALS OF DIAGNOSIS

- ▶ Erythema multiforme minor: prodrome of low-grade fever, malaise, and upper respiratory symptoms, followed by a nonspecific symmetric eruption of erythematous macules, papules, and urticarial plaques.
- ▶ Evolves into concentric rings of erythema with papular, dusky, necrotic, or bullous centers (target lesions) over 1–2 days but also may be annular, polycyclic, or purpuric (multiforme).
- ▶ Erythema multiforme with mucous membrane involvement: high fever, headache, myalgias, and sore throat, with more than one mucosal surface affected. Stomatitis is conspicuous, beginning with vesicles on the lips, tongue, and buccal mucosa. The vesicles rapidly evolve into erosions and ulcers covered by hemorrhagic crusts.

General Considerations

Historically, erythema multiforme (EM), Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN) were lumped into the same diagnostic group *erythema multiforme* because they shared clinical and histologic features. In recent years, a new classification scheme has been proposed that distinguishes EM from SJS and TEN. This new scheme is based on the observation that EM is triggered by herpes simplex virus (HSV) infection in nearly all cases, and SJS and TEN are adverse reactions to medications. EM may present with a wide range of severity. Patients with herpes simplex–associated EM (HAEM) and mild or no mucosal involvement are classified as having *EM minor*. Some patients with EM have more severe disease called *erythema multiforme with mucous membrane involvement* (also called *EM major*). EM major is caused by HSV in about half the cases. There is a long list of other suspected etiologic triggers that have been reported to trigger EM major (Table 28-3), but only *Mycoplasma pneumoniae* and radiation therapy have been reproducibly documented associations.

EM minor is an acute, self-limited, recurrent inflammatory disease of the skin or mucous membranes. EM major is a severe and occasionally fatal form characterized by marked oral and ocular mucosal involvement. Erythema multiforme occurs in all age groups.

Table 28-3. Common causes of erythema multiforme major.

Drugs: See Table 28-2.

Infection

Herpes simplex
M. pneumoniae
Streptococcus
Yersinia
 Tuberculosis
 Histoplasmosis

Other conditions

Irradiation of tumors
 Sarcoidosis
 Pregnancy
 Carcinomas
 Leukemias
 Collagen-vascular diseases
 Inflammatory bowel disease

Idiopathic

The pathogenesis of erythema multiforme is not fully understood. According to one hypothesis, foreign antigens are sequestered in the epithelium, leading to immune-mediated apoptosis and epithelial damage. Polymerase chain reaction (PCR) studies have demonstrated HSV DNA in the skin lesions of many patients, even in patients with no obvious clinical association with HSV.

Clinical Features

A. Symptoms and Signs—Both EM minor and EM major have similar skin lesions that characteristically appear 1–3 weeks after an HSV infection, although some episodes will not be preceded by an obvious outbreak of herpes. In EM minor, a prodrome of low-grade fever, malaise, and upper respiratory symptoms may develop. In EM major, high fever, headache, myalgias, and sore throat develop abruptly, often associated with coryza, vomiting, diarrhea, and joint pains. This is followed by a nonspecific symmetric eruption of erythematous macules, papules, and urticarial plaques that evolve into target lesions over a 1–2-day period. The classic *target* or *iris lesions* are concentric rings of erythema with papular, dusky, necrotic, or bullous centers. The lesions also may be annular, polycyclic, or purpuric, demonstrating the polymorphous (multiforme) nature of the eruption. The extensor surfaces of the forearms, the face, the neck, the legs, and the palms and soles are the most commonly involved sites. The lesions appear in crops over 1–2 weeks and usually resolve within 4 weeks, often with residual hyperpigmentation. The mucous membranes commonly reveal hemorrhagic crusting of the lips, painful oral erosions, and purulent conjunctivitis.

In EM major, patients appear extremely ill and may have tachycardia and tachypnea. More than one mucosal surface is

affected. Stomatitis is conspicuous, beginning with vesicles on the lips, tongue, and buccal mucosa. The vesicles evolve rapidly into erosions and ulcers, covered by hemorrhagic crusts. Bilateral catarrhal conjunctivitis, corneal ulcers, erosive rhinitis, balanitis, and vulvovaginitis may develop. The urethra, larynx, esophagus, trachea, and bronchi also may be involved. Occasionally, the skin is spared, but in most instances a vesiculobullous or erythematous eruption appears on the face and distal extremities. Complications include dehydration resulting from the ulcerative stomatitis and blindness resulting from the corneal ulcers. In patients with extensive disease, the mortality rate approaches 5%, with deaths usually a result of sepsis.

B. Laboratory Findings—There are no specific laboratory abnormalities. Leukocytosis, elevated erythrocyte sedimentation rate, abnormal liver function tests, proteinuria, and occasionally, hematuria are seen. The diagnosis is based on characteristic clinical features with histopathologic confirmation.

Underlying causative factors should be sought. Evaluation of the patient with EM major should include the following: complete blood count, erythrocyte sedimentation rate, urinalysis, and a purified protein derivative (PPD) test. Other tests may include cold agglutinin titers; chest, sinus, and dental x-rays; hepatitis B serologic tests; cultures for bacteria, viruses, and fungi; and antinuclear antibody (ANA) and rheumatoid factor determinations. Other tests for the evaluation of diseases such as sarcoidosis or occult malignancies also should be considered.

Differential Diagnosis

EM may resemble many other skin disorders, especially when the classic target lesions are absent. The presence of target lesions and characteristic histopathologic features helps to distinguish EM from urticaria, viral exanthems, and vasculitis, as well as from other mucocutaneous disorders such as Reiter's syndrome, Behçet's syndrome, herpes gingivostomatitis, and Kawasaki's disease. When blisters are present, EM must be differentiated from bullous impetigo, bullous pemphigoid, pemphigus vulgaris, SJS, and TEN. The skin lesions in SJS are characteristically purpuric macules and atypical target lesions on the torso, face, and extremities, involving less than 10% of the body surface

Treatment

If the specific cause is identified, treatment directed at that cause is indicated. In most cases, therapy is supportive and symptomatic. The patient should be monitored closely for potential progression to secondary infection and sepsis. Cool compresses, followed by the application of mupirocin ointment, are useful for crusting and secondary infection.

For patients with compromised oral intake or extensive erosions, proper attention must be paid to fluids, electrolytes, and nutrition. An antiseptic mouthwash or hydrogen peroxide should be used to keep the oral cavity clean. Viscous lidocaine

or a mixture of equal parts of diphenhydramine hydrochloride and an oral antacid may alleviate pain on swallowing.

Eye involvement should be managed in consultation with an ophthalmologist. Avoid sulfonamide-containing eye drops because they can cause or exacerbate sulfonamide-induced reactions. Topical or systemic steroids have not been proved to prevent ocular sequelae or progression of cutaneous disease, and they may be harmful. However, some authorities advocate systemic steroids early in the course of the reaction (within 48 hours).

Auquier-Dunant A et al: Correlations between clinical patterns and causes of erythema multiforme majus, Stevens-Johnson syndrome, and toxic epidermal necrolysis: Results of an International Prospective Study. *Arch Dermatol* 2002;138:1019–24. [PMID: 12164739]

▶ Stevens-Johnson Syndrome & Toxic Epidermal Necrolysis

ESSENTIALS OF DIAGNOSIS

- ▶ Severe, acute blistering diseases associated with significant morbidity and mortality.
- ▶ Often a recent history of drug ingestion.
- ▶ Prodrome of fever, nausea, vomiting, diarrhea, malaise, headache, cough, sore throat, myalgia, and arthralgia 1–14 days before the skin eruption.
- ▶ SJS: widespread red or purpuric macules or flat atypical target lesions with subepidermal detachment over less than 10% of body surface at worst; mucosal erosions frequent; no correlation between extent of mucosal involvement and extent of epidermal detachment; subepidermal separation of skin (Nikolsky's sign).
- ▶ TEN: variant of same process with epidermal detachment greater than 30% of surface; features of SJS: stomatitis, blotchy eruption with target lesions.

General Considerations

SJS and TEN are acute, severe blistering diseases of the skin and mucous membranes caused by drugs or infections. The mortality rate of SJS approaches 5%, but the mortality rate of TEN may be closer to 30%. TEN is a rare, life-threatening syndrome characterized by skin tenderness, erythema, and exfoliation of the epidermis and mucous membranes reminiscent of a scald injury. The pathophysiology is not known, but these disorders are believed to be immunologically mediated. Most cases are drug-induced by such agents as antiepileptics (eg, phenytoin, phenobarbital, and carbamazepine), sulfonamides, sulfones, nonsteroidal anti-inflammatory drugs (especially pyrazolone derivatives), allopurinol, and ampicillin. Identification of the causative drug is often difficult because many patients are treated with

multiple medications. In general, the interval between initial dose of the drug and onset of the disease is 1–3 weeks, except for phenytoin-induced cases, which may occur as late as 8 weeks following the start of therapy. If the patient has a history of SJS or TEN from previous exposure to a drug, the time period may be reduced to 24–48 hours. Patients with AIDS appear to have an increased risk for TEN.

Clinical Features

A. Symptoms and Signs—Fever, nausea, vomiting, diarrhea, malaise, headache, upper respiratory symptoms, chest pain, myalgia and arthralgia, and conjunctivitis usually precede the skin and mucous membrane lesions by 1–14 days. Cutaneous involvement appears acutely as tender, discrete, symmetric erythematous or purpuric macules and urticarial plaques with atypical target lesions with dusky centers on the face and upper trunk. Coalescence and extension to the entire body rapidly ensue. Subsequently, large flaccid bullae develop within the areas of erythema, and the necrotic epidermis sloughs in sheets. Pressure applied directly over an intact blister produces lateral spread of the lesion. Gentle rubbing of erythematous areas induces separation of the epidermis (Nikolsky's sign). In SJS, the extent of epidermal detachment is less than 10% of the body surface area. In TEN, coalescence and extension to the entire body ensue rapidly, with detachment of the epidermis exceeding 30% of the body surface area. The palms and soles may be involved, but the hairy part of the scalp characteristically is spared. Mucous membrane involvement is extensive, with erosions or ulcers of the conjunctiva, lips, oropharynx, trachea, esophagus, and anogenital area.

The extent of epidermal separation is a major prognostic factor. Sepsis is the most frequent cause of death and may be heralded by a sudden drop in temperature. Pulmonary embolism, pulmonary edema, and GI bleeding are other important causes of death. Pneumonia superimposed on sloughing of the tracheobronchial mucosa may require ventilatory assistance. Fluid loss, thermoregulatory impairment, and increased energy expenditure result from extensive skin loss, as in burn victims. The mortality rate ranges from 25–75% and is higher in elderly patients. Disabling ocular sequelae affect up to 50% of survivors. Cutaneous reepithelialization requires 2–3 weeks, whereas the mucous membrane lesions persist longer.

B. Laboratory Findings—Routine laboratory studies reflect the extent and severity of the disease but are not specific. There may be evidence of electrolyte depletion and dehydration. Serum creatinine may be elevated owing to prerenal azotemia or acute tubular necrosis. Serum aminotransferase levels often are slightly increased. In virtually all patients, anemia is present; lymphopenia, neutropenia, and thrombocytopenia sometimes are seen and may indicate a poor prognosis. Biopsy of involved skin may be very helpful, revealing full-thickness epithelial necrosis.

Differential Diagnosis

Clinically, TEN and staphylococcal scalded skin syndrome are quite similar. The latter disorder is caused by an epidermolytic toxin produced by *Staphylococcus aureus*. The toxin produces superficial (subcorneal) skin separation. Nikolsky's sign is present, but skin tenderness and mucous membrane lesions usually are absent. Staphylococcal scalded skin syndrome more frequently affects neonates and toddlers, is rare in adults, and has a much better prognosis than TEN.

Historically, SJS and EM major were considered part of the same disease group. EM major can be differentiated from SJS by the presence typical target lesions localized in a symmetric acral distribution, low or no fever, and frequent association with HSV infection.

Other differential diagnostic considerations include pemphigus vulgaris and other blistering diseases, toxic shock syndrome, chemical or thermal burns, and Kawasaki's disease. TEN shares many features with—and is considered by some to be a severe form of—SJS.

Treatment

The principles of therapy are similar to those for major second-degree burn victims. Ideally, patients should be managed in a burn unit.

A. General Measures—Discontinue the most likely offending medication, provide pain control as necessary, and attend to fluids, electrolytes, and nutrition. Aggressive nutritional support should be started early; nasogastric feeding is preferred to parenteral nutrition.

B. Infection Control—Prophylactic antibiotics may promote the emergence of resistant strains of bacteria or *Candida* and should be avoided. Obtain blood, urine, and skin cultures frequently, and start empirical broad-spectrum antibiotics at the earliest sign of infection. Consider acyclovir in HIV-infected patients because secondary HSV infection may be clinically undetectable.

C. Skin and Mucous Membrane Care—Ophthalmologic consultation is essential to prevent blindness and other ocular sequelae. Oral hygiene and antisepsis are important. Intact bullae should be left in place because they provide a natural dressing. Nonviable, necrotic, and loosely attached areas of epidermis should be débrided. Apply biologic dressings, such as porcine xenografts and cryopreserved cadaveric allografts, or synthetic coverings, such as hydrogel dressing or paraffin gauze, to denuded areas. Silver sulfadiazine must be avoided in patients suspected of sulfonamide sensitivity.

Current Controversies and Unresolved Issues

Toxic epidermal necrolysis has been considered by some to be at the most severe end of the spectrum of EM and SJS, but the two disorders instead may be distinct reactional states with clinicopathologic similarities. Supporting the latter view is the observation that the three do not have the same etiologic spectrum.

Although corticosteroids have been used for decades, recent studies suggest that systemic steroid therapy is more detrimental than useful in TEN. Claims for a reduction of morbidity and mortality in response to a large dose of systemic steroids in the first 24–48 hours have not been substantiated, and most authors now suggest that corticosteroids should not be used. Plasmapheresis, cyclophosphamide, intravenous immunoglobulin, cyclosporine, and infliximab likewise have been claimed to be beneficial on the basis of case reports and uncontrolled studies, but again, there is no proof.

▶ Phenytoin Hypersensitivity Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ High spiking fever, malaise, and rash 2–3 weeks after starting phenytoin therapy—or sooner if prior exposure to drug.
- ▶ Patchy erythematous rash evolving into extensive pruritic maculopapular rash, occasionally with follicular papules and pustules.
- ▶ Exfoliative erythroderma, EM, SJS, or TEN may develop, especially in those with prior adverse reactions to phenytoin; edema of palms, soles, and face.
- ▶ Tender localized or generalized lymphadenopathy; mild to severe hepatic injury; sometimes conjunctivitis, pharyngitis, diarrhea, myositis, reversible acute renal failure, and eosinophilia.

General Considerations

A number of adverse skin reactions, ranging from morbilliform eruptions to vasculitis, exfoliative erythroderma, EM, SJS, and TEN, occur in up to 3–15% of patients receiving

phenytoin. In a small percentage of these patients, a distinctive syndrome occurs, characterized by an extensive rash, fever, eosinophilia, and hepatic injury. The disorder is believed to be immune-mediated. All age groups are affected. The incidence is highest in blacks.

Clinical Features

A. Symptoms and Signs—Onset is usually 2–3 weeks after initiation of therapy—or within days if prior exposure has occurred—heralded by high spiking fevers, malaise, and a rash. The cutaneous eruption is variable. It often begins as patchy erythema that evolves into an extensive pruritic maculopapular rash. Some patients have follicular papules and pustules. The rash may generalize into an exfoliative erythroderma. EM, SJS, and TEN may occur, especially in patients with previous adverse reactions to the drug and in those who continue to receive the drug after developing signs of hypersensitivity. Erythema and edema of the palms and soles and prominent facial edema are common. The eruption usually resolves with desquamation.

Tender localized or generalized lymphadenopathy is a consistent finding. Virtually all patients with this syndrome have hepatic injury, which varies from mild and transient to severe and fulminant, resulting in massive hepatic necrosis. Hepatosplenomegaly is found in most patients. Other features of the syndrome, not uniformly present, are conjunctivitis, pharyngitis, diarrhea, myositis, and reversible acute renal failure. In general, the signs and symptoms resolve rapidly once the medication is discontinued; however, multiorgan abnormalities may progress even after the phenytoin has been stopped. Some patients endure a prolonged and complicated course of exacerbations and remissions. The mortality rate approaches 20% in patients with severe liver damage.

B. Laboratory Findings—Laboratory studies are important for monitoring the severity and progression of the reaction. Leukocytosis with eosinophilia (5–50%) is common. Coombs-negative hemolytic anemia and atypical circulating lymphocytes may be seen. The degree of elevation in serum aminotransferases and alkaline phosphatase levels reflects the severity of liver injury, and renal function may be abnormal. It is of note that the erythrocyte sedimentation rate and serum complement levels are normal in this disorder.

Differential Diagnosis

Other anticonvulsant medications, particularly phenobarbital, may cause reactions indistinguishable from phenytoin hypersensitivity disorder. Infectious mononucleosis may resemble this syndrome.

Treatment

The medication must be discontinued. Data regarding cross-reactivity among the anticonvulsants is scanty, but if anti-convulsant therapy is still necessary, valproic acid or carbamazepine may be safer alternatives.

General supportive care is vital because of the multisystem involvement. Systemic corticosteroids are sometimes used, but their effectiveness has not been documented.

PURPURA

Purpura results from hemorrhage into the skin or mucous membranes. Incomplete blanching on pressure is characteristic. Purpuric lesions may be a clue to acutely life-threatening diseases but are seen in benign conditions as well. An important step in evaluating the patient with purpura is to determine

whether the lesions are macular (flat) or palpable. Nonpalpable purpura, the result of bleeding into the skin without inflammation, is due to disorders of hemostasis and vessel wall integrity. In these cases, small petechial hemorrhages (<3 mm) occur. Common causative factors are thrombocytopenia and disorders of platelet function. Petechiae also may be a clue to diseases that affect the integrity of blood vessels, for example, scurvy or amyloidosis. In contrast, disorders of coagulation cause bleeding from larger vessels, producing ecchymoses (ie, hemorrhagic macules >3 mm). Palpable purpura, the expression of inflammatory damage to the vasculature and consequent extravasation of blood, is the hallmark of small vessel vasculitis but also may be seen with septic emboli.

Purpura develops occasionally as a secondary manifestation in an inflammatory dermatosis. For example, macular drug eruptions or exanthematous infectious diseases such as measles and scarlet fever can become purpuric as a result of increased permeability of the blood vessels and extravasation of red cells into the surrounding tissue. Causes of purpura are classified arbitrarily in [Table 28–4](#). In this section, leukocytoclastic vasculitis, disseminated intravascular coagulation, and purpura fulminans are discussed.

Table 28–4. Causes of purpura.

Vascular Disorders	Abnormal distribution
<i>Inflammatory disorders</i>	Diseases associated with splenomegaly
Palpable purpura	Kasabach-Merritt syndrome
Vasculitis	<i>Purpura with normal platelet counts</i>
Septic emboli	Platelet function defects
Nonpalpable purpura	Drugs (eg, salicylates, NSAIDs)
Viral infections	Uremia
Rickettsial infections	Coagulopathies
Drugs and chemicals	<i>Purpura with high platelet counts</i>
Pigmented purpuric dermatoses	Myeloproliferative syndromes
<i>Noninflammatory disorders</i>	Postsplenectomy
Trauma	Various neoplasms and inflammatory diseases
Amyloidosis	Disorders of Coagulation
Scurvy	<i>Acquired</i>
Dysproteinemic states	Vitamin K deficiency
Solar purpura	Disseminated intravascular coagulation
Abnormalities of Platelet Number and Function	Parenchymal liver disease
<i>Thrombocytopenic purpuras</i>	Cardiopulmonary bypass surgery
Increased platelet destruction	Lupus anticoagulant syndrome
Microangiopathic diseases	<i>Inherited</i>
Infections	Classic hemophilia
Immunologic disorders	von Willebrand's disease
Idiopathic thrombocytopenic purpura (ITP)	<i>Thrombotic disorders</i>
Drug-induced thrombocytopenia	Protein C and S deficiency
Autoimmune diseases (eg, SLE)	Antithrombin III deficiency
Decreased platelet production	Drugs (eg, aminocaproic acid, estrogen compounds)
Neoplastic replacement of bone marrow	Nephrotic syndrome
Myelosuppressive disorders	Anticoagulant necrosis
Radiation	
Chemotherapy	
Infections	

▶ Leukocytoclastic Vasculitis

ESSENTIALS OF DIAGNOSIS

- ▶ Palpable purpura; hemorrhagic bullae, purpuric plaques, vesicles, pustules on a purpuric base, and urticaria-like papules may be present.
- ▶ Systemic symptoms occur in 40–50%, including fever, myalgias, and arthralgias; abdominal pain, GI bleeding, and pulmonary disease (eg, pneumonitis, pleuritis, or hemoptysis) occur less frequently.
- ▶ Biopsy of involved skin shows necrotizing vasculitis with prominent neutrophilic infiltrates in and around the vessel walls, extravasated red blood cells, and deposition of fibrin.

General Considerations

Vasculitis is defined as inflammation and subsequent necrosis of the vessel wall. Various clinical syndromes share vasculitis as a feature and may be classified according to the size and type of involved vessels (eg, postcapillary venule, arteriole, vein, or artery), the type of inflammatory infiltrate (eg, necrotizing or granulomatous), and the organs affected (Table 28–5). Some forms of vasculitis are confined to the skin, whereas others involve internal organs and may cause

Table 28–5. Classification of vasculitis.

Degos' disease (malignant atrophic papulosis)
Kawasaki's disease
Lucio phenomenon

severe and potentially fatal disease. When the small vessels of the skin are involved, the most common finding is palpable purpura. Involvement of larger vessels produces subcutaneous nodules, stellate-shaped purpura, or necrosis.

Pathophysiology

Most of the vasculitic diseases are immunologically mediated and probably are due to immune complex deposition. The evidence for immune complex–mediated damage is most compelling for small-vessel, or “leukocytoclastic,” vasculitis. The pathologic process involves the following sequence of events: deposition of circulating soluble antigen-antibody complexes in postcapillary venule walls, activation of the complement cascade, chemotaxis of neutrophils to the sites of immune complex deposition, and release of lysosomal enzymes and other products from neutrophils, resulting in necrosis of the vessel wall. Hemorrhage, thrombosis, and surrounding tissue necrosis follow. The inflammatory cell infiltrate and edema in and around the vessels cause the lesions to become palpable. In some situations, vasculitis may result from direct invasion of vessels by infectious agents. Cell-mediated immune damage may be involved in granulomatous vasculitis.

Clinical Features

A. Symptoms and Signs—As noted earlier, the classic cutaneous finding in leukocytoclastic vasculitis is palpable purpura (although the palpability may be subtle). However, hemorrhagic bullae, purpuric plaques, vesicles, pustules on a purpuric base, and urticaria-like papules may be present. Affected patients also may have ulcerative, infarcted, or reticulated lesions. The lesions arise in crops, predominantly on the lower extremities and in dependent areas. Edema of the lower legs is common. About 40–50% of patients with leukocytoclastic vasculitis have systemic symptoms. Fever, myalgias, and arthralgias may accompany the cutaneous manifestations. Kidney involvement may be transient, with hematuria or proteinuria, or may lead to glomerulonephritis or renal failure. Abdominal pain, GI bleeding, and pulmonary disease (eg, pneumonitis, pleuritis, or hemoptysis) occur less often. Peripheral neuropathies occur infrequently and portend a poor prognosis.

B. Laboratory Findings—The definitive diagnosis of cutaneous vasculitis depends on compatible cutaneous lesions plus histopathologic confirmation of blood vessel damage. Necrotizing vasculitis is characterized by a prominent neutrophilic infiltrate in and around the vessel wall associated with nuclear fragments (“nuclear dust”), extravasated red blood cells, and deposition of fibrin. Furthermore, granulomatous vasculitis shows fibrinoid necrosis of the blood vessels associated with intravascular and extravascular granulomas.

Evaluation of lesions by direct immunofluorescence for the presence of immunoglobulins and complement may help to confirm the diagnosis. However, negative results are common, and this test is often of little clinical value.

Once the diagnosis of cutaneous vasculitis is established, a comprehensive evaluation is necessary to determine the presence and extent of internal involvement and to identify potential underlying causes (Table 28–6). Some recommended screening studies include the following: complete blood count and erythrocyte sedimentation rate; chemistry profile; serum protein electrophoresis and cryoglobulin titer; hepatitis B and C screens; antinuclear antibody titer, anti-Ro and anti-La titers, C3, C4, total hemolytic complement, and VDRL; urinalysis and stool occult blood; throat culture and antistreptolysin O titer; and chest x-ray. Depending on the clinical situation, other tests may include antineutrophilic cytoplasmic antibody titers, anti-cardiolipin antibodies, direct immunofluorescence, biopsy of affected organs, radiographic studies (including angiograms) of affected organs, malignancy screening tests, echocardiography, visceral angiography, and nerve conduction studies.

Differential Diagnosis

Palpable purpura occurs in both vasculitis and septicemia. Certain clinical patterns favor the diagnosis of sepsis and sometimes can provide clues to the causative organism. The skin lesions associated with staphylococcal sepsis are acraly located, asymmetric, and fewer in number than those associated with vasculitis. The characteristic lesions of gonococcal

bacteremia are discrete, tender pustules on a hemorrhagic base, often accompanied by polyarthralgias, tenosynovitis, or septic arthritis. The well-known skin findings in infective endocarditis are painful nodules on the volar surfaces of the fingers and toes (Osler's nodes), nontender hemorrhagic macules on the palms and soles (Janeway's lesions), and subungual splinter hemorrhages. Petechiae, ecchymoses, hemorrhagic vesicles and pustules, and ulcerated nodules all may be seen with sepsis. The diagnosis is confirmed by a positive blood culture or a positive culture or Gram stain from the skin lesions. Palpable purpura also can occur in nonseptic embolic disorders such as atheromatous emboli or left atrial myxoma.

Treatment

The therapy of vasculitis is based on the extent and severity of the disease. Any associated disease, infection, chemical, or drug should be treated or removed. For vasculitis limited to the skin, conservative therapy is appropriate because most cases are acute and self-limited. Bed rest, antihistamines, and nonsteroidal anti-inflammatory drugs may suppress or control cutaneous lesions effectively. For necrotic or highly symptomatic eruptions, colchicine, dapsone, or prednisone may be useful.

For systemic vasculitis, therapy with immunosuppressive and/or cytotoxic agents such as corticosteroids, azathioprine, cyclosporine, methotrexate, and mycophenolate mofetil is usually necessary. Plasmapheresis may be tried in patients refractory to other therapeutic modalities. Monoclonal antibody therapy with infliximab may be of value.

Cutaneous ulcers or bullae are treated with debridement, tap water soaks, topical antibiotics, and vapor-permeable membranes.

▶ Disseminated Intravascular Coagulation & Purpura Fulminans

ESSENTIALS OF DIAGNOSIS

- ▶ Extensive skin necrosis, fever, and hypotension associated with evidence of disseminated intravascular coagulation.
- ▶ Sudden appearance of large, irregular areas of purpura, especially over the extremities.
- ▶ Skin lesions are tender, enlarge rapidly, and may evolve into hemorrhagic bullae with subsequent necrosis and black eschar formation; necrosis of an entire extremity may develop.
- ▶ May be associated with pulmonary, hepatic, or renal failure; GI bleeding; and hemorrhagic adrenal infarction.

General Considerations

Disseminated intravascular coagulation (DIC) is a dynamic process associated with a variety of underlying diseases and is the result of uncontrolled activation of coagulation and fibrinolysis. Purpura fulminans is an acute, severe, often rapidly fatal syndrome characterized by extensive necrosis of the skin associated with fever and hypotension. Purpura fulminans represents the extreme end of the spectrum of DIC.

Pathophysiology

The central pathogenic events in DIC are excessive generation of thrombin and formation of intravascular fibrin clots, secondary activation of the fibrinolytic system, and consumption of platelets and coagulation factors. Abnormalities of the endogenous anticoagulants protein C and protein S may be directly related to the pathogenesis of purpura fulminans by contributing to the thrombotic tendency in patients with DIC. Neonates with homozygous protein C deficiency present with massive thrombosis of skin capillaries and veins, resulting in cutaneous necrosis, secondary sepsis, and death (purpura fulminans neonatalis). Acquired deficiencies of proteins C and S have been reported in liver disease and sepsis. Purpura fulminans occurs most commonly in children and often follows an infectious process such as scarlet fever or streptococcal pharyngitis, meningococemia, varicella, rubella, or Rocky Mountain spotted fever. Purpura fulminans also has been associated directly with *S. aureus* strains that produce high levels of toxic shock syndrome toxin 1 or staphylococcal enterotoxins. Adults also may be affected, and the syndrome may occur without a preceding illness.

Clinical Features

A. Symptoms and Signs—Cutaneous findings of DIC may range from insignificant bruising and oozing from venipuncture

sites to massive hemorrhage and necrosis of skin and vital organs. Purpura fulminans is characterized by the sudden appearance of large, irregular areas of purpura, especially over the extremities. The lesions are tender, enlarge rapidly, and may evolve into hemorrhagic bullae with subsequent necrosis and black eschar formation. The trunk, ears, and nose may be involved. Necrosis of an entire extremity may develop. Fever, chills, and hypotension almost always accompany the disorder. Complications may include pulmonary, hepatic, and renal failure, as well as GI bleeding and hemorrhagic adrenal infarction (Waterhouse-Friderichsen syndrome). Mortality rates range from 20–40%. The differential diagnosis of purpura fulminans encompasses the entire spectrum of purpuric conditions.

B. Laboratory Findings—Because of the dynamic balance between intravascular clot deposition and dissolution, serial laboratory studies may be required to diagnose and monitor DIC. The blood count usually shows thrombocytopenia, and anemia may result from bleeding or microangiopathic hemolysis. Consumption of coagulation factors and fibrinogen causes prolongation of the prothrombin time and partial thromboplastin time. There is hypofibrinogenemia, and increased fibrin degradation products (fibrin split products) are present. More specific tests, such as measurement of the D-dimer fragment, a breakdown product of cross-linked fibrin, may be helpful.

Treatment

Immediate attention must be directed toward stabilizing the patient and treating the underlying cause. Heparin may prevent further clot formation but should be avoided in patients with suspected or documented intracranial bleeding. Plasma or platelet replacement therapy may be indicated in patients with active bleeding, but efficacy has not been proved in randomized, controlled trials. Recombinant human activated protein C should be considered in sepsis-related DIC. Surgical debridement of necrotic eschars, grafting, and even amputation are sometimes necessary.

LIFE-THREATENING DERMATOSES

► Pemphigus Vulgaris

ESSENTIALS OF DIAGNOSIS

- ▶ Flaccid, easily ruptured blisters on noninflamed skin; after rupture, nonhealing crusted erosions remain.
- ▶ Superficial detachment of the skin after pressure or trauma variably present (Nikolsky's sign).
- ▶ Skin biopsy shows characteristic intraepidermal cleft just above the basal cell layer, with separation of keratinocytes from one another (acantholysis).
- ▶ Direct immunofluorescence of normal-appearing skin shows intercellular IgG and complement deposition throughout the epithelium.

General Considerations

Pemphigus vulgaris is a rare life-threatening autoimmune disease characterized by intraepithelial vesicles and bullae. Stratified squamous epithelium of both skin and mucosal surfaces is involved. The pathogenic process involves circulating IgG autoantibodies directed against the intercellular substance of the epidermis. The mean age at onset is the sixth decade.

Clinical Features

A. Symptoms and Signs—Nonhealing oropharyngeal erosions are common and often precede the skin findings by weeks or months. The primary cutaneous lesion is a flaccid blister on noninflamed skin. These blisters rupture easily, leaving nonhealing erosions that ultimately develop crusts. A positive Nikolsky sign (tractional pressure adjacent to a lesion causes skin separation) is characteristic but not pathognomonic. With treatment, the lesions generally heal without scarring. The sites of predilection are the scalp, face, axillae, and oral cavity. The conjunctival, vaginal, and esophageal mucosa and the vermilion border of the lips also may be involved. The process may become generalized. Oropharyngeal involvement causes difficulty in swallowing, and laryngeal involvement produces hoarseness. Prior to the availability of corticosteroids, the mortality rate of pemphigus approached 60–90% owing primarily to protein, fluid, and electrolyte losses or to sepsis. More recently, the mortality rate has dropped to the range of 5–15%; the most common causes of death today are infection and complications of treatment.

B. Laboratory Findings—The diagnosis is based on pathologic findings, including skin biopsy showing a characteristic intraepidermal cleft just above the basal cell layer, with separation of keratinocytes from one another (acantholysis). The acantholytic cells line the vesicle and also lie free within the

cavity. A Tzanck smear from the base of a bulla may show acantholytic epidermal cells. Direct immunofluorescence of normal-appearing skin near a lesion shows intercellular IgG and complement deposition throughout the epithelium. Indirect immunofluorescence of the patient's serum demonstrates circulating intercellular autoantibodies in about 80–90% of patients specific for desmoglein-3 alone when lesions are limited to the mouth and for both desmoglein-3 and -1 when skin lesions are present in addition to oral lesions. However, titers of the circulating autoantibodies do not correlate with disease severity but often parallel disease activity.

Fluid, electrolyte, and nutritional disturbances may occur but are less pronounced than in disorders involving loss of the entire thickness of the epidermis (eg, TEN).

Differential Diagnosis

Histopathologic examination, immunofluorescent microscopy, and bacterial cultures permit differentiation from EM, SJS, TEN, bullous drug eruptions, and bullous impetigo, as well as from other primary blistering diseases such as bullous pemphigoid and dermatitis herpetiformis.

Treatment

Discontinue drugs known to cause pemphigus (eg, penicillamine and captopril).

A. Specific Treatment—Prednisone, 60–120 mg/day, in combination with azathioprine, 100–150 mg/day, is usually effective. Prior to initiation of therapy, the patient should be evaluated for contraindications to systemic steroids. Patients with a history of tuberculosis or a positive skin test for tuberculosis need concomitant isoniazid while receiving immunosuppressive therapy. When control of the blistering is achieved, prednisone is reduced gradually as tolerated. Methotrexate, cyclophosphamide, mycophenolate mofetil, cyclosporine, intravenous high-dose immunoglobulins, gold, chlorambucil, and plasmapheresis are alternative modalities, as is pulse corticosteroid therapy. Monoclonal antibodies may be of value in the future.

B. Topical Therapy—Silver sulfadiazine or mupirocin ointment may reduce secondary infection. Whirlpool treatments are helpful in removing crusts from lesions. Oral mucosal erosions may benefit from topical steroids, antiseptics, viscous lidocaine, and attention to oral hygiene.

▶ Generalized Pustular Psoriasis

ESSENTIALS OF DIAGNOSIS

- ▶ Acute onset of widespread sterile pustules arising on tender, warm, erythematous skin that coalesce into lakes of pus; the tongue and mouth are commonly involved.
- ▶ Recurrent waves of pustulation and remissions occur; fever and leukocytosis are often present; bacterial infections and sepsis may be complications.
- ▶ Arthritis and pericholangitis are sometimes present; rarely, there is associated hypotension, high-output heart failure, and renal failure; a history of psoriasis may or may not be present.
- ▶ Characteristic subcorneal pustules are seen on histologic examination.

General Considerations

In addition to the exfoliative erythrodermic form of psoriasis, another serious and sometimes fatal type is generalized pustular psoriasis. It is characterized by the acute onset of widespread erythematous areas studded with many sterile pustules and associated with fever, chills, and leukocytosis. The disease may develop either de novo or in individuals with a history of psoriasis. The exact pathogenesis is unclear; however, precipitating events include topical and systemic corticosteroid therapy and its subsequent withdrawal, other medications (eg, sulfonamide drugs, penicillin, lithium, and pyrazolones), infections, pregnancy, and hypocalcemia. Pustular psoriasis tends to occur in patients over 40 years of age.

Clinical Features

A. Symptoms and Signs—The primary lesions are sterile pustules that arise on tender, warm, erythematous skin and coalesce into lakes of pus. Lesions typical of psoriasis vulgaris may coexist. The tongue and mouth are commonly involved, with geographic tongue and superficial erosions. These patients appear ill and complain of itching and burning. The course is punctuated by recurrent waves of pustulation and remissions. Arthritis and pericholangitis sometimes occur. Circulatory shunting through the skin may lead to significant edema and, rarely, hypotension, high-output heart failure, and renal failure. Superimposed bacterial infections or sepsis can complicate the clinical picture.

B. Laboratory Findings—Laboratory data are nonspecific but may be helpful. Leukocytosis, hypoalbuminemia, and hypocalcemia are seen often during flares of this disorder, although Gram stains and bacterial cultures of lesions are negative. HIV serology should be checked because severe exacerbations of psoriasis can be seen in HIV-infected individuals. Histologic examination of a lesion shows a characteristic subcorneal pustule.

Differential Diagnosis

The diagnosis of pustular psoriasis is generally clear-cut on clinical and histologic grounds. Other diagnostic considerations include miliaria rubra, acneiform secondary syphilis, pustular drug eruptions, and folliculitis. Cellulitis may be suggested by the marked edema and erythema of the legs.

Treatment

A. Specific Treatment—The drugs of choice in this severe form of psoriasis are the retinoids acitretin and isotretinoin. These drugs should not be used in patients with lipid abnormalities or active hepatitis, and effective contraception must be ensured during and for at least 3 years after treatment in women of childbearing potential. Most patients show significant improvement in 5–7 days. Precipitating causes, including lithium, antimalarials, diltiazem, propranolol, and irritating topical medications, must be identified and removed. Withdrawal from systemic corticosteroids is the most common trigger. Oral acitretin works rapidly; but in women of childbearing age, isotretinoin may be a better choice because it has a shorter period of teratogenicity. Methotrexate and cyclosporine are alternatives in carefully selected patients; methotrexate is absolutely contraindicated in HIV-infected patients. Hydroxyurea, mycophenolate mofetil, and azathioprine have been used in some patients. Recent case reports suggest that monoclonal antibodies to tumor necrosis factor- α may be very helpful in patients with pustular psoriasis. Systemic steroids should be avoided.

B. General Measures—A medium-potency topical steroid applied twice daily to affected areas, emollient creams, cool compresses, and baths alleviate discomfort. Attention must be paid to fluid and electrolyte imbalances. The patient should be monitored for secondary infection and sepsis.

▶ Exfoliative Erythroderma

ESSENTIALS OF DIAGNOSIS

- ▶ Generalized or nearly generalized diffuse erythema with desquamation.
- ▶ Pruritus, malaise, fever, chills, and weight loss may be present.
- ▶ There may be a history of primary dermatologic disease, or the erythroderma may be a sign of malignancy (T-cell lymphoma); the cause in many cases remains undetermined.

General Considerations

Exfoliative erythroderma is a clinical syndrome characterized by generalized or nearly total diffuse erythema of the skin accompanied by variable degrees of desquamation. Exfoliative erythroderma is a nonspecific endpoint of skin reactivity; multiple conditions can lead to it (Table 28-7). Approximately half of all cases are due to exacerbation of a primary dermatologic condition. Underlying skin diseases such as psoriasis and various forms of eczema may become generalized through neglect, the abrupt discontinuation of therapy, or intercurrent cutaneous or systemic infection (eg, HIV-infected individuals are at risk of development of erythrodermic psoriasis). Less commonly, exfoliative erythroderma is the initial manifestation of a dermatosis. The remaining cases are nearly equally divided among undetermined causes, drug reactions, and underlying malignancies, most commonly cutaneous T-cell lymphoma.

Table 28-7. Causes of exfoliative erythroderma.

Underlying dermatosis

- Eczematous conditions
 - Contact dermatitis
 - Atopic dermatitis
 - Seborrheic dermatitis
- Psoriasis
- Pityriasis rubra pilaris
- Pemphigus foliaceus
- Norwegian scabies
- Others

Drugs: See Table 28-2.

Malignancies

- Cutaneous T cell lymphoma
- Hodgkin's disease
- Miscellaneous lymphomas and leukemias

Idiopathic

Clinical Features

A. History—A careful history with attention to preexisting dermatoses, family history of skin conditions, medication history, and clues to occult malignancy may suggest a specific cause.

B. Symptoms and Signs—Most patients complain of pruritus. The entire skin surface is red, scaly, and indurated. Excoriations, peripheral edema, and moderate symmetric lymph node enlargement are common; massive or asymmetric lymphadenopathy and splenomegaly are suggestive of an underlying lymphoma. The mucous membranes usually are spared. There may be symptoms of orthostatic hypotension owing to increased insensible water loss. Congestive heart failure owing to marked circulatory shunting through the skin may develop in patients with preexisting cardiac disease.

Thermoregulatory dysfunction can result in relative hypothermia and chills, thereby concealing the fever of sepsis. Nevertheless, patients with erythroderma owing to drugs or lymphoma—or patients with secondary infections—often present with fever. Secondary bacterial infection manifests as purulent exudate or crusting. Sepsis, pneumonia, and complications of malignancy are the leading causes of death.

C. Laboratory Findings—Laboratory studies are usually of limited value in establishing the underlying cause but are necessary for assessing response to the skin disease. Leukocytosis and anemia are common, whereas eosinophilia suggests a drug offender. Atypical circulating lymphocytes (Sézary cells), if present in sufficiently high numbers, suggest Sézary's syndrome, the leukemic phase of cutaneous T-cell lymphoma. Hypoalbuminemia and negative nitrogen balance result from protein loss by desquamation and an elevated metabolic rate. Serologic testing for HIV is recommended for patients with erythrodermic psoriasis.

Other tests should include urinalysis and stool occult blood, chest x-ray, and ECG. Skin biopsy results usually are nonspecific but may be diagnostic in leukemia, cutaneous T-cell lymphoma, or Norwegian crusted scabies. Routine biopsy of superficial lymph nodes is even less helpful because the pathologic findings are usually reactive (dermatopathic lymphadenopathy). However, biopsy of unusually prominent or asymmetric lymph nodes may yield a diagnosis of lymphoreticular malignancy.

Differential Diagnosis

Exfoliative erythroderma should be differentiated from other conditions associated with diffuse erythema, such as common morbilliform drug eruptions, various viral and bacterial exanthems, early phases of TEN, toxic shock syndrome, and graft-versus-host disease.

Treatment

Irrespective of the underlying cause, all exfoliative erythrodermas may be treated initially in a similar manner. The

goals of therapy are relief of symptoms and reduction of cutaneous inflammation.

A. Specific Treatment—Once the cause is established, specific treatment may be initiated. Systemic steroids should be avoided unless indicated as specific therapy for the underlying disease.

B. General Measures—Patients must be monitored closely for complications of erythroderma, including anemia, electrolyte imbalances, high-output heart failure, hypothermia, pneumonia, and sepsis. Administer systemic antibiotics to patients with cutaneous or systemic infection. Adequate nutrition is essential. One should stop any potentially offending medications and keep the patient warm. Daily whirlpool treatments aid in removing scale and decreasing bacterial colonization. Baths and wet compresses also may be used. After each whirlpool treatment, apply a medium-potency topical steroid such as fluocinolone acetonide 0.025% and bland emollient such as petrolatum to the entire body; frequent applications of the emollient each day help to partially restore skin barrier function. Topical medium-potency steroids such as fluoninolone acetonide 0.025% ointment may be used 2–3 times daily. Antihistamines are helpful in controlling pruritus.

Inspect the skin regularly for morphologic changes that may be diagnostic of an underlying dermatitis as the erythroderma subsides.

Sigurdsson V et al: Erythroderma: A clinical and follow-up study of 102 patients, with special emphasis on survival. *J Am Acad Dermatol* 1996;35:53–7. [PMID: 8682964]

CUTANEOUS MANIFESTATIONS OF INFECTION

The febrile patient with a rash often presents a clinical dilemma in that both noninfectious and infectious causes must be considered. Among the noninfectious causes already discussed are drug eruptions, vasculitis, and exfoliative erythroderma. In addition, systemic lupus erythematosus, juvenile rheumatoid arthritis, and Kawasaki’s disease may be manifested as eruptions associated with fever.

Systemic viral, bacterial, rickettsial, and fungal diseases may involve the skin, producing a multiplicity of cutaneous reactions that, in general, are not pathognomonic either for infection or for a specific organism. The following discussion focuses on life-threatening infections with sufficiently distinctive skin findings to facilitate early diagnosis. Cutaneous manifestations of sepsis were addressed earlier.

▶ Varicella-Zoster

ESSENTIALS OF DIAGNOSIS

Primary infection—varicella

- ▶ After a prodromal period of 1–3 days, small erythematous macules appear and evolve into clear vesicles; pruritus is intense; new crops appear at 3–5-day intervals.
- ▶ Vesicles form crusted erosions; oropharyngeal vesicles rupture quickly to form superficial mucosal ulcers.
- ▶ In normal adults as well as immunosuppressed individuals, varicella may be complicated by life-threatening pneumonia, hepatitis, myocarditis, encephalitis, and DIC.

Reactivation infection—herpes zoster

- ▶ Acute, usually painful unilateral eruption in dermatomal distribution, with clusters of vesicles occurring on a background of erythema; in persons with compromised immune systems, the lesions may become severe and necrotic.

General Considerations

Varicella-zoster virus (VZV) is a herpesvirus that typically causes a self-limited infection but is capable of producing life-threatening illness. Primary infection produces varicella; reactivation of latent virus in sensory ganglia results in herpes zoster (shingles). Varicella is spread by direct person-to-person contact or inhalation of infected droplets. Contact with the lesions of herpes zoster may produce varicella in a person not previously infected with VZV.

Clinical Features

A. Symptoms and Signs—After primary exposure to VZV, the incubation period ranges from 11–21 days but may be shorter in immunocompromised persons. The prodromal symptoms in children are minimal and consist of low-grade fever and malaise. In adults, the symptoms are more severe and include prolonged fever, malaise, and arthralgias. One to a few days after onset of illness, small erythematous macules appear on the trunk, face, and proximal extremities. The primary lesion evolves rapidly into a clear vesicle that, if left undisturbed, becomes cloudy. The vesicles eventually rupture to form crusted erosions. New crops appear at irregular intervals over the next 3–5 days, giving the characteristic finding of lesions in various stages of development. Pruritus is often intense. Healing with scarring is not uncommon, particularly in excoriated or secondarily infected lesions. Oropharyngeal vesicles rupture quickly to form superficial mucosal ulcers. In normal adults as well as immunosuppressed individuals, varicella may be especially severe and complicated by life-threatening pneumonia. Hepatitis,

myocarditis, encephalitis, and DIC also may occur along with extensive hemorrhagic skin lesions.

In the normal host, herpes zoster is an acute, self-limited, usually painful unilateral eruption in a dermatomal distribution. Characteristically, clusters of vesicles occur on a background of erythema. Occasionally—especially in persons with compromised immune systems—herpes zoster may become severe and necrotic. Wide dissemination of multiple, small, varicella-like vesicles may develop. In such patients, secondary bacterial infection is an added risk.

B. Laboratory Findings—A Tzanck smear demonstrates diagnostic multinucleated epithelial giant cells. This test is performed by scraping the base of a vesicular lesion with a scalpel blade, transferring the material to a glass slide, and staining with Giemsa's or Wright's stain. The Tzanck smear is also positive in HSV infections. Culture of a lesion may confirm the diagnosis but requires approximately 10 days of growth. An immunofluorescent antibody test using materials from a lesion is also available. Acute and convalescent sera may be helpful.

Differential Diagnosis

Varicella may be confused with widespread impetigo, disseminated herpes zoster, disseminated herpes simplex, eczema herpeticum, and smallpox. Eczema herpeticum is a widespread cutaneous infection with HSV occurring in patients with preexisting skin disorders such as atopic dermatitis. The lesions in smallpox begin as red macules and evolve in synchrony through vesicular and pustular stages, and they predominately affect the face and extremities.

Treatment

Systemic acyclovir in the doses listed is recommended in the following situations: (1) All VZV infections in immunocompromised individuals (10 mg/kg intravenously every 8 hours for 7–10 days), (2) varicella in teenage and adult patients (800 mg orally five times a day for 5–7 days), and (3) elderly patients and patients with severe, painful, or destructive zoster when seen within 48–72 hours after onset (800 mg orally five times a day for 7 days). Alternative drugs for acute herpes zoster are famciclovir, 500 mg three times daily for 7 days, and valacyclovir, 1 g three times daily for 7 days.

Secondary bacterial infection should be treated aggressively. Cool compresses and antihistamines may help to remove crusts and alleviate pruritus. Analgesics should be provided as necessary.

▶ Rubeola (Measles)

ESSENTIALS OF DIAGNOSIS

- ▶ Incubation period of 7–14 days, followed by high fever, malaise, cough, coryza, and conjunctivitis with photophobia.
- ▶ Three to 5 days later, discrete erythematous macules and thin papules appear on the forehead and behind the ears, spreading to the trunk and extremities, with coalescence and increased redness.
- ▶ Koplik's spots usually appear on buccal mucosa 1–2 days before exanthem.
- ▶ Complications include secondary bacterial infection, otitis media, pneumonia, viral myocarditis, liver function abnormalities, and thrombocytopenia.

General Considerations

Rubeola is an acute epidemic disease characterized by marked upper respiratory symptoms and a widespread erythematous maculopapular rash. It is caused by a paramyxovirus transmitted by inhalation of infected droplets. The severity of the illness varies with the age and immunologic status of the patient.

Clinical Features

A. Symptoms and Signs—After an incubation period of 7–14 days, a prodrome of high fever develops, associated with malaise, cough, coryza, and conjunctivitis with photophobia. In 3–5 days, discrete erythematous macules and thin papules appear on the forehead and behind the ears. Over the next few days, the lesions spread to the trunk and extremities (including the palms and soles), coalesce on the face and upper trunk, and intensify in color to a deeper red. The eruption fades after 5–10 days in the order of its appearance, often with fine desquamation and postinflammatory hyperpigmentation. Koplik's spots—blue-white pinpoint macules with a red halo—usually appear on the buccal mucosa 1–2 days before the exanthem and remain for several days. Up to 40% of immunocompromised patients with measles have no rash; the remainder have either typical or unusual skin findings, including urticarial plaques, petechiae, and palpable purpura. Rubeola must be distinguished from cutaneous drug reactions as well as other viral exanthems.

Complications may arise from viral dissemination, secondary bacterial infection, or hypersensitivity phenomena. Otitis media, sinusitis, pneumonia, and liver function abnormalities are common. Viral myocarditis and thrombocytopenic purpura (owing to immune-mediated platelet destruction) may occur. Death, resulting from pneumonitis or encephalitis, occurs in about 0.1% of patients in the

United States. The complication and case-fatality rates for the very young, the elderly, the malnourished, and patients with malignancies or HIV infection are significantly higher. The clinical presentation in immunocompromised patients is frequently atypical. One-third of such patients present with no rash.

B. Laboratory Findings—Serologic studies of paired specimens are the most practical method of confirming the diagnosis. Measles virus may be isolated from the blood, urine, nasopharyngeal washings, and throat or from conjunctival secretions.

Treatment

Therapy is supportive because no proven antiviral agent is available. Aerosolized ribavirin may be beneficial for the treatment of measles pneumonitis, but its effectiveness has not yet been proved. Intravenous immunoglobulin and interferon are other treatment options for measles pneumonitis and encephalitis. Isolation precautions must be observed.

Perry RT, Halsey NA: The clinical significance of measles: A review. *J Infect Dis* 2004;189:S4–16. [PMID: 15106083]

► Meningococemia

ESSENTIALS OF DIAGNOSIS

- ▶ Petechial (or, less commonly, urticarial or morbilliform) rash on the trunk and lower extremities; also on the palms, soles, and mucous membranes; petechiae are frequently palpable, with gun-metal gray centers and irregular borders.
- ▶ If complicated by purpura fulminans, extensive hemorrhagic bullae and areas of necrosis.
- ▶ Other features of meningococcal meningitis or disseminated meningococemia, including meningeal signs, arthritis, myocarditis, pericarditis, and acute adrenal infarction; hypotension and shock are often present.
- ▶ Confirmation of *Neisseria meningitidis* by culture, Gram stain, or immunologic tests.

General Considerations

N. meningitidis is a gram-negative diplococcus responsible for a spectrum of illnesses ranging from a mild upper

respiratory infection to fulminant septicemia. Disease occurs most often in children under age 15, with the attack rate highest in infants 6–12 months of age. Peak incidence of infection is in the winter and spring. Asymptomatic colonization of the nasopharynx is common and provides a source of person-to-person transmission through infected droplets. People with deficiencies of the terminal components of the complement cascade (C5–9) are particularly susceptible to invasive and recurrent meningococcal disease. The cutaneous lesions are a consequence of damage to small dermal blood vessels both by direct bacterial involvement of skin vessels and by lipopolysaccharide endotoxins.

Clinical Features

A. Symptoms and Signs—Invasive meningococcal disease usually results in meningitis or meningococemia. The incubation period varies from 2–10 days. The onset may be insidious, following a flulike illness, or abrupt, with fever, chills, malaise, signs of meningeal irritation, prostration, and shock. A rash that is characteristically petechial or, less commonly, urticarial or morbilliform is often among the earliest signs of generalized infection. The petechiae typically appear on the trunk and lower extremities but also can be found on the palms, soles, and mucous membranes. They are frequently palpable, with gun-metal-gray centers and irregular borders.

Extensive hemorrhagic bullae and areas of necrosis develop in patients with meningococemia whose disease is complicated by purpura fulminans. Obtundation, hypotension, and death may ensue within hours despite appropriate antimicrobial therapy. Absence of meningeal signs is a feature of this acute fulminant form of meningococcal disease. Children under age 2 have the highest mortality rate, perhaps as a consequence of immaturity of the protein C system.

Other complications of invasive meningococcal disease are arthritis, myocarditis, pericarditis, cervicitis, and Waterhouse-Friderichsen syndrome. More rare meningococcal diseases include occult bacteremia and chronic meningococemia.

B. Laboratory Findings—Confirmation of the diagnosis depends on demonstration of the organism. This may be by culture, Gram stain, or immunologic tests. Blood and cerebrospinal fluid cultures are indicated in all patients suspected of having invasive disease. Nasopharyngeal and synovial cultures are positive in some cases. Counterimmunoelectrophoresis or latex agglutination with group-specific antisera of cerebrospinal fluid, urine, or tears can facilitate rapid diagnosis. A Gram stain of material from purpuric lesions may reveal the organism. Other laboratory studies are otherwise nonspecific but should be performed as indicated to assess and monitor the illness, including evaluation for DIC.

Differential Diagnosis

Meningococcal infection must be considered in patients with the combination of fever and a petechial rash, especially in association with meningitis. Depending on the clinical presentation, other infections, such as gram-negative septicemia, Rocky Mountain spotted fever, echovirus and coxsackievirus infections, and atypical measles, must be excluded. Vasculitis and other causes of purpura also are diagnostic possibilities.

Treatment

Intravenous penicillin G or ampicillin is the therapy of choice. Ceftriaxone is an acceptable alternative (see Chapter 15). Hemodynamic and other supportive measures must be provided as necessary to maintain organ system function. Respiratory isolation is mandatory. Close contacts of patients with meningococcal disease should be given rifampin prophylaxis and monitored closely.

Ramos-e-Silva M, Pereira AL: Life-threatening eruptions due to infectious agents. *Clin Dermatol* 2005;23:148–56. [PMID: 15802208]

▶ Rocky Mountain Spotted Fever

ESSENTIALS OF DIAGNOSIS

- ▶ Potential exposure to ticks in endemic area.
- ▶ After incubation period of 1–14 days, sudden onset of fever, headache, myalgia, and nausea or vomiting.
- ▶ Appearance on days 2–4 of blanchable pinkish red macular rash over ankles, wrists, and forearms, spreading to involve the soles, palms, extremities, trunk, and face within hours; bilaterally symmetric petechiae of the palms and soles are a major finding.
- ▶ May be complicated by CNS, cardiac, pulmonary, renal, or other organ involvement; DIC and shock leading to death may occur.
- ▶ Diagnosis can be confirmed by serologic tests, but these are not reliable before the second week of illness.

General Considerations

Rocky Mountain spotted fever is an acute systemic illness characterized by fever and a purpuric eruption. The disease is transmitted to humans by the bite of a tick infected with the causative organism *Rickettsia rickettsii*. Transmission reflects the tick season in a particular geographic area, with highest incidence in spring and summer. The disease is widespread in the United States and Canada; most cases are from

the southeastern and Rocky Mountain states. All age groups are affected, but most are between 5 and 9 years old.

Clinical Features

The incubation period is usually about 1 week, ranging from 1–14 days.

A. Symptoms and Signs—Sudden onset of fever, headache, myalgia, and nausea or vomiting are initial features. On the second to fourth days of illness, a blanchable pinkish red macular rash appears over the ankles, wrists, and forearms, spreading to involve the soles, palms, extremities, trunk, and face within hours. Over the next 1–2 days, the eruption becomes papular and nonblanchable (purpuric) and may evolve into gangrene of the digits, nose, earlobes, scrotum, or vulva. Bilaterally symmetric petechiae of the palms and soles is a major finding. The illness can persist up to 3 weeks and may be complicated by CNS, cardiac, pulmonary, renal, or other organ involvement. DIC and shock leading to death may occur.

B. Laboratory Findings—The diagnosis of Rocky Mountain spotted fever can be established retrospectively by one of many serologic techniques, including complement fixation, latex agglutination, or microagglutination tests. However, these tests are not reliably positive before the second week of the illness.

Skin biopsy reveals a necrotizing vasculitis. A Giemsa-stained smear of tissue sections occasionally may demonstrate the organism. Immunofluorescent microscopic examination of skin biopsy specimens may confirm the diagnosis as early as the fourth day of illness.

Differential Diagnosis

Rocky Mountain spotted fever must be differentiated from other serious febrile illnesses such as viral and bacterial meningitis, meningococcemia, measles, vasculitis, and thrombotic thrombocytopenic purpura.

Treatment

Treatment should be initiated as soon as the diagnosis is suspected. Doxycycline is the drug of choice for patients with Rocky Mountain spotted fever. Gangrene of the earlobes, digits, nose, etc. requires additional antibiotics if secondarily infected.

▶ Necrotizing Fasciitis

ESSENTIALS OF DIAGNOSIS

- ▶ Typically occurs following surgery or penetrating trauma; diabetes may be a predisposing condition.
- ▶ Erythema, edema, and pain develop 1–2 days following surgery or trauma with central areas of dusky gray-blue discoloration, occasionally in association with serosanguineous blisters.
- ▶ Involved areas become gangrenous within a few days; culture frequently grows multiple aerobic and anaerobic bacteria.
- ▶ Severe systemic toxicity is usually present.

General Considerations

Necrotizing fasciitis is a rare, life-threatening soft tissue infection characterized by acute and widespread fascial necrosis. It typically occurs following surgery or penetrating trauma. Diabetes may be a predisposing condition. The pathogenesis involves the introduction of organisms into the subcutis with subsequent spread through fascial planes. Many different virulent bacteria have been isolated in association with necrotizing fasciitis, including β -hemolytic streptococci, staphylococci, coliforms, enterococci, *Pseudomonas*, and *Bacteroides*. *Rhizopus* and *C. albicans* have been cultured from tissue. The process is often fatal unless diagnosed quickly and treated aggressively.

Clinical Features

A. Symptoms and Signs—Erythema, edema, and pain develop 1–2 days following introduction of the organism into the subcutis. The infection spreads rapidly and deeply, resulting in local tissue ischemia. Clinically, there are central areas of dusky gray-blue discoloration, occasionally in association with serosanguineous blisters. Crepitus is usually absent in necrotizing fasciitis. Within a few days, these areas become gangrenous; liberation of toxins and organisms into the bloodstream leads to severe systemic toxicity. The extremities are the most commonly affected site, but the trunk, perineum, and abdomen also may be affected. Fournier's gangrene is necrotizing fasciitis of the perineum, scrotum, or penis that spreads rapidly to the anterior abdominal wall. Necrotizing fasciitis may be confused with cellulitis, angioedema, eosinophilic fasciitis, and clostridial myonecrosis.

B. Laboratory Findings—Incisional biopsy of both the advancing edge and the involved tissue should be performed early, looking for necrotic fascia and the causative organism. Tissue cultures frequently grow multiple aerobic and anaerobic bacteria as well as fungi. Radiographs of soft tissue rarely may reveal tissue gas.

Treatment

Radical surgical debridement, intravenous broad-spectrum antibiotics, and general supportive care are the mainstays of therapy. The major indication for operative treatment is fasciitis spreading despite empirical antibiotics in an acutely ill patient.

▶ Toxic Shock Syndrome (TSS)

ESSENTIALS OF DIAGNOSIS

- ▶ Highest incidence in menstruating women, persons with focal staphylococcal infection or colonization, and women using a diaphragm or contraceptive sponge—but may occur in others.
- ▶ Rapid onset of fever, vomiting, watery diarrhea, sore throat, and profound myalgias, with hypotension.
- ▶ Diffuse, blanching erythema appears early, predominantly truncal, with accentuation in the axillary and inguinal folds and spreading to the extremities; desquamation of the involved skin and of the palms and soles seen during the second or third week.
- ▶ Acute renal failure, acute respiratory distress syndrome (ARDS), refractory shock, ventricular arrhythmias, and DIC may occur.

General Considerations

Toxic shock syndrome is a multisystem illness characterized by the acute onset of high fever associated with myalgias, vomiting, diarrhea, headache, pharyngitis, and hypotension. Mucocutaneous findings are prominent. Staphylococcal pyogenic toxin superantigens (TSST-1) and enterotoxins B and C are involved in the pathogenesis. Streptococcal toxic shock syndrome is caused mainly by toxin-producing group A strains but also by strains of groups B, C, F, and G. In the 1980s, most cases occurred in menstruating women using superabsorbent tampons. Currently, most cases are caused by nonmenstrual *S. aureus* infection—postoperative,

influenza-associated, or recalcitrant erythematous desquamating syndrome—or by colonization of contraceptive diaphragms or sponges. Streptococcal toxic shock syndrome may or may not be associated with necrotizing fasciitis or myositis.

Clinical Features

The Centers for Disease Control and Prevention (CDC) case definition of toxic shock syndrome is based on six major criteria—high fever, rash, desquamation, hypotension, involvement of three or more organ systems (eg, GI, muscular, mucous membrane, renal, hepatic, hematologic, and CNS)—and exclusion of other causes.

A. Symptoms and Signs—Patients usually present with rapid onset of fever, vomiting, watery diarrhea, sore throat, and profound myalgias. Significant hypotension develops during the first 48–72 hours of illness. Multisystem organ involvement probably results both from poor tissue perfusion and from toxin-induced damage. Potentially devastating complications include acute renal failure, ARDS with pulmonary edema, refractory shock, ventricular arrhythmia, and DIC. Some patients have relatively mild episodes.

The cutaneous and mucous membrane findings are prominent but not diagnostic. A diffuse, blanching erythema (scarlatiniform exanthem) appears early. The rash is predominantly truncal, with accentuation in the axillary and inguinal folds and spreading to the extremities. Erythema and edema of the palms and soles may develop. Generalized nonpitting edema is also common. Intense hyperemia of the conjunctival, oropharyngeal, and vaginal surfaces is a frequent finding. Desquamation of the involved skin and of the palms and soles is seen during the second or third week of illness. Toxic shock syndrome recurs in approximately 30% of untreated patients. Mortality is higher (12%) in patients with nonmenstrual causation.

B. Laboratory Findings—Laboratory studies are useful for assessing and monitoring the severity and progression of the illness. Patients often have leukocytosis with a left shift and thrombocytopenia. If DIC is suspected, coagulation studies should be obtained. Serum electrolytes, calcium, phosphorus, creatine kinase, renal function and liver function tests, albumin, total serum protein, and amylase may be abnormal. Urinalysis may show proteinuria and pyuria.

Chest x-ray, arterial blood gas determinations, and echocardiography may provide useful information. Cultures of blood, soft tissue sites of infection, and all mucosal surfaces (including the trachea if intubation is performed) should be obtained. Serologic tests should be ordered for Rocky Mountain spotted fever, leptospirosis, or measles, as indicated in individual patients, to exclude alternative diagnoses.

Differential Diagnosis

Toxic shock syndrome is a clinical diagnosis. Appropriate laboratory tests help to distinguish it from several serious and potentially life-threatening exanthematous diseases, including streptococcal toxic shock–like disease, scarlet fever, Kawasaki's disease, Rocky Mountain spotted fever, SJS, drug eruptions, bacterial sepsis, measles, and leptospirosis.

Treatment

Tampons or other contraceptive devices must be removed immediately, followed by irrigation of the vagina. Any surgical packings also should be removed. Soft tissue abscesses, empyema, and other sites of infection require surgical drainage and irrigation.

An antistaphylococcal antibiotic should be administered intravenously based on a presumptive diagnosis, although its effect on the outcome of the acute episode is unclear. Antibiotics do reduce the recurrence of menses-related toxic shock syndrome. Treatment of group A streptococcal toxic shock syndrome includes penicillin or ceftriaxone plus clindamycin or erythromycin.

Supportive care, including management of organ system failure and treatment of hypotension, is the mainstay of therapy. Systemic corticosteroids, if given within 3–4 days of disease, reduce its severity and shorten the duration of fever.

Critical Care of Vascular Disease & Emergencies

James T. Lee, MD
Frederic S. Bongard, MD

The critical care of patient with peripheral vascular disease requires considerable diagnostic skill and clinical acumen. Associated medical comorbidities—diabetes, renal insufficiency, coronary artery disease, and many others—necessitate admission to an ICU for preoperative optimization and postoperative observation. Acute arterial occlusion, pulmonary embolism, and—with the advent of endovascular interventions—pseudoaneurysm formation are among the more common vascular-related complications encountered in the otherwise routine care of medical and surgical patients. This chapter addresses acute vascular emergencies in critically ill patients and discusses the management of complications following both elective and emergency vascular surgical procedures.

VASCULAR EMERGENCIES IN THE ICU

▶ Acute Arterial Insufficiency

ESSENTIALS OF DIAGNOSIS

- ▶ The “six Ps”: pain, paralysis, paresthesia, pallor, pulselessness, and poikilothermia.
- ▶ Loss of light touch and position sense followed by paralysis.
- ▶ Absence of previously palpable distal pulses and slow capillary refill.
- ▶ Cool extremity with skin mottling, often with a detectable line of demarcation.
- ▶ Collapse of the superficial venous system and development of venous thrombosis and rigid muscular compartments in prolonged ischemia.

General Considerations

The management of acute limb ischemia continues to challenge today's critical care specialist. Patients often present in a severely compromised state with unclear symptomatology and may have multiple associated medical illnesses. Despite improved therapeutic options in recent years, outcome remains poor. In a review of 35 reported series, a mortality rate of 26% and an amputation rate of 37% were documented.

Decreased arterial inflow in a previously normal limb may be due to embolization from a remote origin (owing to *in situ* thrombosis from preexisting occlusive disease) or may occur in association with a low-flow state. Although thrombosis occurs more frequently than embolic occlusion in the general population, progression to complete occlusion of an atherosclerotic thrombus is an unusual cause of acute arterial insufficiency in a critically ill patient admitted for other reasons. Depending on the artery affected and the adequacy of collateral circulation, clinical presentation may be along a continuum from subtle to overt limb threat.

The most common site of origin of an embolus is the heart, with atherosclerotic disease the predominant underlying factor. Other sources include aortic and peripheral aneurysms, atherosclerotic debris from ulcerating plaques, and less commonly, paradoxical embolus through a cardiac anomaly, arteritis, or vascular trauma. Atrial fibrillation, often seen in the postoperative setting, is currently associated with two-thirds to three-quarters of peripheral emboli.

Acute arterial insufficiency in the ICU is most commonly caused by intrinsic obstruction produced by the embolization of clot from distant sites. Atherosclerotic cardiac vascular disease accounts for 60–70% of all arterial emboli. Most arise in patients with atrial fibrillation and stasis in the left atrial appendage. Those who have sustained a recent myocardial infarction also may develop mural thrombi, most commonly at the cardiac apex or in a trabeculation of the left ventricle. No clear temporal relationship exists between the time of the myocardial infarction and when embolization

occurs. When congestive heart failure or cardiomyopathy is present, dyskinetic segments again result in areas of relative stasis that lead to the formation of thrombi. After separation from its site of origin, an embolus may be swept into the innominate or left subclavian artery and travel distally in an upper extremity until the arterial tree narrows sufficiently to trap it. If it is carried into either of the internal carotid or vertebral arteries, a bland (dry) stroke results. Distal emboli typically lodge where vessels taper or branch and consequently are seen in the superior mesenteric artery, resulting in visceral ischemia, or in the iliac, femoral, or popliteal arteries. Peripheral emboli travel to the lower extremities 10 times more often than to the upper extremities. Commonly involved arterial segments are listed in [Table 29-1](#).

Other intrinsic sources of arterial emboli are atherosclerotic debris from aneurysms, fibrin plugs, or collections of platelets. It is unusual for atherosclerotic emboli to present de novo in a patient admitted to the ICU for another reason. The exception to this is the blue toe syndrome, which results from occlusion of digital vessels by atherosclerotic emboli. However, when the possibility of an expanding aneurysm or symptomatic chronic aortic dissection was the reason for admission, acute limb ischemia should arouse concern that the atherosclerotic plaque or the grumous clot lining the aneurysm has embolized.

Patients with atherosclerotic microemboli frequently have transient focal ischemia associated with minor tissue loss. The clinical distinction between arterial embolism and

Table 29-1. Sites of peripheral arterial emboli.

Segment	Incidence (%)
Femoral	36
Aortoiliac	22
Popliteal-tibial	15
Upper extremity	14

arterial thrombosis is often difficult to make, although an effort should be made to confirm the diagnosis because of the differences in therapeutic approach and outcome ([Table 29-2](#)). Fibrin plugs and platelet emboli occur most commonly in patients with disseminated intravascular coagulation (DIC) or in those anticoagulated with heparin who develop antiheparin antibodies.

Extrinsic emboli are produced when foreign material such as catheter tips, balloon fragments, and endovascular

Table 29-2. Differentiation of embolism from thrombosis.

Characteristics of Occlusion	Embolus	Thrombosis
Onset of symptoms	Rapid or immediate	Slower or insidious
Prior symptoms: claudication	Rare	Frequent
Length of time to presentation	Acute	Chronic
Identifiable source	Recent cardiac disease (eg, atrial fibrillation, myocardial infarction)	None
Physical findings	Normal contralateral extremity	Bilateral peripheral vascular disease
Angiography	Multiple sharp cutoffs, "reversed meniscus," scant collaterals	Diffuse peripheral vascular disease, irregular cutoff, many collaterals
Goal of immediate therapy	Eliminate embolus	Correct disease
Long-term pharmacologic treatment	Anticoagulation	Platelet inhibition
Results of thromboembolectomy	Good	Poor
Amputation risk	Lower	Higher
Causes of mortality	Cardiac disease	Limb ischemia

occluding devices migrate to distant sites. Bullet emboli should be remembered as a possible cause of acute arterial insufficiency in a trauma victim in whom the missile was not recovered or was unreachable at the time of surgery. Other penetrating injuries, such as stab wounds, may partially disrupt the vascular intima and begin the process of dissection and thrombotic occlusion.

Once arterial flow is halted, three pathophysiologic events occur, each worsening the overall ischemic insult. Initially, propagation of thrombus can occlude potential collateral vessel orifices and lend to the *no-reflow phenomenon* once large vessel revascularization is established. Second, cellular swelling owing to local hypoxia may cause red blood cell trapping and effectively increase the ischemic period even after adequate inflow is restored. The cause of cellular swelling is debated but may consist of failure of the sodium pump. This inability to reperfuse after ischemic intervals is termed the *no-reflow* or *low-reflow phenomenon*. As fluid leaves the interstitium and enters the cellular matrix, the effective viscosity of the blood increases, raising the pressure required to overcome the blood's inertia (yield stress) and causing significant narrowing and occlusion of the arterioles, capillaries, and venules. The more protracted the ischemic period, the greater is the fluid loss and the higher is the yield stress. Muscle damage produced by ischemia and reperfusion is more related to "reflow" than to the absolute period of ischemia. Animal models have shown that graded return of inflow over a period of time did result in improved postischemic muscle function and less edema. The mediators of capillary endothelial injury are highly active oxygen metabolites such as superoxide (O_2^-) and hydroxyl ($-OH$) radicals. On reperfusion, the lactic acid, potassium, myoglobin, and cardiodepressants such as thromboxane that have accumulated in the ischemic limb are systemically released. The resulting metabolic acidosis and biochemical insult can have profound consequences in an already fragile patient.

Peripheral nerve fibers that mediate light touch and position sense are much more vulnerable than skin and subcutaneous tissue. Thus deficits in these areas, although subtle, present an illusion of surface viability while masking the presence of complete functional loss.

Clinical Features

A. Symptoms and Signs—Acute ischemia is often manifested by some or all of the six cardinal signs known as the "six P's." Ischemic pain is profound, and most patients require large doses of opioid analgesics before they obtain relief. The diagnosis of acute arterial ischemia is usually entertained because of the localized nature of the pain. The level of the obstruction is typically in the artery lying one joint above the area of discomfort (Table 29–3). Emboli to the axillary artery, which has excellent collateral flow, are either asymptomatic, detected primarily by a pulse deficit, or noted only with physical activity. Conversely, emboli to the common femoral or popliteal arteries typically produce

Table 29–3. Demarcation of physical findings in relation to site of arterial occlusion.

Site of Occlusion	Line of Demarcation
Infrarenal aorta	Mid abdomen
Aortic bifurcation and common iliac arteries	Groin/pelvis
External iliac arteries	Proximal thigh
Common femoral artery	Lower third of thigh
Superficial femoral artery	Upper third of calf
Popliteal artery	Lower third of calf

profound ischemia, and symptoms appear rapidly. On examination, the extremity is pallid and cool. Unlike venous thrombosis, arterial ischemia produces a white rather than a violaceous limb. Occasionally, the sensorial perception of numbness and paresthesias predominates and may mask the primary component of pain. A late sign, paralysis is the result of motor nerve ischemia followed by muscle necrosis. Distal pulses are usually absent, although profound ischemia may occur in the presence of a normal pulse when the embolus is lodged distally in the small arteries of the hand or foot. In some patients—especially those with chronic disease and generalized edema or anasarca—pulses may be difficult or impossible to detect. The extremity may be firm because of muscle swelling. A compartment syndrome occurs when muscle swelling limits venous outflow from within a fascial compartment. An indurated and hard compartment is an indication for release of the pressure by fasciotomy.

Although indicative of arterial insufficiency, these symptoms are in essence nonspecific. They serve to alert the clinician to the presence of ischemia but do not lend themselves to grading or quantification. It is of paramount importance to assess the degree of ischemia, which is stratified into three categories based on the physical findings: viable, threatened, and irreversible. Symptoms depend on the location of the embolus and the adequacy of the collateral circulation. The Joint Council of the Society for Vascular Surgery and the North American Chapter of the International Society for Cardiovascular Surgery has developed a consensus that divides severity of limb ischemia into three categories (Table 29–4). Category I (viable) limbs usually present as an acute on chronic process. Patients in this category have abundant collaterals and develop an acute femoral artery thrombosis overlying a chronic stenosis. The prognosis of category II patients is dictated by the time interval between diagnosis and revascularization. Prompt versus immediate intervention

Table 29-4. Clinical categories of acute limb ischemia.

Category	Description	Sensory Loss	Muscle Weakness	Arterial Doppler	Venous Doppler
I. Viable	No immediate threat	None	None	+	+
II. Threatened	Salvage with prompt treatment	Minimal	None	-	+
Marginal	Salvage with immediate treatment	Rest pain	Mild to moderate	-	+
Immediate	Permanent tissue loss	Anesthetic	Paralysis	-	-
III. Irreversible					

Adapted from Rutherford RB et al: Recommended standards for reports dealing with lower extremity ischemia: Revised version. *J Vasc Surg* 1997;26:517.

is dictated by the severity of presentation. Amputation is the only recourse in category III patients.

B. Noninvasive Diagnostic Studies

1. DOPPLER EXAMINATION—A Doppler flow probe is useful in patients who are edematous or in whom a pulse may not be detectable for other reasons. Evidence of flow by Doppler examination indicates only that obstruction is not complete—it *does not mean that flow is adequate*. One should guard against grading “Doppler pulses” because they are influenced by several factors, including the angle of insonation, the gain of the system, and the flow in the artery. The more superficial the vessel under consideration, the higher is the frequency of the probe that should be used.

2. ANKLE-BRACHIAL INDEX (ABI)—Although used primarily in patients with chronic arterial disease, the ABI may be useful in patients who complain of subtle changes in their extremities. The ABI is also useful in postoperative vascular patients for monitoring graft patency. The index is calculated by placing a blood pressure cuff at the high calf position, just below the knee, where it will occlude the tibial arteries. A Doppler probe is placed over either the posterior tibial or the dorsalis pedis artery, and the cuff is then deflated. The pressure at which flow resumes is documented to obtain an opening pressure. The brachial artery pressure is measured in a similar manner, taking the arm with the higher systolic pressure. The ankle-brachial index then is calculated (by dividing ankle Doppler pressure by brachial Doppler pressure). An index greater than 1.0 is normal, and an index less than 0.4 signifies a threat to the limb. Of greatest value are changes in the index from previous values or a discrepancy between the two extremities.

3. DUPLEX SCANNING—In equivocal cases or when angiography is not available, noninvasive color-flow duplex ultrasonography has been a major advance in the diagnosis and treatment of vascular diseases. It has several components. A two-dimensional real-time image is projected in the B mode, which can locate vessels in soft tissues, measure vessel

diameters, and reveal irregularities within the lumen. This may be helpful in locating the position of the embolus. Pulsed-wave Doppler technology determines the velocity of blood flow at a specified location that is superimposed on the B-mode image. Turbulent flow is seen with a mosaic pattern, whereas a color-flow void signifies occlusion. Although duplex scanning can be performed conveniently at the bedside, it has the disadvantage of being highly operator-dependent. Duplex scanning can provide essentially the same information as arteriography with respect to localization of arterial segments with either stenosis or total occlusion.

4. AIR PLETHYSMOGRAPHY—Although it is seldom used, air plethysmography remains a valuable noninvasive diagnostic technique. Several types are available, but all measure the same physiologic parameter: change in volume. A blood pressure cuff is placed around the affected extremity and inflated to 65 mm Hg. A pressure waveform tracing is then recorded, and occlusive disease is graded based on pulse contour. An advantage of this application is that the recording obtained is not affected by vessel wall stiffness. In conjunction with segmental pressure measurements, an accurate assessment in patients with peripheral occlusive disease can be made. However, in the setting of acute limb ischemia, other more specific modalities are necessary.

C. Angiography—Radiographic studies are best obtained in consultation with a vascular surgeon to avoid unnecessary delays. Arteriography remains the standard and is extremely useful in the planning of operative procedures and is recommended in all but the most straightforward cases. Only when the location of the occlusion is apparent (eg, femoral embolus) and coupled with an acutely ischemic limb is preoperative angiography required. However, when symptoms are atypical in a threatened limb, arteriography is helpful in determining the surgical strategy or in the institution of catheter-directed thrombolytic therapy. The major disadvantage of radiologic studies in this setting is the time required to obtain them. Delayed can lead to irreversible soft tissue ischemic injury.

Differential Diagnosis

Acute arterial insufficiency owing to an embolus may be mimicked by low-flow states produced by congestive heart failure and hypovolemic shock. In the latter conditions, however, global ischemia is present, and the localizing symptoms associated with an embolus are lacking. Acute stroke or transient ischemic attacks may produce muscle weakness but are seldom associated with pain. Aneurysmal disease or aortic dissection not only may be the source of emboli but also may result in rupture. If a dissection extends distally, it may become thrombotic, producing acute ischemia of the organs that receive blood from its false channel. Diabetic neuropathy and neuritis may produce hypesthesias in the extremities but seldom are a diagnostic dilemma.

Treatment

Prompt restoration of inflow is the most important management priority. In general, the extent of tissue necrosis and the resulting disability are directly proportional to the duration of ischemia. Tolerance of ischemia varies widely among different tissues, extremities, and individuals. Thus a safe upper limit for arterial compromise cannot be established, although most authorities cite 4–6 hours as the usual time limit beyond which irreversible injury of muscles and nerves may have occurred, even though the overlying skin still may be viable. For this reason, once a threat to limb survival has been recognized, prompt treatment is paramount.

A. Anticoagulation—Systemic anticoagulation with heparin is used unless life-threatening contraindications such as active GI or cerebral bleeding is present. Heparin prevents the distal propagation of thrombus, protects the distal vascular bed, and preserves the extremity's outflow. The usual dose of heparin is 100 units/kg given as a bolus, followed by 10–20 units/kg per hour. Before heparin is started, one should record a baseline partial thromboplastin time (aPTT), prothrombin time (PT), and platelet count. Heparin is cleared when bound to receptors on endothelial cells and macrophages, where it is depolymerized. Consequently, its half-life depends on the initial bolus. The half-life increases from approximately 30 minutes following an intravenous bolus of 25 units/kg to 60 minutes with a bolus of 100 units/kg and to 150 minutes with a bolus of 400 units/kg. Based on the standard dosage, most authors recommend titrating a continuous heparin drip to lengthen the aPTT to twice baseline. Heparin should be started before any diagnostic maneuvers and may be continued through to the time of surgery. Titration of the heparin dosage should not substitute for or delay appropriate surgical management. The use of heparin should be followed by oral anticoagulation to prevent recurrent embolism in patients undergoing thromboembolectomy.

Some surgeons recommend nonoperative management for acute arterial ischemia, in which case heparin in “high” doses (20,000 units as an IV bolus followed by 4000 units/h) is used as the sole form of treatment. Extreme caution must

be exercised in recommending such therapy, however, and only patients without signs of limb threat should be treated with anticoagulation alone. This therapy is best reserved for upper extremity lesions in which collateral flow is good—or in lower extremity cases in patients whose neural function is not diminished or in whom it improves quickly after institution of therapy.

B. Rheologic Agents—The increase in blood viscosity associated with acute ischemia has led some vascular surgeons to recommend the use of either mannitol or low-molecular-weight dextran (dextran 40; MW 40,000) to reduce cellular swelling. An additional benefit of these agents is that they produce an osmotic diuresis and may help to prevent renal failure owing to myoglobin released from ischemic and necrotic muscle. Mannitol is started with an intravenous bolus dose of 25–50 g. Care must be exercised in patients with congestive heart failure because the increased intravascular volume may worsen cardiac symptoms.

C. Platelet-Active Agents—Aspirin, the agent prescribed most commonly for this purpose, has been thoroughly evaluated and found to prevent vascular death by approximately 15% and nonfatal vascular events by about 30% in a meta-analysis of over 50 secondary prevention trials in various groups of patients. The role of aspirin in acute limb ischemia is more restricted to postoperative adjunctive cardiac prophylaxis.

Integrin glycoprotein IIb/IIIa receptor antagonists (eg, abciximab) inhibit the final common pathway of platelet aggregation. Their development objective was to prevent restenosis in patients undergoing percutaneous coronary intervention. Three large randomized trials involving approximately 27,000 patients resulted in a higher mortality and excessive bleeding complications when compared with aspirin. The role of this class of medications is evolving.

Thienopyridines such as clopidogrel inhibit ADP-induced platelet aggregation with no direct effects on arachidonic acid metabolism. Use of this agent in the acute setting has not been studied; however, in a comparison trial with aspirin involving a subset of 6400 patients, virtually all the benefit associated with clopidogrel was observed in the group with symptomatic peripheral vascular disease. As a group, these patients had fewer myocardial infarctions and fewer vascular-related deaths than did the aspirin-treated group. The main disadvantage is the permanent platelet defect encountered, which can be replaced only with platelet turnover.

D. Thrombin Inhibitors—Direct thrombin inhibitors (eg, lepirudin, desirudin, bivalirudin, and argatroban) have been used successfully to treat arterial and venous thrombotic complications of heparin-induced thrombocytopenia. Despite producing a more predictable anticoagulant response than heparin, direct thrombin inhibitors have yet to find a place in the treatment of acute arterial thrombosis. Potential disadvantages include the irreversible nature of this complex, because no antidote is available if bleeding occurs, and its narrow

Table 29–5. Currently available thrombin inhibitors.

Drug	Dose*	Duration	Notes
Lepirudin	Load: 0.4 mg/kg IV then 0.15 mg/kg/hr	2–10 days	Keep aPTT between 1.5 and 2.5 times normal. Indicated for use in patients with HIT.
Bivalirudin	Load: 1.0 mg/kg IV, followed by 2.5 mg/kg/h for 4 h, then 0.2 mg/kg/h	20 h	Has only been studied with concomitant aspirin treatment.
Argatroban	Initial dose 2 µg/kg/min IV		Indicated as an anticoagulant in heparin-induced thrombocytopenias. Monitor aPTT beginning 2 h after start of infusion—steady state should be 1.5–3 times initial baseline.

*Check current prescribing information. Doses may need to be adjusted in the presence of comorbidities such as hepatic and/or renal failure.

therapeutic window when combined with thrombolytic therapy. Table 29–5 details the currently available thrombin inhibitors. Lepirudin and argatroban are approved for the treatment of thrombosis in patients with heparin-induced thrombocytopenia. There are no currently agents available for reversing the effects of the direct thrombin inhibitors.

E. Thrombolytic Agents—Thrombolytic agents such as urokinase, streptokinase, and recombinant tissue plasminogen activator (rt-PA; alteplase) have been evaluated in numerous clinical trials for safety and efficacy and in comparison with operative management. Initially, an intense thrombolytic state was induced with systemic therapy sustained by constant intravenous infusion. In 10 uncontrolled studies involving 1800 patients, best results were obtained within 72 hours of onset of symptoms. Lysis was observed in 40%, with no difference in success rates between embolic or thrombotic occlusions. Unfortunately, serious hemorrhagic complications occurred in one-third of patients.

Regional or intraarterial thrombolysis has become an alternative to systemic therapy. The rate of successful reperfusion (50–85%) appears to be higher than what is reported with systemic infusion. Local infusion coupled with arteriography conferred an additional advantage in delineating the cause of the arterial occlusion (thrombosis versus embolus). Vessel wall morphologic characteristics that may lead to early recurrent thrombosis also were unmasked and further directed appropriate management (surgery versus angioplasty). Prolonged arterial catheterization (hours to days) resulting in major bleeding (6–20%) remains the main disadvantage of this approach. Current thrombolytic agents include streptokinase, urokinase, alteplase, reteplase, and tenecteplase.

Urokinase, a relatively inexpensive trypsin-like protease, converts plasminogen directly to plasmin. Initially, the main advantages of urokinase over streptokinase were its direct

action on plasminogen and its nonantigenicity. However, pyretic reactions have been observed and attributed to interleukins present during the manufacturing process. As a result, urokinase is currently not available in the United States.

Alteplase is now the only thrombolytic agent available for peripheral arterial thrombolysis. A naturally occurring activator of plasminogen, it is produced and released by the endothelium. Manufactured through recombinant DNA techniques, it is nonantigenic, has a half-life of 3.5–4 minutes, and has a high affinity for fibrin, which enhances lysis at the thrombus level. Similar to urokinase, the primary route of metabolism is hepatic.

Reteplase is a new plasminogen activator approved for treatment of acute myocardial infarction and is used anecdotally in the peripheral vasculature. Designed for use as bolus therapy through recombinant DNA technology, experience with reteplase in arterial and venous thromboembolic disease is limited.

An inert zymogen activated by the presence of fibrin clot, prourokinase is converted to an active two-chain urokinase that is highly fibrin-specific. Availability of this agent is also limited.

Tenecteplase, a genetically engineered variant of alteplase, has a prolonged half-life, increased fibrin specificity, and higher resistance to inhibition by circulating plasminogen activator inhibitor-1. A three-amino-acid substitution resulted in a 14–19-minute half-life and more specific fibrinolysis in comparison with alteplase. Pending approval by the Food and Drug Administration (FDA) for treatment of acute myocardial infarction, the role of tenecteplase in the management of peripheral arterial and venous thrombotic occlusion has yet to be explored.

Because of the lack of evidence demonstrating the benefits of improved limb salvage, lower mortality, or cost-effectiveness, thrombolytic therapy cannot be regarded as

Table 29–6. Thrombolytic agents.

Drug	Half-Life	Intravenous Dose	Intraarterial Dose
Alteplase (t-PA)	3.5 min	50 mg over 2 h, followed by	0.05–0.1 unit/kg/h
Retepase	14 min	10 units over 2 min, then 10	0.25–1 unit/h
Tenecteplase	15 min	0.5 mg/kg	Unknown

Data from Schmittling ZC, Hodgson KJ: Thrombolysis and mechanical thrombectomy for arterial disease. *Surg Clin North Am* 2004;84:1237–66.

first-line treatment in the management of acute limb ischemia. However, it remains a reasonable alternative in a select group of patients, especially those with distal thromboembolic occlusions in surgically inaccessible small arteries of the hands and feet and in patients who are at high risk for surgery (Table 29–6).

F. Surgery—Operation is the best treatment of acute extremity ischemia, achieving both life and limb salvage. Adequate preoperative support is essential. In the presence of active cardiac risk, use of local anesthesia must be considered and adequate intravenous hydration provided to minimize renal insufficiency. At the time of surgery, placement of the incision is guided by the cause of occlusion, the presence of a palpable pulse, and a history of previous revascularization.

In patients with embolic occlusion, exploration of the femoral artery is considered in the presence of femoral and distal pulses. A below-the-knee approach is preferred in patients presenting with a palpable popliteal pulse and distal embolization. Patients with acute ischemia and a previous bypass graft usually are explored through the distal anastomosis.

A transverse incision is often sufficient for passage of a Fogarty catheter. Longitudinal arteriotomy is considered if the cause is not known for certain or if bypass is necessary. Removal of the entire embolic material is essential, and success is confirmed through an intraoperative arteriogram to ensure patency of the arterial runoff distal to the embolus. Approximately 35–40% of completion angiograms will identify residual thrombus.

Although highly successful in embolic occlusion, blind thromboembolectomy in patients with acute on chronic thrombosis is highly dangerous and risks further intimal disruption to an already diseased vessel. Often these patients require further surgical revascularization (eg, bypass or endarterectomy) or endovascular management (eg, thrombolysis, angioplasty, or stent placement in debilitated patients).

Intraoperative lytic therapy has been reported in several series for the following indications: residual thrombus on angiography, slow flow despite the absence of an angiographic defect, prolonged ischemia with evidence of thickened blood

on retrograde bleeding, and persistent ischemia despite restoration of sufficient proximal inflow. In a series of 78 patients, limb salvage was achieved in 73% of the 67% treated successfully.

A new approach to intraoperative thrombolysis undergoing recent investigation is high-dose isolated limb perfusion. Surgical cutdowns of the femoral vessels are performed, with intraarterial insertion of standard infusion pumps. A tourniquet is applied proximal to the exposed vessels, and venous effluent is drained by gravity or through the use of extracorporeal pump support with concomitant dialysis.

Fasciotomy should be considered in all patients following successful revascularization in the setting of prolonged ischemia. Common clinical indications are pain out of proportion to findings, pain on passive stretch, tense muscular compartments with elevated pressures, and compartmental hypesthesia and paralysis.

G. Supportive Care—Perioperative care of the patient following revascularization of an acutely ischemic limb can vary from simple to extremely complex. Reperfusion of an ischemic extremity can lead to the release of toxic cellular products, the generation of oxygen-free radicals, hyperkalemia, increased intracellular calcium overload, myoglobinuria, and altered arachidonic acid metabolism. Critical care therefore is directed toward ameliorating the damage done by cellular breakdown.

Appropriate hemodynamic monitoring is essential. Correction of electrolyte abnormalities and prompt treatment of hyperkalemia through brisk diuresis and administration of insulin and glucose can prevent fatal cardiac arrhythmias. Adequate fluid volume and the administration of mannitol—a free-radical scavenger and osmotic diuretic—is the best strategy to correct acidosis and to prevent acute renal failure caused by myoglobin precipitates.

Local mechanical factors are also important to prevent skin and soft tissue breakdown. The extremity should be kept warm but must not be heated in an effort to restore flow because this will increase the metabolic rate, further the lactic acidosis, and contribute to tissue destruction. Similarly, cooling is inappropriate. Care must be taken to prevent

pressure on an ischemic extremity. Heel pads and cushions should be used as needed. Other vascular precautions include keeping linens suspended with a bed cradle and positioning the patient in reverse Trendelenburg.

In patients who have not undergone fasciotomy, frequent and careful assessment of the lower extremities is warranted. In the event that a compartment syndrome is diagnosed, prompt decompression is required to preserve tissue viability.

Pain control typically requires high doses of an opioid such as morphine. Analgesia must not be increased to the point that symptoms are masked and a reliable neurologic examination cannot be obtained. Short-acting intravenous agents such as fentanyl have been used with success, provided that the dose is regulated so as not to obscure worsening of symptoms.

Prognosis

Despite recent advances in perioperative critical care, the mortality rate after acute leg ischemia remains relatively high. Both the mortality rate and the need for amputation are directly related to the duration of ischemia. A recent study found that no amputations were required when surgery was undertaken within 2 hours compared with a 44% amputation rate when operation was delayed up to 7 days. The mortality rate was 10% in patients with symptoms present for less than 2 hours and 32% in those whose symptoms were present for up to 8 hours. Coexisting cardiopulmonary complications were the underlying cause of most fatalities, especially in patients with acute arterial thrombosis in contrast to peripheral embolism.

Current Controversies and Unresolved Issues

The cause of ischemic injury remains unclear. While it is logical to assume that hypoxia is the culprit, investigations have shown that most of the tissue damage actually occurs during the time of reperfusion. Even short periods of ischemia followed by reperfusion can cause cell damage. A recent canine study found that 3 hours of partial ischemia resulted in more tissue damage than the same period of complete ischemia. Furthermore, the extent of postreperfusion damage can be decreased by graded reflow. These investigations suggest that scavengers of free radicals may be useful in the treatment of acute vascular insufficiency.

Although numerous investigations have been undertaken, little improvement has been made over the last 2 decades in morbidity and mortality associated with surgical thrombectomy in this fragile patient group. The advantage of surgery stems from rapid restoration of blood flow. On the contrary, pharmacologic thrombolysis is much less invasive. The main disadvantage is the time lag involved for revascularization. What is needed is an ideal therapeutic option that achieves rapid blood flow and is minimally invasive. The advent of endovascular surgery has spurred the development

of percutaneous mechanical thrombectomy devices to answer this need. Current devices in various stages of clinical trials include rheolytic, clot aspiration, and microfragmentation catheters.

▶ Deep Venous Thrombosis

ESSENTIALS OF DIAGNOSIS

- ▶ Multiple risk factors.
- ▶ Aching pain exaggerated by motion.
- ▶ Calf and thigh swelling.
- ▶ Tenderness to palpation and dorsiflexion.
- ▶ Erythema, cyanosis, or venous distention.

General Considerations

Three factors (*Virchow's triad*) contribute to the development of venous thrombosis: stasis, increased coagulability, and vessel wall damage. Contrary to former belief, low flow alone is not sufficient to cause thrombosis. Thrombophlebitis is venous thrombosis that follows inflammation of the vessel wall. Because of underlying intimal irregularities, the clot adheres firmly and is unlikely to become dislodged. Phlebothrombosis occurs without vessel wall injury and results in minimal clot adherence.

Patients at risk for the development of deep venous thrombosis may be divided into three groups: (1) Low-risk patients are under 40 years of age and are free of systemic disease. Surgery lasts less than 60 minutes and is uncomplicated. Overall risk for the development of deep venous thrombosis is less than 2%, and the chance of proximal progression is less than 1%. (2) Moderate-risk patients are over age 40 and have undergone general anesthesia for more than 60 minutes. They also may have risk factors such as cancer, obesity, varicose veins, bed rest, or cardiac failure. If prophylaxis is not given, the risk for development of deep venous thrombosis is between 10% and 40% and that of proximal propagation is between 2% and 8%. The risk of fatal pulmonary embolism is almost 1%. (3) High-risk patients have a history of deep venous thrombosis or of pulmonary embolism. They undergo extensive abdominal or pelvic procedures for advanced disease or for some orthopedic indication. The risk of calf vein thrombosis is between 40% and 80% without prophylaxis. Proximal extension occurs in 10–20%, leading to fatal pulmonary embolism in up to 5%. Risk factors for the development of venous thrombi and recommended prophylaxis are listed in [Table 29–7](#). Most deep venous thrombi are initiated by platelet adhesion either to endothelial tissue or to exposed collagen of damaged vascular

Table 29–7. Risk stratification for venous thrombosis and recommended prophylaxis.

	Low Risk	Moderate Risk	High Risk
Event or condition			
General surgery	Age <40 years or time <60 minutes	Age >40 years or time >60 minutes	Age >40 years or time >60 minutes plus risk factor
Orthopedic surgery	—	—	Elective hip or knee surgery
Trauma	—	—	Extensive soft tissue injury; major fractures; multiple trauma
Medical conditions	Pregnancy	Myocardial infarction postpartum, especially with previous deep venous thrombosis; estrogen use; varicose veins	Stroke, paraplegia, spine fracture, prolonged bed rest, burns, hypercoagulable state, obesity
Incidence of thromboembolism without prophylaxis (%)			
Distal calf veins	2	10–40	40–80
Proximal veins (pelvis, thigh, popliteal veins)	0.4	2–8	10–20
Symptomatic pulmonary embolism	0.2	1–8	5–10
Fatal pulmonary embolism	0.002	0.1–0.4	1–5
Recommended prophylaxis	Graduated compression stockings; early ambulation	Heparin (5000 units SC twice daily), LMWH, external or pneumatic compression	Heparin (5000 units SC three times daily), LMWH, external pneumatic compression, inferior vena caval filter, warfarin

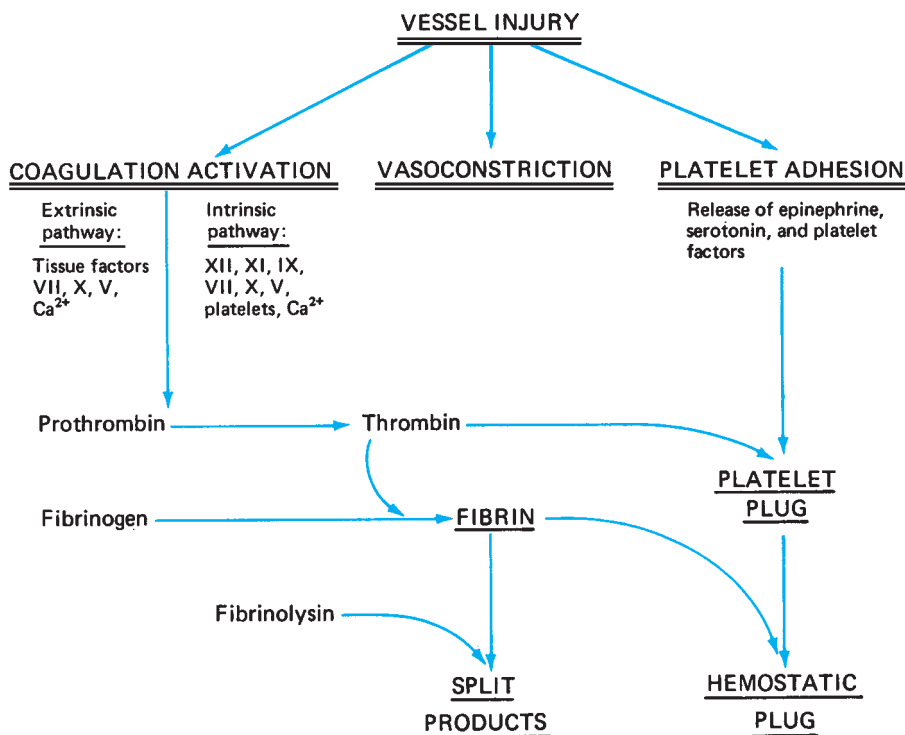

Adapted from Colman RW et al (eds): *Hemostasis and Thrombosis: Basic Principles and Clinical Practice*. Philadelphia: Lippincott, 1994.

walls. As platelet aggregation continues, the clot becomes organized and begins to trap circulating white and red blood cells. Deposition of fibrin organizes the clot and allows it to build a stable matrix.

Activation of either the intrinsic or the extrinsic clotting system contributes to thrombus formation. Adhesion of factor XII to exposed endothelium results in progressive activation of factor X. Activated factor X (Xa), along with factor V, converts prothrombin to thrombin and fibrinogen to fibrin, producing an insoluble clot. Platelets accumulate within the matrix and provide a surface for further fibrin deposition. Thromboxane A₂, produced and released by platelets, aids the process by contributing to vasoconstriction and further platelet aggregation. Prostacyclin, which is produced by vascular intima, limits the process by causing vascular dilation and by inhibiting platelet aggregation. Antithrombin III inhibits the action of factors IX, X, XI, and XII. Proteins C and S, produced by the liver, inhibit coagulation by destroying factors V and VII and provide negative feedback to control the generation of thrombin (Figure 29–1).

The velocity of blood flow is inversely proportional to the propensity for intravascular clotting. However, the threshold for thrombus formation is decreased in the face of vascular endothelial injury. Such injury may be caused by catheters, infection, or external influences. In normal veins, the endothelium is well supplied with prostacyclin and plasminogen, which prevent thrombus formation even at low flow rates. However, when intimal damage is present—or in the face of a hypercoagulable state—thrombus accumulates rapidly. Red clots predominate in the venous system and consist of platelets, red blood cells, and fibrin. White thrombi, which contain chiefly platelets, are usually found in the arterial system.

Hypercoagulable states are common in postoperative critical care patients. The plasma concentration of clotting factors rises after surgery. Maximum procoagulant activity corresponds temporally with the peak incidence of thromboembolism. Detection of hypercoagulability remains difficult except in certain pathologic conditions such as decreased concentrations of antithrombin III, protein C, and

▲ **Figure 29–1.** Factors involved in arrest of hemorrhage. Injury to the blood vessel wall initiates a series of reactions that arrest hemorrhage. The exposed subendothelial collagen initiates formation of the platelet plug (primary hemostasis). The coagulation system is activated, leading to production of fibrin, which interacts with the platelet aggregate to form a hemostatic seal. These relationships are also involved in spontaneous thrombus formation, although the inciting event is usually not identifiable. protein S. Use of some medications, such as oral contraceptives, is known to increase the risk of thromboembolic disease. Ill-defined alterations in the clotting mechanism that predispose to clotting accompany some severe systemic diseases such as cancer and sepsis.

Most deep venous thrombi begin in the veins of the calf. When limited to this location, they are usually asymptomatic except for mild calf pain and minimal swelling. Extension into the deep venous system of the thigh produces more swelling, pain, and purpura. Proximal propagation involves the veins of the pelvis (iliofemoral thrombosis). As outflow is restricted, the lower extremity swells and causes obstruction of lymphatic channels, producing a blanched “milk leg” (*phlegmasia alba dolens*). If patency is not restored, cyanosis and venous gangrene result. This condition, known as *phlegmasia cerulea dolens* (“blue leg”), is more common in the left lower extremity than in the right from compression of the left iliac vein as it passes under the right iliac artery. *Phlegmasia cerulea dolens* is usually associated with disseminated malignancies or sepsis. It is accompanied by hypotension and hypovolemia, which result from venous pooling in the leg.

Thrombosis of the deep veins of the thigh and pelvis dramatically increases the risk of pulmonary embolism. Approximately 85% of clinically significant pulmonary emboli arise from the thighs and pelvis. Eighty percent of deep venous thrombi remain confined to the calf, whereas 20% extend proximally. In the latter group, 40–50% will result in pulmonary embolism if not treated appropriately. Unfortunately, only 30% of those with confirmed pulmonary embolism have objective signs consistent with deep venous thrombosis.

Venous thrombosis of the upper extremities is becoming increasingly prevalent in the ICU as a result of chronic indwelling central venous catheters. Patients being maintained on long-term parenteral nutrition, hemodialysis, antibiotics, or chemotherapy or those with poor peripheral access are some of those at risk. Other predisposing factors include exertion, thoracic outlet syndrome, congenital malformations, and trauma (Table 29–8). Approximately 3–6% of all pulmonary emboli and 1–2% of fatal pulmonary

emboli have been reported to originate from clots in the deep veins of the upper extremity.

Superficial venous thrombi typically present as a small lump or cord. These are usually of no systemic significance except in the saphenous vein of the thigh, where they can propagate through the saphenofemoral junction and gain access to the deep iliofemoral system. When such proximal extension is noted, ligation of the saphenous vein just distal to its origin is warranted.

Clinical Features

A. Symptoms and Signs—Patients may complain of a vague aching sensation or tightness in the calf or thigh. This is worsened by active motion of the calf or foot. When superficial thrombosis is present, localized tenderness is usually also present.

Physical examination is notoriously unreliable for deep venous thrombosis and accurately detects only 50% of cases. Areas with increased tenderness to palpation include the sole, the region deep to Achilles’ tendon, the groove between the tibia and fibula, the regions over the soleus and gastrocnemius muscles, in the popliteal fossa, over the adductor muscles of the thigh, and at the femoral vein near the inguinal ligament. Tenderness induced by compression of the calf muscles anteriorly against the interosseous membrane or with passive dorsiflexion of the ankle (Homans’ sign) is present in less than 30% of patients. Inflation of a sphygmomanometer cuff (40 mm Hg) placed above the knee may provoke pain at the site of the thrombosis. A difference of 1.5 cm in diameter between the swollen and the contralateral leg supports the diagnosis.

Deep venous thrombosis of the axillary and subclavian veins of the upper extremity results in swelling of the entire arm. Pitting edema is usually absent. Percussion over the clavicle and the course of the axillary vein often elicits tenderness.

B. Noninvasive Diagnostic Techniques—Hand-held continuous-wave Doppler devices test for continuity between the deep system of the leg and the intrathoracic vena cava. The probe is placed initially at the popliteal fossa and subsequently over the femoral vein. The patient is instructed to inspire, at which time an augmentation of flow should be heard. The increased flow is due to transmission of the negative intrathoracic pressure to the deep system. This is a useful screening test that can be performed at the bedside, but it has a sensitivity of only about 75% when compared with venography. Duplex scans and color-coded Doppler examinations have accuracy rates between 90% and 100% for detecting large thrombi of the femoral veins in symptomatic patients. The sensitivity decreases to 59%, although the sensitivity remains at 98%, in asymptomatic patients. Accuracy also diminishes when examining the distal veins of the calf owing to poor visualization. Isolated instances of iliac vein thrombosis are also not detectable by ultrasound imaging but may be diagnosed by simple Doppler examination.

Table 29–8. Etiology of upper extremity venous thrombosis.

Source	Incidence (%)
Catheter-associated	30–40
Spontaneous (effort-induced)	20–30
Miscellaneous	30–40
Intravenous drug use	
Thoracic tumors	
Trauma	
Radiation	

Multiple studies have shown that repeat duplex scanning has an improved negative predictive value in patients suspected of deep vein thrombosis but who have negative initial scans. Pressure on the underlying vein by the ultrasound probe helps to establish the age of the clot because fresh thrombi are poorly organized and easily compressible. This is the diagnostic test of choice for most patients, although it requires an experienced technician to perform and interpret.

Impedance plethysmography relies on changes in electrical resistance associated with alteration in limb volume. Deep venous thrombosis impedes venous outflow and causes a slower change in impedance when a proximally occluding cuff is deflated. This technique is very accurate in ambulatory patients but should be interpreted cautiously in those with congestive heart failure or hypervolemia. It is more sensitive for iliac and femoral vein thrombosis than for calf thrombi and generally cannot be used in patients with fractures or bandages that prevent proper electrode positioning. A positive test correctly indicates the presence of thrombosis in 90% of patients. Recently, however, the sensitivity for plethysmography in symptomatic patients was found to be much less than earlier studies reported. In asymptomatic patients, the specificity also falls. Impedance plethysmography can overlook sizable thrombi that are not totally occlusive and can interpret any pelvic venous outflow obstruction (eg, enlarged nodes or pregnancy) as a venous thrombus. It also may be falsely negative in patients with well-developed collaterals.

CT scanning and MR venography have successfully diagnosed thrombi in the proximal veins and have proved to be superior to conventional phlebography in visualizing the great veins, identifying intraluminal thrombi, distinguishing new thrombi, and delineating adjacent abnormalities. Ongoing prospective trials are confirming these initial findings.

C. Invasive Diagnostic Studies—Contrast venography is the “gold standard” with which all noninvasive modalities are compared. It is the most reliable technique for detecting thrombi in any location. Positive findings on venography include constant filling defects, abrupt termination of the dye column, nonfilling of the entire deep venous system or portions thereof, and diversion of flow through collaterals. The venogram catheter may be exchanged for one capable of delivering thrombolytic agents if that therapeutic route is chosen. Overall accuracy is better than 90%. A negative study virtually eliminates the possibility of venous thrombosis. Complications include foot pain at the site of injection and a 2–3% incidence of thrombosis owing to contrast material–induced endothelial cell injury. Not routinely used for primary diagnosis, phlebography has been advocated in the diagnosis of symptomatic recurrent venous thrombosis and after hip operations in suspected patients in whom noninvasive means lack sensitivity.

D. Laboratory Findings—Several blood tests are available that detect activation of the clotting cascade, including measurement of fibrinopeptide A, fibrin monomers, and fibrin

degradation products. Plasma D-dimer, a degradation product of plasmin digestion of mature cross-linked fibrin, is elevated in patients with venous thrombosis. The sensitivity measured by enzyme-linked immunosorbent assay approaches 97%. Although highly accurate, confirmation of venous thrombosis with an elevated D-dimer concentration is necessary with objective imaging tests.

Differential Diagnosis

See Table 29–9.

Prevention

All critically ill patients should be considered for thromboembolic prophylaxis. Particular attention should be paid to those with preexisting risk factors (see Table 29–7).

A. Physical Measures—Early ambulation or exercise of the lower extremity muscles is probably the best and most cost-effective prophylactic measure for preventing subsequent venous thrombosis. Lower extremity elevation and active flexion–extension exercises of the ankle will prevent stasis. Prolonged standing in one position should be discouraged because it promotes venous pooling. Use of thigh-high antiembolism stockings is encouraged when they are fitted properly. Casual application of stockings that extend only to the knee are unlikely to be of value.

Of the compression techniques available, intermittent compression garments are best. Garments with single compartments for the calves or multiple sequential compartments are available. Maximum benefit is realized when they are applied prior to surgery. Direct sequential compression promotes blood flow and also stimulates systemic fibrinolytic activity. Therefore, benefit still accrues even with only unilateral application can be achieved because of bandages or casts. Studies have shown a reduction in the incidence of thrombosis from 23–7% in patients so treated.

B. Anticoagulation—When used properly, preoperative anticoagulation decreases the incidence of postoperative deep venous thrombosis and secondary pulmonary embolism.

Nephrosis
Arterial occlusion

1. WARFARIN—Coumarin derivatives act by suppressing the formation of vitamin K–dependent clotting factors (II, VII, IX, and X). When these agents are initiated before and continued after operation, they are safe and effective. Coumarins require several days to reach full effect because of the time interval required for clearance of normal coagulation factors. These agents are usually started after the patient has already been systemically anticoagulated with unfractionated heparin. Initiation of therapy with warfarin alone can have deleterious effects. Protein C and protein S—natural anticoagulants—are similarly reduced (especially protein C) with factor VII, thereby shifting the hemostatic balance toward coagulation. In patients with underlying protein C and protein S deficiency, warfarin-induced skin necrosis can occur from thrombotic occlusion of small vessels in the subcutaneous tissue. This effect is manifested within 3–8 days of administration of the initial dose. Patients with protein C and protein S deficiency should not receive a loading dose of warfarin, and heparin should be continued until the international normalization ratio (INR) is therapeutic for 2 consecutive days.

Several drug interactions are known to occur with warfarin. Of particular importance are those that increase hepatic degradation (eg, barbiturates) and those that displace warfarin from albumin (eg, aspirin and nonsteroidal anti-inflammatory agents). Coumarins are also teratogenic and should not be given to pregnant patients.

2. HEPARIN—Unfractionated heparin binds with antithrombin III to prevent the conversion of prothrombin to thrombin. A “low dose” unfractionated heparin (LDUH) regimen is used customarily prior to surgery and in the postoperative period while the patient is still at risk. The postulated mechanism of action is enhancement of antithrombin III. The usual regimen consists of 5000 units given subcutaneously 2 hours before surgery and every 8–12 hours during the postoperative period. No changes in the usual coagulation parameters can be detected at this dosing level. Increased bleeding at the time of surgery generally does not occur. Heparin prophylaxis is unlikely to be effective when started in the postoperative period. It is not effective for patients undergoing hip surgery and should not be used in those with bleeding disorders or for scheduled intracerebral procedures.

An adjusted-dose heparin regimen has been described for patients undergoing total hip replacement. Two days prior to surgery, the patient receives 3500 units of heparin subcutaneously every 8 hours, with the dose adjusted to elevate the aPTT to the high-normal range. This regimen has been shown to reduce the incidence of deep venous thrombosis in hip replacement patients from 39–13%.

3. LOW-MOLECULAR-WEIGHT HEPARIN (LMWH)—LMWHs are produced by depolymerization of unfractionated heparin. They have a more uniform molecular weight, longer half-life, and more predictable pharmacokinetics. Significantly, when compared with unfractionated heparin, they have a higher ratio of anti-factor Xa activity to anti-factor IIa activity and are less likely to lead to heparin-induced

thrombocytopenia. LMWH has several clinical advantages over unfractionated heparin. First evaluated in the 1980s in high-risk surgical patients, one daily dose administered subcutaneously is as effective as two or three doses of unfractionated heparin for deep vein thrombosis prophylaxis. It has become the anticoagulant of choice for preventing deep vein thrombosis in most orthopedic procedures. Its long half-life precludes the need for laboratory monitoring, and it is more effective than unfractionated heparin in preventing recurrence of venous thrombosis. Inpatient and outpatient uses of LMWH have equivalent safety and efficacy. LMWH and LDUH appear to be equally effective in reducing the incidence of deep vein thrombosis in general surgical patients. Studies have reported contradictory results with regard to the incidence of wound hematomas and bleeding complications when comparing LMWH and LDUH likely because of the doses used. Higher doses of LMWH are associated with more bleeding, whereas lower doses are equivalent to LDUH in preventing venous thromboembolism in moderate-risk patients and have a lower rate of bleeding complications.

Currently, two LMWH preparations are approved in the United States for the prevention of deep venous thrombosis (Table 29–11). Enoxaparin is approved for use in patients undergoing abdominal surgery as well as hip and knee surgery. It is also approved for use in medical patients who are at risk owing to severely restricted mobility during acute illness. The usual dose of enoxaparin in abdominal surgical patients is 40 mg by subcutaneous injection given once daily. The first dose should be administered 2 hours prior to surgery, and the drug should be continued for 7–12 days after surgery. The same dosing regimen applies to medical patients with the exception that the drug should be started at the time of immobilization. Dalteparin is approved for use in patients undergoing hip replacement surgery and those undergoing abdominal surgery who are at risk for thromboembolic complications. The dose for abdominal surgical patients is 2500 IU given by subcutaneous injection starting 1–2 hours prior to surgery, and then the drug is given once daily for 5–10 days. Neither of the LMWH preparations requires routine monitoring of coagulation parameters during its use. Careful monitoring for bleeding complications is mandatory. The dose of LMWH may need to be reduced in older patients and in those with renal and/or hepatic impairment.

4. LOW-MOLECULAR-WEIGHT DEXTRAN—Dextran 40 acts by coating platelet surfaces to reduce adhesion. It also increases plasma volume and decreases the viscosity of blood. An important mechanism of action may be the prevention of platelet adhesion to venous valve cusps. The usual dose of dextran 40 is 100–200 mL as an intravenous bolus (intraoperatively), followed by 30–40 mL/h for 2–3 days after surgery. Because dextran 40 is a volume expander, patients with congestive heart failure or respiratory distress should be monitored carefully for hypervolemia. Dextran potentiates the effects of heparin, reducing the dosing requirements of the latter by up to 50%.

5. FACTOR Xa INHIBITORS—Fondaparinux is a synthetic molecule that is an indirect inhibitor of factor Xa. It acts by potentiating the anti-factor Xa activity of antithrombin. Fondaparinux has no platelet effect, nor does it modulate primary hemostasis. It is currently approved in the United States for deep vein thrombosis prophylaxis in patients undergoing hip fracture or replacement surgery and knee replacement surgery. Fondaparinux has no effect on routine coagulation studies, and monitoring is not necessary. The usual dose is 2.5 mg given subcutaneously starting 6–8 hours after surgery. Administration either prior to surgery or soon after surgery is associated with an increased risk of major bleeding.

Management of Deep Vein Thrombosis

The objectives of treatment are to limit further accumulation of thrombus, prevent embolization, and minimize injury to venous valves.

A. Supportive Therapy—Treatment of calf vein thrombi remains largely controversial, with most centers recommending supportive care. In several large trials, anticoagulation was withheld safely in patients with suspected deep vein thrombosis and normal results on serial examinations with compression ultrasonography. Only supportive therapy is required, consisting of bed rest, leg elevation, and mild analgesics. Although some advocate the use of warm soaks, this measure can macerate the overlying skin and promote infection. Early ambulation should be encouraged, with elastic stockings as required. Anticoagulation is indicated in patients with symptomatic deep vein thrombosis identified by duplex scanning and those with recurrent venous thrombosis.

B. Anticoagulation—Thrombi of the proximal veins (ie, popliteal vein, femoral vein, and iliac veins) or of the axillary and subclavian veins requires anticoagulation. Heparin, either unfractionated or low-molecular weight, is the agent of choice because it limits further propagation of the thrombus. A recent consensus conference found that there is no difference between them regarding their efficacy or safety. However, because of the advantages of convenient dosing, facilitation of outpatient therapy, and a potentially lower risk for recurrent deep vein thrombosis, some prefer the use of LMWH over unfractionated heparin (UFH). Additionally, there may be a survival advantage favoring the use of LMWH in venous thromboembolic disease associated with malignancy. For most patients, an initial bolus dose of 100 units/kg (UFH) followed by a continuous infusion of 10 units/kg per hour is adequate. Larger doses (200 units/kg as bolus injection) may be given if the clot extends into the iliac or femoral system, if there is profound edema of the leg, or if imaging studies indicate the presence of a long tail extending proximally. Anticoagulation should be assessed by monitoring either the aPTT or the activated clotting time (ACT). The heparin infusion should be titrated to keep the aPTT between 1.5 and 2.5 times normal. Failure to achieve a

therapeutic level of anticoagulation within 24 hours carries a 25% risk of recurrent deep venous thrombosis. Bleeding complications are reduced if dosage is regulated by monitoring of anticoagulation and if the heparin is given by continuous infusion rather than by intermittent bolus administration. Five days of intravenous heparin therapy followed by oral warfarin is usually effective and generally is regarded as conventional therapy.

Although warfarin therapy can be started concomitantly with heparin, most prefer to wait several days before starting oral anticoagulation. Titration of the dose to achieve an INR of 2.0–3.0 is adequate. Oral anticoagulation is continued for 3–6 months following discharge from the hospital based on risk factors (Table 29–10).

Platelet counts should be obtained initially and every other day to detect the development of heparin-induced antiplatelet antibodies. Immune heparin-induced thrombocytopenia (HIT) is suspected when the platelet count falls below 100,000/ μ L or less than 50% of the baseline value. This IgG-mediated platelet deficiency is seen in 3% of patients and occurs 5–15 days after heparin therapy is initiated. Management of patients with persistent thrombosis and HIT can be difficult. Two agents, argatroban and lepirudin, have been approved for patients with HIT needing anticoagulant therapy. Argatroban is begun with a continuous intravenous infusion at 2 μ g/kg per minute and titrated to keep the aPTT 1.5–3 times the initial baseline. Lepirudin (recombinant hirudin) achieves rapid anticoagulation with a loading dose of 0.4 mg/kg followed by an infusion of 0.15 mg/kg per hour. It is adjusted to maintain an aPTT 1.5–3 times normal. Oral warfarin then is instituted for the appropriate duration.

Approximately 3% of patients receiving oral anticoagulation will present with recurrent deep venous thrombosis. These patients should be assessed for a deficiency in antithrombin III and proteins C and S. Bleeding is the major complication of anticoagulation and occurs in 5–10% of patients. This often presents as oozing from wounds, melena, or a heme-positive gastric aspirate. If bleeding continues despite discontinuation of heparin, protamine sulfate, a heparin inhibitor, may be required. Infusion of fresh-frozen plasma and vitamin K can counteract the effects of warfarin.

When LMWH is employed, the dose used depends on the preparation (Table 29–11). Meta-analysis has failed to find a clear advantage of one LMWH over the others with regard to both safety and efficacy. Once-daily administration appears as safe and effective as twice-daily use. Although anticoagulation monitoring generally is unnecessary, anti-factor Xa levels may be followed for 4 hours after injection, with a desirable therapeutic range of 0.6–1.0 units/mL for twice-daily administration and 1.0–2.0 units/mL for once-daily administration. Monitoring is recommended for patients with renal impairment because of the risk of accumulation of anti-factor Xa activity.

C. Thrombolytic Therapy—There are currently two thrombolytic agents available for use in venous thrombosis.

Table 29–10. Recommendations for long-term management of venous thromboembolism.

Patient Characteristic	Recommendation
Calf vein thrombosis	Up to 3 months of anticoagulant therapy
Proximal venous thrombosis or pulmonary embolus without previous episode	Anticoagulant therapy for 4–6 weeks or until risk factor is resolved and patient is mobile, whichever is later. Long-term anticoagulation (indefinite) Either 3–6 months of therapy
a. Transient clinical risk factor—major orthopedic surgery or trauma	
b. Metastatic cancer c. Hypercoagulable risk factors*	
Idiopathic thromboembolism	Lifelong anticoagulation
Recurrent venous thromboembolism	1 year or lifelong anticoagulation
Any venous thromboembolism during pregnancy	Unfractionated intravenous heparin for 5 days, followed by adjusted-dose subcutaneous heparin every 12 hours [†] or low-molecular-weight heparin until delivery followed by oral warfarin for 4–6 weeks.

*Hypercoagulable risk factors include protein C and S, antithrombin III, plasminogen deficiencies; resistance to activated protein C; hyperhomocystinemia, and antiphospholipid antibodies.

[†]aPTT should be checked 6 hours after initial subcutaneous dosing.

Adapted from Ginsberg JS: Management of venous thromboembolism. *N Engl J Med* 1996;335:1816.

Multiple investigations have determined that streptokinase and recombinant tissue plasminogen activator (rt-PA; alteplase) are superior to intravenous heparin in preserving venous patency and valvular function. Approximately 50% of patients treated with thrombolytic agents retain valve function compared with 7% of those treated with heparin alone. If complete thrombolysis is achieved, the incidence of post-phlebotic syndrome is reduced. However, owing to the variable nature of this syndrome, further investigation is warranted to confirm these early findings.

Thrombolytic agents followed by heparin result in more rapid resolution of lower extremity and pulmonary emboli, restoring hemodynamic homeostasis. The main disadvantage is the additional 1–2% risk of intracranial hemorrhage. Because the incidence and mortality of pulmonary embolism are the same in the two treatment modalities, systemic thrombolysis is reserved for acute massive pulmonary embolus in an unstable patient with no bleeding dyscrasias. Young patients with massive iliofemoral venous thrombosis (eg, phlegmasia cerulea dolens) also may benefit from thrombolysis.

Neither streptokinase nor alteplase directly dissolves the clot but rather requires activation of the fibrinolytic system. Absolute contraindications to the use of lytic therapy include active bleeding, recent (<2 months) cerebrovascular accident, or intracranial disease. Major contraindications include recent surgery and evidence of GI hemorrhage. Prior to institution of therapy, the fibrinogen level, thrombin time, PT and aPTT, platelet count, and hematocrit should be determined. Heparin administration should be discontinued. Dosing regimens vary widely, but common doses are as follows: (1) streptokinase, 250,000 units over 30 minutes, followed by an infusion of 100,000 units/h up to 72 hours, or (2) alteplase, 100 mg infused over 2 hours. Within 4 hours of commencing therapy, thrombin time, fibrinogen level, and fibrin degradation products should be assessed. A lytic state is documented by an elevated thrombin time and the presence of fibrin degradation products. Hematocrit should be assessed every 6 hours. Elevation of fibrin degradation products is anticipated. Infusion for more than 24 hours seldom produces additional results. Lytic therapy should be

Table 29–11. Low-molecular weight heparins.

Drug Name	Subcutaneous Dose for Treatment of Venous Thromboembolism
Enoxaparin	100 anti-Xa units/kg every 12 h ^{*,†} or 150 anti-Xa units/kg every 24 h [‡]
Dalteparin	100 anti-Xa units/kg twice daily [‡] or 200 anti-Xa units/kg once daily [‡]
Tinzaparin	175 anti-Xa U/kg once daily [†]

*For enoxaparin, 100 anti-Xa units/kg corresponds to a dose of 100 mg/kg.

[†]FDA approved for this indication.

[‡]FDA approved for this indication.

Data from McRae SJ, Ginsberg JS: Initial treatment of venous thromboembolism. *Circulation* 2004;110:13–19.

instituted as early as possible because thrombi older than 3–5 days are less likely to respond. Bleeding, both superficial and internal, is the most common complication. When a severe coagulopathy develops, transfusion with fresh-frozen plasma may be necessary to correct the deficit.

The use of thrombolytic agents in the treatment of venous thromboembolism continues to be highly individualized. In general, patients with hemodynamically unstable pulmonary embolus or massive iliofemoral thrombosis, who are at low risk to bleed, are the most appropriate candidates. Endovascular placement of stents for residual iliac stenosis after venous thrombolysis also has been reported. In a small group of patients, patency was shown to be superior than with conventional heparin and warfarin. Survival rates on Kaplan-Meier life-table analysis, however, were equivalent.

D. Vena Caval Interruption—Historically, ligation of the vena cava was performed to prevent thrombi arising in the lower extremities and pelvis from reaching the pulmonary bed. Plication with a clip also has been attempted. Avoidance of complete occlusion maintained circulatory stability and resulted in a lower frequency of recurrent pulmonary emboli than complete ligation. In the latter, dilation of collateral vessels in the retroperitoneum became a potential route for pulmonary emboli.

Placement of a stainless steel filter, such as the Greenfield filter, is now the preferred procedure. Absolute indications for filter placement include recurrent thromboembolism despite adequate anticoagulation and deep venous thrombosis in patients at risk for hemorrhage. Relative indications include the presence of a propagating iliac or femoral vein thrombus despite adequate anticoagulation and a high-risk patient with a large, free-floating iliac or femoral vein thrombus demonstrated on venography. Sepsis is not a contraindication to filter placement.

Filters usually are placed percutaneously through the uninvolved femoral vein or through a jugular vein and positioned below the renal veins. The long-term patency rate of the device is 98%, with a recurrent embolism rate of 4%. Up to 80% of the filter may become filled with thrombus before it loses its efficacy. Recurrent embolism is an indication for inferior venacavography to evaluate the filter for the presence of proximal thrombus. The most common complication is displacement, which occurs in 7% of patients.

E. Operative Embolectomy—Operative removal of a deep venous thrombus is usually reserved for cases of phlegmasia cerulea dolens with limb threat. The highest success rate is achieved when the procedure is performed within 24 hours after onset of symptoms. Although early postoperative results may be encouraging, subsequent venograms usually show rethrombosis. This is often due to incomplete thrombus removal and injury to the venous endothelium. Reocclusion is often well tolerated as long as it occurs after the formation of sufficient venous collaterals. Mechanical thrombectomy with creation of a temporary arteriovenous fistula can improve early patency and allow collaterals to

develop. A recent study that examined long-term results after embolectomy found fewer instances of venous hypertension, valvular incompetency, and restrictions in activity among patients who had embolectomy performed for deep venous thrombosis of less than 3 days duration.

Postthrombotic Syndrome

Venous thrombosis is often accompanied by symptoms of pain, swelling, and skin ulceration occurring immediately or years after an episode of deep venous thrombosis. It is present in over 50% of patients with proximal thrombosis and has been reported in a third of patients with calf thrombosis. The symptoms are thought to stem from the development of venous hypertension caused by valvular dysfunction. Residual venous obstruction also may contribute to the syndrome to a lesser extent. Thrombolytic therapy preserves valvular function and potentially can reduce the incidence of this phenomenon. Early results are promising. Standard treatment involves the use of graduated compression stockings and sequential compression devices.

Venous Thromboembolism in Pregnancy

Care of the pregnant patient focuses on avoiding teratogenic injury to the fetus. Patients can be treated with continuous UFH and gradually switched over to multiple daily subcutaneous doses of LMWH until delivery. Warfarin, reportedly safe for infants of nursing mothers, is continued for 4–6 weeks postpartum. Supplemental calcium should be given in cases of prolonged heparinization (>1 month) to prevent heparin-induced osteoporosis. In the event of a bleeding contraindication or a documented pulmonary embolus, a vena caval filter can be placed. The procedure should be performed in the third trimester through an internal jugular approach. The site of deployment—contrary to what is done for a non-pregnant patient—is above the renal veins. This avoids kinking and displacement of the device by a gravid uterus.

▶ Acute Mesenteric Ischemia

ESSENTIALS OF DIAGNOSIS

- ▶ Severe acute abdominal pain out of proportion to the physical examination.
- ▶ GI symptoms: nausea, emesis, forceful evacuation.
- ▶ Abdominal distention and GI hemorrhage.
- ▶ Leukocytosis, acidosis, and hyperamylasemia.
- ▶ Mesenteric arterial occlusion with minimal collateralization on angiography.

General Considerations

Acute mesenteric ischemia of the bowel is an uncommon but dramatic occurrence among ICU patients, with an estimated overall incidence of 0.1% of all hospital admissions. Predisposing factors include age, cardiovascular disease, atherosclerosis, systemic disorders (eg, collagen-vascular disease), hypercoagulable states, malignancy, portal hypertension, inflammation, and trauma. Semiacute and chronic syndromes have been described, but they are rare among ICU patients admitted for other reasons.

The consequences of vascular occlusion depend on the vessel involved, the extent of collateral flow, and the time period over which the occlusion took place. Acute occlusion of vascular inflow or outflow quickly causes ischemia and leads to transmural necrosis within 6–12 hours. The seromuscular layer is particularly sensitive and begins to slough within 4 hours. Xanthine oxidase, found in high concentrations within the villi, is responsible for the production of superoxides that mediate many of the toxic reactions. Ulceration and bacterial overgrowth follow ischemic sloughing. Bacterial proliferation leads to increased edema and further thrombosis of small vessels. Increased capillary permeability and the absorption of toxic products across the compromised mucosa cause remote complications such as respiratory distress syndrome. Continued ischemia leads to intraluminal sequestration of fluid, which ultimately results in hypovolemia and hypotension. Four general categories of acute mesenteric ischemia are recognized.

A. Acute Embolic Occlusion—Emboli to the superior mesenteric artery account for 40–50% of all cases. Because these are almost always mural thrombi of cardiac origin, up to 20% of patients have synchronous emboli to other arteries. In the majority of cases, the embolus lodges just distal to the origin of the superior mesenteric artery. Occasionally, the emboli fracture and travel into the distal arcades of the artery before they become lodged. Initially, collateral flow is adequate to maintain viability of the intestine. However, after a period of partial occlusion, vasoconstriction develops both proximal and distal to the embolus and produces profound ischemia.

B. Mesenteric Thrombosis—Progressive atherosclerotic narrowing of the origin of the superior mesenteric artery is responsible for mesenteric thrombosis. Conditions that compromise flow through the stenotic orifice can lead to thrombotic occlusion. Between 20% and 50% of patients with mesenteric thrombosis will give a history of postprandial pain and weight loss within the 6 months prior to admission. Many have severe and diffuse atherosclerosis, with a history of coronary, cardiac, or peripheral vascular arterial insufficiency. Mesenteric thrombosis occurs in 10–15% of all cases of acute mesenteric ischemia.

C. Venous Thrombosis—Once thought to be the major cause of acute mesenteric ischemia, venous thrombosis is diagnosed in 8–10% of patients. Hypercoagulable states

including neoplasms, cirrhosis and portal hypertension, pancreatitis, peritonitis, diverticular disease, trauma, and splenectomy are precipitating factors. Presentation can be either acute or protracted, developing over a period of several weeks. Up to 60% of patients have a history of deep venous thrombosis in an extremity.

D. Nonocclusive Intestinal Ischemia—Hypoperfusion or a low-flow state is the inciting event of acute mesenteric ischemia in 25% of cases. Coexisting conditions—predominantly cardiac pump failure—lead to prolonged visceral arterial spasm and subsequent tissue infarct. Shunting of arterial blood away from the seromuscular layer and villi causes activation of toxic intermediates. The vasoconstriction may persist long after the inciting cause or agent has been removed. Pharmacologic agents such as ergotamine derivatives, digitalis, cocaine, and peripheral vasoconstrictors administered for sepsis or after cardiovascular surgery are also associated with acute mesenteric ischemia. In 4% of patients undergoing repair of an aortic coarctation, postoperative hypertension may lead to a necrotizing vasculitis from reperfusion injury.

Clinical Features

A. Symptoms and Signs—Acute abdominal pain is the most common finding. Peritoneal signs are often absent on physical examination despite the complaint of sharp excruciating pain—thus the *sine qua non* of “pain out of proportion.” Shortly thereafter, many patients experience rapid and forceful evacuation of the bowels. Nausea and vomiting—seen in 50% of patients—hematochezia, hematemesis, abdominal distention, back pain, and shock are late signs that usually accompany progression of intestinal necrosis. The presence of peritoneal signs often heralds the onset of systemic toxicity. Up to 30% of elderly patients develop mental confusion. The duration of symptoms, however, does not correlate with the reversibility of injury. A history of weight loss and an acute exacerbation of chronic abdominal pain are suggestive of acute thrombosis owing to underlying chronic occlusive disease.

Mesenteric venous thrombosis also presents with pain as the initial finding, but only two-thirds of patients manifest clear signs of peritonitis. Occult blood is often present, although frank hematochezia or hematemesis is found in 15% of patients, usually from bleeding esophageal varices. The most common findings are abdominal pain (90%), vomiting (77%), nausea (54%), diarrhea (36%), and constipation (14%). Most patients have temperatures higher than 38°C. Hemorrhage resulting from gastric varices owing to isolated splenic vein thrombosis is termed *sinistral portal hypertension*. In this case, intestinal ischemia is not expected.

A variant of splanchnic venous disease has been described recently. Mesenteric inflammatory veno-occlusive disease results in unexplained acute mesenteric ischemia. Diagnosis is based on the presence of venulitis or phlebitis with a lymphocytic, necrotizing, granulomatous mural infiltrate on pathologic specimen examination.

B. Laboratory Findings—A marked leukocytosis, often greater than 15,000/mm³, is usually present, although 10% of patients have a normal white blood cell count. The smooth muscle fraction (BB) of creatine kinase (CK) is elevated in the presence of intestinal infarction. Elevations of lactate dehydrogenase (LDH) also may be seen. Serum inorganic phosphate is often elevated owing to either spillage from phosphate-rich intestinal cells or degradation of intracellular ATP. Approximately 80% of patients with intestinal infarction have high serum levels of inorganic phosphate, and 50% demonstrate hyperamylasemia. Fluid sequestration results in hemoconcentration and oliguria. Increased base deficit may occur but was found in only 18 of 43 patients in a retrospective study. Peritoneal fluid analysis typically reveals leukocytosis and bacteria proportionate to the extent of necrosis. It may not be helpful in the early stages.

C. Imaging Studies—Plain films of the abdomen should be obtained as an initial screening procedure. Nonspecific findings consistent with the diagnosis include air-fluid levels, dilated and thickened bowel wall, blunted plicae circulares, and distention of the bowel to the level of the splenic flexure. Specific findings of bowel necrosis include transmural air, pneumatosis intestinalis, or gas in the portal system. Barium contrast studies may reveal decreased motility and thumbprinting owing to necrosis.

Angiography is the mainstay of the diagnosis and should be individualized. The presence of peritoneal signs and systemic toxicity requires immediate operative treatment to remove devitalized tissue. Mesenteric angiography can be performed early in hemodynamically stable patients suspected of having the disease with a sole complaint of abdominal pain. Radiographic findings will vary depending on the cause. When an embolus is present, early truncation of the superior mesenteric artery is observed. With acute thrombosis, complete obliteration of the trunk of the artery is common. The findings of nonocclusive ischemia are (1) tapered narrowing of the origins of multiple branches of the superior mesenteric artery, (2) segmental irregularities of the intestinal branches, (3) spasm of the arcades, and (4) impaired filling of the intramural branches. Findings consistent with mesenteric venous thrombosis include (1) demonstration of a thrombus in the superior mesenteric vein with partial or complete occlusion, (2) failure to visualize the superior mesenteric vein or portal vein, (3) slow or absent filling of the mesenteric veins, (4) arterial spasm, (5) failure of the arterial arcades to empty, (6) reflux of contrast material into the artery, and (7) a prolonged blush phase. Abdominal CT scanning can establish the diagnosis in more than 90% of patients with venous occlusion. Thrombus with enhanced venous wall opacification is a highly indicative finding. Hypodensity of the superior mesenteric vein, thickening of the bowel wall, and the presence of peritoneal fluid are a diagnostic triad seen on CT suggesting probable bowel infarction. Scintiangiography with ^{99m}Tc sulfur colloid-labeled leukocytes has been described but is too unreliable for general use. Recently, the use of duplex scanning has been proposed

as a bedside screening test, although the technique is limited by intestinal gas overlying the vessels of interest and the need for a skilled technician.

D. Special Studies—Laparoscopy can be useful in diagnosis, although complete exploration of the abdomen with the laparoscope is difficult. Furthermore, abdominal insufflation to more than 20 mm Hg reduces mesenteric blood flow and may exacerbate the condition. Preliminary evidence indicates that if CO₂ is used for insufflation at lower pressures, it may provide some mesenteric vasodilation. Colonoscopy may be useful if the large intestine is involved, although nonspecific colitis may be the only finding. Esophagogastroduodenoscopy can be used to detect and sclerose bleeding varices but does not treat the underlying venous thrombosis. Both modalities avail little in small bowel ischemia, the most common location of acute mesenteric ischemia. Bowel tonometry using an inflatable balloon to provide information about intramucosal pH (pH_i) may be helpful, although decreased motility may prevent proper peroral placement.

Differential Diagnosis

Other conditions associated with abdominal pain in the ICU such as a perforated ulcer, pancreatitis, acalculous cholecystitis, appendicitis, and gynecologic pathology in women must be investigated. These often can be identified by ultrasound and specific serum tests. Renal calculi produce colicky pain radiating to the groin. Aortic dissection and rupture of an abdominal aortic aneurysm are rare occurrences in patients admitted to the ICU for other reasons.

Treatment

Optimal outcome depends on rapid recognition and treatment. Initial therapy consists of fluid resuscitation, correction of electrolyte and acid-base abnormalities, and management of cardiac arrhythmias. Systemic heparinization is instituted in patients with suspected superior mesenteric artery thrombosis or venous occlusion. If time permits, demonstration of the offending lesion by angiography is ideal. When arterial spasm is present, 25 mg tolazoline may be injected, followed by repeat angiography. If an embolus is the cause, an infusion of papaverine into the superior mesenteric artery orifice should be instituted immediately. The dose customarily used is 30–60 mg/h. Some also use papaverine in the face of mesenteric thrombosis, although catheter placement is difficult owing to the occluded arterial orifice. Papaverine infusion should be continued while the patient is readied for surgery. Because arterial spasm and the hypercoagulable state may persist even after successful surgery, papaverine and heparin infusions should be continued following operation. Broad-spectrum antibiotics are indicated both before and after surgery. Nonoperative therapy is appropriate (1) if there are significant contraindications to surgery, (2) if there are no peritoneal signs, and (3) if there is adequate perfusion of the vascular beds distal to the site of partial obstruction.

Infusion of thrombolytic agents has been successful anecdotally in both venous and arterial thromboses. Gastroesophageal varices—once thought to be a contraindication to this practice—were seen to resolve with successful venous clot lysis. Problems with access to the splanchnic venous system have limited this approach. In arterial thrombosis, lytic therapy should be instituted only in the most stable patients because of the time required for clot lysis. When patients are treated without operation, repeat angiography at 6–8-hour intervals is required to monitor the progress of therapy. Any worsening in the patient's condition is an indication for immediate operation.

Surgical management is aimed at restoration of flow and resection of nonviable bowel. Arterial inflow may be restored either by bypass, endarterectomy, or embolectomy. When venous thrombosis is present, extensive bowel resections may be required. Assessment of intestinal viability is often difficult, and adjuncts such as Doppler flow probes and tissue fluorescence are often used, although no method is always reliable in separating viable from ischemic bowel. A wide resection is usually undertaken as long as more than 6 feet of normal bowel remains. Sixty percent of recurrent infarcts occur in the area adjacent to the anastomosis. If the majority of the intestine is compromised, resection is more conservative, and “second look” procedure to determine the viability of unresected bowel commonly is performed within 12–24 hours of the initial procedure.

Nonocclusive ischemia is best managed through treatment of the underlying disorder causing the low-flow state. Resuscitation and optimization of the patient's hemodynamic status are essential. Vasopressors should be discontinued if possible. An alternative to digoxin should be sought, especially in patients with portal hypertension. Digitalis derivatives promote mesenteric vasoconstriction in patients with hepatic congestion from congestive heart failure. Ergotamine poisoning is treated with selective infusion of vasodilators (eg, papaverine), sympatholytics, and anticoagulants. Angiotensin-converting enzyme (ACE) inhibitors (eg, captopril) also serve to assuage the vasoconstrictive effects of the renin-angiotensinogen axis in hypovolemic patients. Surgery is reserved for resection of nonviable intestine. In addition to careful hemodynamic support, perioperative anticoagulation has been shown to improve survival in patients with mesenteric venous thrombosis. In one study, half of patients receiving no postoperative anticoagulation died. Without anticoagulation, one-third of patients also will experience a recurrence. Most centers recommend continuing anticoagulation indefinitely unless there is a contraindication or the factor responsible for the venous thrombosis has been corrected. Recently, intravenous glucagon administered during the early phase of reperfusion of ischemic intestinal segments has been shown experimentally to improve mucosal recovery, suggesting possible adjunctive use in the clinical setting.

Prognosis

Acute mesenteric ischemia carries a high mortality rate—in some series approaching 70%. When more than half the small

bowel must be resected, the death rate increases to as high as 85%. The cause of death in most cases is irreversible shock or advanced intestinal necrosis. Reconstruction is attempted in less than 10% of patients because findings at laparotomy often show advanced disease. Patients diagnosed with superior mesenteric artery thrombosis have an overall worse prognosis than those in whom distal embolization has occurred. Acute venous thrombosis has a 30% mortality rate, whereas nonocclusive intestinal ischemia has been associated with death rates as high as 90%. Early recognition of low-flow states, resuscitation, and aggressive therapy have lowered mortality.

CRITICAL CARE OF THE VASCULAR SURGERY PATIENT

Atherosclerosis affects one in four Americans and constitutes a major international health problem. There are over 600,000 episodes of stroke and 1.5 million myocardial infarctions each year in the United States alone. Medical care of these patients is complicated by advanced age and additional medical comorbidities that create a challenge in pre- and postoperative management. This section will address specific problems encountered when caring for vascular surgery patients.

▶ Respiratory Management

Vascular surgery patients often have an extensive smoking history. Chronic obstructive pulmonary disease (COPD), bronchitis, and asthma therefore are not unexpected. A room-air arterial gas measurement often determines whether more extensive pulmonary workup is necessary. Formal pulmonary function tests are useful to determine the nature and extent of respiratory compromise. Encouragement in cessation of smoking for a minimum of 2 weeks prior to elective surgery and maximization of pulmonary reserve with adequate pharmacologic support for patients with obstructive or restrictive airway disease are ideal. Instruction in the use of incentive spirometry and deep breathing exercises is also helpful in restoring postoperative lung function. Mechanical ventilator support is the rule in patients undergoing intracavitary aortic operations. An aggressive attempt at weaning should be instituted once the patient is sufficiently awake to cooperate and maintain airway patency. This should be followed by aggressive incentive spirometry, adequate pain control, and early ambulation. The details of ventilator management are presented in Chapter 12.

▶ Nutritional Management

Nutritional support is a mandatory but frequently neglected aspect of postoperative care. The catabolic response following aortic surgery is pronounced. Because most vascular surgery patients are well nourished prior to surgery, immediate institution of nutritional support is not necessary. However, if resumption of oral intake is not anticipated within 5–7 days after surgery, enteral nutrition should be started through a nasogastric feeding tube. Extensive manipulation of the small bowel may cause mechanical ileus, although absorptive capacity is maintained. Transient pancreatitis also can be encountered in aortic surgery from retractor blade pancreatic irritation. Feeding with an elemental formula can be instituted at low rates (30 mL/h) and increased in volume as tolerated. Enteral feedings reduce the risk of septicemia associated with hyperalimentation catheters. This is of particular importance in vascular disease patients who have unincorporated graft surfaces exposed to the circulation.

If nutritional support is required for more than 1 week, a nitrogen balance study should be completed to ensure that protein needs are being met.

► Management of Ischemic Heart Disease

Atherosclerosis is a systemic disease that affects both the peripheral vasculature and the coronary arteries. An analysis of pooled data from 50 studies with more than 10,000 patients demonstrated the presence of coronary artery disease in 50% of patients who had operations for aortic aneurysms, carotid artery disease, and lower extremity ischemia. In another series of patients with known coronary artery disease undergoing vascular surgery, 63% were found to have ischemic cardiac events. In the Cleveland Clinic series, fatal myocardial infarction accounted for a 3.3% mortality rate after lower extremity procedures and a 6% mortality rate after aortic aneurysm resection. A study from the same institution using routine coronary angiography before aortic surgery found that 85% of patients had some degree of coronary artery disease, whereas 31% had severe disease consisting of either two- or three-vessel involvement or stenosis of the left anterior descending artery. In a study of 1000 patients undergoing routine coronary angiography, 14–22% of patients without any prior clinical history of coronary artery disease had severe coronary artery disease on angiography. It should be remembered, however, that demonstration of an anatomic lesion does not necessarily equate with physiologic compromise.

The pathophysiology of acute perioperative infarction is not completely understood, although multiple factors are certainly involved. These include catechol release, increased myocardial sensitivity to catechols, fluid sequestration, alterations in oxygen transport, hypercoagulable states, and tachycardia. Because elevations in heart rate and blood pressure increase the tension-time index, they result in increased oxygen consumption. Tachycardia further limits oxygen delivery by decreasing the diastolic filling time, during which the myocardium receives its perfusion.

Valvular heart disease also increases morbidity after vascular procedures. In the presence of aortic stenosis, up to 20% mortality may be expected for abdominal or thoracic operations and up to 10% for peripheral procedures.

Preoperative Assessment of Risk Owing to Coronary Artery Disease

The high incidence of cardiac ischemia after vascular surgery frequently occasions preoperative admission of these patients to the ICU for hemodynamic evaluation and optimization of cardiac status. Several scales have been devised to predict surgical risk based on clinical assessment. The American Association of Anesthesiologists score is based on assessment of overall health and chronic disease. While generally useful, it is not sufficiently specific for use in

patients with critical illnesses. An evaluation developed by Goldman employs nine variables to predict cardiac risk. Unfortunately, it underestimates cardiac complications in vascular patients and is able to predict cardiac mortality in only 50% of cases. An alternative scale includes a history of previous myocardial infarction, congestive heart failure, unstable angina, diabetes, and age over 70. Patients classified as intermediate or high risk were expected to have an event rate of 10–15%. Those in the low-risk group had a less than 5% incidence of cardiac ischemia.

A. Ambulatory Electrocardiographic (Holter) Monitoring—

Continuous ambulatory monitoring of the ECG is used to detect clinically silent ischemia. A positive finding consists of six or more episodes in a 24-hour period of ST-segment depression of more than 2 mm. A significantly greater incidence of perioperative cardiac morbidity and mortality occurs in those with abnormal results. A recent study found that 38% of patients with preoperative ischemia had postoperative cardiac events, whereas fewer than 1% of patients without ischemia suffered cardiac morbidity. Continuous preoperative monitoring identifies patients with clinically silent ischemia who might benefit from therapy. Although this method is simple, noninvasive, and inexpensive, it suffers from low sensitivity and has a positive predictive value of only 38%.

B. Exercise Electrocardiographic Testing—

Exercise stress-induced alterations in the ECG have been used extensively to assess cardiac risk. Because they typically require walking or running, they are not suitable for use in dysvascular patients whose exercise tolerance is limited by claudication. Submaximal effort may yield false-negative results.

C. Dipyridamole-Thallium Scintigraphy—

In this test, a pharmacologic agent is substituted for exercise to increase coronary artery blood flow. Intravenously administered dipyridamole promotes coronary artery blood flow without increasing myocardial oxygen consumption by increasing the intracellular concentration of adenosine. Blood flow increases through normal arteries that dilate maximally. Stenotic arteries do not respond because of fixed anatomic lesions. Prior to administration of dipyridamole, thallium-201 is injected to demonstrate areas of myocardial ischemia. Because thallium-201 is preferentially taken up by the normal myocardium, areas of hypoperfusion appear as “cold” spots. If homogeneity improves after dipyridamole is given, thallium redistribution is said to have occurred, and the scan is considered positive. Redistributed areas consist of viable but ischemic myocardium that are at risk for infarction. Areas that fail to improve after dipyridamole infusion probably consist of previously infarcted muscle that is not at risk for a future ischemic event. Thallium redistribution is associated with a 30–50% risk of some postoperative cardiac event. The positive predictive value of the test is only 22%.

A negative scan indicates a low likelihood of perioperative infarction, but a positive scan is of ambiguous import. The specificity of thallium scans can be increased by combining them with other risk factors for myocardial ischemia, including age, a history of angina, the presence of Q waves on ECG, the presence of type 1 diabetes, and a history of therapy-dependent ventricular ectopy. The risk of a cardiac event in intermediate-risk patients (one or two predictors) is as high as 30%. This finding has since been challenged by reports from several centers finding little use for dipyridamole-thallium scanning in moderate-risk patients and suggesting that a new procedure be investigated.

D. Radionuclide Ventriculography—Multiple-gated acquisition (MUGA) blood pool scans provide quantitative information about the left ventricular ejection fraction (LVEF) and ventricular wall motion. The normal LVEF is 55% or greater. Those with a normal LVEF are at low risk for postoperative cardiac events. Those with LVEF values between 36% and 55% are at intermediate risk, with a perioperative infarction risk of 20%. High-risk patients have LVEF values of less than 35% and had an 80% risk of myocardial infarction. Unfortunately, the test has a low sensitivity (44%), which means that a negative study does not necessarily eliminate the risk of myocardial infarction.

E. Dobutamine Stress Echocardiography—Dobutamine stimulates myocardial contractility and increases heart rate through β_1 activity. Administration of this pharmacologic agent results in higher oxygen demand. Two-dimensional echocardiography then is used to visualize regional wall dysfunction from myocardial ischemia. Compared with dipyridamole-thallium scanning, this test also was initially more successful in predicting perioperative cardiac events. However, ensuing studies reported inconsistent results with a sensitivity ranging from 54–96% and specificity in the range of 57–95% in comparison with cardiac catheterization.

F. Coronary Angiography—Coronary angiography should be used only in selected patients whose noninvasive studies place them at high risk for coronary events. The results of angiography can be used to plan further procedures such as angioplasty or coronary artery bypass.

Postoperative Cardiac Management

Postoperative cardiac ischemia and myocardial infarction are caused by an increased myocardial oxygen requirement in the face of inadequate supply. Myocardial oxygen consumption is related to the tension-time index, which is the product of systolic blood pressure and heart rate. Animal studies have shown that cardiac work and myocardial oxygen consumption both increase when the heart pumps against elevated diastolic pressures. Prolonged work against increased afterload results in myocardial hypertrophy, which

also increases oxygen consumption. Tachycardia has two adverse effects on myocardial oxygen balance. First, it directly increases oxygen demand by increasing the time-tension index, and second, it reduces the diastolic filling time, thereby limiting the period during which myocardial blood flow occurs. Pharmacologic management is frequently necessary to improve myocardial oxygenation by decreasing the heart rate and lowering blood pressure.

Antihypertensive Therapy

Postoperative hypertension occurs in up to 50% of patients after aortic or carotid surgery. Pain is one of the most common causes and should be addressed initially. Small intravenous doses of morphine sulfate should be titrated to effect. Hypotension and respiratory depression are the major complications of opioid administration. Opioids should be given to carotid surgery patients only after they have recovered from their anesthetic and a postoperative neurologic examination has been completed. Lorazepam is a relatively short-acting benzodiazepine that provides sedation. It may be used as an adjunct to the analgesic effect of morphine. Lorazepam is particularly useful in aortic surgery patients who require mechanical ventilation after operation. The initial intravenous dose is usually 2–3 mg titrated to effect at intervals of 4–6 hours.

Excessive intraoperative volume administration may cause postoperative hypertension. This is particularly true among patients who have received epidural anesthetics that cause vasodilation. Resolution of the block and return of normal vascular tone may result in hypertension. Hypervolemia also may follow mannitol administration and excessive volume loading instituted prior to removal of the aortic cross-clamp. Postoperative volume status should be evaluated and optimized with the aid of a pulmonary artery flotation catheter. Careful administration of diuretics is required to avoid inadvertent iatrogenic hypervolemia.

Once remediable causes of hypertension have been eliminated, persistent hypertension should be treated to reduce myocardial oxygen demand owing to increased wall stress. The threshold for treatment will vary with the patient, the type of procedure performed, the duration of hypertension, and preoperative risk factors. Elevation of systolic blood pressure above 120% of baseline is a reasonable point at which therapy should be instituted. Agents with shorter half-lives allow more precise titration of blood pressure, whereas longer-acting agents have the advantage of decreased dosing requirements. Nitroprusside and nitroglycerin are both fast-acting agents that can be given intravenously. Nitroprusside has a balanced effect because it dilates both arterioles and veins. As an arterial vasodilator, it lowers blood pressure by decreasing arteriolar vascular resistance without increasing venous capacity. The decreased afterload reflexively increases cardiac sympathetic stimulation that may result in undesirable tachycardia. Nitroglycerin is preferred because it produces coronary artery vasodilation in addition to

decreasing preload. Because nitroglycerin can precipitously decrease filling pressures, it is imperative to ensure normal pulmonary capillary wedge pressure (PCWP) prior to the institution of therapy. Intravenous doses are started near 5 $\mu\text{g}/\text{min}$ and increased by this amount every 5–10 minutes until the desired effect is reached. The normal vasodilatory dose is between 50 and 100 $\mu\text{g}/\text{min}$, although some patients require doses as high as 400 $\mu\text{g}/\text{min}$. High doses can be tolerated for several days, although methemoglobin concentration should be monitored.

Agents that provide β -adrenergic blockade also may be used to treat postoperative hypertension. Labetalol is particularly useful because it provides not only nonspecific beta blockade but prevents reflex increases in vasoconstriction by its α -adrenergic blocking activity. Labetalol has a relatively long half-life of 6–8 hours and should be used with caution in patients with hepatic and renal insufficiency because of its route of elimination. The initial intravenous dose is 10–25 mg, supplemented every half-hour to desired effect. ACE inhibitors, initially used to decrease afterload in heart failure, were demonstrated recently to significantly reduce mortality, myocardial infarction, stroke, cardiac arrest, and heart failure. The Heart Outcomes Prevention Evaluation Study investigators found that treating 1000 patients with ramipril (a long-acting ACE inhibitor) for 4 years prevented approximately 150 events in 70 patients.

Tachycardia

Fever, pain, and hypovolemia are the most common causes of tachycardia (heart rate >100 beats/min) in postoperative patients. Hypovolemia may be caused by inadequate volume replacement or by continued volume loss such as hemorrhage or osmotic diuresis. Unrecognized causes of obligatory osmotic diuresis include hyperglycemia and intravenous contrast material administered prior to or during surgery. Pulmonary artery flotation catheters facilitate the evaluation of tachycardia by providing information on relative volume status. After inciting causes have been addressed, primary tachycardia should be treated if the heart rate remains elevated. Esmolol is an agent that is relatively β_1 -selective and has a half-life of only 9–10 minutes. A loading dose of 500 $\mu\text{g}/\text{kg}$ is administered over 1 minute, followed by a continuous infusion of 50 $\mu\text{g}/\text{kg}$ per minute. The infusion rate is decreased as tachycardia resolves.

Renal Failure

The incidence and prognosis of acute renal failure occurring after vascular surgery depend on the overall preoperative status of the patient, the nature of the surgery performed, and associated complications such as cardiac failure or sepsis. The reported incidence of acute renal failure after elective aortic surgery ranges from 1–15%. Following surgery for ruptured aortic aneurysms, it is between 21% and 100%, with associated mortality rates between 50% and 95%. Despite improved intra- and postoperative management, the

incidence of acute renal failure after vascular surgery has not changed appreciably in the past 20 years. Several factors contribute to the development of renal failure, including suprarenal aortic cross-clamping, renal artery occlusion, declamping hypotension, and embolization of atherosclerotic debris to the kidneys. Autopsy studies of patients with postischemic acute renal failure have found minimal alterations of glomerular architecture in the face of profound disruption of tubular morphology. Acute tubular necrosis or luminal obstruction caused by sloughing of tubular cells is thought to be the inciting event.

Intraoperative maneuvers aimed at protecting renal function are directed mainly at reducing the severity and duration of renal ischemia. Circulating blood volume and cardiac output should be optimized prior to interruption of renal blood flow. The intravenous infusion of 12.5–25 g mannitol prior to aortic occlusion is common practice. Mannitol offers a protective effect by (1) expanding circulating blood volume, (2) acting as an osmotic diuretic to promote urine flow and prevent stasis, (3) attenuating the reduction in cortical blood flow, and (4) serving as a free-radical scavenger. Intraoperative contrast angiography produces a postoperative osmotic diuresis and makes absolute urine output an unreliable indicator of renal perfusion. When dye has been used, sufficient fluid should be administered to reduce urine specific gravity below 1.015. In the postoperative period, maintenance of adequate blood volume and cardiac output are the best defenses against renal failure. A pulmonary artery catheter should be used to assess venous return and cardiac function in patients who have had intraabdominal surgery. Sufficient maintenance and replacement fluid must be given to ensure adequate cardiac preload. Inotropic agents such as dopamine or dobutamine also may be required. Dopamine in doses below 5 $\mu\text{g}/\text{kg}$ per minute promotes diuresis by dilating renal afferent arterioles. Recently, the administration of oral acetylcysteine along with hydration has been shown to prevent the reduction in renal function caused by low-osmolality contrast agents in patients with chronic renal insufficiency. Its vasodilatory and antioxidant properties are speculated to be the mechanisms of action. Acetylcysteine is given in a dosage of 600 mg twice on the day prior to and on the day of contrast material administration.

Reperfusion of severely ischemic muscle beds may cause the release of myoglobin into the circulation. A positive dipstick reaction for urine hemoglobin without the presence of red blood cells on microscopic analysis is evidence of myoglobinuria. Sodium bicarbonate (100 meq/L) admixed with maintenance intravenous solutions should be administered to alkalinize the urine. Urine volume must be maintained above 1–2 mL/kg per hour. The myonephrotic syndrome of renal failure in the face of progressive rhabdomyolysis carries a mortality rate of more than 50%.

Other causes of oliguria include aminoglycoside toxicity and postrenal obstruction. The latter may be caused by a kinked urinary catheter or by inadvertent intraoperative ureteral ligation. After other causes of oliguria have been

excluded, radionuclide imaging is reasonable to assess renal blood flow and urinary excretion. If concern about postrenal obstruction exists, bedside ultrasound can be used to identify hydronephrosis.

► Complications of Vascular Surgery

Infection

Prosthetic graft infection is a devastating complication that occurs in 1–6% of patients depending on comorbid factors, location, and type of graft. The organism usually responsible is *Staphylococcus aureus*, although others, including yeasts, anaerobic bacteria, and mycobacteria, have been identified. Most graft infections are diagnosed after discharge (>4 months) rather than in the early postoperative period. Perioperative antibiotic prophylaxis usually consists of a first-generation cephalosporin with good activity against *S. aureus* and *S. epidermidis*. It should be noted that comparable rates of graft infection have been reported both with and without the use of perioperative antibiotics.

Antibiotic administration should be continued until all indwelling intravenous and urinary catheters have been removed. Patients who have undergone reconstruction following vascular trauma should be observed closely for evidence of necrosis at wound sites. Devitalized tissue is an excellent culture source for bacteria. Early debridement and sufficient autologous coverage can prevent the late sequelae of graft infections—namely, thrombosis, rupture, and the development of paraanastomotic pseudoaneurysms.

Gastrointestinal Complications

Ischemic colitis and mesenteric ischemia are feared complications following resection of an abdominal aortic aneurysm. Interruption of the blood supply to the left colon following ligation of the inferior mesenteric artery is the usual cause, especially after repair of a ruptured aneurysm. In patients with severe chronic occlusive disease or those who have had previous abdominal procedures, interruption of vital visceral collaterals also can contribute to bowel ischemia. Early nonspecific harbingers of this complication include an acute fever spike with increased white blood cell count, lactic acidosis, and bloody diarrhea. Antibiotics, intravenous fluid administration, and immediate sigmoidoscopy and colonoscopy are undertaken. Once the diagnosis is verified, a transmural infarct requires operative resection. Expectant management is justified in patients in whom ischemia does not involve the full thickness of the bowel wall.

Acalculous cholecystitis occurs in 1% of all patients undergoing aortic surgery. Right upper quadrant abdominal pain, fever, leukocytosis, and hyperbilirubinemia are common. Bedside ultrasonography is preferred over ^{99m}Tc-HIDA scanning to establish the diagnosis. Immediate cholecystectomy or cholecystostomy is usually required. Ischemic pancreatitis may be confused with cholecystitis. Elevations of

the serum amylase and lipase allow separation of the two. A mild pancreatitis is caused by exposure of the aorta and retractor injury. It is usually self-limiting.

► Complications of Common Vascular Procedures

Carotid Endarterectomy

Either hypotension or hypertension may occur early in the postoperative course. Hypertension may lead to the formation of neck hematomas and hemorrhagic stroke. Hypotension can lower the cerebral perfusion pressure that a hypertensive patient is normally accustomed to and thus results in cerebral infarct. Judicious use of fast-acting vasodilators (eg, nitroglycerin or nitroprusside), β -blockers (eg, esmolol), or vasoconstrictors (eg, dopamine) in the immediate perioperative period to maintain a constant and stable blood pressure is a sound management stratagem. Effective weaning from these agents is accomplished once sufficient volume is infused.

The incidence of postoperative strokes ranges from 1–3%. Although the majority result from intraoperative embolization or cerebral ischemia, up to 19% may be due to acute thrombosis of the carotid artery. Transient ischemic attacks within the first week have been reported to be as high as 8%. When a patient is first noted to have a neurologic deficit, determining internal carotid artery patency is important because prospects for neurologic recovery are directly related to the speed with which flow is restored. If no intraoperative completion studies were performed, initial diagnostic evaluation should be via noninvasive bedside imaging such as Doppler ultrasound or duplex scanning. Patients with abnormal or equivocal findings require immediate reexploration. If noninvasive studies are normal, emergency carotid angiography is indicated to identify small defects that can be repaired. If the patient had a normal intraoperative completion arteriogram or duplex scan, the source of deficit is embolic, and reoperation offers little benefit.

Headaches after carotid surgery are not uncommon. Severe headaches in the face of hypertension should be monitored carefully and the blood pressure expeditiously controlled. A CT scan of the brain is obtained, and a diagnosis of cerebral hyperperfusion syndrome is then entertained. This can happen in patients undergoing endarterectomy for chronic severe occlusive disease or in patients with an acute cerebrovascular accident. The common denominator is reactive hyperemia or cerebral reperfusion injury. Lesser forms of this condition result in symptoms consistent with mild cerebral edema, headache, and seizures. A more severe presentation results in catastrophic intracerebral hemorrhage from vessel rupture. Prompt recognition and treatment with antihypertensives, osmotic diuretics, and anticonvulsants can be lifesaving. If intracerebral hemorrhage has occurred, the prognosis is poor.

Aortic Operations

Abdominal aortic aneurysm repair in the elective setting has a mortality rate of 1–3%. Repaired emergently, mortality is often greater than 50%. Predictors that herald poor survival include the duration and severity of perioperative shock, hypothermia, and cardiac reserve. Postoperatively, myocardial infarction, coagulopathy, renal failure, respiratory insufficiency, ischemic bowel, poor nutrition, and infection often contribute to morbidity. Meticulous ICU monitoring with a pulmonary catheter and aggressive treatment are mandatory. Adequate intravascular volume replacement is necessary to maintain organ perfusion. Patients often require a significant amount of volume for the first 24–48 hours owing to shifts of intravascular fluid into the interstitium. On the third or fourth day, reentry into the vascular system occurs, and a brisk diuresis ensues. At this stage, electrolytes are replaced carefully and urine output maintained, with diuretics if necessary. Prolonged mechanical ventilation is required for respiratory failure and hemodialysis for renal compromise. Mesenteric ischemia and ischemic colitis may result, and the first sign is often an uncorrectable metabolic acidosis, fever, and rapid leukocytosis. Melena and hematochezia are late signs and portend bowel necrosis. Prolonged shock and ischemia of the spinal cord result in paraplegia in 2% of patients. Corticosteroids may be used once other causes of spinal shock have been eliminated.

Peripheral Operations

The most common cause of morbidity in lower extremity bypass operations is cardiac insufficiency. Preoperative optimization and dosing with β -blockers have been shown to decrease postoperative events. Prolonged hypotension or hypovolemia may lead not only to myocardial ischemia but also to thrombosis of the bypass graft. Careful hemodynamic monitoring and support can prevent these complications. If a palpable pulse is present distal to the graft, it should be monitored regularly for any change in strength or character. An abrupt decline in or absence of the pulse is highly suggestive of graft occlusion. In patients who are admitted to the ICU without palpable pulses, a Doppler probe or piezoelectric pulse monitor can be used to evaluate graft patency. A pulse oximeter probe placed on a finger or toe distal to the bypass site is another convenient technique for monitoring graft patency. Revascularization for traumatic injury or chronic ischemia may cause limb swelling that resolves with elevation. The development of a compartment syndrome should be recognized immediately and treated promptly with fasciotomies. In patients with prolonged ischemia, myoglobinuria may occur after revascularization and may lead to renal failure unless recognized and treated with adequate hydration and diuresis.

Critical Care of Neurologic Disease

Hugh B. McIntyre, MD, PhD
Linda Chang, MD
Bruce L. Miller, MD

Alterations of consciousness including coma, seizures, and neuromuscular disorders account for many of the neurologic problems in patients admitted to ICUs. Therefore, this chapter emphasizes encephalopathy and coma, seizures and status epilepticus, and problems associated with neuromuscular disorders. A comprehensive review of cerebrovascular disease and stroke syndromes is beyond the scope of this book, but since the critical care physician undoubtedly will have to deal with cerebrovascular diseases, some fundamental aspects of these disorders are described. In addition, certain aspects and complications of CNS infectious diseases are included.

ENCEPHALOPATHY & COMA

► Coma

The brain controls the individual's ability to breathe, obtain food and water, and avoid noxious stimuli in the environment. When the individual slips into coma, the ability to perform these functions is lost, and the patient will not survive unless coma is reversed. In this sense, coma represents a global failure of brain function. There are many causes of coma, some of them reversible. The first responsibility of the physician caring for a patient in coma is to ensure that breathing, circulation, and nutrition are maintained. The cause of coma then must be determined and reversible causes treated appropriately.

Normal consciousness has two main components: content and arousal. They have different anatomic substrates, with the former localized largely in the cerebral cortex and the latter depending on the brain stem reticular activating system. Injury to the dominant cortical hemisphere leads to impairment or loss of language function, but bilateral cortical injury is required for complete loss of consciousness. Furthermore, the cortex is responsible for interpreting incoming signals. This includes encoding and assigning "meaning" to emotional and sensory inputs. When the cortex is diffusely injured, the ability to reflect on and interpret experience is lost, and for this reason, the content of consciousness is lost as well.

The major role of the brain stem reticular activating system is to arouse and alert the cortex so that the organism can reflect on and react to stimuli from the environment. A patient can lose consciousness by two different mechanisms: diffuse dysfunction of the cerebral cortex or injury to the reticular activating system. Coma often develops as a result of injury to both areas. However, cortical neurons are extremely sensitive to a variety of metabolic and toxic injuries, including hypoxia, hypercapnia, hyponatremia, hypernatremia, hypoglycemia, hyperglycemia, and many drugs, whereas the brain stem is more resistant to these injuries. Thus toxic and metabolic injuries first cause dysfunction in cortical neurons, and only with increasing severity influence the brain stem. In contrast, coma owing to primary brain injury affects the reticular activating system. These major anatomic differences allow the clinician to distinguish metabolic from structural causes of coma.

Neuroimaging techniques suggest that there may be a fundamental pathophysiologic basis for many of the metabolic causes of coma, perhaps explaining why so many patients with different causes present with such similar clinical profiles. In comas owing to metabolic encephalopathy, a profound and diffuse decrease in cerebral glucose metabolism has been shown using positron-emission tomography. Similarly, severe and diffuse cerebral hypoperfusion as measured with ^{133}Xe appears in patients in coma owing to sepsis, hepatic encephalopathy, hypoxia, head trauma, and cocaine intoxication. Studies in comatose patients using ^{31}P magnetic resonance spectroscopy have shown dramatic decreases in the brain's energy-containing phosphorus compounds, including ATP and phosphocreatine. This work suggests that any process that compromises cortical neuronal energy production may lead to a comatose state.

Clinical Features

One key issue in the evaluation of any unconscious patient is whether the unconscious state is due to metabolic, toxic, or structural brain injury. Because there are only

minor differences in the clinical characteristics of comatose states owing to varying types of metabolic and toxic insults, the clinical examination cannot definitively distinguish one metabolic cause from another; thus the cause must be sought or confirmed with laboratory investigations. In contrast, if the clinical examination suggests structural brain injury, emergency imaging tests must be performed to determine the cause so that appropriate treatment can be initiated.

Simultaneously with the assessment of the neurologic examination, it is critical that the physician obtain an accurate history. Although a comatose patient cannot give a history, relatives, housemates, and others often describe the onset of coma and provide information regarding medications and preexisting illnesses. Even when information from these sources is not available, paramedics usually can provide details about the circumstances in which the patient was found. In all cases, a check of the patient's pockets and purse or wallet may help to elicit important medical data, and some patients wear medical bracelets or necklaces, which will alert the examiner to potential causes of coma.

Rapidity of onset is an important clue to the cause of coma. Certain metabolic insults such as hypoxia, ischemia, or hypoglycemia may come on suddenly, whereas others such as hyponatremia, hypernatremia, and hyperglycemia develop subacutely. Similarly, subarachnoid hemorrhage or brain stem ischemic stroke can lead to sudden coma, whereas coma related to chronic subdural hematoma, cortical ischemic stroke, or brain tumor usually develops slowly.

The five main areas that need to be assessed in the evaluation of a patient in coma are (1) level of consciousness, (2) pupillary responses and ophthalmoscopic examination, (3) oculomotor system, (4) motor system, and (5) respiratory and circulatory systems.

Based on the findings in these domains, usually it is possible to localize accurately the specific regions in the brain that are impaired. Table 30-1 lists changes that occur with injury in different anatomic areas of the brain. A precise

anatomic localization of the area of dysfunction in the brain often helps to elucidate the cause of coma. Although coma scales are helpful in assessing prognosis, they are not a substitute for neurologic examination because they neither localize the area of dysfunction nor help in determination of the cause.

A. Level of Consciousness—Many terms such as *stuporous*, *lethargic*, *drowsy*, and *semicomatose* have been used to characterize degrees of altered consciousness. However, it is better to describe the patient's spontaneous activity, response to verbal stimuli, and reaction to painful stimuli in precise terms that do not have different meanings to different observers. A carefully recorded description of the patient's level of consciousness on entry into the hospital will be invaluable in following the progression of the comatose state. With herniation from a large unilateral cerebral hemisphere mass, drowsiness occurs when the reticular activating system in the thalamus is compressed; coma ensues when injury to the reticular activating system reaches the midbrain.

The best places to apply painful stimuli to determine arousability are over the sternum or the nail beds; these maneuvers also help to determine whether the patient responds with evidence of focality, for example, if there is no movement of one side while the other hand attempts to remove the painful stimulus.

B. Pupillary and Ophthalmoscopic Evaluation—Perhaps no component of the neurologic examination is as valuable for differentiating metabolic or toxic coma from coma owing to structural brain disease as inspection of the pupils. Pupillary size is determined by the relative contributions of the parasympathetic and sympathetic autonomic fibers. Coma associated with brain injury usually exhibits changes in the pupillary response. These changes occur because most structural comas are associated with injury to the reticular activating system in the brain stem where the Edinger-Westphal and sympathetic autonomic fibers are located.

Table 30-1. Localization of brain lesions in a comatose patient.

Anatomic Level	Mental Status	Pupillary Size and Position	Eye Movement	Motor Responses	Respiration and Circulation
Diencephalon	Drowsy	Small (1-2 mm)	Normal	Abnormalities of flexion	Cheyne-Stokes
Midbrain	Coma	Fixed in mid position	Dysconjugate	Abnormalities of extension	Hyperventilation
Pons	Coma	1 mm in primary pontine injury; fixed and 4-5 mm with prior midbrain injury	Complete paralysis	Abnormalities of extension	Hyperventilation
Medulla	Variable	Variable	Variable	Flaccid	Apnea, circulatory collapse

With acute injury to the midbrain, the pupils become fixed in midposition as a result of simultaneous injury of sympathetic and parasympathetic fibers. In contrast, injury to the pons often is associated with pinpoint, minimally reactive pupils. Lateral tentorial herniation of the temporal lobe may result in compression of the third cranial nerve and the parasympathetic fibers traveling with it, causing dilation of the pupil on the side of the herniation. In some lateral herniations there will be compression of the contralateral third nerve against the edge of the tentorium.

A major characteristic of coma owing to metabolic diseases is sparing of the pupillary response. This occurs because metabolic coma causes selective dysfunction of the cortex, whereas the centers in the brain stem that control the pupils are spared. Many comas owing to drugs spare the pupils, although some commonly used drugs do influence the pupillary response (Table 30–2).

The ophthalmoscopic examination can provide valuable information. Papilledema usually implies increased intracranial pressure, whereas subhyaloid hemorrhage, which appears as a fresh, red flame-shaped hemorrhage between the retina and vitreous, is virtually pathognomonic of subarachnoid hemorrhage.

Despite the importance of the ophthalmoscopic evaluation, under no circumstances should the pupil be dilated in a comatose patient because changes in the pupils are often the most reliable clinical indication of deterioration following brain injury.

C. Oculomotor System—As with pupillary responses, changes in the oculomotor system often occur with primary

neurologic injury. The system responsible for moving the eyes is located between the sixth nerve in the pons and the third nerve in the midbrain. Closely adjacent to the sixth nerve is a gaze center known as the *pontine paramedian reticular formation* (PPRF). Just prior to moving one of the eyes laterally, which is accomplished with the sixth nerve, there is rapid firing in the PPRF. The contralateral eye will deviate medially via fibers that travel from the PPRF, cross in the pons, and travel medially to the contralateral third nerve nucleus in the medial longitudinal fasciculus.

The simplest way to test the viability of this system is the oculocephalic (“doll’s eye”) reflex. For this test, the patient is positioned with 30-degree neck extension, and the head is moved from side to side. If the brain stem PPRF and the vestibular system are intact, the eyes should move smoothly in the direction opposite to that in which the head is moved. A more precise test is the caloric oculovestibular response. For this test, the comatose patient is elevated to a 30-degree angle, and one tympanic membrane is irrigated with ice-cold water. Ten milliliters usually is sufficient to produce a response. Within 1–2 minutes, both eyes should deviate laterally toward the side where the cold water was instilled. In metabolic or toxic coma this system is spared, whereas in many structural comas the oculovestibular system is impaired; in brain death, it is absent. In the normal, awake patient, slow deviation toward the side of the stimulus is lost, and nystagmus in the contralateral direction is observed.

D. Motor Systems—Primary brain lesions often are associated with focal motor deficits, but in metabolic or toxic states, focal motor findings are normally absent. With lateral cortical or internal capsular injury, the examination shows contralateral motor deficit. Posturing in flexion (decorticate posturing) supervenes when diffuse dysfunction of the diencephalon occurs. Injury of the brain stem motor systems between the red nucleus in the midbrain and the vestibulospinal nuclei in the medulla leads to an abnormal extensor response in the arms with flaccid or extensor response in the legs (decerebrate posturing). Injury to motor systems at or below the level of the vestibulospinal nuclei results in flaccidity. With progressive neurologic injury, moving from higher to lower centers, one sees a progression from paralysis to flexor posturing to extensor posturing to flaccidity.

E. Respiratory and Circulatory Changes—With injury at the level of the pons, abnormal respirations may occur. Once the medulla is injured, there is loss of respiratory function, and apnea ensues. Similarly, in the beginning stages of medullary compression, abnormalities in blood pressure—usually hypertension—can present. As the medullary injury progresses, hypotension intervenes.

The first manifestation of a compressive lesion of the medulla often is respiratory or circulatory collapse. Severe hypertension is sometimes the first or main manifestation of posterior fossa lesions. For these reasons, posterior fossa lesions are difficult to diagnose and can be catastrophic when missed.

Table 30–2. Physical findings in drug-induced comas.

Drug Type	Pupillary Response	Other Changes
Opioids	Pinpoint	None
Barbiturates and benzodiazepines	Reactive	None
Anticholinergics (scopolamine, etc.)	Pupils dilated	Tachycardia, seizures
Anticholinesterases (organophosphates)	Pupils constricted	Bradycardia, sweating, salivation
Cocaine and amphetamine	Pupils dilated	Tachycardia, hypertension, hypotension, arrhythmia
Neuroleptics	Pupils variable	Motor rigidity, hypotension, hyperthermia
Antidepressants	Pupils dilated	Rarely seizure

Differential Diagnosis

The major group of diseases that cause coma include metabolic, toxic, and primary neurologic injury. The cause usually can be determined by neurologic examination.

A. Metabolic Coma—In any patient with unexplained coma suggesting metabolic dysfunction, it is important to measure serum sodium, glucose, urea nitrogen, and creatinine; to determine PaO₂ and PaCO₂; and to perform liver and thyroid function tests. A toxicology screen also is mandatory. Sepsis can lead to coma, and evidence for infection should be sought in any delirious or comatose patient. The physician should have a low threshold for obtaining lumbar puncture for cerebrospinal fluid (CSF) analysis in a patient with unexplained coma. Comas owing to various metabolic factors have more similarities than differences. Table 30–3 lists the major metabolic causes of coma and comments on subtle differences in coma owing to these various metabolic abnormalities.

Elderly people are particularly vulnerable to the effects of metabolic insults and poorly tolerant of mild fluctuations in metabolic status. Therefore, it is common to observe an elderly patient in coma owing to relatively mild metabolic abnormalities, whereas this same combination of metabolic changes might not lead to coma in a young, otherwise healthy individual. One typical example is the elderly patient who develops delirium or even coma associated with a pulmonary or urinary tract infection. In fact, elderly patients' changes in mental status sometimes are the first manifestation of sepsis. Many patients with primary brain

injury, however, demonstrate mild metabolic abnormalities, and one should not automatically assume that subtle metabolic changes explain why a patient is in coma.

B. Toxic Coma—Coma secondary to drugs often resembles coma from other metabolic processes. However, respiratory suppression may be more common in patients with drug-induced coma. Similarly, some groups of drugs have specific effects on the pupils. The drugs that can cause coma are too numerous to list in this chapter. Table 30–2 lists some commonly abused drugs and emphasizes the characteristics of coma associated with drug overdose.

C. Primary Brain Injury—CNS infection, trauma, and stroke can lead to coma. Massive rises in intracranial pressure such as those seen with severe head injury, subarachnoid hemorrhage, or blockage of CSF flow by a ventricular mass cause sudden coma. Coma also occurs with acute injury to the reticular activating system in the brain stem owing to basilar artery thrombosis or pontine hemorrhage. In any patient with altered consciousness and focal motor findings, it should be assumed that a focal brain lesion is present.

Once it has been determined that a primary neurologic event is a possible cause of the coma, emergency scan of the brain is required. CT generally can be done quickly, is very sensitive for acute hemorrhage, and demonstrates most focal injuries. However, many patients with coma secondary to ischemic brain injury, isodense subdural hematomas, encephalitis, and meningitis will not show changes on CT unless contrast material is used. If readily available, MRI is a

Table 30–3. Metabolic comas: mechanisms and treatment.

Disease	Coma	Mechanisms and Features	Treatment
Hyponatremia	Acutely: <120 meq/L Chronically: <110 meq/L	Leads to true cytotoxic edema. Skin can be doughy.	Hypertonic saline. Overly rapid correction may lead to central pontine myelinolysis.
Hypernatremia	>155 meq/L	Loss in brain water. Seizures common.	Slow rehydration.
Hypoglycemia	<30 meq/dL	Deprivation of brain glucose for energy metabolism. Seizures are common.	Needs urgent glucose replacement.
Hyperglycemia	Ketotic or nonketotic	Changes in brain water and pH contribute to both. Nonketotic coma often has focal findings.	Slow correction.
Hypoxia	Pao ₂ usually <40 mm Hg	Loss of brain O ₂ for aerobic metabolism.	Needs urgent correction.
Renal failure	Variable	Brain acidosis is a factor.	Renal dialysis.
Hepatic failure	Variable. Often precipitated by medications or gastrointestinal bleeding	Brain ammonia and changes in glutamine or dopamine hypothesized as causes. Hyperventilation and decerebrate posturing.	Treat precipitating factor. Lactulose administration.
Hypothyroidism	Chronic low levels	Clinical findings of myxedema.	Slow thyroid hormone replacement.

good choice, although the imaging process takes longer than CT scanning and is more expensive. Cerebral blood flow imaging, single-photon-emission computed tomography (SPECT), and diffusion MRI also may be helpful in the evaluation and management of patients with acute brain injury.

D. Brain Death—The diagnosis of brain death is an unavoidable issue in the practice of critical care medicine and must be approached with sensitivity to the patients' close associates and an awareness of the possibility of organ donation. When brain death appears likely, a frank discussion with family members usually is indicated. It should be recognized that spinal reflexes and even myoclonus may persist in the brain-dead patient and can be misunderstood both by medical personnel and by family members. Declaration of brain death requires the demonstration of irreversible loss of both brain stem and cerebral function and should be done in consultation with a neurologist. Permanent loss of cerebral function with preservation of brain stem function is termed the *chronic vegetative state*, and current practice requires that such patients be given appropriate supportive care.

Treatment

The first step in the management of a patient in coma is to secure the airway and ensure adequate oxygenation. This may require intubation. Furthermore, intubation should be considered when control of PaCO_2 is necessary. Hypercapnia causes cerebral vasodilation, and hypocapnia causes vasoconstriction; the former can increase intracranial pressure, and the latter can reduce it. In addition, aspiration is a common problem in the patient with altered consciousness and another reason to consider intubation.

Just as important in the management of coma is the quick assessment and control of the circulatory system. Even in patients with initially normal blood pressures, sudden loss of systemic perfusion can occur and can lead to irreversible brain injury. Therefore, a large-bore intravenous catheter should be placed in all comatose patients so that circulatory access is assured. Following this and when dealing with an unknown cause, 100 mg thiamine and then a bolus of dextrose should be administered as treatment for potential cases of Wernicke's encephalopathy or hypoglycemia. In many patients with brain lesions and increased intracranial pressure, reflex systemic hypertension occurs. In the case of cerebellar or ventricular mass lesions, focal findings may be subtle or even absent and can lead to the incorrect assumption that the coma is due to hypertension and the primary problem ignored. Unexpected herniation can occur in such patients. Irrespective of the cause of increased intracranial pressure, lowering of systemic blood pressure could result in loss of cerebral perfusion.

Once respiration and circulation are maintained, the focus is on treatment appropriate to the diagnosis. The next chapter outlines the management of coma owing to increased intracranial pressure. Many metabolic causes of coma such as hypernatremia, hyponatremia, hyperglycemia, and hepatic encephalopathy have protocols that demand

meticulously organized treatments that often require days. Similarly, drug-induced comas may require specific treatment. In coma owing to barbiturate or benzodiazepine toxicity, simply maintaining respiratory and circulatory support until the drug is cleared will be sufficient, whereas other poisons may require administration of specific antidotes (see Chapter 37).

SEIZURES

All physicians in critical care medicine on occasion will have to manage seizures, which may be seen as the patient's primary problem or as a problem complicating other illnesses. Prompt recognition and treatment of seizures are important because prolonged or frequently repeated generalized seizures may lead to permanent brain injury.

The basic functional property of neurons is electrochemical, and the basic disturbance of this property that underlies all seizures is termed the *paroxysmal depolarization shift*. The various lesions that produce seizures result in a paroxysmal production of synaptic potentials, which brings neurons above their threshold and causes repetitive action potentials. Thus the electrochemical disturbance is propagated, and clinical seizures result.

Seizures may occur as a result of substrate deprivation, synaptic dysfunction, or brain injury or as a manifestation of primary generalized epilepsy. The brain depends on two major substrates—oxygen and glucose—and deprivation of either may result in seizures. Similarly, sodium is required to maintain the electrochemical property of neurons, and extreme changes in sodium concentration also can lead to seizures. In general, the magnitude of hypoglycemia, hypoxia, and hyponatremia must be great enough to result in alteration of consciousness, following which seizures occur. Similarly, various toxic insults can result in seizures by altering synaptic function.

Direct brain injury may cause seizures, both acutely and in delayed fashion. In acute head injury, mechanical factors probably disturb membrane function, and the resulting seizures are seen within minutes to hours following the trauma. These seizures may be limited and do not typically recur. Brain injury from laceration in open head wounds or direct tissue damage in closed head injury may result in post-traumatic seizures. Pathologically, this occurs after healing and gliosis have taken place at the injured site. Typically, these seizures begin a few months to a year following trauma. The precise nature of this “ripening” process is unclear, but dendritic abnormalities have been observed on surviving neurons in the areas of gliosis. Direct electric shock also can cause seizures and is a classic method for testing the effectiveness of proposed anticonvulsant medications in animal models.

Finally, a common cause of seizures is primary generalized epilepsy. The precise pathophysiologic mechanisms are unknown, but most investigators believe the disturbance probably is related to ion channel, neurotransmitter, and

synaptic dysfunction. Potential insights into the pathophysiology of primary generalized epilepsies are provided by the proposed mechanism of action of anticonvulsant medications. For example, phenytoin and carbamazepine are thought to act at sodium channels, whereas valproic acid is thought to act at sodium and calcium channels. In addition, a great deal of investigation with valproic acid concerns its action on γ -aminobutyric acid (GABA) receptors. Phenobarbital has been found to block posttetric potentiation produced by electroshock and also may act at calcium and chloride channels.

Classification of Seizures

Recognition and understanding of the seizure type is the first step in the evaluation process and serves as a guide for workup and management. The types of seizures are summarized in Table 30-4.

A. Partial Seizures—Partial seizures are those that arise from a focal area of the cortex. The clinical nature of the seizure is dictated by the functional specialization of the cortical area from which it arises. Focal motor seizures are a good example. Note that a seizure is an activation of function and not a loss of function, as occurs in a transient ischemic attack. Partial seizures that are limited and not associated with alteration of consciousness are termed *simple partial seizures*. Impairment of consciousness coupled with a partial seizure is called a *complex partial seizure*.

Complex partial seizures generally arise from the temporal lobe or other limbic structures. At the onset of this type of seizure, the patient commonly experiences some autonomic or emotional symptoms, such as a feeling of fear, associated with a rising or breathless sensation within the chest or a sense of being startled. Abdominal sensations are reported commonly. The patient may experience other phenomena such as *déjà vu* or may experience visual or olfactory hallucinations. These altered perceptions tend to be stereotyped from seizure to seizure in any given patient and are usually brief in duration. Following this type of onset, the patient has an alteration of consciousness and usually has little memory of what occurs until the seizure is completed.

To an observer, the onset of a complex partial seizure may appear only as a motionless stare. After the onset, the patient may develop some type of automatic and repetitive movements. Examples are lip smacking or movements of one or both extremities or repetitive picking at some part of the body or a piece of clothing. During this time, the patient is poorly responsive to the environment but still may have some limited interaction. The patient then seems to recover but remains confused for variable periods, usually only a few minutes. Most seizures last from a few minutes to about 15 minutes. In repetitive, frequent complex partial seizures, the patient seems to be in a twilight state, awake yet poorly responsive to the examiner and the environment.

B. Generalized Tonic-Clonic Seizures—These were at one time called *grand mal seizures*. Such seizures are sometimes preceded by a cry. They are always accompanied by loss of consciousness, but the tonic and clonic phases are variable. The tonic phase usually precedes the clonic phase, and all the extremities are involved in both phases. During the tonic phase, there is expression of extensor motor dysfunction, whereas throughout the rhythmic clonic phase, there is flexor motor predominance. The duration of a single generalized seizure is measured in minutes, and there always will be a period of postictal confusion that is likewise usually brief.

Generalized tonic-clonic seizures may develop as a consequence of spread from a partial seizure; in this instance, it would be designated as *secondarily generalized*. Tonic-clonic seizures, generalized at onset, may be caused by metabolic abnormalities, drug withdrawals, poisons, or other pathologic states that affect overall brain function. Primary generalized epilepsy is a major cause of generalized tonic-clonic seizures. However, the essential pathogenesis of primary generalized epilepsy is poorly understood. In general, the primary generalized epilepsies (both generalized and absence) have their onset in childhood.

C. Absence Seizures—Typical absence seizures were formerly called *petit mal seizures*. They are due to another type of primary generalized epilepsy and always begin abruptly with the patient losing cognitive contact. There may be some fluttering of the eyelids, but body tone is maintained, and the patient does not fall. Typically, after a few moments (occasionally up to 1 minute or longer), the patient abruptly regains awareness and will continue the interrupted activity. Some patients recognize that the period of absence has occurred, but others do not. This type of seizure is *not* associated with a postictal state. The EEG shows generalized three per second spike-and-wave discharges during the seizure. Characteristically, the discharges are provoked by hyperventilation. Absence seizures can be very frequent and prolonged—a condition referred to as *absence status*.

D. Status Epilepticus—Status epilepticus exists whenever seizures are persistent or there is incomplete recovery between seizures. Generalized tonic-clonic status epilepticus is a medical emergency. The consequences of status can

Table 30-4. Classification of seizures.

Partial (<i>epilepsia partialis continua</i>)

include aspiration pneumonia, hypoxia, hypotension, hyperthermia, autonomic instability with cardiac arrhythmias, hyperkalemia, lactic acidosis, myoglobinuria, decreased cerebral perfusion, and death. Furthermore, prolonged generalized tonic-clonic seizures can result in permanent neuronal injury, particularly in the hippocampus, cerebellum, and neocortex.

In *nonconvulsive status*, the patient has impairment or loss of consciousness without generalized motor seizures. Nonconvulsive status can be quite subtle and difficult to recognize in the critical care setting. The patient may show an occasional twitch of an extremity or a facial twitch. Sometimes the only evidence for seizure activity involves eye movements, which can be observed only by lifting the eyelids. Nonconvulsive status of this type often is associated with significant metabolic encephalopathy and sometimes with underlying structural brain disease. Electroencephalography is required for diagnosis.

Another type of generalized nonconvulsive status is *absence status*, also called *spike-wave status*. Absence status most often occurs in children who have generalized epilepsy. In adults it is rare, but it may occur suddenly in elderly patients and present as a confusional state with minor automatisms such as eye blinking or facial twitching.

Status epilepticus also can occur with partial seizures. This has been called *epilepsia partialis continua*, and focal motor seizures are the type most apt to be seen by the critical care physician. Complex partial status presents with a patient in a confusional state, often with various automatisms as described previously.

Clinical Features

A. History and Examination—The history is critical in the diagnosis of seizures, and a comprehensive review of the history and the hospital course is required. Patients may describe their symptoms, particularly in the case of complex partial seizures; however, many patients are unaware of activity during the episode because consciousness has been impaired. In fact, patients are sometimes even unaware that they have had a lapse of consciousness. Thus it is important to obtain a history from the patient and from witnesses such as nurses, other patients in the room, family members, or other attending physicians. Neurologic examination should be directed toward signs of metabolic encephalopathy, increased intracranial pressure, and lateralized findings indicative of focal brain disease. An EEG may help to clarify the nature of the seizure, particularly if it is obtained during or soon after the seizure activity. Unless an obvious cause for a seizure is known (eg, medication noncompliance in a patient who has a known and previously evaluated seizure disorder), brain imaging is necessary to see if structural brain disease is present. If an infectious cause is suspected and there is no contraindication owing to intracranial mass effect, lumbar puncture should be performed to obtain CSF for examination. If mass effect is present, neurosurgical consultation should be obtained.

With new-onset seizures in the critical care setting, a useful approach is to consider reversible causes first. In most instances, these seizures will be generalized, tonic-clonic in nature. Hypoxic-ischemic events are a common cause of such seizures. The magnitude and duration of brain oxygen deprivation will determine the severity of the seizure, as well as the ultimate outcome. A brief seizure or several brief seizures with rapid resolution may require no anticonvulsant therapy. If the hypoxia-ischemia is severe, the seizures may be prolonged and difficult to treat, and hypoxia-ischemia also may be a cause of nonconvulsive status epilepticus.

The most common causes of drug-withdrawal seizures are ethanol, barbiturates, and opioids. Ethanol-withdrawal seizures usually occur after 24–72 hours of abstinence and rarely lead to status epilepticus unless there are other underlying diseases. Theophylline is probably the most common pharmacologic cause of seizures in the ICU. Lithium toxicity may cause an encephalopathy that may include seizures. Penicillin toxicity causes seizures but is a rare occurrence usually associated with kidney failure. A more common metabolic cause of seizures is hyponatremia, which often is associated with inappropriate antidiuretic hormone secretion, and/or fluid overload.

Seizures occurring with acute neurologic disease often are partial, or partial with secondary generalization, and the partial onset may not be clinically apparent. Herpes simplex encephalitis tends to be focal, whereas encephalitis from other causes is more generalized. Electroencephalography and imaging studies are helpful in the differential diagnosis. Seizures usually do not occur with uncomplicated meningitis. If they occur in bacterial meningitis, one should suspect a complicating cortical venous thrombosis. Brain abscesses commonly cause seizures.

The EEG is very useful in critical care neurology. To obtain the maximum information from the EEG, the clinician should provide the electroencephalographer with a brief history that includes the patient's age, a description of the level of consciousness, and a list of the medications being administered. One syndrome that can be defined with the EEG is called *periodic lateralized epileptiform discharges* (PLEDs). Affected patients are stuporous or comatose, may have occasional epileptiform twitching movements of one side of the face, and show the characteristic lateralized epileptiform discharges. PLEDs usually are associated with some underlying structural brain disease, such as an old infarct, and a superimposed metabolic encephalopathy. In general, the prognosis is hopeful with correction of the metabolic disturbance and, usually, administration of anticonvulsant medication.

In the case of seizures, the EEG can be diagnostic if obtained during the seizure, but also it may show interictal discharges and abnormalities supportive of the diagnosis and indicate any focal aspect. Sometimes it is helpful to employ closed-circuit TV, together with an electroencephalographic monitoring system, to fully evaluate the seizure as well as the progress of therapy. The EEG also is helpful in establishing the diagnosis of a generalized toxic-metabolic encephalopathy whether or not seizures are present.

Differential Diagnosis

Seizures may be associated with many different pathologic states, including structural disease owing to neoplasms, vascular anomalies, old strokes, and past trauma, or metabolic encephalopathies. Other common problems leading to seizures include poisoning, drug withdrawal, infections such as viral encephalitis, and primary generalized epilepsies. Poor compliance with the anticonvulsant regimen is a common reason for a patient with epilepsy to develop status epilepticus as well as to have poor seizure control. Drug level monitoring in these patients is essential.

Partial seizures of any type imply an underlying structural brain disease. Likewise, a postictal paresis (Todd's paresis) implies underlying focal disease.

Treatment

The management of seizures in critical care practice requires first the removal or correction of precipitating causes and second the administration of anticonvulsant medication. Often it will seem prudent to administer anticonvulsant medication on a temporary basis while causative conditions are resolving. Whether anticonvulsants are administered orally or intravenously, it is critical to monitor serum concentrations to ensure a therapeutic range. Phenytoin (fosphenytoin IV preparation fully converted to phenytoin after injection), phenobarbital, and valproate can be administered either intravenously or orally. Lorazepam and diazepam are useful anticonvulsants only when given intravenously.

Table 30-5 lists the doses and average half-lives of these anticonvulsant medicines administered intravenously. Since these half-lives are variable, the information provides an approximation of the duration of action.

The major limiting factor for diazepam is that it peaks into the therapeutic range for only a brief time; seizures may

recur 15–20 minutes after it is given. On the other hand, it is rapidly effective. There may be some risk of apnea when diazepam and phenobarbital are given together. Lorazepam also is rapidly effective and has a longer duration of action. The dose of lorazepam is usually 2–10 mg, or 0.1 mg/kg. It can be administered in 2-mg increments at intervals of a few minutes until the seizures are controlled or the maximum dose is reached.

Both fosphenytoin or phenytoin and phenobarbital are effective anticonvulsants, although their onset of action may be slower than that of the benzodiazepines. Phenytoin, phenobarbital, and valproate can be continued orally. Phenytoin must be administered at a rate no faster than 50 mg/min because of the risk of cardiac arrhythmia. Electrocardiographic monitoring is advised while phenytoin is given. Phenytoin should not be mixed in a dextrose solution because it will precipitate. The initial intravenous dose is 18–20 mg/kg of body weight; the maximum dose is 30 mg/kg. Fosphenytoin is dosed in phenytoin equivalents (PEs); it can be mixed in normal saline or a 5% dextrose solution and infused at a rate up to 150 mg PE per minute. Extravasated phenytoin solution often is harmful to surrounding tissues, whereas extravasated fosphenytoin usually results in no tissue damage.

The intravenous dose of phenobarbital is 300–1000 mg (or 15–20 mg/kg) for seizure control. Usually it is supplied in 60-mg units, so an initial dose of 300 mg is convenient and can be repeated every 10–20 minutes until seizure control occurs or the maximum dose is reached.

Valproate sodium injection is a broad-spectrum anticonvulsant; it has complete bioequivalence with oral valproate and may be mixed in normal saline or 5% dextrose solution. The recommended infusion rate is up to 20 mg/min. Valproate is the drug of choice for absence seizures. Intravenous valproate, lorazepam, and diazepam are effective in absence status.

Levetiracetam also is available as an intravenous solution as well as an oral preparation. It is approved as adjunctive therapy in the treatment of partial-onset seizures in adults when oral administration is not feasible. The intravenous dose is equivalent to the oral dose (1000–3000 mg/day given twice daily) and is supplied in 500-mg/5-mL vials. It should be diluted in 100 mL normal saline and infused over 15 minutes. Levetiracetam is 66% excreted unchanged in the urine and has no metabolism involving hepatic cytochrome P450 isoenzymes.

Seizures from metabolic encephalopathies, nonconvulsive status, and PLEDs often do not respond fully and quickly to anticonvulsive medications. In this circumstance, it is best to maintain therapeutic anticonvulsant blood concentrations while pursuing therapy of underlying diseases. Partial seizures or partial status likewise may be resistant to treatment. In such cases, two anticonvulsant drugs can be tried, but it is best to maintain them in the usual therapeutic range and determine if with time there is greater benefit.

Generalized tonic-clonic status epilepticus does constitute an emergency and must be controlled. Ventilation and cardiac function must be supported. If hypoglycemia is a consideration, 50 mL of a 50% dextrose solution should be

Table 30-5. Intravenous anticonvulsants.

Drug	Average Half-Life	Dose*
Diazepam	1 hour	10-30 mg
Lorazepam	3 hours	2-10 mg
Phenytoin	12 hours	18-20 mg/kg
Fosphenytoin	12 hours†	20 mg phenytoin equivalents (PE)/kg
Phenobarbital	99 hours	15-20 mg/kg
Valproate sodium injection‡	10 hours	250-500 mg

*Status epilepticus or loading.

†Converted to phenytoin in 10-15 minutes.

‡ $T_{MAX} = 1$ hour.

administered promptly. If there is any possibility that the patient is an alcoholic, dextrose should be preceded by 100 mg thiamine to prevent Wernicke's encephalopathy. Anticonvulsant medication for status epilepticus always must be administered intravenously and be given in full loading doses. A common mistake is to give inadequate amounts of several different drugs.

If generalized tonic-clonic seizures persist despite the patient's being given intravenous anticonvulsants, pentobarbital anesthesia is recommended. This should be accomplished with neurologic consultation and under electroencephalographic control. Pentobarbital is given in a dosage of 5 mg/kg for induction of anesthesia and 0.5–2 mg/kg per hour for maintenance. The drug is administered so as to titrate the EEG to a burst-suppression pattern. When it is judged that an appropriate interval of time has lapsed (about 24–48 hours), the pentobarbital dose may be reduced to test for seizure recurrence. If the seizures are controlled, the pentobarbital may be withdrawn, but therapeutic levels of an anticonvulsant such as phenytoin must be present and maintained.

Current Controversies and Unresolved Issues

Resistant partial or lateralized seizures and nonconvulsive generalized status epilepticus remain problems in management, and there is some uncertainty about how vigorous the physician should be in the administration of medications.

No absolute indication exists for the choice of first medication to treat generalized tonic-clonic status; rather, it is a matter of common practice and personal choice.

In the past few years, the number of oral antiepileptic drugs available has increased dramatically, and experience with them in daily practice is accumulating but is not yet great. Use of these drugs, as well as other treatments, including surgical and vagus nerve stimulation, and the management of chronic seizure disorders are mostly beyond the scope of critical care practice. Neurology consultation is recommended when newly prescribing or switching oral antiepileptic medicine.

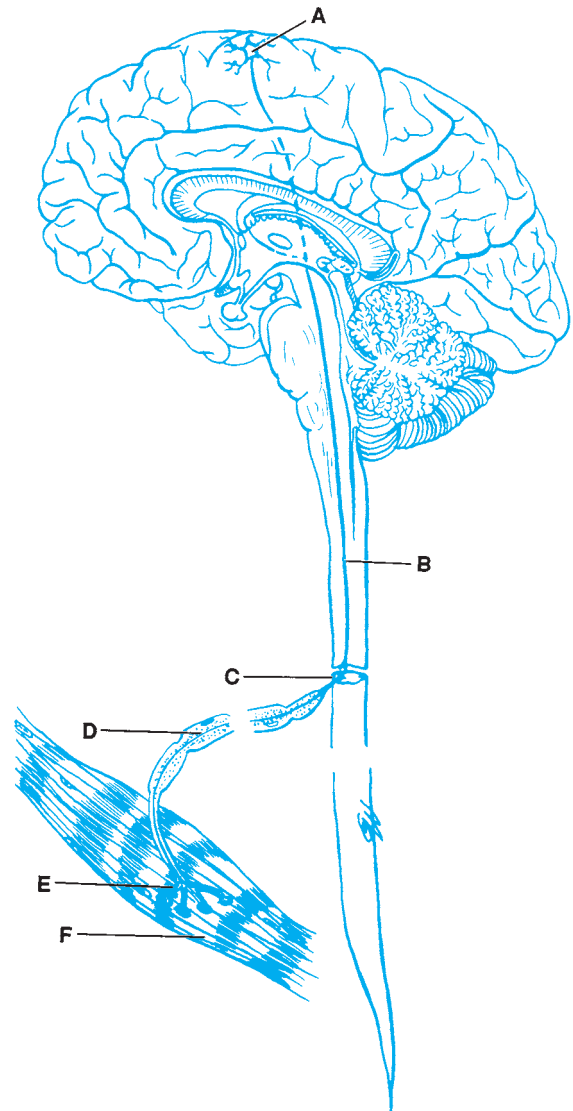

NEUROMUSCULAR DISORDERS

Respiratory failure and cardiac failure are the most serious potential complications of neuromuscular diseases and can lead to death if not treated appropriately. Diseases directly affecting respiration include Guillain-Barré syndrome, myasthenia gravis, amyotrophic lateral sclerosis, and Duchenne's muscular dystrophy. Less commonly, botulism, tetanus, porphyria, and diphtheritic polyneuropathy cause neuromuscular failure. Similarly, a number of neuronal poisons can lead to severe weakness and even respiratory failure. Chronic neuromuscular diseases can lead to secondary pulmonary problems, including phrenic nerve injury, kyphoscoliosis, pulmonary emboli, atelectasis, and most frequently, aspiration pneumonia. Another potential problem associated with neuromuscular diseases involves cardiac complications such as arrhythmias, as seen in Guillain-Barré

syndrome, or conduction blocks with sudden death, as seen in myotonic dystrophy. Advances in the ICU treatment of these patients have decreased morbidity and mortality rates, avoiding sudden death in some instances.

Pathophysiology

Progressive weakness may result from disorders anywhere along the motor tract (Figure 30–1). Lesions in the brain, particularly the upper motor neuron pathways (site A) or

▲ **Figure 30–1.** Localization of lesions causing neuromuscular diseases. **A.** Cortex (upper motor neuron). **B.** Spinal cord. **C.** Anterior horn cell. **D.** Peripheral nerve (axon or myelin). **E.** Neuromuscular junction. **F.** Muscle.

brain stem (site B), may lead to progressive weakness. Likewise, disorders at the level of the spinal cord or the lower motor neurons (site C), either at the anterior horn cell bodies, motor axons, or myelin (site D) or at the pre- or postsynaptic terminals (site E), may lead to weakness. Furthermore, many of the muscle diseases (site F) can directly impair effective ventilation. Table 30–6 lists some examples of diseases that can occur at each site.

One general rule associated with respiratory failure secondary to neuromuscular disorders is that unlike primary

pulmonary illnesses, where dysfunction in gas exchange often results predominantly in *hypoxemia*, respiratory failure secondary to neuromuscular dysfunction usually leads to hypoventilation. Arterial blood gases often demonstrate CO₂ retention, or *hypercapnia*, with relatively mild hypoxemia. By the time PaCO₂ begins to increase, hypoventilation has gone beyond the safe limit. Decrease in vital capacity is associated with predictable signs of pulmonary dysfunction (Figure 30–2). Therefore, the single most important parameter to measure in patients with neuromuscular diseases is the vital capacity.

In order to make an etiologic diagnosis of neuromuscular disease leading to weakness and respiratory failure, specific clinical symptoms and signs as well as laboratory diagnostic studies are used to localize the lesions. Measurements of vital capacity and cardiac monitoring are essential in patients admitted to the ICU owing to exacerbation of neuromuscular diseases because respiratory compromise and cardiac arrhythmias can develop rapidly. The clinical presentation of the illness depends on the site of the lesion.

▶ Spinal Cord Compression

ESSENTIALS OF DIAGNOSIS

- ▶ Back pain, limb paresis, and spasticity.
- ▶ Sensory loss below the level of the spinal cord lesion.
- ▶ Bowel or bladder incontinence.
- ▶ Neuroimaging studies of the clinically suspected spinal levels.
- ▶ Blood cultures and purified protein derivative (PPD) test if an abscess is suspected.
- ▶ Biopsies to evaluate tumors and abscesses.

General Considerations

Back pain can be caused by a variety of diseases, such as local structural disorders, retroperitoneal disease, trauma, infection, and neoplasms. However, tumors, abscesses, or disk fragments in the spinal canal may produce an acute syndrome of spinal cord compression. This is a neurologic emergency that may lead to permanent paralysis if not treated rapidly. Diagnostic signs or symptoms vary depending on the spinal level of the compression.

Intra- and extramedullary spinal cord malignancies, as well as various infections with parasitic (eg, cysticercosis), bacterial (eg, anaerobes, tuberculomas, and gummas), or viral (eg, varicella-zoster or poliomyelitis) organisms, may produce direct or compressive lesions to the spinal cord. Most abscesses are in the thoracic or lumbar areas, and the agent is usually *Staphylococcus aureus*. Tuberculosis also may infect the vertebral column (Pott's disease), causing kyphosis,

▲ **Figure 30-2.** Effects of decreasing vital capacities secondary to weakness from neuromuscular diseases.

which then may cause cord compression or respiratory difficulties.

Clinical Features

A. Symptoms and Signs—Diagnosis of a spinal cord lesion depends on clinical examination and neuroimaging studies. Limb weakness and the presence of a sensory level (particularly to pinprick and vibratory senses) are useful in approximating the level of involvement. Tendon reflexes below the level of the lesion may be increased, and Babinski signs may be present. Fever associated with back pain and myelopathic signs should arouse suspicion of epidural abscess.

B. Laboratory Findings—When an infectious cause is suspected, blood cultures and a tuberculin test will help to direct specific antibiotic therapies. Biopsy examination is indicated for suspected tumor or abscess.

C. Imaging Studies—MRI or CT scan is necessary to accurately localize the lesion.

Treatment

Early recognition and treatment can prevent irreversible neurologic damage. Tumors generally respond to surgical removal or radiotherapy. High-dose corticosteroid therapy also may be indicated. Selection of antibiotic therapy for epidural abscess depends on biopsy or culture results.

▶ Guillain-Barré Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Antecedent flulike illness.
- ▶ Acute or subacute ascending flaccid paralysis.
- ▶ Early loss of tendon reflexes.
- ▶ Subjective distal paresthesias and pain.
- ▶ Occasional cranial nerve deficits.
- ▶ Elevated protein in CSF with no cells.

General Considerations

Guillain-Barré syndrome is an acute or subacute primarily motor polyneuropathy that is usually idiopathic, although a number of etiologic factors, including *Mycoplasma pneumoniae* and hepatitis B, have been implicated in rare cases. In more than 50% of patients with Guillain-Barré syndrome, an antecedent flulike illness or vaccination occurred within 4 weeks prior to the neurologic symptoms.

Acute or subacute ascending muscle weakness develops over 2–4 weeks, followed by gradual recovery over a few weeks to many months. Eighty-five percent of patients will have complete functional recovery.

Clinical Features

A. Symptoms and Signs—Cranial nerve deficits, especially of those controlling eye movements and facial muscles, can be present either alone or associated with limb weakness. Deep tendon reflexes are absent, whereas pupils and eyelids often are spared. Miller-Fisher syndrome is a variant of Guillain-Barré syndrome characterized by absent reflexes, gait ataxia, and ophthalmoparesis. The prognosis for complete recovery of this form of Guillain-Barré syndrome is excellent.

B. Laboratory Findings—Lumbar puncture can be diagnostic by the second week, when CSF shows an elevated protein concentration without pleocytosis (*albuminocytologic dissociation*).

C. Nerve Conduction Studies—Nerve conduction studies show segmental demyelination and reduction of velocity in 85–90% of patients by the second week. Up to 40% of patients develop respiratory muscle weakness and/or autonomic instability. Therefore, ICU admission is best for most patients, and frequent vital capacity measurements and cardiac monitoring are necessary for timely detection of these complications.

Treatment

A. Respiratory Care—Respiratory weakness requiring ventilatory support develops in 40% of patients and may be rapidly progressive in the early phases. Intubation may be required. Bulbar muscle weakness can lead to aspiration pneumonia, which is potentially preventable by placement of a nasogastric tube, as well as by intubation.

B. Cardiac Care—In up to 40% of patients with Guillain-Barré syndrome, autonomic dysfunction may occur and accounts for much of the morbidity and most of the deaths in this group of patients. The cardiac abnormalities frequently include sinus tachycardia, and asystole can occur. Therefore, it is essential to maintain cardiac monitoring and to administer antiarrhythmic drugs as necessary.

C. Other Treatment—When the weakness is progressive and severe, plasmapheresis or intravenous immune globulin (IGIV) is recommended. Because most of these patients experience a significant amount of pain (which may be difficult to recognize when the patient is intubated), use of opioids as needed is indicated.

► Critical Illness Polyneuropathy

ESSENTIALS OF DIAGNOSIS

- ▶ Associated with multiorgan failure, often with sepsis.
- ▶ Difficulty weaning from respirator owing to weakness.
- ▶ Distal limb weakness with diminished or absent reflexes.
- ▶ EMG nerve conduction studies characteristic.

General Considerations

Critical illness polyneuropathy has been recognized in association with sepsis and multiorgan failure in the ICU setting. Sometimes it is first identified because of difficulty weaning a patient from the ventilator owing to respiratory muscle weakness. It is an axonal sensorimotor polyneuropathy of obscure origin; there is no inflammation or demyelination of the nerves.

Clinical Features

A. Symptoms and Signs—The typical findings on examination are distal limb weakness with flaccidity and hyporeflexia or areflexia as well as respiratory muscle weakness or even quadriplegia in severe cases. Mild facial weakness sometimes occurs, but ophthalmoparesis is uncommon. Distal sensory loss may be expected, but under the usual circumstances of this condition, sensory deficits are difficult or impossible to assess accurately. Superimposed entrapment or compression neuropathies, because of positioning problems, should be considered in the differential diagnosis. Also to be differentiated is *critical illness myopathy*, which is a syndrome of weakness that develops in some critically ill patients after the use of corticosteroids, often in combination with neuromuscular blocking agents. Creatine kinase usually is elevated, many times to very high levels, and can be associated with rhabdomyolysis and myoglobinuria. Another condition to be differentiated is prolonged neuromuscular blockade, which may occur in critically ill patients after neuromuscular blocking agents have been discontinued; the duration can range from hours to days.

B. Laboratory Findings—Electromyographic and nerve conduction studies show reduced motor and sensory amplitudes but preserved conduction velocities and distal latencies. This is distinguished from Guillain-Barré syndrome, in which conduction block and segmental slowing are found. The CSF protein is normal in critical illness polyneuropathy.

Treatment

Treatment consists of correction and management of underlying illnesses. The neuropathy often improves after weeks or months as sepsis and organ failure resolve. Patients who have mild or moderate neuropathy may have complete recovery, whereas those severely affected probably will have residual and permanent weakness. It is prudent to minimize the use of neuromuscular blocking agents, especially in patients who are receiving corticosteroids.

► Toxic Neuropathies

There are three anatomic locations where toxins can affect the peripheral nerve: the cell body, the nerve sheath myelin, and the axon. Diphtheria toxin, tetanus toxoid, and antibiotic treatments may lead to acute sensory neuropathy secondary to myelin loss, whereas the most common toxic neuropathies

result in axonal injuries. Many drugs and industrial chemicals can be neurotoxic. Examples of such drugs are isoniazid, chloramphenicol, metronidazole, disulfiram, amiodarone, gold, cisplatin, vincristine, lithium, nitrofurantoin, nitrous oxide, and pyridoxine.

Exposure to industrial chemicals such as arsenic, acrylamide, carbon disulfide, mercury, the organophosphate parathion, and vinyl chloride can cause distal axonal neuropathy. The clinical course depends on the concentration of the offending agent. Chronic exposure to these agents leads to an insidious onset of paresthesia in glove-stocking distribution. With more acute exposure, patients develop other systemic signs along with a more rapid onset of neuropathy. Two important ubiquitous toxins, lead and arsenic, both have characteristic clinical presentations.

Lead Poisoning

Lead poisoning can occur via the GI tract, lungs, or skin and is associated with abdominal cramps and encephalopathy (particularly in infants). Blood smears show basophilic stippling in the erythrocytes. The elevated lead level can be measured in serum. Although other nerves may be affected, lead has a peculiar predilection for radial nerves, resulting in weakness of wrist and finger extension. Sensory symptoms are unusual.

Arsenic Poisoning

Arsenic poisoning often results from accidental ingestion of rat poisons or industrial sprays, although intentional poisonings do occur. These patients often develop an acute polyneuropathy several weeks after exposure. The nail beds show pale bands called *Mees's lines*. After exposure, urine, hair, and nails all may contain arsenic. With higher exposure, a painful sensory neuropathy may evolve to a flaccid paralysis beginning in the lower extremity but eventually affecting the respiratory muscles and upper extremities.

Urine and serum for a heavy metal screen, along with a careful drug and toxin exposure history, are mandatory in any patient presenting with an acute neuropathy. Finally, nerve conduction studies will help to differentiate demyelinating versus axonal types of neuropathy.

▶ Myasthenia Gravis

ESSENTIALS OF DIAGNOSIS

- ▶ History of fluctuating weakness and fatigability.
- ▶ Positive edrophonium (Tensilon) test.
- ▶ Decremental responses on nerve conduction studies.
- ▶ Positive serologic tests for acetylcholine receptor antibodies.
- ▶ Chest CT scan or MRI may show thymoma.

General Considerations

Myasthenia gravis appears to be an autoimmune disease, primarily a disorder of the postsynaptic neuromuscular junction. Acetylcholine receptor antibodies are found in 85–90% of patients. Other immunologic diseases such as thyroid disease, polymyositis, rheumatoid arthritis, and systemic lupus erythematosus all have been associated with myasthenia gravis.

Repetitive stimulation of a motor nerve at 3 Hz shows a decremental response of electromyographic motor units in up to 85% of patients with myasthenia gravis, whereas diseases affecting the presynaptic nerve terminal such as Lambert-Eaton syndrome or botulism demonstrate an incremental response at a higher rate of stimulation.

Clinical Features

A. Symptoms and Signs—Myasthenia gravis is characterized by variable weakness and easy fatigability. The motor weakness worsens with exercise and improves after rest. Diplopia often is an early symptom, and over 90% of patients develop ocular muscle involvement. Patients feel strongest in the morning and weakest at night because their muscles tire during the day.

B. Laboratory Findings—The edrophonium test demonstrates that an increase in peripheral acetylcholine improves motor function. It is performed as follows: (1) Stop other anticholinesterase medications 24 hours prior to the test if possible. (2) Atropine sulfate, 0.4 mg (1 mL), which blocks muscarinic “side effects” of edrophonium but not the nicotinic effect at the neuromuscular junction, and normal saline (1 mL) are used first as control injections. (3) Edrophonium should elicit a response in 30–60 seconds that should last for 10–30 minutes. Draw up 10 mg and give 2 mg for the first dose; if there is no response, follow with 8 mg. (4) Assess strength of affected muscles 1–2 minutes after each intravenous dose.

The absence of acetylcholine receptor antibodies does not exclude the diagnosis, but their presence is confirmatory. Antistriational antibodies are found in 90% of myasthenic patients with thymoma.

C. Imaging Studies—Approximately 10% of patients develop thymoma, and 70% will have thymic hyperplasia. Therefore, chest CT scan or MRI is performed to search for mass lesions.

Treatment

A. Oral Therapy—Pyridostigmine often is successful first-line therapy. The usual initial dose is 30 or 60 mg. The interval of dosing can be adjusted in individual patients depending on observed duration of action but is usually on the order of 4 hours. Prednisone and other immunosuppressive drugs also are used in difficult cases.

B. Intravenous Therapy—Plasmapheresis, 2–3 L per exchange three times a week over 2 weeks, has been successful

in some patients who do not respond to anticholinesterase medications. Intravenous immune globulin (IGIV) is an alternative to plasmapheresis, and both are useful in preparing patients for thymectomy.

C. Thymectomy—Thymectomy improves long-term outcome in patients with myasthenia gravis, and all patients undergoing thymectomy should be monitored carefully pre- and postoperatively in the ICU under the supervision of a neurologist. Postoperatively, immunosuppression with high-dose prednisone is helpful in many patients.

D. Exacerbations—When a myasthenic patient presents with increased weakness, it is important to differentiate between myasthenic versus cholinergic crisis. A myasthenic crisis requires treatment with additional anticholinesterase medications, whereas weakness owing to cholinergic crisis only improves if the medication is withheld. An edrophonium test may be helpful in differentiating the two. In myasthenic crisis, look for causes such as infection (especially aspiration pneumonia), drugs with a potential for blocking neuromuscular transmission, and excessive use of sedative drugs. In general, if vital capacity is less than 1 L, it is best to intubate and stop all myasthenic medication until the cause of the exacerbation is determined.

▶ Botulism

ESSENTIALS OF DIAGNOSIS

- ▶ GI symptoms with dry mouth.
- ▶ Blurred vision, dilated pupils, and diplopia.
- ▶ Respiratory distress.
- ▶ Incremental response with repetitive nerve conduction studies.
- ▶ Stool examination positive for *Clostridium botulinum* and its exotoxin.

General Considerations

Unlike myasthenia gravis, the neuromuscular junction defect in botulism results primarily from presynaptic cholinergic conduction blockade. It is an acute poisoning resulting from ingestion of *C. botulinum* exotoxin. The organism is found in inadequately cooked or defectively canned food. Also, it may be found in clostridial wound infections, which is a source of the disease in people injecting illicit drugs. In infants between the ages of 1 and 38 weeks, the toxin may be found in the GI tract.

Clinical Features

A. Symptoms and Signs—Symptoms begin within 5–50 hours of eating the contaminated food or exposure to the

toxin. Dry mouth and GI symptoms such as cramps, nausea, vomiting, and diarrhea or constipation, as well as malaise and headache, are noted initially. Extraocular muscle weakness and dilated, sluggishly reactive pupils cause diplopia and blurred vision. These patients may rapidly develop dysphagia and respiratory distress. Respiratory failure and aspiration pneumonia may be the principal causes of death from botulism. The nervous system is involved in descending fashion, beginning with muscles innervated by the cranial nerves. Consciousness and sensation remain intact, however.

B. Laboratory Findings—Botulinus toxin can be isolated from infected serum, stool, or contaminated food. Since cultures of the organism or evaluation for the toxin may take several days, repetitive nerve stimulation should be performed as soon as possible in patients suspected of having botulism. CSF is normal.

C. Nerve Conduction Studies—Diagnostic studies with high-rate (40 Hz) repetitive nerve stimulation demonstrate incremental responses of the compound action potentials in the motor nerves.

Treatment

A. Antitoxin—Type E antitoxin has the greatest clinical efficacy and should be administered as quickly as possible. The dose may be repeated in 4 hours if the condition worsens. Skin testing to exclude hypersensitivity should precede administration of the antitoxin. One vial of antitoxin should be given orally and one intravenously.

B. Antibiotics—When botulism occurs from a wound infection, antibiotic therapy with penicillin, 300,000 units/kg per day intravenously, is preferred. Other useful drugs are clindamycin (30 mg/kg per day intravenously) and chloramphenicol (50 mg/kg per day intravenously); guanidine hydrochloride (50 mg/kg per day orally) may improve muscle function.

▶ Inflammatory Myopathies

Most inflammatory myopathies result from autoimmune processes, although some result from infections. Typical examples include dermatomyositis, polymyositis, secondary involvement with lupus erythematosus, and viral myositis. In 20% of older patients (>50 years), polymyositis and dermatomyositis may be associated with an occult malignancy.

Myalgia and proximal muscle weakness are the most common complaints in patients with inflammatory myopathies. Most forms are self-limited, lasting 2–3 weeks. However, fulminant myositis may lead to rhabdomyolysis, which can be fatal. Occasionally, when the swallowing muscles are involved, the patient requires nasogastric tube feedings.

Laboratory studies often reveal an elevated creatine kinase and sedimentation rate. Electromyography shows signs of muscular irritability with fibrillation potentials and small polyphasic waveforms—all characteristic of inflammatory

myopathies. Perivascular infiltrates and perifascicular atrophy are seen in muscle biopsy specimens, and this information may be necessary for definitive diagnosis.

▶ Neuroleptic Malignant Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Encephalopathy.
- ▶ Markedly elevated core temperature.
- ▶ Autonomic dysfunction.
- ▶ “Lead pipe” muscular rigidity with elevated creatine kinase

General Considerations

Neuroleptic malignant syndrome is a life-threatening idiosyncratic reaction to neuroleptic agents. The drugs that produce this syndrome typically include phenothiazines, butyrophenones, and other postsynaptic dopamine blocking agents. Failure to recognize the syndrome may lead to a rapidly fatal course over hours to several days. Even brief exposure to the drug may produce the syndrome.

Clinical Features

A. Symptoms and Signs—The clinical presentation may be variable but frequently consists of encephalopathy, markedly elevated core temperature, and muscular rigidity. Fever and increased muscle activity are the main features. Mental status changes may vary from confusion or agitation to coma. Involuntary movements such as tremor or dyskinesia occasionally accompany muscular rigidity—so-called lead pipe rigidity. When severe rigidity occurs, rhabdomyolysis may result and in turn lead to myoglobinuria and acute renal failure.

B. Laboratory Findings—There is no unequivocal diagnostic test or criterion for neuroleptic malignant syndrome. Creatine kinase elevations may range from several hundred to over 10,000 units per liter.

Differential Diagnosis

Many nonneuroleptic drugs can produce similar disorders. Examples include cocaine, amphetamines, reserpine, metoclopramide, and tricyclic antidepressants in combination with lithium or monoamine oxidase inhibitors. The differential diagnosis also includes many causes of encephalopathy and fever, catatonia, and malignant hyperthermia.

Malignant hyperthermia is a genetically determined hypermetabolic state with onset shortly after the use of certain anesthetics. Although it is similar to neuroleptic malignant syndrome in the markedly elevated temperature and creatine kinase concentrations, it can be distinguished by the lack of encephalopathy or autonomic dysfunction.

Furthermore, the generation of fever is most likely peripheral in malignant hyperthermia and central in neuroleptic malignant syndrome. The genetic trait for malignant hyperthermia does not appear to impose any risks for development of neuroleptic malignant syndrome.

Treatment

A. General Measures—Effective treatment requires early recognition and critical care monitoring of possible multiple-organ failure. Fever must be controlled, and vigorous intravenous hydration is necessary to lower the body temperature and minimize the effects of possible rhabdomyolysis. Blood pressure and urinary output must be monitored carefully. Most important, dopamine-blocking agents must be discontinued.

B. Drug Therapy—Centrally acting bromocriptine, 7.5–100 mg/day, has been used to control the high temperature and rigidity; effects may be seen within hours. Dantrolene, a peripherally acting muscle relaxant, also is highly effective. It can be given intravenously at a dosage of 0.25 mg/kg twice daily and increased as needed to control the rigidity. When the patient is able to take oral medications, 25–600 mg/day may be effective.

▶ Muscular Dystrophies

ESSENTIALS OF DIAGNOSIS

- ▶ Proximal extremity weakness.
- ▶ Pseudohypertrophy of the gastrocnemius muscles.
- ▶ Muscle fiber necrosis and minor regeneration on biopsy.

General Considerations

There are a number of inherited muscular diseases that may have respiratory or cardiac complications that ultimately require management in the ICU. Duchenne’s muscular dystrophy and myotonic dystrophy are the most common diseases of this type.

Muscular dystrophy patients have an increased rate of adverse reactions to many anesthetics and frequently have respiratory complications and prolonged postoperative courses if they undergo general anesthesia. When possible, surgery or general anesthesia should be avoided in these patients. In general, sedatives also are contraindicated because of their adverse effects on weakened muscles.

Clinical Features

A. Symptoms and Signs—Diagnosis of Duchenne’s muscular dystrophy can be made by the family history (X-linked recessive, but one-third can be spontaneous mutations),

clinical examination showing characteristic proximal extremity weakness, and pseudohypertrophy of the gastrocnemius muscles by age 3–4.

B. Laboratory Findings—Muscle biopsies demonstrate progressive muscle fiber necrosis and minor degrees of regeneration. These patients pursue a steady downhill course and develop lumbar lordosis and scoliosis. Laboratory studies will show markedly elevated (10–50 times normal) serum creatine kinase and characteristic abnormalities on electrocardiography, electromyography, and muscle biopsies. New findings from molecular genetic studies show absent dystrophin protein in muscles of patients with Duchenne’s muscular dystrophy, whereas patients with the Becker variant (clinically similar but a later age at onset) have a slightly lower than normal level or an altered protein. Genetic linkage analysis, although inaccurate, usually provides a carrier status or prenatal diagnosis as a “percentage risk” rather than a definite yes or no.

Treatment

A. Respiratory Care—Elective intubation is recommended when vital capacity falls below 15–20 mL/kg. Ventilator settings should be monitored along with arterial blood gases. Baseline blood gases can be obtained after 20 minutes of FIO_2 at 100%, after which inspired oxygen concentration can be decreased to maintain the PaO_2 between 75 and 85 mm Hg. Positive end-expiratory pressure (PEEP) should be set at 3–5 cm H_2O and tidal volume at 6–8 mL/kg. The intermittent mandatory ventilation (IMV) rate should be approximately 12/min with 30–40 L/min inspiratory flow. If the patient requires prolonged intubation—more than 2–3 weeks—a tracheostomy should be performed to maintain a stable airway.

Criteria for weaning a neuromuscular patient from a ventilator include several parameters, the most important of which is the vital capacity, which should be greater than 15 mL/kg. Inspiratory pressure should be greater than –25 cm H_2O and expiratory pressure greater than 40 cm H_2O . PaO_2 should be greater than 80 mm Hg and PaCO_2 less than 42 mm Hg at FIO_2 of .40. Spontaneous respiration should be less than 20/min, and there should be no other adverse medical conditions such as fulminant pneumonia or serious cardiac problems.

All patients presenting with weakness should be followed carefully for respiratory status. Good pulmonary toilet is mandatory. It is helpful to have an accurate diagnosis so that special precautions can be taken to anticipate or prevent the progression of symptoms. A superimposed infection may exacerbate the weakness of many neuromuscular diseases, and temporary life support will enable the patient to return to baseline strength. Therefore, it is imperative to exclude the possibility of a reversible cardiopulmonary complication.

B. Cardiac Care—Between 70% and 90% of patients with Duchenne’s muscular dystrophy will develop electrocardiographic abnormalities consisting of tall right precordial R waves and precordial Q waves. Arrhythmias and persistent

tachycardia are noted frequently in Duchenne’s muscular dystrophy. Patients with myotonic dystrophy also develop cardiac arrhythmias secondary to conduction abnormalities and can present with sudden death if not detected early.

Differential Diagnosis

There are many CNS disorders that can mimic neuromuscular diseases. For example, a brain stem lesion may produce diplopia that may be mistaken for myasthenia gravis or bulbar symptoms that may be mistaken for amyotrophic lateral sclerosis. Neuroleptic malignant syndrome often is difficult to differentiate from other causes of fever and encephalopathy. Blood cultures, drug screens, and brain imaging may be necessary to exclude systemic infections, drug exposures, or disorders producing changes in autonomic control and temperature such as injury to the hypothalamic region.

A careful history (including family history) and physical examination generally will distinguish the major groups of illnesses. However, electrophysiologic studies or laboratory evaluations sometimes are necessary to differentiate the specific types of diseases. Nerve conduction studies with repetitive stimulation will help to differentiate presynaptic from postsynaptic diseases, and serum creatine kinase will help to distinguish a primary myopathy from neurogenic weakness.

▶ Current Controversies and Unresolved Issues

A particularly difficult problem is whether to intubate a patient who has an irreversible advanced neuromuscular disease. If possible, the issue of code status should be discussed with the patient and the family prior to clinical deterioration. Perhaps the patient already has a living will or a family member has power of attorney to help with the decision-making process.

CEREBROVASCULAR DISEASES

ESSENTIALS OF DIAGNOSIS

- ▶ Stepwise impairment usually produced by occlusive disease.
- ▶ Emboli produce sudden deficits.
- ▶ Intracerebral hemorrhage causes rapid onset of symptoms, often with increased intracranial pressure.

General Considerations

Brain stem and cerebral infarctions occur as a result of either progressive occlusive vascular disease, usually hypertensive and atherosclerotic, or embolism. In occlusive disease, infarcts are bland, and in embolic disease, infarcts are hemorrhagic if the embolus fragments and the vascular territory

is reperfused. A hemorrhagic infarct implies embolism. Spontaneous intracerebral hemorrhage occurs as a result of hypertensive vascular disease, but in elderly people it also can be caused by amyloid angiopathy.

Clinical Features

A. Symptoms and Signs—Stroke owing to occlusive vascular disease, or *thrombosis*, tends to have its onset in a stepwise or progressive fashion. It occurs commonly while the patient is sleeping. An *embolic stroke* is sudden in onset and produces maximum neurologic deficit at the outset. *Transient ischemic attacks* can precede either thrombotic or embolic infarction but probably are more frequent in association with thrombotic disease. An intracerebral hemorrhage also is sudden in onset and may cause an acute rise in intracranial pressure owing to mass effect. The location of a stroke is clinically helpful; for example, a small lacunar infarct in the internal capsule is almost certainly due to intracranial, small vessel, or occlusive disease. The first step in localizing the lesion is a careful neurologic examination.

B. Imaging Studies—Brain imaging will confirm the location of the infarct and determine whether hemorrhage has occurred. This information is required before anticoagulation therapy can be started. Typically, a bland infarct will not show on CT scan in the first few hours up to about 24 hours after onset. CT imaging, however, is very sensitive for the detection of fresh bleeding. MRI, especially with diffusion studies, is sensitive for acute infarction. MR angiography can demonstrate occluded or stenotic large- and medium-sized arteries.

Differential Diagnosis

A history of hypertension, diabetes mellitus, or tobacco smoking and a family history of stroke or myocardial infarction are common in occlusive disease. A history of hypertension is common in intracerebral hemorrhage. If an embolic infarction is present, a source should be found; this may be clots arising in the heart or clots from the periphery reaching the brain as a result of right-to-left cardiac shunting, as may occur with a patent foramen ovale. Artery-to-artery embolization, usually from an internal carotid artery, also may be considered. Strokes secondary to cocaine abuse currently are a problem not to be overlooked. Also occasionally encountered are strokes caused by carotid artery or vertebral artery dissection. These are traumatic in origin, and symptomatic onset usually is 24–72 hours following trauma. Often a history of neck extension is obtained. An intimal tear and flap are demonstrated by either endovascular or MR angiography. A brain CT scan is very sensitive for demonstrating intracerebral hemorrhage or hemorrhagic infarction, but an acute bland infarct does not show until density of the infarcted tissue has decreased and edema occurs. MRI is sensitive in all cases. Occlusion of large vessels supplying the brain can be demonstrated with Doppler ultrasound, MR angiography, and CT angiography. Selective

contrast angiography is indicated when the diagnosis is in doubt and a surgically treatable vascular lesion could be present. The workup for an embolic source should include electrocardiography and, if a rhythm disturbance such as atrial fibrillation is not found, echocardiography. An embolic source sometimes can be demonstrated only on the transesophageal echocardiogram.

Rarer causes of stroke include polycythemia, sickle cell disease, collagen-vascular diseases, lupus anticoagulant, and hypercoagulable states. Infrequent causes of stroke also are moyamoya disease, fibromuscular hyperplasia, Takayasu's disease, and tuberculous or other arteritis. Infarction caused by arterial spasm associated with ruptured berry aneurysm and subarachnoid hemorrhage is well known in neurosurgical practice.

Treatment

In general, the management of an acute stroke consists of supportive care and control of blood pressure. In this circumstance, autoregulation of cerebral blood flow is impaired or lost, and regional brain perfusion is passive and essentially dependent on systemic blood pressure. Therefore, hypotension is to be avoided. Edema characteristically develops 24–72 hours following infarction and can lead to complications owing to mass effect; this is especially critical in the posterior fossa, where obstruction of CSF flow and secondary hydrocephalus can result (Figure 30–3). Fluid balance in acute stroke patients therefore should be watched carefully and kept on the “dry side” to minimize the risk of hyponatremia and further brain swelling. Inappropriate antidiuretic hormone secretion sometimes can complicate this problem. When progressive mass effect with secondary hydrocephalus occurs, management is as described in Chapter 29, and will require consultation with a neurosurgeon. Since many stroke patients develop dysphagia or have poor mental status, aspiration precautions should be taken, and a nasogastric tube should be placed. Swallowing evaluations often are necessary before allowing oral intake.

Anticoagulation is clearly indicated in embolic disease but usually must be delayed in the presence of a significant hemorrhagic infarct because of the risk of further bleeding. However, this factor must be weighed against what one judges to be the risk for repeated embolization. Common practice is to delay for about 10–14 days. The efficacy of anticoagulation in occlusive vascular disease is less clear, but it is common practice at this time to anticoagulate patients with strokes in progression or frequently repeated transient ischemic attacks. In the critical care situation, initial anticoagulation for cerebrovascular disease is accomplished with intravenous heparin.

Antiplatelet therapy has been shown to reduce the incidence of future stroke in patients at risk, including those with present or prior stroke, and it can be initiated in the acute phase of a new stroke. The available agents are aspirin or enteric-coated aspirin, 81–325 mg/day; clopidogrel bisulfate,

B

C

D

▲ **Figure 30-3.** *A, B.* Hypodense lesion in the right cerebellar hemisphere with swelling and mass effect resulting in obliteration of the fourth ventricle and cisterns surrounding the brain stem and secondary enlargement of the third ventricle and the temporal and lateral ventricles. Approximately 2½ hours after this CT scan was obtained, the patient became comatose and lost brain stem function owing to progressive obstructive hydrocephalus and brain stem compression. Also, intracranial pressure may exceed cerebral perfusion pressure in this circumstance. Timely neurosurgical intervention can prevent this sequence of events and thus be lifesaving. *C, D.* Normal studies for comparison. 1 and 5, cistern; 3, fourth ventricle; 2 and 6, temporal ventricle; 4, lateral ventricle. Third ventricle unlabeled.

75 mg/day; or aspirin and extended-release dipyridamole, one 25/200-mg capsule twice daily. Ticlopidine, 250 mg twice daily, also is available but is associated with a higher incidence of adverse reactions than the others.

Treatment of acute ischemic stroke with intravenous recombinant tissue plasminogen activator (rt-PA; alteplase) has been shown to be beneficial but only if initiated within 3 hours of stroke onset; thus a clear history of time of onset and prompt transportation to a treatment facility are crucial. The benefit realized is reduction in long-term disability; improvement taking place in the acute phase is not clearly attributable to the treatment. Nevertheless, many specialists in this area believe that within the 3-hour time window, the sooner the better is the rt-PA treatment. The major adverse event of this treatment is intracerebral hemorrhage, but even so, the long-term outcome may be improved if the patient survives. Overall, the most frequently reported hemorrhage rate is in the 3–6% or more range. It is essential that the treating institution establish a system for immediate patient evaluation and have a protocol in place. Table 30–7 lists the inclusion and exclusion criteria adopted by the authors' institution, and Table 30–8 gives the protocol for evaluation and treatment.

Table 30–7. rt-PA (alteplase) criteria.

Inclusion criteria

- Age 18 or older
- Clearly defined time of onset (very important!)
- Ability to initiate rt-PA within 180 minutes from time of onset

Exclusion criteria

- Minor stroke or rapidly improving symptoms
- Hemorrhage or edema on noncontrast head CT
- Suspected subarachnoid hemorrhage
- Stroke or serious head trauma within 3 months prior to current stroke
- Major surgery or trauma within 14 days prior to current stroke
- History of intracranial hemorrhage
- Systolic blood pressure >185 mm Hg or diastolic blood pressure >110 mm Hg
- Gastrointestinal or urinary tract hemorrhage within 21 days prior to current stroke
- Arterial puncture at a noncompressible site within 7 days prior to current stroke
- Acute myocardial infarction or pericarditis
- Patient taking anticoagulants or has received heparin within the 48 hours preceding the onset of stroke and has elevated aPTT
- Platelet count <100,000/ μ L
- PT >15 seconds (INR >1.7) or aPTT >34 seconds
- Glucose <50 mg/dL or >400 mg/dL
- Seizure at onset of stroke
- Known or suspected pregnancy or lactating woman
- Aggressive treatment required to maintain blood pressure below indicated parameters
- Lumbar puncture within 7 days prior to current stroke
- Occult blood in urine or stool

Table 30–8. rt-PA (alteplase) protocol.

1. When notified of a possible rt-PA candidate, call designated medical personnel immediately.
2. Get the time of onset, a medication list, and complete neurologic examination. Patient needs a monitored bed in the emergency room.
3. Obtain stat head CT scan (noncontrast) to rule out hemorrhage; stat labs: CBC, PT/aPTT/glucose; stat ECG.
4. Go through all exclusion criteria (Table 30–7) and put sheet on chart.
5. Dose: Alteplase (Activase) 0.9 mg/kg (maximum 90 mg total dose) IV. Give 10% as bolus over 1 minute, remainder by continuous infusion over 60 minutes.
6. If patient receives rt-PA, needs ICU bed.
7. Order vital signs and neurologic checks (specify what you want checked):
 - Every 15 minutes for 2 hours
 - Every 30 minutes for 6 hours
 - Every 1 hour for 16 hours
8. Strict blood pressure control (185/95 mm Hg or less). Use IV labetalol or nitroprusside drip.
9. Urgent: No anticoagulants and no antiplatelet agents whatsoever for 24 hours after rt-PA given.
10. If there is any worsening on neurologic or mental status examination, *stop rt-PA* if still being infused and order stat head CT (noncontrast) to rule out hemorrhage.

Current Controversies and Unresolved Issues

Carotid endarterectomy generally is recommended to reduce the risk of future stroke when 70–80% or more of stenosis is present in a symptomatic artery (it is contraindicated in an occluded artery). Some data exist indicating that endarterectomy on an asymptomatic, high-grade stenotic carotid artery is beneficial, but this remains controversial.

Work is in progress to better assess outcome of patients treated with intravenous rt-PA and to refine selection criteria for identifying those more or less likely to respond. Also, protocols are in place to define the role of intraarterial r-tPA and a device for clot removal in acute cerebrovascular occlusion.

► Complications of Central Nervous System Infections

ESSENTIALS OF DIAGNOSIS

- **History:** neurologic symptoms, exposures.
- **Examination:** level of consciousness, neck stiffness, focal neurologic findings, seizures.
- **Brain imaging with and without contrast material.**
- **CSF analysis.**

General Considerations

The initial patient examination should lead to an etiologic diagnosis and selection of appropriate therapy. Infectious disease consultation may be necessary in the process. Beyond this, the critical care physician should be alert to certain aspects and complications of CNS infections. Viral, granulomatous, parasitic, and bacterial infections each have special features requiring consideration, and all have some common features.

Clinical Features

A. Viral Infections—Meninges and neurons are the site of most CNS viral infections; human immunodeficiency virus (HIV), which infects microglia and leads to the formation of multinucleated cells in the brain, is a notable exception. *Viral meningitis* usually runs a self-limited course with supportive therapy only, and the specific virus usually is not identified, no more than headache, fever, neck stiffness, and abnormal CSF findings are expected clinical features. On the other hand, *viral encephalitis* reflects neuronal dysfunction. Altered mental status, seizures, and even focal neurologic signs are common. Early recognition is especially important in herpes simplex type I (HSV) encephalitis because early and prompt treatment with acyclovir improves outcome. This virus has a predilection for temporal lobes; thus presenting features commonly are confusion, change of usual behavior patterns, memory disturbance, and complex partial seizures, which may secondarily generalized (see section on seizures). Inflammation, sometimes with a hemorrhagic component, and edema may be enough to affect nearby cortex, giving rise to additional focal features such as hemiparesis, sensory deficit, or language disturbance. If HSV encephalitis is suspected, acyclovir should be started immediately and not postponed awaiting confirmatory workup.

HIV infection of the CNS may result in mental and motor slowing (AIDS dementia complex) by mechanisms not yet understood, but aside from the acute phase of infection, the occurrence of seizures, focal neurologic symptoms, and findings or symptoms and signs of meningitis indicate a superimposed complication such as infection with *Toxoplasma*, *Cryptococcus*, fungus, or mycobacteria or an intracerebral lymphoma.

B. Parasitic Infections—Cysticercosis is the most common parasitic CNS infection encountered in the United States. It is most common in states bordering Mexico and is seen most often in Mexican immigrants. It is a major public health problem in other parts of the world as well. It is acquired by ingestion of eggs of the tapeworm *Taenia*, which are shed in the feces of human carriers. Three forms of the disease exist. The most common site of infection is the parenchyma of the cerebral hemispheres, and the natural course of this form of the disease is eventual death of the organisms and subsequent calcification of the lesion, which

is readily identified as punctate calcifications on CT scans. This process often is entirely asymptomatic, but sometimes the tissue reaction and associated edema caused by the organisms' death produce focal neurologic symptoms and signs, and imaging studies may not clearly distinguish such a lesion from a primary or metastatic neoplasm. In this instance, neurologic consultation is indicated. The characteristic locus of parenchymal cysticercosis is at the gray-white junction, and the usual clinical manifestation is a seizure disorder, which sometimes is limited in time and sometimes chronic. The seizures are partial, often with secondary generalization, which may be so rapid that the partial onset is unrecognizable. Treatment with antiepileptic medication is indicated.

Another form of this disease is intraventricular cysticercosis, in which the organism remains cystic and is located within the ventricular system. It is asymptomatic unless it causes obstructive hydrocephalus with headaches as the initial symptom. This is a very dangerous situation because the cysts often are free to move within a ventricle and thus can cause acute hydrocephalus and relatively sudden and unexpected death of the patient. A high degree of suspicion is necessary and should lead to brain imaging studies, which could include CT brain scan, intraventricular positive-contrast CT brain scan to outline a cyst, and MRI of the brain. Neurosurgical intervention for shunting of CSF or cyst removal is required.

Finally, the organism may reside in the subarachnoid space, where it exists in the racemose form and can cause meningeal inflammation. This is an indolent and chronic form, and racemose membrane formation with cystic loculations usually is slowly progressive. If this occurs around the base of the brain, it also may result in obstructive hydrocephalus and require placement of a CSF shunt. Nonsteroidal anti-inflammatory medication is indicated for relief of headache owing to the meningeal reaction and may decrease the inflammatory response.

Praziquantel or albendazole will kill the organism in the parenchymal form and perhaps the racemose form, but no controlled evidence exists that treatment with these agents changes the natural outcome of the disease. Furthermore, the increased rate of organism death and the subsequent brain tissue reaction have increased patient morbidity and in some instances, particularly when the disease was present in the posterior fossa and around the brain stem, have contributed to death of the patient.

Amebic meningoencephalitis occurs but is rare in the United States. Usually it is acquired from swimming or bathing in infected fresh warm water springs. Fever, headache, and seizures are the presenting signs. Amphotericin B has been recommended for treatment.

Toxoplasmosis—infection with *Toxoplasma gondii*, an obligate intracellular parasite—is one of the most frequent opportunistic infections in patients with AIDS and as a consequence is encountered much more frequently than it used

to be. Symptoms are those of meningoencephalitis and often include headache, confusion, delirium, obtundation, and less often, seizure. Brain imaging studies and CSF examination, including serum *Toxoplasma* IgG antibody titer, are useful in diagnosis, but sometimes a favorable response to treatment with pyrimethamine and sulfadiazine (usually judged by reduction of lesions seen on imaging studies) is necessary for diagnostic confirmation. Brain biopsy will be diagnostic if response to treatment is uncertain or fails.

C. Granulomatous Infections—Among fungi and yeast infections, coccidioidomycosis and cryptococcosis are encountered most frequently. While their infectious agents and mycobacteria may form parenchymal lesions, a chronic progressive meningitis is the rule, and it has a predilection for meninges at the base of the brain. A common complication is the development of hydrocephalus owing to blockage of CSF flow from the foramina of Luschka and Magendie. It is usually a relatively slow and progressive process, occurring in the middle to later stages of these diseases, and it often requires placement of a CSF shunt. Brain CT scan or MRI will show the presence and progression of hydrocephalus. With contrast material, those studies also show the presence of the inflammatory basilar meningitis. Other complications are cranial nerve deficits and infarctions caused by inflammation and constriction from the proliferative meningitis around arteries. Fluconazole and intravenous amphotericin B are the primary drugs for treatment of coccidioidomycosis and cryptococcosis, but sometimes the response is insufficient, and intrathecal administration of amphotericin B is necessary. One must be aware that if the drug is delivered into a lateral ventricle in the presence of hydrocephalus and a shunt, it will not reach the site of infection but rather be diverted away. Under these circumstances, placement of a reservoir for delivery into the foramen magnum or lumbar subarachnoid space may be possible. This will require neurosurgical consultation.

D. Bacterial Infections—CNS infection with *Listeria monocytogenes* is singled out here because it is unusual in that it can cause a rhombencephalitis with prominent brain stem findings, and it also may cause meningitis. Persons with chronic illness are predisposed to this disease. In general, prompt diagnosis and appropriate therapy of bacterial infections can prevent or reduce complications.

When seizures or focal neurologic deficits occur in the course of bacterial meningitis, one should suspect *cortical vein thrombosis*, which can be demonstrated by brain imaging studies. In the case of seizures, an antiepileptic drug such as phenytoin or phenobarbital should be administered and probably will have to be given intravenously (see section on seizures). Acute *sagittal sinus thrombosis* is a life-threatening complication because of brain swelling and bleeding into the parenchyma; neurologic findings can include obtundation and signs of increased intracranial pressure, seizures, and perhaps focal neurologic deficits—typically paresis of the legs because of the functional localization of the area of brain

drained by the sinus. CT scan or MRI will confirm the diagnosis. Administration of an anticoagulant may diminish clotting but may serve to increase bleeding from veins feeding the sinus. Seizures should be treated with an antiepileptic drug. As prompt a resolution as possible of the underlying infection will improve outcome.

Hydrocephalus can be an early or late complication of bacterial meningitis. Impairment of CSF absorption at the arachnoid granulations caused by purulent accumulation, inflammation, and adhesions is a significant factor in this case. CSF shunting may be necessary.

Neurologic features of bacterial *brain abscesses* characteristically are focal neurologic findings and seizures. These abscesses often develop because of cardiac or pulmonary right-to-left shunting or extension of a sinus infection. In addition to antibiotic therapy, neurosurgical drainage and excision may be necessary. The dreaded complication is rupture of an abscess into the ventricles; this results in an acute ventriculitis, which almost always is fatal. Because of postinfectious scarring and gliosis, a chronic seizure disorder can develop.

Lastly, it is notable that a partially treated bacterial meningitis can mimic viral meningitis.

E. Laboratory Findings—The EEG should be normal in viral meningitis, but it is highly likely to be abnormal in viral encephalitis, showing generalized slowing and, sometimes, epileptiform events. Characteristic of herpes encephalitis are periodic seizure discharges, predominant over the affected temporal area; absence of this finding does not rule out herpes encephalitis. Hydrocephalus, especially from disease in the posterior fossa, can show background disorganization and slowing with intermittent runs of high-voltage slow waves. Any focal brain disease may result in focal slow activity in the EEG, and often it is especially prominent in brain abscesses. The presence of epileptiform discharges will confirm the diagnosis of seizures and, if focal, indicate the site of the epileptogenic process.

The CSF examination will show an increased cellular content in all active meningeal infections, although rarely the specimen may be obtained just preceding the cellular response; in this case, another specimen after a day or so should show increased cells. In general, bacterial infections will show polymorphonuclear leukocytes (PMNs) and the other infections predominantly mononuclear cells. Some viral infections, notably herpes simplex, may show a significant proportion of PMNs early in the course of the disease. It is typical in herpes encephalitis for the CSF to contain red blood cells, but their absence does not rule it out. Partially treated bacterial meningitis can show predominantly mononuclear cells. Eosinophils are found occasionally in cases of cysticercosis. The organism can be demonstrated by India ink preparation in cryptococcosis and by wet preparation in amebic infection, but not finding them does not rule out either one. The Gram stain may find bacteria and the acid-fast stain mycobacteria. Low CSF glucose results from infections interfering with its transport into the CSF, and it is

characteristically quite low in bacterial, fungal, and tuberculous meningitis. It is usually little altered in viral meningitis. Since the CSF glucose level is normally close to half the blood glucose level, significantly high or low blood glucose can confuse the issue. CSF glucose concentration lags behind blood glucose 1–2 hours, but a blood glucose measured near the time of obtaining the CSF specimen is usually satisfactory for judging the CSF level. In viral infections, the CSF protein content, like the glucose, is little altered, whereas it is elevated in the other infections. If the protein content is very high, blockage and impairment of CSF flow should be suspected. Culture of CSF can provide a definitive diagnosis in most infections other than viral, in which it is unusual to recover the agent. Anaerobic organisms are common in brain abscesses. Frequently the best management is to initiate appropriate therapy while awaiting the results of culture. Serologic tests of CSF include latex agglutination or other techniques for detection of bacteria-specific antigens (usually available as a panel), measurement of cryptococcal antigen, and assay of coccidioidal antibody titer—the latter two are useful to follow as an index of response to treatment. False-negative immunologic tests frequently are encountered in neurocysticercosis, and a positive test may be found in extraneural cysticercosis, so the practical value of such testing is limited. Serum-specific HSV antibody titers rising over the course of the illness can confirm the diagnosis, but usually in retrospect. Polymerase chain reaction (PCR) testing for CSF herpes simplex antigen has rarely been helpful in the authors' experience. *Toxoplasma* IgM titer is helpful if positive; a negative result does not exclude the disease in AIDS. HIV infection of the CNS can be accurately followed by assaying the CSF viral load.

Neurosurgical Critical Care*

Duncan Q. McBride, MD

Neurosurgical critical care covers a wide array of disorders with varying pathophysiologic features. These conditions also may be associated with unique complications that must be recognized and treated promptly. Physicians involved in the ICU management of neurosurgical patients therefore must be familiar with the clinical features, complications, and treatment of CSN disorders.

This chapter focuses on the management of patients with head injury, aneurysmal subarachnoid hemorrhage, brain tumor, and cervical spinal cord injury. These disorders comprise the majority of neurosurgical ICU admissions.

Following injury, the CNS is vulnerable to a variety of secondary insults that can occur minutes, hours, or days following the primary injury. Systemic conditions such as hypoxia, hypotension, and electrolyte disorders may result in morbidity in severely injured patients. Cerebral complications such as elevated intracranial pressure, seizure, hemorrhage, and ischemia also have the potential to cause neurologic impairment. The main focus of current intensive care is to avoid or quickly reverse conditions that can lead to secondary injury. Therefore, meticulous management of all aspects of critical care is required to prevent increased neurologic damage and improve patient outcome.

▶ Head Injuries

ESSENTIALS OF DIAGNOSIS

- ▶ Signs depend on severity and anatomic location.
- ▶ **Concussion:** transient loss of consciousness, memory loss, headache, autonomic dysfunction.
- ▶ **Herniation:** depressed level of consciousness, anisocoria, abnormal motor findings.

*Chris A. Lycette, MD, Curtis Doberstein, MD, Gerald E. Rodts, Jr., MD, and Duncan Q. McBride, MD, were the authors of this chapter in the second edition.

General Considerations

Injuries to the brain remain the most common cause of trauma-related death and disability. More than 500,000 people suffer some degree of head trauma annually in the United States. In the past, patients with traumatic brain injuries were viewed with pessimism because both surgical and medical therapeutic resources were limited. However, with recent advances, including prompt, intensive management of head-injured patients, the outcome has improved. One of the major reasons for the better results has been improved critical care management, particularly the recognition and prevention of disorders that cause secondary brain injury.

Classification

A. Primary Injuries—By definition, primary traumatic brain injury occurs at the time of impact. This may lead to irreversible damage from cell disruption depending on the mechanism and severity of the inciting event. Head trauma may cause damage to the scalp, skull, and underlying brain. Scalp lacerations can cause significant hemorrhage, but in most cases hemostasis can be achieved easily. Fractures are classified as linear, depressed, compound, or involving the skull base. Linear or simple skull fractures require no specific treatment. Depressed skull fracture occurs when the outer table of the skull is depressed below the inner table and may result in tearing of the dura or laceration of the brain. Operative repair may be required, especially if the depressed fracture involves the posterior wall of the frontal sinus or is associated with intracranial hematoma. Compound depressed fractures are defined as those associated with laceration of the overlying scalp and are treated by surgical wound debridement and fracture elevation, if severe. Basal skull fractures, which may be diagnosed by the clinical findings of periorbital ecchymosis (“raccoon eyes”), ecchymosis of the postauricular area (Battle’s sign), hemotympanum, or cerebrospinal fluid (CSF) leak, may be complicated by meningitis or brain abscess. Patients suffering from skull fractures have an increased risk

of delayed intracranial hematoma and should be observed for 12–24 hours after the initial injury.

Brain injury can occur directly under the injury site (*coup injury*), but because the brain may move relative to the skull and dura, compression of the brain remote from the site of impact also can occur. This explains why brain injury can occur in intracranial regions opposite the point of impact (*contrecoup injury*). Craniocerebral trauma can cause concussion, cerebral contusion, intracranial hemorrhage, or diffuse axonal injury.

1. CONCUSSION—Concussion is an episode of transient loss of consciousness following craniocerebral trauma. There is no evidence of pathologic brain damage. Patients may suffer from variable degrees of memory loss, autonomic dysfunction, headaches, tinnitus, and irritability.

2. CEREBRAL CONTUSIONS—Cerebral contusions are heterogeneous areas of hemorrhage into the brain parenchyma and may produce neurologic deficits depending on their anatomic location. The anterior portions of the frontal and temporal lobes are particularly vulnerable because of the rough contour of the skull in these regions. Contusions are often associated with disruption of the blood-brain barrier and may be complicated by extension of the hemorrhage, edema formation, or seizure. Large contusions can cause a mass effect resulting in elevation of intracranial pressure or brain herniation.

3. INTRACRANIAL HEMATOMAS—Head injury may cause hemorrhage into the epidural, subdural, or subarachnoid spaces. This bleeding, which may require surgical evacuation depending on its size and location, is usually diagnosed prior to admission to the ICU. However, delayed intracranial hematomas or postoperative hematomas are not uncommon following craniocerebral trauma and can develop and progress during ICU observation. Intracranial bleeding may result in mass effect that can cause intracranial pressure elevation (see below) and brain herniation with compression of vital cerebral structures.

a. Epidural hematoma—This lesion is typically associated with skull fracture and laceration of a meningeal vessel, most commonly the posterior branch of the middle meningeal artery. This may occur following low-velocity impact injuries. Because the dura is firmly tethered to the inner table of the skull, the hematoma usually takes on a homogeneous lentiform configuration (Figure 31-1A).

b. Subdural hematoma—Subdural hematoma can be secondary to tearing of the cortical vessels, such as the bridging veins that drain from the cortex to the dura and superior sagittal sinus. It is commonly associated with other injuries such as cerebral contusions and has a worse prognosis than epidural hematoma. Because it is not contained by dural attachments, the hemorrhage often spreads diffusely across the cortical surface resulting in a crescent-shaped image on CT scan (Figure 31-1B).

▲ **Figure 31-1.** **A.** Left temporoparietal epidural hematoma with obliteration of the left lateral ventricle and midline shift. **B.** Right frontoparietal and interhemispheric subdural hematoma with massive right-to-left midline shift.

c. Subarachnoid hemorrhage—Subarachnoid hemorrhage is caused most commonly by craniocerebral trauma. The subarachnoid bleeding itself does not usually cause neurologic damage, but hydrocephalus and cerebral vasospasm, which are delayed complications, can lead to neurologic impairment. Subarachnoid hemorrhage as a result of a ruptured intracranial aneurysm always should be considered as a possible causative factor in trauma and needs to be ruled out with an angiogram if there is reasonable concern.

4. DIFFUSE AXONAL INJURY—Diffuse axonal injury is shearing of brain tissue with disruption of neuronal axon projections in the cerebral white matter resulting from rotational deceleration of the brain. This diffuse injury to axons occurs microscopically and can result in severe neurologic impairment. Evidence of diffuse axonal injury is often not demonstrable on CT scan. However, macroscopic hemorrhagic lesions can be seen in deep brain structures such as the corpus callosum or brain stem in association with diffuse axonal injury.

B. Secondary Injuries—Many studies have observed that cerebral autoregulation is impaired after traumatic brain injury. This causes patients with head injuries to be unusually vulnerable to secondary ischemic insults such as hypotension, intracranial hypertension, and hypoxia. Further ischemic damage often can be prevented with an understanding of the pathophysiology of these secondary insults and an aggressive targeted management protocol. These conditions can be conveniently divided into intracranial and systemic disorders (Table 31–1). Following traumatic brain injury, some cells are directly and irreversibly damaged. However, other cells may be functionally compromised and not mechanically disrupted. These may recover if provided with an optimal environment for survival. Compromised cells are vulnerable to the pathophysiologic challenges imposed by secondary insults. Prevention or rapid recognition and treatment of secondary insults is the primary focus of modern critical care management of head-injured patients.

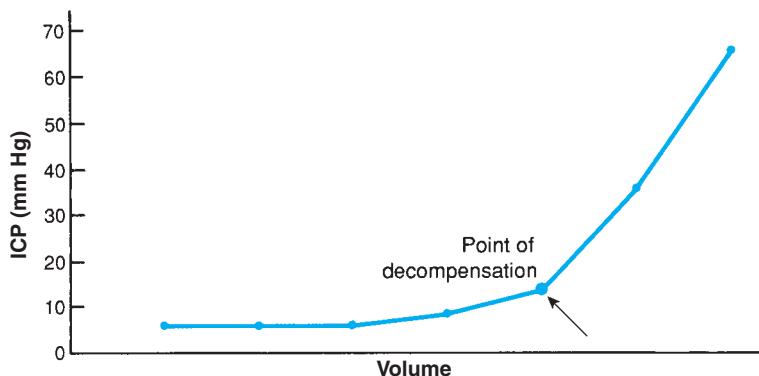

1. SECONDARY INTRACRANIAL INSULTS (RAISED INTRACRANIAL PRESSURE)—Intracranial hypertension following craniocerebral trauma may be caused by intracranial hematomas, cerebral edema, or cerebral hyperemia. The Monro-Kellie doctrine proposes that small increments in intracranial volume ultimately may cause intracranial pressure (ICP) to rise because of the rigid and inelastic properties of the skull. Under normal circumstances, intracranial volume is composed of roughly 80% brain tissue, 10% CSF, and 10% blood. An increase in volume of one of these compartments—or the addition of a new pathologic compartment (eg, intracranial hematoma)—must be compensated for by a reduction in the volume of another compartment to maintain pressure. Compensatory mechanisms that buffer such volume changes include increased CSF absorption, redistribution of CSF from the intracranial cavity into the spinal subarachnoid space, and a reduction in cerebral blood volume. Cerebral compliance relates the change in intracranial volume to the resulting change in ICP (Figure 31–2). High compliance

signifies a system that can use buffering mechanisms to keep ICP stable with changes in intracranial volume. However, when the buffering becomes saturated, large pressure elevations result from small volume changes (poor compliance; arrow in Figure 31–2). Therefore, although ICP may lie within a relatively normal range (up to 20 mm Hg), a low-compliance state may exist, and rapid elevations in ICP may result from small increases in intracranial volume.

The falx cerebri, tentorium cerebelli, and foramen magnum are relatively rigid structures that compartmentalize regions of the brain. Because many pathologic processes are focal, pressure gradients can be generated between the intracranial compartments. Elevated ICP may exert its deleterious effect by causing pressure gradients between different brain compartments. If this pressure gradient is of sufficient magnitude, shifting or herniation of brain tissue occurs and can result in compression of vital structures. For example, transtentorial herniation occurs when increased supratentorial volume and pressure are sufficient to shift the uncus and the medial portion of the temporal lobe through the tentorial notch, causing compression and dysfunction of the midbrain and oculomotor nerve. Compression of the medulla occurs

▲ **Figure 31-2.** Intracranial pressure (ICP) remains normal with increased volume until the point of decompensation is reached. Above this critical volume, ICP increases quickly.

when ICP is elevated and the cerebellar tonsils herniate through the foramen magnum. This condition, known as *tonsillar herniation*, can prove fatal because of the location of vital respiratory and vasomotor centers in this area of the brain stem.

Alternatively, since cerebral perfusion pressure (CPP) is inversely related to ICP,* elevations in pressure may cause impaired cerebral perfusion. If CPP is greatly reduced (<40–50 mm Hg), cerebral ischemia or infarction can occur. Therefore, maintenance of systemic blood pressure is of paramount importance when ICP is elevated.

2. SECONDARY SYSTEMIC INSULTS—Of the various systemic secondary insults, hypoxia and hypotension are the most significant. Prospective clinical studies have demonstrated that these two variables independently have a deleterious

influence on the outcome in severe head injury. Hypotension alone is associated with a 150% increase in mortality rate. In patients with significant head injuries, hypoxemia may be due to upper airway obstruction, pneumothorax, hemothorax, pulmonary edema, or hypoventilation. Whatever the cause, hypoxemia must be corrected rapidly to avoid potential damage to neural tissues. Hypotension reduces cerebral perfusion, which promotes cerebral ischemia and infarction. This is particularly harmful in the face of elevated ICP.

In addition, impaired cerebral autoregulation can occur after brain injury. With normal autoregulation, cerebral blood flow remains constant despite fluctuation in mean arterial pressure between 60 and 180 mm Hg (Figure 31-3). Rapid arteriolar constriction or dilation occurs in response to pressure changes. However, when this normal response is

▲ **Figure 31-3.** Cerebral blood flow (CBF) remains normal over a wide range of cerebral perfusion pressures in normal patients. Under pathologic conditions, CBF varies directly with cerebral perfusion pressure (CPP).

*Cranial perfusion pressure (CPP) = Mean arterial pressure (MAP) – Intracranial pressure (ICP)

impaired, cerebral blood flow becomes directly related to systemic arterial pressure. Thus, if hypotension occurs, reduced tissue perfusion and ischemia may result. Elective surgery for extracranial injuries should be delayed as long as possible because of this issue. Surgery-related hypotensive episodes can have correspondingly negative impact on brain perfusion and ultimately the quality of overall outcome. Other treatable or preventable systemic causes of secondary brain injury include electrolyte disturbances, anemia, hypoglycemia, hyperthermia, coagulopathies, and seizures.

Clinical Features

A. Symptoms and Signs—Clinical examination remains the best method for rapidly identifying neurologic deterioration. The Glasgow Coma Scale, which is based on eye opening as well as verbal and motor responses, is used widely to assess head injury patients (Table 31–2). Other important components of the initial neurologic examination include assessment of brain stem function, including level of consciousness, respiratory pattern, pupillary size and reactivity, as well as oculocephalic, oculovestibular, and gag reflexes. Eye movements, extremity motor and sensory function, and language and speech also should be evaluated. Following this initial brief examination, a more thorough neurologic assessment can be performed.

Transtentorial herniation, usually secondary to an expanding supratentorial mass, produces a classic triad of clinical signs: (1) depressed level of consciousness owing to compression of the midbrain reticular activating system, (2) anisocoria and loss of the pupillary light reflex owing to ipsilateral third nerve compression, and (3) abnormal motor findings from compression of the midbrain. In the early

stages of herniation, the ipsilateral third nerve is compressed; however, if pressure on the brain stem increases, both pupils may become dilated and unreactive. Contralateral hemiparesis owing to direct compression of the ipsilateral cerebral peduncle is the most frequent abnormal motor response. However, in about 25% of patients, hemiparesis may occur on the same side as the mass lesion because the brain stem is displaced away from the mass, compressing the opposite cerebral peduncle against the free edge of the tentorium (Kernohan’s notch phenomenon). The posterior cerebral artery can be occluded during transtentorial herniation and result in infarction of the occipital lobe it supplies.

Signs of *tonsillar herniation* include respiratory irregularities, Cushing’s response (ie, elevated blood pressure associated with bradycardia), nuchal rigidity, and abnormal gag and cough reflexes owing to medullary compression. During early herniation, the patient’s level of consciousness may be normal because the upper brain stem and reticular activating system remain intact.

Neurologic deterioration in the ICU warrants immediate and thorough evaluation in an effort to elucidate the cause. Vital signs, serum electrolytes, O₂ saturation, and arterial blood gas values should be determined if the deterioration is global in nature. However, if the examination suggests a focal lesion, an intracranial hematoma, elevated intracranial pressure with a herniation syndrome, cerebral edema, or cerebral ischemia is probably present. Studies validate that aggressive medical management can reverse herniation and improve outcome.

B. Imaging Studies—

1. CT SCAN—CT scanning is significantly more accurate than conventional radiographs and has replaced them in the evaluation of head injuries. CT scanning can delineate parenchymal hemorrhages and contusions, epidural and subdural hematomas, cerebral edema, hydrocephalus, and cerebral infarction. An intracranial lesion is said to exert a “mass effect” on the brain when there is CT evidence of effacement of the cerebral ventricles, subarachnoid cisterns, or cortical sulci signifying redistribution of CSF. Further CT evidence of a mass effect includes a shift of midline structures away from the lesion and herniation of tissues. The outlet of the contralateral ventricle can become “trapped” as a result of midline shifting, and this can further increase ICP. Because MRI is slower and generally not available emergently, especially in intubated patients, it is not used commonly to assess acute neurologic deteriorations. The availability of portable CT scanners enables the diagnostic study to be performed without transporting an unstable patient and risking harmful respiratory or cardiovascular events.

2. CEREBRAL ANGIOGRAPHY—Prior to the advent of CT scanning, angiography was the primary diagnostic study for evaluating head-injured patients because it detects the mass effect from intracranial lesions. Currently, however, the main role for angiography is the assessment of vascular disorders

such as dissection or traumatic pseudoaneurysm of the internal carotid or vertebral arteries and cerebral vasospasm. Both MRI- and CT-based noncatheter angiography have supplanted invasive techniques for most emergency indications.

3. TRANSCRANIAL DOPPLER ULTRASONOGRAPHY—Transcranial Doppler ultrasonography is a noninvasive technique that measures blood flow velocity in the basal cerebral arteries. It can be performed serially at the bedside in the ICU and can reliably detect arterial narrowing owing to vasospasm, which causes increased flow velocity. It also can aid in the confirmation of absent blood flow owing to brain death.

C. Monitoring of Intracranial Pressure—Measurement of ICP through an open catheter placed in the lateral ventricle (ventriculostomy) is the standard with which all other methods of ICP measurement must be compared. Additionally, CSF may be drained via the ventriculostomy to treat elevated pressures, if present. Ventricular catheters may be placed in the operating room during surgery or can be inserted at the bedside in the emergency room or ICU. Because of the risk of infection, patients with ventriculostomies should be given prophylactic antibiotics with gram-positive coverage such as cefazolin or vancomycin, and the catheters must be changed periodically. Measurement of ICP also can be done using a fiberoptic or strain-gauge device. These monitors are usually more expensive, have a tendency to drift, and are unable to drain CSF.

D. Lumbar Puncture—Lumbar puncture should not be performed in the initial evaluation of head trauma patients because of the risk of tonsillar herniation. The only role for lumbar puncture is to examine CSF in patients who may have meningitis. In such cases, ICP must be thought to lie within the normal range prior to the procedure, or patients should receive mannitol to induce diuresis prior to a small-volume tap with a thin (eg, 22-gauge) spinal needle.

Treatment

A. Surgery—Patients who show neurologic deterioration require rapid intervention to prevent irreversible tissue damage. Cerebral contusions, intracranial hematomas, and foreign bodies may require emergent evacuation depending on their size and location.

B. Reduction of Intracranial Pressure—Raised ICP should be treated using the following measures:

1. Removal of CSF by ventricular drainage.
2. The use of mannitol prior to ICP monitoring should be reserved for signs of transtentorial herniation or progressive neurologic deterioration not attributable to systemic extracranial explanations. Serum osmolality should be maintained below 320 mOsm/L to avoid renal failure, and volume should be replaced with colloid agents or blood if necessary to avoid hypotension or reduced cerebral perfusion. A Foley catheter is essential.

3. Hyperventilation results in cerebral vasoconstriction and can help to reduce ICP for brief and specific periods. The vasoconstrictive effects assist in the management of an intracranial hypertensive crisis; however, the long-term influence can produce permanent injury by reducing blood flow below critical levels in an already injured brain. Therefore, in the absence of high ICP, chronic hyperventilation ($\text{PaCO}_2 < 25$ mm Hg) should be avoided in the first 24 hours after traumatic brain injury. In addition, the use of prophylactic hyperventilation ($\text{PaCO}_2 < 35$ mm Hg) during the first 24 hours should be limited because it can compromise cerebral perfusion during a time of reduced cerebral blood flow (CBF).
4. Head elevation should be maintained to promote cerebral venous drainage. The head should be kept straight, and tape from the endotracheal tube should not cross the jugular area.
5. Sedation and neuromuscular paralysis are recommended in intubated patients. Noxious stimuli may increase ICP, which can be alleviated by sedation. Narcotics are useful because they can be reversed rapidly. Neuromuscular paralysis can reduce ICP in intubated patients by preventing increases in venous pressure associated with the Valsalva maneuver during ventilatory support. Benzodiazepines and propofol can be used as first-line agents for the sedation of head-injured patients.
6. Anticonvulsant therapy (eg, IV keppra or phenytoin) can be used to prevent or control seizure activity that increases cerebral blood flow and subsequently ICP. Available evidence does not indicate that the prevention of early posttraumatic seizures improves outcome following head injury, so these agents should be used with discretion. Bedside electroencephalography should be obtained in patients with suspicious movements, postures, or eye movements and in those with unexplained depression of consciousness. One week of prophylactic anticonvulsant medication generally is sufficient in a patient without evidence of seizure activity.
7. Fever increases ICP and should be prevented when possible. Chilled intravenous fluids or cooling blankets are helpful for the management of refractory temperature elevations.
8. Barbiturate (eg, pentobarbital) coma is useful if all other medical therapies fail because it reduces ICP by decreasing cerebral metabolism and therefore cerebral blood flow. Care must be taken to prevent hypotension.
9. In selected patients in whom maximum medical therapy has failed to reduce ICP, bony decompression or temporal lobectomy can be performed surgically. Hemicraniectomy with duraplasty can be performed in severe, refractory cases.

C. Electrolytes—Cerebral salt wasting is a recognized phenomenon following brain injury and is caused by release of cerebral natriuretic factors. It is defined as renal loss of

sodium during intracranial disease leading to hyponatremia and a decrease in extracellular fluid volume. Hyponatremia produces increased brain swelling, and the volume depletion that accompanies cerebral salt wasting must be treated aggressively to avoid hypotension and reduced cerebral perfusion. Therefore, cerebral salt wasting should be recognized promptly and treated with hypertonic saline solutions.

Traumatic brain injury also can result in a number of other electrolyte disturbances requiring treatment, including hypomagnesemia, hypophosphotemia, and hypokalemia.

▶ Aneurysmal Subarachnoid Hemorrhage

ESSENTIALS OF DIAGNOSIS

- ▶ Headache.
- ▶ Nausea and vomiting.
- ▶ Photophobia.
- ▶ Nuchal rigidity.
- ▶ Depressed level of consciousness.
- ▶ Cranial nerve palsies, motor abnormalities.

General Considerations

Rupture of an intracranial aneurysm is a devastating event because roughly half of these patients die. Of the remainder, almost half are left with significant neurologic deficits as a result of their initial hemorrhage or owing to delayed complications such as rebleeding, vasospasm, or hydrocephalus. In order to optimize outcome following subarachnoid hemorrhage, successful surgical or radiologic intervention and meticulous ICU care are required.

Intracranial aneurysms typically occur at bifurcation sites of major arteries at the base of the brain and usually point in the direction of blood flow. It is believed that a defect in the medial elastic lamina is present that predisposes to aneurysm formation. Aneurysms are associated with a variety of conditions, including hypertension, polycystic kidney disease, coarctation of the aorta, Ehlers-Danlos syndrome, pseudoxanthoma elasticum, and cerebral arteriovenous malformations. Approximately 85% are located in the anterior circulation, with the most common sites being the junction of the anterior cerebral and anterior communicating arteries, the junction of the internal carotid and posterior communicating arteries, the bifurcation or trifurcation of the middle cerebral artery, and the bifurcation of the internal carotid artery. Fifteen percent of aneurysms lie within the posterior circulation; the basilar artery apex is the most common site. Multiple aneurysms can be identified in 15–20% of patients. Since the cerebral arteries course within the subarachnoid space, rupture typically produces subarachnoid hemorrhage. However, intraparenchymal and intraventricular bleeding may occur depending on the location of the aneurysm and the extent of bleeding.

The three major complications following aneurysmal subarachnoid hemorrhage are rebleeding, vasospasm, and hydrocephalus. Rebleeding from a ruptured intracranial aneurysm occurs in 20% of patients during the first 2 weeks after the initial hemorrhage if the aneurysm is untreated. The highest risk is in the first 24 hours, and occlusive treatment with surgery or interventional embolization is required. Cerebral vasospasm is a common delayed complication of subarachnoid hemorrhage and is related to the amount of blood located within the subarachnoid space. Vasospasm typically occurs between 3 and 14 days postbleed. Arterial narrowing is thought to result from degradation of subarachnoid blood, which produces breakdown products that cause smooth muscle constriction. If this smooth muscle constriction is prolonged, morphologic alterations such as fibrosis can occur in the vessel wall, further enhancing arterial narrowing. Communicating hydrocephalus is another complication that can occur after subarachnoid hemorrhage and is secondary to blockage of CSF reabsorption by platelets, erythrocytes, and their breakdown products. Hydrocephalus may present in an acute, subacute, or delayed fashion.

In addition to the previously described neurologic complications, several systemic medical disorders can occur following subarachnoid hemorrhage. Cardiac arrhythmias and myocardial ischemia are observed often. Respiratory complications such as pulmonary edema, acute respiratory distress syndrome (ARDS), and pneumonia are common. Other disorders such as anemia, GI bleeding, deep vein thrombosis, and hyponatremia occur with varying frequency.

Clinical Features

A. Symptoms and Signs—Subarachnoid hemorrhage is described most often as the sudden onset of the worst headache of the patient's life. Other symptoms such as nausea

Table 31-3. Hunt and Hess grades for the assessment of patients with subarachnoid hemorrhage.

Grade 1	Asymptomatic, or minimal headache and slight nuchal rigidity.
Grade 2	Moderate to severe headache, nuchal rigidity, no neurologic deficit other than a cranial nerve palsy.
Grade 3	Drowsiness, confusion, or mild focal deficit.
Grade 4	Stupor, moderate to severe hemiparesis, early decerebrate rigidity, and vegetative disturbances.
Grade 5	Deep coma, decerebrate rigidity, moribund rigidity.

and vomiting, photophobia, nuchal rigidity, depressed level of consciousness (eg, somnolence, obtundation, or coma), cranial nerve palsies, and motor abnormalities can occur. The severity of symptoms is related to the site and extent of the bleeding. Following aneurysmal subarachnoid hemorrhage, the patient is categorized by grade using the Hunt and Hess classification system (Table 31-3). This system has been widely accepted and is the equivalent of the Glasgow Coma Score in trauma patients.

B. Imaging Studies—

1. CT SCANNING—Ninety percent of patients with subarachnoid hemorrhage have evidence of subarachnoid blood on initial CT scans obtained within the first 48 hours after rupture. Scanning also detects intraparenchymal and intraventricular bleeding. The extent and location of subarachnoid hemorrhage can help to determine the location of the aneurysm and identify patients at highest risk for developing cerebral vasospasm. Rebleeding, hydrocephalus, and cerebral infarction also can be verified using this technique.

2. ANGIOGRAPHY—Once the diagnosis of subarachnoid hemorrhage has been established, a form of cerebral angiography should be performed unless a surgical lesion such as a significant intraparenchymal hematoma is present and requires emergent lifesaving evacuation. Angiography is required prior to aneurysm surgery to localize the aneurysm, define its anatomy, and identify areas of cerebral vasospasm that may require postponement of surgery. All cerebral vessels should be imaged because of the occurrence of multiple aneurysms in 15–20% of patients.

3. TRANSCRANIAL DOPPLER ULTRASONOGRAPHY—Transcranial Doppler ultrasonography has become a useful technique for monitoring patients at risk for developing vasospasm. With progressive arterial narrowing, blood flow velocity increases through the constricted segment and can be detected by this procedure. Since this technique is noninvasive and portable, it can be performed at the bedside in the ICU. It can detect arterial narrowing prior to the development of ischemic

symptoms so that therapy aimed at improving cerebral blood flow can be instituted.

C. Lumbar Puncture—In patients in whom no subarachnoid hemorrhage is present on CT and the history is suggestive of rupture of an intracranial aneurysm, lumbar puncture should be performed. Bloody or xanthochromic fluid is the most sensitive indicator of subarachnoid hemorrhage. CSF cultures must be sent to rule out meningitis. However, lumbar puncture never should be performed prior to CT scanning because patients with elevated ICP are at risk for herniation following removal of fluid from the spinal subarachnoid space.

D. Laboratory Findings—Coagulation parameters, including a platelet count, bleeding time, and prothrombin and partial thromboplastin times, should be obtained. If abnormal clotting parameters are present, they should be corrected rapidly because of the increased risk of rebleeding.

E. Electrocardiography—The ECG is abnormal in many cases of subarachnoid hemorrhage and may identify cardiac arrhythmias or ischemia that may require treatment.

Treatment

A. Surgery or Embolization—Most centers advocate early intervention (within 24 hours of rupture) with either surgery or embolization. Early treatment of the aneurysm has the advantage of preventing rebleeding and allowing aggressive therapy for vasospasm should it develop. Because of the risk of exacerbating ischemia by brain retraction, surgery may be delayed in patients who are medically unstable or who have severe vasospasm.

B. Preoperative ICU Therapy—Prior to surgery, treatment is aimed at reducing the risk of rebleeding and preventing ischemic complications related to vasospasm. Patients should remain at bed rest in a quiet setting. Mild analgesics (not aspirin because of its antiplatelet properties) are used if headache or neck pain is severe. Stool softeners are useful to prevent straining, which can increase ICP and promote rerupture.

C. Blood Pressure Control—Systolic blood pressure should be maintained below 150 mm Hg; however, hypotension must be avoided so that cerebral perfusion pressure is not reduced to ischemic levels. Intravenous administration of sodium nitroprusside has the advantage of being rapidly reversible. Mild intravascular fluid augmentation using intravenous colloid infusion (5% albumin, 250 mL every 6–8 hours) helps to maintain adequate cerebral perfusion.

D. Reduction of Ischemic Deficits Owing to Vasospasm—Vasospasm is the most frequent cause of morbidity and mortality in patients admitted after subarachnoid hemorrhage and occurs in 22–44% of patients. Arterial narrowing may lead to diminished perfusion and cause infarction. Vasospasm is induced by products of erythrocyte breakdown, and the risk of developing this complication is related

to the quantity of blood in the subarachnoid space. There is a peak incidence 4–12 days after subarachnoid hemorrhage, and vasospasm then resolves gradually. Prophylactic therapy using calcium channel blockers and mild volume expansion are only partially effective. Once vasospasm has been diagnosed by transcranial Doppler ultrasonography or angiography, more intense therapy is warranted. If ischemic neurologic symptoms are evident, aggressive treatment should be instituted immediately.

Induced hypervolemia, hemodilution, and hypertension (triple-H therapy) may augment cerebral blood flow and prevent ischemic cellular damage. Because cerebral autoregulation can be impaired after subarachnoid hemorrhage, hypertension and hypervolemia may increase cerebral blood flow directly. Decreased blood viscosity by induced hemodilution can improve cerebral blood flow in regions of hypoperfusion. The optimal hematocrit is between 31% and 33%. Oxygen-carrying capacity of the blood is not significantly reduced in this range. Since aggressive therapy is often required, placement of an indwelling pulmonary artery catheter is recommended to monitor hemodynamics. Therapy should be titrated to ameliorate ischemic symptoms. In addition, cerebral blood flow measurements may aid in documenting adequate perfusion following treatment. A poor outcome may occur despite triple-H therapy in most patients with a low Glasgow Coma Score and evidence of hydrocephalus at the onset of vasospasm.

Oral administration of the calcium channel antagonist nimodipine (60 mg orally every 4 hours for 21 days) has been shown to reduce ischemic neurologic deficits attributable to vasospasm following aneurysmal subarachnoid hemorrhage.

E. Prevention of Seizures—Patients who have sustained aneurysmal subarachnoid hemorrhage are at risk for seizures and should receive anticonvulsants (eg, phenytoin, 18 mg/kg intravenously initially, followed by 300–400 mg daily) because of the risk of seizure-induced arterial hypertension, ICP alterations, and local increased cerebral blood flow requirements.

F. Respiratory Management—Intubation and mechanical ventilation are required in comatose patients and those with respiratory compromise. Mild hyperventilation can be useful to control elevations of ICP.

G. Correction of Electrolyte Disturbances—Hyponatremia is common following subarachnoid hemorrhage and can lead to harmful cellular volume changes in the CNS. (Please refer to the preceding discussion of cerebral salt wasting.) Correction of hyponatremia should be accomplished carefully so that abrupt sodium changes do not occur. Administration of hypertonic saline (3%) is often necessary to improve the sodium level and volume depletion.

H. Intracranial Pressure Monitoring—Placement of a ventricular catheter is necessary to monitor ICP in comatose patients and to treat hydrocephalus if present. This also helps

clear erythrocyte breakdown products, which are associated with the development of hydrocephalus. Care should be taken to avoid rapid overdrainage of CSF because abrupt reduction in ICP may induce aneurysm rebleeding. Many patients eventually will require a permanent ventriculoperitoneal shunt.

I. Antifibrinolytic Therapy—Agents such as aminocaproic acid that inhibit dissolution of the fibrin clot have been shown to reduce the incidence of rebleeding. However, this positive effect is offset by an increased risk of permanent ischemic sequelae and systemic venous thrombosis. Treatment with antifibrinolytic agents does not improve clinical outcome following aneurysmal hemorrhage and should not be used.

J. Angioplasty—Even though treatment using hypervolemic hemodilution and induced arterial hypertension is effective, a significant number of patients do not respond to these techniques. Balloon dilation angioplasty can mechanically increase vessel diameter and has been shown to improve cerebral blood flow and relieve symptoms dramatically. Cerebral angioplasty is a new technique and is indicated, where available, in subjects who do not respond to medical therapy. Intraoperative vasodilating agents such as papaverine also can be infused during catheter angiography.

▶ Tumors of the Central Nervous System

ESSENTIALS OF DIAGNOSIS

- ▶ Generalized signs of mass effect.
- ▶ Aphasia.
- ▶ Memory disturbance.
- ▶ Hemiparesis.
- ▶ Sensory impairment.
- ▶ Seizure may be the presenting sign.

General Considerations

The critical care of patients harboring brain tumors requires an understanding of intracranial mass effect, cerebral edema and the blood-brain barrier, progression of neurologic symptoms, seizures, and serum electrolyte abnormalities. Careful serial neurologic examination and physiologic monitoring can result in optimal care for the patient with a brain tumor.

The signs of either a primary or metastatic brain tumor are the result of the tumor's location, mass effect, and rate of growth and of metabolic disturbances. The Monro-Kellie doctrine describes the relationship between intracranial volume (composed of brain, CSF, and blood) and ICP. The brain can accommodate enlarging mass lesions until a critical volume is reached. The actual volume tolerated is increased if growth is gradual. At this point, the ICP increases dramatically (Figure 31–2). Normally, the endothelial tight junctions of cerebral vessels (blood-brain barrier) prevent the leakage of large solutes and water into the brain. Vessels in cerebral tumors tend to have less constant tight junctions and may lack certain enzymes that degrade vasoactive substances in the brain such as leukotrienes. Reactive edema fluid thus accumulates in the extracellular space adjacent to the tumor. Edema can cause neurologic deterioration by increasing ICP and causing a midline shift of brain structures. Hyponatremia can occur in patients with CNS neoplasms and may cause cytotoxic edema and seizures. This can occur secondary to cerebral salt wasting, as described earlier. Conversely, hypernatremia can result from hypothalamic dysfunction and lack of antidiuretic hormone response and is referred to as *diabetes insipidus*. These patients lose excessive amounts of free water. Any serum sodium abnormality can result in altered mental status and eventually coma and neuronal cell death.

Clinical Features

A. Symptoms and Signs—In contrast to the generalized symptoms of mass effect, edema, and sodium imbalance, which include headache, nausea and vomiting, and mental status changes, the precise location of a tumor can cause specific neurologic deficits. These deficits include aphasia, memory or personality disturbances, hemiparesis, and visual or sensory impairment. In many patients, no neurologic deficit is present on initial presentation, and a seizure is the first indication of a CNS neoplasm. In the awake patient, the history should be taken carefully to determine the exact initial symptoms and the rate at which the problems have advanced. This information can indicate the approximate location in the nervous system and serves as a clue to the rate of tumor growth. Neurologic examination in the ICU should include ophthalmoscopy for papilledema, detailed mental status and language assessment, cranial nerve tests, motor, sensory, and reflex tests, and testing of cerebellar function.

B. Imaging Studies—A chest x-ray should be performed to evaluate whether a metastatic source of CNS disease is likely.

The study of choice for a suspected CNS mass lesion is CT scan or MRI. The latter technique gives finer detail and subtracts the image of cortical bone. It is particularly helpful in evaluating the posterior fossa and skull base. SPECT-thallium scans are useful in differentiating high-grade versus low-grade gliomas.

C. Electroencephalography—Electroencephalography can localize dysfunctional cortex and epileptogenic foci related to neoplastic growths.

Differential Diagnosis

Several disease processes should be considered when evaluating a patient who presents with confusion, headache, dysphasia, motor or sensory deficits, seizures, hyponatremia, or any combination of these findings. Stroke usually presents with a sudden onset of fixed neurologic signs and differs from the progressive course of a CNS neoplasm. The gradual progression of a neurodegenerative disease can result in symptoms similar to those caused by a mass lesion, but preliminary CT scanning or MRI can rule out this lesion. Infections such as meningitis, encephalitis, and especially cerebral abscess can result in global or focal neurologic dysfunction and seizures but frequently are accompanied by fever, leukocytosis, and (in the case of cerebral abscess) characteristic findings on CT scan or MRI. An important distinction to be made is whether the mass represents a primary or metastatic lesion. In the latter, a general physical examination with radiologic studies and metastatic evaluation is required.

Treatment

A. Immediate ICU Intervention—Treatment of the patient with altered mental status and findings of papilledema should begin with protection of the airway and elevation of the head. The neck should not be flexed nor the head turned so that optimal venous drainage of the brain via the jugular veins can be ensured. Hyperventilation, systemic arterial hypertension, and bradycardia are signs of Cushing's response (to raised ICP) and identify a patient in great danger. Mannitol, 1 g/kg, should be infused rapidly via an intravenous catheter. This can be followed by 0.25–0.5 g/kg every 4 hours accompanied by frequent testing of serum osmolarity. If seizure activity has been observed or is suspected, a loading dose of phenytoin (18 mg/kg) should be infused intravenously at a rate not to exceed 50 mg/min. A daily dose of 300–400 mg can be started the next day. An immediate CT scan or MRI scan should be obtained. If a tumor is diagnosed and significant mass effect is present, placement of a ventricular catheter can be considered in patients at risk of critical elevation in ICP. Ventricular catheters allow continuous ICP monitoring and drainage of CSF. If a neurologic deficit or significant cerebral edema is present, dexamethasone should be administered. The initial dose can be as high as 20–24 mg intravenously, followed by 10 mg every 6 hours. This steroid can stabilize endothelial

cell membranes and reduce the accumulation of cerebral edema. For the severely ill or deteriorating patient, endotracheal intubation should be performed with hyperventilation to achieve a PaCO₂ of 30–35 mm Hg. Lowering the PaCO₂ constricts cerebral arterioles and reduces the volume of blood in the brain, thereby alleviating one component of intracranial volume and increased ICP.

B. Nonoperative Therapy—For patients in poor medical condition, with multiple metastatic lesions, or with a solitary tumor in an inaccessible location, stereotactic or CT-guided biopsy followed by radiation or chemotherapy (or both) should be instituted. Patients should be weaned from ventilator support and ventricular drainage whenever possible. This may be difficult in a deteriorating patient because of ethical and family considerations.

C. Surgery—The goals of surgery are to obtain a tissue diagnosis and decrease the mass effect by safely removing as much of the lesion as possible. Craniotomy (removal of a replaceable bone flap) or craniectomy (removal of sections of the base of the skull that are not replaced) with microscope-assisted removal of the tumor can be accomplished with very satisfactory morbidity and mortality results. Bipolar coagulation forceps, suction and irrigation, ultrasonic aspirators, and (less frequently) lasers can be used to precisely remove tumor while limiting damage to surrounding brain. For tumors in the sellar region, a transnasal, transsphenoidal approach is most useful. The risks of operation include increased neurologic deficit, bleeding, deep vein thrombosis, pulmonary embolism, and death. Mortality rates in most large centers for patients undergoing removal of intracranial tumors are under 5%.

Current Controversies and Unresolved Issues

Several aspects of the care of critically ill patients harboring brain tumors remain controversial. It is still unclear what the roles of surgery and radiation are in the patient with a low-grade primary brain tumor. The risk of slow progression of tumor growth over many years may not outweigh the ill effects of operation or postirradiation angiopathy and neuronal death (ie, radiation necrosis). Another debatable aspect of care is the role of chemotherapy for high-grade primary tumors. Prolongation of survival of 3–6 months with chemotherapy (beyond the 6–12-month survival of surgery and radiation alone) may not outweigh the short-term morbidity associated with intravenous antineoplastic therapy.

Deep vein thrombosis and pulmonary embolism represent a considerable risk to the patient with a brain tumor who is less mobile or bedridden, yet the role of perioperative anticoagulation remains an unresolved issue. The duration of prophylactic anticonvulsant therapy following craniotomy remains debatable. The range in practice is between 1 month and 12 months.

Future issues that are likely to make a major impact on the therapy for critically ill patients with brain tumors include advances in stereotactic radiation, manipulation of the

blood-brain barrier for selective delivery of antineoplastic agents to the tumor, and molecular engineering to selectively transfect tumor cells with gene fragments capable of inducing differentiation and stopping cellular proliferation. At the present time, however, surgical reduction of the total malignant cell mass and radiation remain standard therapy for malignant brain tumors. Frameless image-guided neurosurgery has improved intraoperative visualization of these tumors and provides hope for improved outcomes in the future.

▶ Cervical Spinal Cord Injuries

ESSENTIALS OF DIAGNOSIS

- ▶ Neck pain.
- ▶ Motor or sensory deficits.
- ▶ Hypoventilation.
- ▶ Neurogenic shock.
- ▶ Priapism.

General Considerations

Approximately 10,000 new cervical and thoracic spinal cord injuries occur each year in the United States. Most result from motor vehicle accidents, falls, gunshot wounds, and sporting accidents. Improved acute management has permitted many patients to survive the initial injury and to have a near-normal life expectancy. Adolescents and young adults suffer the highest incidence of spinal cord injuries, with the majority occurring in young males. Although the loss of motor and sensory function imposes a catastrophic physical and emotional handicap, many spinal cord injury patients are able to return to a nondependent functional state.

Most spinal cord injuries occur in the mobile cervical region. The cervical cord contains lower motor neurons as well as long tracts conveying motor and sensory fibers that, if damaged, can result in variable neurologic dysfunction. In addition, the cervical cord also conducts vital respiratory and sympathetic functions that can be damaged following trauma, leading to devastating respiratory or circulatory collapse. Secondary events such as hypotension, hypoxia, and reinjury of the cord can cause further neurologic deterioration.

Because of these unique features, all patients with cervical cord injuries should be admitted to an ICU staffed by personnel experienced with the complex care of spinal cord injuries.

Pathophysiology

There are a number of anatomic, chemical, and vascular changes that occur in response to blunt injury of the spinal cord. From immediately following and up to 3–5 hours after injury, there is focal swelling of the cord owing to disruption of blood vessels and their endothelial tight junctions. This leads to localized bleeding and leakage of albumin, neurotransmitters, extracellular calcium, lactate, and prostaglandins. There is a decrease in local blood flow beginning in the central regions of the cord and spreading to the surrounding white matter (centripetal decrease in blood flow). This leads to worsening edema over the first 2–3 days and central cavitory necrosis over the ensuing week. The level of injury may rise as much as two vertebral levels in response to these secondary events. Diminished swelling followed by cord atrophy becomes evident after the first week after injury. Experimental and clinical treatment strategies are aimed at blocking this cascade of secondary events following spinal cord contusion. Calcium channel blockers, diuretics, corticosteroids, and other free-radical scavengers may be helpful, although their true efficacy is debated.

Clinical Features

A. History—The key to the initial diagnosis of cervical spine injury is maintaining a high level of suspicion for an underlying bony or ligamentous injury. This is especially true in patients involved in motor vehicle accidents or significant falls, particularly if they have other associated injuries such as head trauma or extremity fractures.

Many trauma patients are conscious and may complain of neck pain, numbness, or weakness suggestive of spinal cord injury. In trauma patients with altered mental status, it is best to assume that an unstable cervical spine injury is present until proved otherwise by radiography.

B. Symptoms and Signs—Several complications of cervical cord injury may require immediate attention and therefore must be diagnosed promptly. Hypoventilation and respiratory compromise secondary to injury of cord segments supplying the phrenic nerve (C3–5) usually can be diagnosed easily and require immediate assisted ventilation. Although respiratory dysfunction may not be apparent immediately after a high cervical injury, respiratory status may deteriorate during the first few days in the ICU. This can be secondary to primary muscle fatigue or “ascending” cord involvement from edema or ischemia. Neurogenic shock may be encountered following cervical cord injury. This results from interruption of sympathetic fibers that are descending to the T1–L2 spinal cord segments and can lead to hypotension, bradycardia, and hypothermia. Priapism also may occur in

males owing to unopposed parasympathetic impulses. Although neurogenic shock patients do not appear to be hypovolemic (eg, the skin is warm and the pulse is slow), their hypotension responds to rapid administration of intravascular colloid and crystalloid solutions, and use of vasopressors such as dopamine or dobutamine is often indicated to maintain arterial pressure and perfusion. Central venous pressure and cardiac monitoring may be required along with the frequent assessment of temperature.

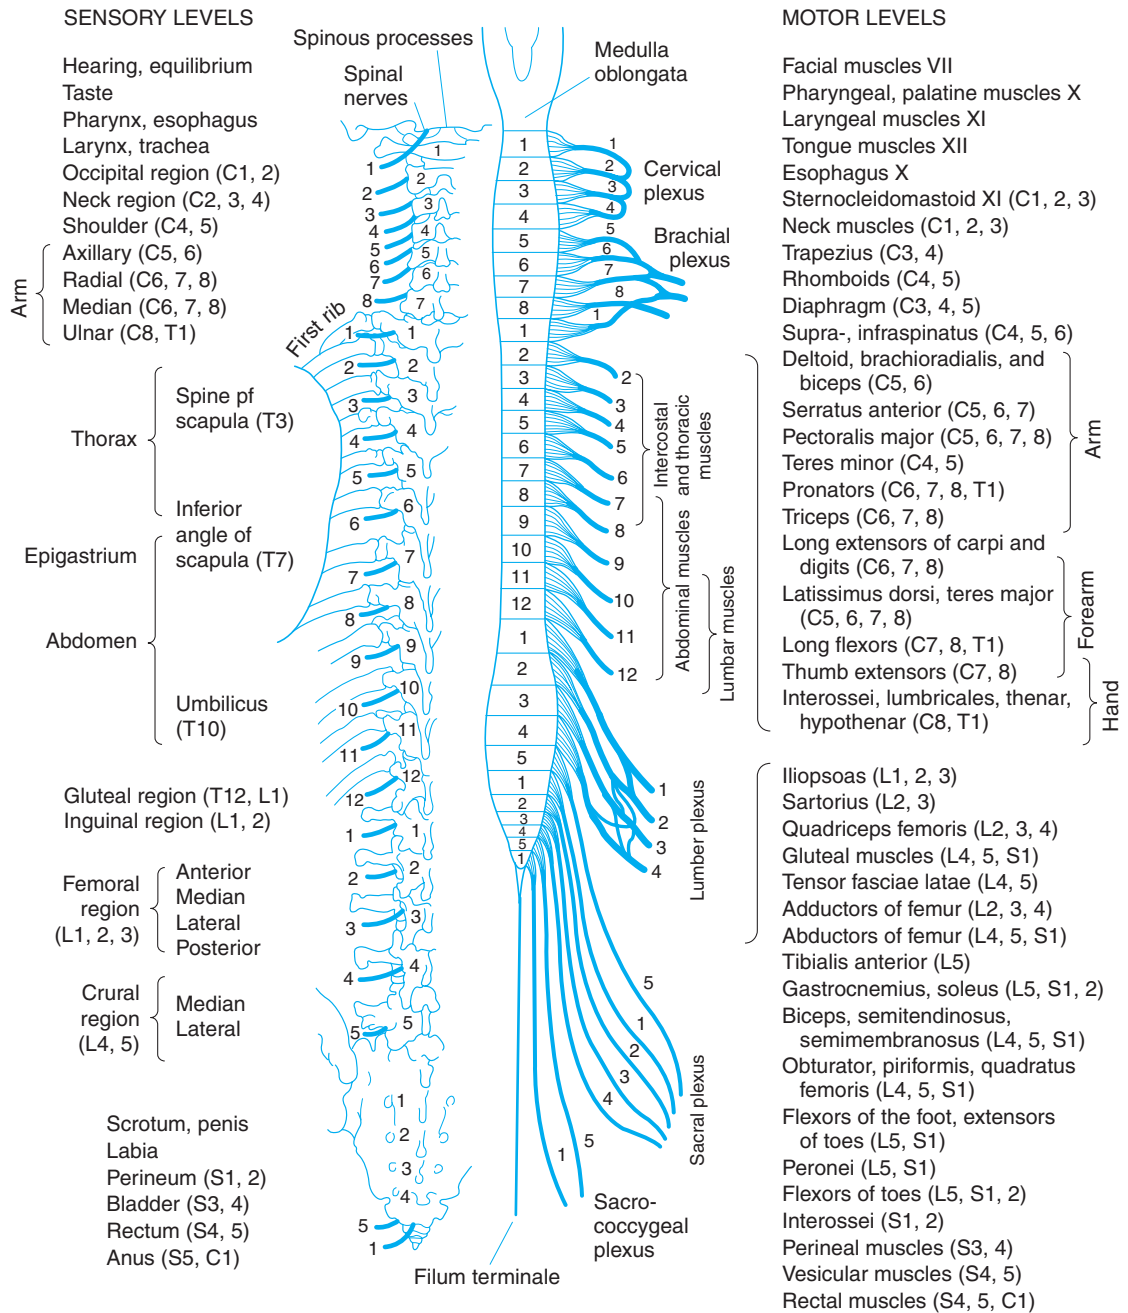

After initial resuscitation, meticulous neurologic assessment should be performed to determine the level and severity of spinal cord damage. Evaluation should include assessment of motor strength; sensory testing; assessment of reflexes, including abdominal cutaneous, cremasteric, and bulbocavernosus reflexes; rectal and perirectal examination; and palpation of the entire spine while the patient is carefully log-rolled to maintain spinal alignment.

A complete spinal cord lesion is defined as total loss of motor and sensory function below the level of injury. One must not be confused by spinal mass reflexes such as reflex withdrawal of an extremity in response to pain, which is not representative of true motor function and may mistakenly lead to classification of the injury as incomplete. [Figure 31–4](#) portrays the motor and sensory levels of the spinal cord, and [Table 31–4](#) lists the important motor findings associated with injuries at different cervical levels.

Patients with complete cervical cord lesions present initially in a state known as *spinal shock*, defined as a total loss of motor and sensory function associated with an areflexic, flaccid trunk and extremities below the level of the lesion. In a complete lesion, spinal shock occurs immediately after the injury and may persist for 1–2 weeks, after which time upper motor neuron findings develop with increased deep tendon reflexes and increased muscular tone associated with spasticity. However, abdominal cutaneous reflexes remain absent. The mass reflex may occur and is characterized by exaggerated involuntary extremity movement owing to loss of descending cortical inhibition. Interruption of autonomic fibers results in bladder paralysis, urinary retention, poor gastric emptying, and intestinal ileus with abdominal distention.

An incomplete lesion is characterized by evidence of any motor or sensory function below the level of the lesion. In severe incomplete injuries, spinal shock may be present initially but begins to wear off within 24 hours. Patients with incomplete cervical cord injuries generally show some degree of neurologic recovery (up to 40% may make a functional recovery), whereas patients with true complete injuries demonstrate no significant neurologic recovery. Rectal examination is an essential part of the complete neurologic assessment because any evidence of sacral sparing, such as voluntary sphincter contraction or sensation in the perianal region, classifies the injury as incomplete and implies the possibility of some functional recovery. Important incomplete spinal cord injury syndromes include the following:

1. ANTERIOR CORD SYNDROME—This syndrome is associated most often with cervical flexion injuries and results in loss of

▲ **Figure 31-4.** Motor and sensory levels of the spinal cord. (Reproduced, with permission, from Waxman SG: *Correlative Neuroanatomy*, 20th ed. New York: McGraw-Hill, 2000.)

Table 31-4. Important motor characteristics associated with injuries at different cervical levels and T1.

Segment	Important Characteristics
C1 to C3	No arm motor function. Absent respiratory muscle contractions. If C3 is spared, patient can support neck.
C4	If the C4 segment is functional, patients may only require initial ventilatory support and then, after strengthening, may self-ventilate.
C5	Useful movements of the deltoid, biceps, and usually the brachialis muscles are present, permitting shoulder shrug, elbow flexion, and forearm pronation.
C6	Allows wrist extension.
C7	Functional upper extremity movements with maintained innervation of the triceps (elbow extension), extensor digitorum (finger extension), and flexor carpi ulnaris (wrist extension). Weak finger flexors with poor grasp.
C8	Improved hand function due to innervation of most hand intrinsic muscles.
T1	Complete hand strength maintained because of innervation of all hand intrinsic muscles.

motor function and pain and temperature perception (ie, corticospinal and spinothalamic tracts), with preservation of proprioception and perception of vibration and light touch (dorsal columns) below the level of the lesion. This is thought to result either from direct anterior trauma or from injury to the anterior spinal artery, which supplies the anterior two-thirds of the spinal cord. The paired posterior spinal arteries supply the dorsal columns and the posterior one-third of the cord.

2. CENTRAL CORD SYNDROME—This is most commonly due to a hyperextension injury in an older patient with preexisting cervical spondylosis or stenosis. The motor and sensory deficits are greater in the upper extremities (more pronounced distally) than in the lower extremities. Hemorrhagic necrosis in the central portions (eg, gray matter) of the cervical cord results in upper extremity weakness. Since the lumbar leg and sacral tracts are peripheral in the cervical cord, they are relatively spared.

3. BROWN-SÉQUARD'S SYNDROME—This syndrome occurs with hemisection of the spinal cord, usually from penetrating injuries such as stab or gunshot wounds. The result is ipsilateral loss of motor and dorsal column function (ie, vibration, proprioception, and discriminatory touch) immediately below the level of injury associated with contralateral loss of pain and temperature sensation one or two

levels below the injury (spinothalamic tracts decussate within one to two levels of their entry).

4. POSTERIOR SPINAL CORD SYNDROME—This rare syndrome results from disruption of the posterior columns, causing loss of vibration, proprioception, and discriminatory sense below the level of the lesion.

C. Imaging Studies—Radiographs are essential for the evaluation and diagnosis of cervical spine injuries. These should include a cervical spine series with lateral, anteroposterior, and odontoid (open mouth) views. Radiographs are inspected for the presence of prevertebral soft tissue swelling, alignment of the anterior and posterior aspects of the vertebral bodies, angulation of the bony spinal canal, and the presence of fractures. The odontoid view is essential to diagnose axis (C2) fractures or Jefferson fractures of the ring of the atlas (displacement of the lateral masses of C1). Ligamentous damage should be suspected in patients with minimal subluxation or persistent neck pain without evidence of a fracture. Dynamic flexion and extension cervical radiographs, which should only be considered in awake and cooperative patients, are useful to detect instability secondary to ligamentous injury. These x-rays may be performed several days after the initial injury so that muscle spasms, which can mask instability by limiting subluxation, may subside.

CT scanning is excellent for visualizing the bony structures of the spinal canal and is the next step in evaluating a fracture or subluxation. In patients with neurologic symptoms or signs and no radiographic evidence of bony abnormalities, MRI should be obtained. MRI demonstrates the cord and soft tissue structures with outstanding clarity and can identify intraaxial contusions and cord compression from a herniated disk or hematoma. However, MRI does not demonstrate bony structures very well.

The role of myelography in spinal cord injury is controversial. Myelography should be performed if there is a significant incomplete neurologic deficit that cannot be explained by bony abnormalities and if an MRI cannot be obtained.

D. Other Studies—Somatosensory evoked potentials are occasionally useful to confirm or dispute the diagnosis of complete spinal cord injury. This is especially true in patients who are difficult to examine, such as those with altered mental status.

Treatment

Optimal treatment of spinal cord injuries must be initiated at the scene of the accident. The spinal cord is susceptible to reinjury after the primary insult, making prevention of secondary injury one of the most important aims of therapy. This includes immediate spinal immobilization with sandbags or a hard collar and rapid correction of hypoxia, hypotension, shock, or hypothermia, if present. Early placement of a nasogastric tube and an indwelling urinary catheter are necessary because an atonic bladder and GI tract commonly accompany cervical cord injuries.

Serial neurologic examinations are important to detect signs of deterioration so that corrective measures can be taken expeditiously. The patient must be maintained in optimal physiologic condition to maximize the chances of neurologic repair and recovery.

A. Respiratory Care—Patients with cervical cord injuries frequently develop worsening of their respiratory status in the ICU. This may be secondary to diaphragm fatigue or ascending neurologic damage from edema or ischemia and may require prompt respiratory support. Intubation in patients with unstable cervical injuries should be performed using fiberoptic nasotracheal intubation (see below for selection of neuromuscular blocking agents). Hypoventilation, particularly during sleep, is not uncommon in the early stages following high cervical cord injury and may require nighttime ventilation. This is probably due to an impaired respiratory drive to CO₂ or diaphragm fatigue. A high index of suspicion for this disorder, which usually resolves in 1–2 weeks, must be maintained in the early phases of ICU care.

Aggressive pulmonary toilet and aerosol bronchodilators should be used to avoid atelectasis, mucus plugs, and pneumonia. Prophylactic antibiotics should not be used to prevent pulmonary infections.

B. Hemodynamic Support—During spinal shock, decreased sympathetic outflow may be manifested by bradycardia or hypotension. However, one must not overlook a source of hemorrhage (eg, liver laceration or pelvic fracture) because such patients will not complain of pain. Hypotension from spinal shock usually responds well to intravenous infusions of crystalloid and colloid solutions. Vasopressors such as dopamine may be required. Atropine, although short-acting, may rapidly reverse hypotension associated with bradycardia. Placement of a temporary cardiac pacemaker may be required for severe bradycardia. Following recovery from spinal shock, reflex hypertension, sweating, pilomotor erection, and rarely, bradycardia or cardiac arrest (autonomic dysreflexia) may occur. This is usually precipitated by painful stimuli such as bladder catheterization, respiratory suctioning, or colorectal manipulation. Hypertensive crises, which can be life-threatening, should be treated by elimination of the precipitating stimulus and administration of rapid-acting intravenous antihypertensive agents. In recurrent severe attacks, prophylaxis with phenoxybenzamine may be useful.

C. Cervical Immobilization—Unstable malaligned cervical spine subluxations or fractures should be managed initially with external immobilization. This can be achieved by attaching tongs or a halo ring to the patient's skull and applying distraction force through a pulley system attached to weights. One must exclude the presence of atlanto-occipital dislocation because traction in this condition can result in overdistraction and serious injury. Gentle application of 5–10 lb is used initially, gradually increasing by up to 5 lb per cervical level (eg, 20 lb for C4 and 30 lb for C6). More weight may be required for reduction, but no more than 10 lb per

level should be administered. After each weight increase, the lateral x-ray should be repeated to determine if realignment has been achieved. It is often necessary to administer muscle relaxants such as diazepam (5–10 mg intravenously every 8 hours) during skeletal traction to reduce muscle contractions or spasms that can hinder spinal realignment. Application of a halo vest orthosis may be the proper choice for certain bony injuries of the cervical spine.

D. Surgery—The principal goal in the management of cervical spine injuries is prevention of secondary neurologic injury and provision of an optimal environment for recovery. Securing a stable cervical spine (ie, bones, muscles, and ligaments) will prevent further neurologic injury and reduce the chance for persistent cervical pain resulting from instability. In general, bony lesions heal well if immobilized properly, whereas ligamentous injuries typically do not heal. The indications for operation are decompression of incompletely injured neural tissue and reduction and stabilization of malaligned or unstable cervical segments. Some of the basic features and treatment modalities for several common cervical injuries are outlined below.

1. ATLANTO-OCCIPITAL DISLOCATION—These injuries, which are seen most commonly in children owing to immature craniovertebral articulations, are often fatal. They involve extensive ligamentous disruption and can cause injury to the brain stem, cervical cord, nerve roots, or vertebral artery. Traction should not be used because it can increase the distraction and cause further CNS damage. These injuries are highly unstable and require operative bony fusion.

2. JEFFERSON FRACTURE OF THE ATLAS—This is a burst fracture of the ring of the atlas resulting from an axial force and is usually asymptomatic. If combined displacement of the left and right lateral masses on open mouth x-ray is more than 6.9 mm, immobilization with a halo vest is suggested; otherwise, a hard cervical collar is sufficient.

3. AXIS FRACTURES—A type 1 odontoid fracture involves only the tip of the odontoid and can be treated with hard cervical collar immobilization. Fractures through the odontoid base are classified as type 2 and have a high incidence of nonunion. Current treatment recommendations are for surgical fusion if the fracture is displaced more than 6 mm or halo vest immobilization for fractures displaced less than 6 mm. Anterior odontoid screw fixation or posterior atlantoaxial fixation may be performed. Type 3 odontoid fractures involve the base of the odontoid with extension into the vertebral body and require only halo vest immobilization for fusion. Hangman fractures are bilateral fractures of the C2 pedicles with anterior displacement of C2 onto C3. They are usually due to hyperextension injuries such as automobile accidents in which the head hits the windshield. Hangman fractures may be unstable and require traction initially if malalignment is present, followed by immobilization in a halo vest. Isolated laminar or spinous process fractures

of the axis usually can be treated with a hard cervical collar. Treatment for combined atlas and axis fractures is usually based on the type of axis fracture present.

4. WEDGE COMPRESSION FRACTURE—This results from a hyperflexion force causing compression of one vertebra against an adjacent vertebra. The optimal management of these injuries is controversial. Simple wedge fractures without associated ligamentous injury or significant subluxation heal well in a hard cervical collar. If the kyphotic angulation is significant, or if instability is present, early surgical fusion or closed realignment with skeletal traction followed by halo vest application may be warranted. Persistent instability may be present in 15% of patients treated by immobilization only and requires subsequent operative surgical fusion. Care must be taken in patients with neurologic deficits to exclude a compressive lesion such as an extruded cervical disk that may require early operation.

5. FLEXION TEARDROP FRACTURE—This is secondary to severe hyperflexion with disruption of the intervertebral disk associated with ligamentous damage and a fracture through the anteroinferior vertebral body. This is a highly unstable injury often associated with devastating neurologic damage and requires early realignment by traction. Management after initial stabilization is controversial and may include halo vest immobilization or surgical fusion. Care must be taken to exclude any compressive lesions, such as bone or disk material, that may contribute to neurologic dysfunction and require removal.

6. FACET DISLOCATION—Bilateral facet dislocation occurs when the inferior articular facet of the upper vertebra slides forward over the superior articular facet of the lower vertebra. This is due to severe hyperflexion injury and is unstable. Lateral cervical x-rays show anterior subluxation of the superior vertebra by over 50% of the length of the vertebral body. Anteroposterior views demonstrate alignment of the spinous processes. Immediate closed reduction using skeletal traction should be attempted; if this fails, open surgical reduction may be necessary. Surgical fusion is required in either case. Unilateral facet dislocation results from simultaneous flexion and rotation injuries. The lateral cervical spine x-ray shows anterior subluxation of the superior vertebra, but this is only 30% or less of the length of the vertebral body. The spinous processes on anteroposterior views are rotated and do not align. Although the unilateral locked facet is a stable injury, it is commonly associated with nerve root injury and chronic pain. In these patients, closed or open reduction may be beneficial.

E. Corticosteroids—Although previous versions of this chapter have advocated use of intravenous methylprednisolone acutely after spinal cord injury, this therapy is now considered an option rather than a recommendation. Critical analysis of the original data as well as the clinical experiences over the past several years have not come out with significant

efficacy of this medication regime. Some clinicians may wish to use the steroid in the hope that local nerve root improvement may be hastened, but the decision needs to be weighed against potential complications.

F. Pulmonary Embolism Prophylaxis—Pulmonary embolism is a constant threat to patients with weak limbs and should be combated using subcutaneous heparin (5000 units twice daily), pneumatic compression stockings, or both. Intravascular insertion of a vena cava filter is highly recommended for patients with lower limb paralysis.

G. Gastrointestinal Considerations—Atony and paralytic ileus may occur for days to weeks following spinal cord injury. Early nasogastric decompression is required to reduce abdominal distention. Serum electrolytes should be evaluated regularly. Because these patients are in a catabolic state after injury, they often require early nutritional support. Reflex evacuation of the rectum occurs following the acute phase of spinal cord injury and can be aided by a regular regimen of laxative agents.

H. Urinary Care—Bladder atonia and sphincter paralysis result in urinary retention after spinal cord injury. Initial placement of an indwelling bladder catheter is required, but the catheter should not be left in place for longer than 2–3 weeks. After this time, reflex emptying of the neurogenic bladder can occur spontaneously or in response to stimuli such as suprapubic compression. Many patients require intermittent bladder catheterization, and this can be self-administered using meticulous technique. Urologic consultation is frequently helpful to determine individual bladder care programs.

I. Skin Care—Prevention of decubitus ulcers is a primary concern in spinal injury patients. Patients should be turned at least every 2 hours, pressure points should be padded, and kinetic therapy beds should be used if available.

J. Avoidance of Depolarizing Neuromuscular Blocking Agents—Denervated muscles are hypersensitive to depolarization, and administration of a depolarizing agent (eg, succinylcholine) can result in rapid hyperkalemia that may be complicated by ventricular fibrillation.

Acute Abdomen

Allen P. Kong, MD
Michael J. Stamos, MD

The term *acute abdomen* denotes an abdominal pathologic condition that, if left undiscovered and untreated, would have a deleterious effect on the patient's health status. Numerous factors make the diagnosis and treatment of abdominal conditions more difficult in ICU patients.

Physiologic Considerations

The peritoneum is a complex mesothelium-lined organ that invests the intraabdominal viscera (visceral peritoneum) and the abdominal cavity (parietal peritoneum). The peritoneum functions to maintain the integrity of the intraabdominal organs and provides lubrication by peritoneal fluid (normally <50 mL). For free movement of the viscera, the nondiaphragmatic peritoneal surface behaves as a passive semipermeable membrane that allows bidirectional exchange of water and electrolytes. The diaphragmatic surface is highly specialized, with numerous gaps in the peritoneal lining that serve as entrances to a plexus of lymphatic channels that drain via substernal lymph nodes into the thoracic duct. This diaphragmatic absorptive pathway is enhanced by respiratory excursion and normally accounts for at least 30% of the total lymphatic drainage of the abdomen, helping to maintain the balance between visceral parietal transudation and parietal peritoneal fluid uptake.

The omentum participates in absorption of peritoneal fluid and particulate material up to 10 μm in diameter. The omentum is highly mobile and can act to seal off a perforated viscus or contain a bacterial inoculum.

Pain from intraabdominal disease is transmitted via somatic sensory and visceral autonomic pathways. Visceral pain, primarily elicited by distention, is referred in a logical fashion in the same order as embryologic development; the nerves accompany the major splanchnic vessels. Foregut sources (eg, esophagus, stomach, liver, pancreas, biliary tract, duodenum, and spleen) elicit upper epigastric pain, midgut lesions (eg, jejunum, ileum, appendix, and right colon) elicit periumbilical pain, and hindgut lesions (eg left colon and rectum) radiate to the hypogastrium. This visceral pain is typically

colicky in nature and somewhat vague in location—in contrast to somatic pain, which is usually constant and well localized to the site of direct parietal peritoneal irritation.

Intraabdominal disease also can cause pain to be referred to other areas through neural pathways or other anatomic constraints. Examples of referred pain include shoulder pain from splenic or hepatic hemorrhage, causing phrenic nerve irritation, and hip or thigh pain from a psoas abscess.

▶ Pathophysiology

Critical care patients are susceptible to common causes of abdominal disease such as appendicitis, diverticulitis, and calculous cholecystitis with approximately the same frequency as the general population. More important, they are prone to develop more complex and unusual abdominal processes resulting from a variety of predisposing conditions. For example, recent surgery, especially involving enteric anastomoses, may lead to intraabdominal abscess or small bowel obstruction.

Shock with associated low flow states leads to an increased risk of mesenteric ischemia, acalculous cholecystitis, and possibly gut translocation of bacteria. Present or previous antimicrobial therapy also may contribute to illness with overgrowth of resistant organisms, including *Clostridium difficile* (pseudomembranous) colitis. The fasting state of many critically ill patients may contribute to the development of acalculous cholecystitis or, along with opioid use, lead to a colonic pseudo-obstruction (Ogilvie's syndrome; see below).

Iatrogenic complications are common in patients undergoing multiple procedures and receiving several medications. Inadvertent visceral injury may occur during paracentesis or thoracentesis. Missed intraabdominal disease in traumatized patients should be strongly considered in any patient not recovering as expected. The problem of stress gastritis and stress ulcers has been diminished with aggressive pH monitoring and pharmacologic prophylaxis but still presents a formidable challenge.

Clinical Features

A. Symptoms—While many patients in the ICU are unable to give a history because of intubation or altered mental status, a detailed review of recent symptomatology should be obtained whenever possible. Family members and friends should be interviewed. Patients may have been transferred from a hospital ward or may have had recent contact with the hospital or emergency room. However obtained, the history should describe any preexisting medical conditions, previous surgery, present medications, prior abdominal complaints, changes in eating or bowel habits, and recent weight loss. Exposure to toxic substances (including alcohol) and recent trauma should be noted. The obstetric and gynecologic history should include data about menses and sexual contacts.

Events leading to hospitalization need to be reviewed, and if pain is part of the symptomatology, a history of its presentation and progression is helpful. Despite efforts to elicit a detailed history, this is often not possible in critically ill patients.

1. LOCATION OF THE PAIN—The location of pain can give valuable information about its cause. Even more important is an account of its progression and changes in location (Table 32-1). Knowing where the pain began occasionally means more than determining where it is at presentation. A perforated ulcer may cause lower abdominal pain from intestinal contents collecting in the pelvis owing to gravitational effects or even owing to a pelvic abscess, whereas a detailed history may reveal days or weeks of epigastric or right upper quadrant pain. Pain radiating to some other area of the body also may give valuable information. For example, epigastric pain that radiates through to the back is more likely to be due to pancreatitis than to reflux esophagitis.

2. NATURE OF THE PAIN—Episodic or crampy pain is usually due to blockage or obstruction of a hollow viscus during contraction or attempted peristalsis such as in bowel obstruction or during an attack of acute cholecystitis. Questioning and observation often will determine what factors increase or relieve the pain. Patients with direct peritoneal inflammation will resist movement, whereas patients with renal colic will writhe about with no apparent exacerbation from the movement itself.

3. PROGRESSION OF THE PAIN—Since virtually all patients subjected to abdominal operations have postoperative pain, progression of the pain gives important information about its source. Incisional pain usually begins to subside after the first 72 hours, whereas pain owing to other causes such as an intraabdominal abscess or bowel obstruction often will begin after 72 hours and become progressively worse.

B. Physical Examination—A comprehensive physical examination of the ICU patient can be difficult and frustrating, especially just after an operation. Nevertheless, a complete examination is essential on admission to the unit,

Table 32-1. Locations of common etiologies of acute abdomen.

Epigastrium	Suprapubic and Pelvic
Esophageal disease	Cystitis
Peptic ulcer disease	Diverticulitis
Pancreatitis (including pseudocyst)	Proctitis
Cardiac disease	Pelvic abscess
Hiatal hernia (including paraesophageal)	Renal colic
Right Upper Quadrant	Left Upper Quadrant
Cholecystitis	Pancreatitis (including pseudocyst)
Cholangitis	Splenic disease
Pancreatitis (including pseudocyst)	Hiatal hernia (including paraesophageal)
Peptic ulcer disease	Renal colic
Renal colic	Left lower lobe pneumonia
Hepatitis	Colitis (especially ischemic)
Appendicitis	Subphrenic abscess
Cecal volvulus	Periumbilical
Hepatic abscess	Umbilical hernia
Subphrenic abscess	Early appendicitis
Right lower lobe pneumonia	Small bowel obstruction
Right Lower Quadrant	Mesenteric ischemia
Appendicitis	Aortic aneurysm
Diverticulitis	Left Lower Quadrant
Crohn's disease	Diverticulitis
Colonic obstruction	Sigmoid volvulus
Psoas abscess	Colitis (especially ischemic)
Pelvic inflammatory disease	Renal colic
Ovarian cyst or torsion	Inguinal hernia
Ectopic pregnancy	Pelvic inflammatory disease
Inguinal hernia	Ovarian cyst or torsion
Epididymitis	Ectopic pregnancy
Pelvic abscess	Epididymitis
	Pelvic abscess
	Psoas abscess

starting with measurement of routine vital signs. Body temperatures should be obtained from a reliable site—rectal, bladder, or core measurements from a Swan-Ganz catheter probe will suffice. Oral and axillary temperatures are often unreliable. Fever with or without hypotension arouses suspicion of abdominal disease, and the presence of both often will suggest an acute abdomen. Examination to exclude an extraabdominal source of sepsis should include inspection of old and existing intravenous sites, chest auscultation and percussion, inspection of all wounds (traumatic and surgical), and gross evaluation of urine, especially in catheterized patients.

1. OBSERVATION—Abdominal examination should begin with careful observation of not only the abdomen but also the patient's body position and general demeanor. Is the patient resting comfortably or in significant distress, with guarding of the abdominal area? Any distention, ecchymoses,

and old surgical scars should be noted. Some abdominal distention is normal in the postoperative abdominal surgical patient, but any increase in distention postoperatively may signify problems such as a nonfunctioning nasogastric tube, prolonged ileus, small bowel obstruction, or development of ascites. Recent incisions should be inspected, and any erythema, edema, or fluid discharge should alert the examiner to a potential wound or intraabdominal infection.

2. AUSCULTATION—Auscultation is difficult in a noisy ICU environment and therefore frequently neglected. Absent bowel sounds may be normal in recent postoperative patients but in others may be viewed appropriately with suspicion. Hyperactive, high-pitched rushes may signify bowel obstruction. Abdominal bruits indicate the presence of aneurysms, arteriovenous fistulas, or severe atherosclerotic disease.

3. PERCUSSION—Gentle percussion with close attention to grimacing or other movement by the patient can give subtle information about localized peritoneal irritation. The presence of a tympanic area in the right upper quadrant overlying the liver suggests pneumoperitoneum. Percussion also can help to detect bowel obstruction (calling for nasogastric intubation) or ascites or may disclose a distended bladder owing to a nonfunctioning or nonexistent Foley catheter.

4. PALPATION—Palpation may reveal hepatomegaly or splenomegaly, an abdominal wall hernia, a distended gallbladder, an intraabdominal tumor or abscess, or an aortic aneurysm. Rebound tenderness is intended to elicit peritoneal irritation. Gentle percussion is a good test for localized peritonitis. Gently bumping the patient or the bed or having the patient cough will cause enough peritoneal movement to exacerbate pain from peritoneal inflammation. Careful observation of the patient's facial expression and body position will be revealing. Deep palpation of the abdominal wall and sudden release to elicit rebound tenderness is often misleading and in the presence of peritonitis often will increase guarding and make subsequent examinations more difficult.

When cholecystitis is in the differential diagnosis, right upper quadrant palpation may reveal tenderness or even a positive Murphy sign (ie, arrested inspiration during palpation of the right upper quadrant). Although the retroperitoneum and pelvis are less accessible to direct palpation, indirect evidence of inflammation can be elicited. Pain on hyperextension of the hip, on stretching the iliopsoas muscle (psoas sign), and on flexion and internal rotation of the hip, stretching the obturator muscle (obturator sign), can indicate an adjacent inflammatory process. Gentle palpation or percussion of the posterior costovertebral angles should diagnose or exclude pyelonephritis.

5. RECTAL AND PELVIC EXAMINATION—Genitourinary and rectal examinations are essential to evaluate for incarcerated hernias, pelvic or rectal masses, cervical motion tenderness, prostatic or scrotal disease, and bloody stools. Stool may be

guaiac-tested to confirm a clinical suspicion, but—at least in the ICU patient population—this test is too insensitive and nonspecific to be useful in making clinical decisions.

C. Laboratory Findings—A white blood cell count is nonspecific and relatively insensitive—its absolute level is less useful than its trend. A differential count indicating a left shift increases the sensitivity of this test. The hematocrit is helpful or even essential in diagnosing intraabdominal or GI bleeding.

Urinalysis should be performed with attention to the presence of white blood cells or white blood cell casts indicating of urinary tract infection. Urine specific gravity can give information useful in fluid resuscitation efforts, and the presence of glucose or ketones is of diagnostic and therapeutic importance.

Elevated liver enzymes (eg, AST, ALT, and alkaline phosphatase) direct attention to the liver (eg, hepatitis) and biliary system (eg, cholangitis or cholecystitis). Bilirubin elevation is seen in hepatobiliary disease but also can be associated with sepsis, hemolysis, and cholestasis owing to parenteral nutrition.

Serum amylase is neither sensitive nor specific, although markedly elevated values usually indicate pancreatitis. Elevated serum amylase is also seen with perforated ulcer, mesenteric ischemia, facial trauma, parotitis, and ruptured ectopic pregnancy. Lipase or Pankrin values may improve specificity in the diagnosis of pancreatitis. Arterial blood gas measurements may demonstrate acidosis or hypoxia. Acidosis may reflect severe sepsis or ischemia, whereas hypoxia may reflect acute respiratory distress syndrome (ARDS) owing to uncontrolled sepsis. Additionally, arterial lactate levels may be more specific in identifying worsening acidosis, especially in the setting of preexisting acidosis such as renal failure.

D. Imaging Studies—Although bedside studies are relatively risk free, CT scans, MRI, arteriography, and nuclear medicine scans usually require patient transport. In this select group of critically ill patients, transfer to other areas of the hospital carries significant risks.

1. BEDSIDE FILMS—Radiographs of the chest can evaluate for pulmonary infections as well as free air when performed with the patient in a sitting position. Pleural effusions, especially when asymmetric, may signify an intraabdominal process. Abdominal radiographs may show a colonic volvulus or obstructed bowel gas pattern, biliary or renal calculi, or (rarely) pneumobilia. Ultrasound can be useful as a diagnostic and therapeutic tool—intraabdominal abscesses can be identified with this procedure and percutaneous drainage facilitated. Cholecystitis (calculous or acalculous) can be diagnosed and even treated (percutaneous cholecystostomy). In questionable cases, percutaneous aspiration with analysis of gallbladder contents (ie, Gram stain and culture) can be invaluable.

2. RADIOLOGY DEPARTMENT STUDIES—CT scans have assumed a primary position in the diagnosis of acute

abdomen. They should not be used indiscriminately, however, and are of little value in the first week after abdominal surgery, when normal postoperative findings (ie, blood, air, and seromas) make identification of an abscess difficult. In the critically ill patient with multiple-organ-system failure, transport to the radiology department may carry a greater risk than the potential benefit. These patients perhaps should be considered for early laparotomy. CT scanning for intraabdominal abscesses has an accuracy rate greater than 95%. Studies that have looked specifically at critically ill surgical patients, however, are not so promising, with sensitivity rates as low as 50% and with only 25% of the scans actually providing beneficial information that perhaps altered the outcome of therapy. CT scans should be performed only when the information obtained is expected to have that result.

GI contrast studies can be useful occasionally in patients with recent anastomoses or in those with possible missed injuries (especially esophageal injuries). In general, water-soluble agents (eg, Gastrografin) should be used. Angiography is useful in patients with suspected mesenteric ischemia and should be performed early after initial resuscitation. In addition to securing the diagnosis, intraarterial vasodilators (eg, papaverine) can be used as primary therapy or to demarcate and salvage marginally viable intestine. Angiography also plays a diagnostic role in selected patients with GI bleeding, aiding in localization of the bleeding site, and it has therapeutic applications in the delivery of intraarterial vasopressin or embolization. Blood loss of at least 0.5 mL/min is required before it can be detected by angiography. ^{99m}Tc -tagged red blood cell scans have a reported sensitivity of 0.05–0.1 mL/min and may play a role in screening patients for the more invasive angiographic approach.

Gallium- or indium-tagged white blood cell scans are useful occasionally in relatively stable patients. The poor specificity of the tests, especially in the postoperative patient, and the 24–48-hour time period for completion limit their usefulness.

E. Peritoneal Lavage—Extensively used in abdominal trauma, diagnostic peritoneal lavage also may be quite useful in selected ICU patients. The same factors that make assessment of critically ill patients difficult (eg, altered mental status, intubation, etc.) make lavage an attractive alternative. Numerous studies have shown its utility in selected patients with white blood cell counts greater than 500/ μL or red blood cell counts greater than 50,000–100,000/ μL . Lavage has limited if any usefulness in the recent postoperative patient. In this setting, CT- or ultrasound-guided percutaneous aspiration is safer and more reliable.

F. Endoscopy—In the presence of active upper GI bleeding, esophagogastroduodenoscopy is of proved diagnostic and therapeutic benefit. Flexible sigmoidoscopy and colonoscopy also may be of diagnostic value in the patient with possible ischemic colitis or pseudomembranous colitis. Up to a third of patients with pseudomembranous colitis have negative

C. difficile toxin assays; visualization and biopsy will increase the diagnostic accuracy to over 95%. Ischemic colitis can occur as a result of embolic disease, shock (low-flow state), or—not uncommonly in the ICU setting—after aortic surgery. Endoscopy can confirm the diagnosis and can allow observation of the progression of disease in selected patients. Endoscopic retrograde cholangiopancreatography has a proven therapeutic role in septic patients with cholangitis, allowing stone extraction or stenting.

Evaluation of the Postoperative Abdomen

Postoperatively, a number of potential intraabdominal complications can occur in the ICU patient. These include such diverse problems as intraperitoneal bleeding, anastomotic dehiscence, early small bowel obstruction, and fascial dehiscence. Early recognition and aggressive corrective action are required.

To identify a failure to recover on schedule after laparotomy, one must understand the normal course following major abdominal surgery. Third-space fluid sequestration occurs in approximate proportion to the magnitude of the surgery. Mild to moderate abdominal distention and oliguria—frequently seen in the first 24–72 hours after surgery—can make identification of postoperative hemorrhage difficult. Not infrequently, a declining hematocrit is attributed to dilutional effects or to equilibration. The accompanying tachycardia may be falsely attributed to pain. Alert watchfulness for possible postoperative bleeding can avert a disastrous outcome.

Fever is the most commonly observed postoperative physiologic abnormality. The presence of fever suggests infection, but the approach to evaluation must be methodical. A single febrile episode in most patients should call for nothing more than a review of the history and a physical examination. Intermittent spikes of recurrent fever may warrant a more thorough investigation—again directed by a thorough physical examination. The goal should be to identify a complication early while intervention still may improve the outcome.

Other than missed injuries to hollow viscera (traumatic or iatrogenic), intraabdominal sepsis—including abscess and anastomotic leaks or dehiscences—typically is manifested between 5 and 10 days after surgery. Early recognition and treatment are critical. Subtle signs may aid in early diagnosis. Third spacing should resolve within 48–96 hours, and observation of a vigorous postoperative diuresis during this period is a reliable sign of improvement. Leukocytosis following major surgery is frequently regarded as a normal finding (largely owing to demargination), whereas failure of the white blood cell count to return to normal or an increase from a declining value should suggest the possibility of intraabdominal sepsis. Other findings include glucose intolerance, continued tachycardia, worsening acidosis, prolonged ileus, or persistent diarrhea on return of bowel function (owing to adjacent pelvic abscess).

Treatment

Following the initial evaluation of an ICU patient for consideration of an acute abdomen, the primary decision is whether urgent surgery is required. Resuscitation with intravenous fluids is usually necessary to correct third-space losses or bleeding. A bladder catheter should be inserted to monitor urine output and, unless contraindicated, a nasogastric tube to decompress the stomach. Both H₂ blockers and antacids are effective, with greatest efficacy achieved by maintaining the gastric pH higher than 5.0. An arterial and a pulmonary artery flotation catheter may be necessary in some patients to monitor hemodynamic function and intravascular volume. Antibiotics should be given as indicated. Caution should be exercised in giving antibiotics to patients with undiagnosed but suspected sepsis because of concerns about obfuscating the clinical picture and frustrating further evaluation. Antibiotic therapy is largely adjunctive, although small abscesses or phlegmonous processes owing to contained enteric leaks often will resolve with their use.

SPECIFIC PATHOLOGIC ENTITIES

▶ Bowel Obstruction

The diagnosis of early postoperative small bowel obstruction frequently is delayed primarily because of the differential consideration of persistent adynamic ileus. The characteristic symptoms of obstruction include abdominal distention, obstipation, and vomiting. These symptoms also characterize adynamic ileus, and the first step in differentiation is consideration of the diagnosis. Further confusing the clinical picture is the side effect of opioid analgesics on decreasing GI motility.

The clinical history and physical examination are often nondiagnostic, although the patient who has brief return of GI function followed by its cessation probably has an adhesive obstruction. Plain radiographs likewise are frequently nondiagnostic in this setting.

A nasogastric tube should be inserted. Hypovolemia should be corrected and electrolytes checked, with special attention to hypokalemia and hypocalcemia. If there is a possibility of intraabdominal abscess or sepsis, CT scan or ultrasonography is indicated. If the diagnosis is still in doubt, a water-soluble contrast study (eg, Gastrografin) can be diagnostic as well as therapeutic because of the cathartic effect of the hyperosmolar solution. Drainage of an abscess may relieve the localized ileus or obstruction. Patients who are receiving adrenal corticosteroids may develop adynamic ileus if the drug is withdrawn too quickly. High doses (300 mg hydrocortisone daily or equivalent) intravenously will give prompt resolution.

Complete obstruction warrants reoperation as soon as resuscitation is complete. Partial obstruction often will resolve with conservative management.

▶ Enteric Fistula

Risk factors for enteric fistula include previous radiation, inflammatory bowel disease, and chronic corticosteroid administration. After initial resuscitation, the first maneuver is to determine the need for early operation. A controlled fistula is present when enteric contents are captured by a drain or when rapid egress from a wound results in little or no peritoneal contamination or irritation—such cases can be expected to resolve with nonoperative therapy. Percutaneous drainage of an associated abscess found by ultrasound or CT scan may allow closure of the fistula and improve the patient's physiologic status prior to definitive management. Complicating conditions include radiation damage, malignancy, inflammatory bowel disease, the presence of a foreign body, and distal intestinal obstruction. Water-soluble contrast studies are occasionally helpful to visualize the site of fistula, evaluate the adequacy of drainage, and rule out distal obstruction. Once a decision to attempt conservative management is made, useful therapeutic maneuvers may include restriction of oral intake, parenteral nutrition, octreotide acetate (50–200 µg subcutaneously twice to three times daily), and nasogastric suction. Elemental diets may be substituted for parenteral nutrition in selected patients—especially those with distal fistulas or with fistulas not in continuity (eg, duodenal stump and pancreatic).

Conversely, an anastomotic leak or dehiscence that results in free peritoneal spillage requires emergent operation for patient survival. The clinical setting and physical examination usually will allow an accurate assessment. Oliguria and hypovolemia often portend extensive peritoneal contamination and third spacing, whereas diffuse peritoneal irritation manifested by a rigid abdomen on examination offers no real dilemma. The patient with localized peritoneal signs, mild to moderate leukocytosis, and perhaps minimal additional fluid requirements presents a more difficult decision.

▶ Intraabdominal Abscess

Intraabdominal abscess is usually the result of contamination at the time of surgery or leakage of enteric contents. The process has been contained by the patient's immune system and defense mechanisms, including the omentum. Antibiotics—especially with smaller collections—may resolve the process. Larger abscesses—especially those with continued enteric communication—may require percutaneous or open drainage or even intestinal resection to control the process. The exact role and limitations of percutaneous drainage seem to depend more on the availability of an experienced interventional radiologist than on any absolute criteria, although multiloculated and interloop abscesses may be less amenable to this technique. Success rates range from 25–100%. Infected pancreatic necrosis and other phlegmonous processes are not amenable to the percutaneous approach. Of particular importance is appropriate attention to ensure continued success, including catheter irrigations, frequent rescanning, and contrast studies.

► Cholecystitis

Patients in the ICU may develop calculous or acalculous cholecystitis as well as cholangitis or biliary pancreatitis. The diagnosis may already be known or suspected, as in the patient admitted for observation of acute pancreatitis, or may be a confounding factor, as in the recent cardiac surgical patient developing acalculous cholecystitis.

The typical findings of right upper quadrant pain, fever, and Murphy's sign may not be present even in an awake, responsive patient. Elevated liver enzymes or unexplained fever often prompt consideration of biliary disease. Well-recognized risk factors for cholecystitis (ie, NPO, parenteral nutrition, recent surgery, and shock) should arouse suspicion. Perhaps the main difficulty is the lack of a reliable diagnostic examination in a critically ill patient, especially one with acalculous disease. The findings of sludge in the gallbladder by ultrasound and nonvisualization on ^{99m}Tc-HIDA scan are nonspecific and even expected in patients being maintained on long-term parenteral nutrition. The technique of percutaneous cholecystostomy (transhepatic) or aspiration of gallbladder contents with analysis (eg, Gram stain and culture) can be useful and deserves consideration in the most unstable patients. The diagnosis remains largely a clinical one, and exploration is often required for confirmation and treatment. Surgical exploration frequently is based on clinical suspicion and nonexclusionary test results.

► Colonic Pseudo-Obstruction (Ogilvie's Syndrome)

Typical findings include abdominal distention, abdominal pain, and obstruction. Plain abdominal radiographs are usually diagnostic, although contrast studies or endoscopy may be necessary to exclude volvulus and distal colonic obstruction. Predisposing factors include bed rest, spinal fractures and cord injuries, and prolonged opioid use. Treatment is required when the cecal diameter exceeds 10 cm on a plain film of the abdomen. Therapy should include correction of electrolyte disturbances (especially hypokalemia), cessation of narcotics, and nasogastric decompression to prevent further gaseous distention. Neostigmine has emerged as the treatment of choice. If the cecal diameter exceeds 12 cm, and if there is no improvement with the preceding measures, colonoscopic decompression is usually effective, with 15–20% of patients requiring repeated procedures. Operative treatment (eg, tube cecostomy or right colectomy) is reserved for patients with signs of present or impending perforation or a situation in which a skilled endoscopist is not available.

► Abdominal Compartment Syndrome

The concept of elevated intraabdominal pressure having detrimental clinical sequelae was enunciated over two decades ago. Initially, renal "toxicity" was focused on, and oliguria remains one of the earlier clinical signs. Other

sequelae include pulmonary compromise and mesenteric ischemia. The important factors to keep in mind are to have a high index of suspicion (especially in patients with significant abdominopelvic trauma), to use bladder pressure measurements as a reflection of intraabdominal pressure, and to consider or perform decompressive laparotomy early if indicated. Control of the open abdomen may be accomplished by superficially securing an opened 3-L intravenous fluid bag. Also, the application of an external vacuum-assisted closure (VAC) device can be applied in this setting.

CURRENT CONTROVERSIES & UNRESOLVED ISSUES

Bacterial Translocation and Enteral Feedings

The clinical picture of a critically ill patient succumbing to sepsis and multiple-organ-system failure without any apparent septic focus is a not infrequent clinical problem. A large volume of data—largely experimental or anecdotal—points to bacterial translocation across a dysfunctional GI barrier as the cause. Attempts at correction or prevention have included selective gut decontamination, maintenance of intravascular volume, and enteral feedings. Adequate enteral feedings initiated early appear to maintain adequate GI barrier function. Crucial to this effect seems to be the amino acid glutamine, a specific nutrient that supports intestinal mucosal cell growth and replication. Glutamine-containing enteral nutrition may prevent or at least lessen the severity of multisystem organ failure induced by bacterial translocation and bypass the difficulties inherent in enteral feedings in this group of patients. Additionally, the concept of "immune enhancing" diets rich in arginine, nucleotides, and fish oil is being investigated.

Activated Protein C and Corticosteroids in Sepsis

Despite recent advances in critical care, patients continue to succumb to septic states. This may occur as a result of delayed recognition or presentation, diminished immune responses, or overwhelming insults.

Sepsis is associated with widespread inflammation and intravascular coagulation. Activated protein C is an anticoagulant currently being evaluated in the setting of sepsis, diffuse systemic inflammation, and multiple-organ-system dysfunction. A recent study has shown a statistically significant decrease in 28-day mortality associated with use of activated protein C. Downsides to use of this drug include its cost and the associated risk of coagulopathy.

The use of corticosteroids in septic patients is widely controversial. One recent study revealed that small-dose hydrocortisone and fludrocortisone in very select patients conferred a slight decrease in mortality. However, the routine use of corticosteroids in all patients with sepsis is not justified. Further research is needed on this topic.

Monoclonal Antibodies

Numerous monoclonal antibodies have been tested and show promise. These agents are targeted against mediators of sepsis and in no way obviate standard identification and treatment of the septic source. They include antibodies against gram-negative endotoxin as well as tumor necrosis factor and interleukin-1. Of these, monoclonal antibodies against tumor necrosis factor are the only ones with proven efficacy in human trials, albeit with a modest benefit (3.5–4% increase in survival). Appropriate selection of patients and timing of therapy are among the ongoing clinical issues. Additionally, their widespread use may be limited by the expected prohibitive costs.

Laparoscopy

The laparoscope has become a common tool of the general surgeon in the last 20 years, and it is only natural that its role in critical care patients has been explored. The laparoscope is likely to be mainly a diagnostic instrument for the near future because of the untoward cardiovascular and respiratory side effects of prolonged abdominal insufflation, especially in this group of high-risk patients. If anecdotal results are supported by further prospective investigations, laparoscopy may supplant peritoneal lavage for the bedside diagnosis of peritonitis or visceral perforation.

Gastrointestinal Bleeding*

Sofiya Reicher, MD
Viktor Eysselein, MD

33

Overt gastrointestinal (GI) bleeding is a quintessential gastroenterologic emergency. Appropriate and timely patient resuscitation and treatment are crucial. GI bleeding carries considerable morbidity, and 7–10% mortality rates have been reported. Mortality is up to 30% in patients with in-hospital onset of GI bleeding. GI bleeding is common, with incidence of 20–100 per 100,000 adults.

Management of GI bleeding presents unique challenges owing to the wide spectrum of etiologies, clinical presentations, and diagnostic and treatment modalities. Furthermore, treatment approaches to GI bleeding have changed significantly over the past decade.

This chapter discusses major causes of severe GI bleeding, focusing on management aspects pertinent to critical care medicine. We consider bleeding as severe when hemoglobin falls acutely by more than 2 g/dL, requiring patient hospitalization and consideration of blood transfusion. Occult GI bleeding is not discussed in this chapter.

▶ Upper Gastrointestinal Bleeding

ESSENTIALS OF DIAGNOSIS

- ▶ Hematemesis and melena: hematochezia is almost always lower GI bleeding but may be seen with severe upper GI bleeding.
- ▶ Ulcers/erosions and varices are responsible for the majority of upper GI bleeding.
- ▶ Lifelong risk of variceal bleeding is about 50% in cirrhotic patients.
- ▶ Hemodynamic status and comorbid illnesses are key in the initial assessment of a bleeding patient. Age, syncope or orthostatic change in blood pressure, fresh blood in the emesis or nasogastric aspirate, or presence of cardiopulmonary or liver disease portend poor prognosis and need for urgent endoscopy.

General Considerations

Upper gastrointestinal (UGI) bleeding is defined by the location of bleeding lesion proximal to the ligament of Treitz. UGI bleeding is five to six times more common than lower GI bleeding. It is found twice as frequently in men than in women. Despite recent advances in management and treatment, UGI bleeding mortality and medical costs remain high. In the United States, UGI bleeding accounts for more than 300,000 hospital admissions annually with an estimated cost of \$750 million.

Clinical Presentation

Hematemesis (vomiting of blood) is the hallmark of UGI bleeding. Bright red blood in the emesis or in nasogastric (NG) aspirate is indicative of recent active bleeding, whereas “coffee grounds” indicate older blood that has had time to be reduced by acid in the stomach. Melena, another frequent complaint, is black tarry stools with a foul odor caused by degradation of blood in the small intestine and colon.

The distinction between upper and lower GI bleeding based on stool color is not always reliable. Hematochezia (bright red blood or maroon color stools with clots), typical of lower GI bleeding, also can occur in severe UGI bleeding. Hematochezia in UGI bleeding is a sign of massive hemorrhage, and patients are usually orthostatic. In a recent series of 80 patients with hematochezia, UGI bleeding was found in 11% of patients.

Initial Evaluation

Initial evaluation of a patient with overt GI bleeding starts with hemodynamic status assessment, critical for proper

*Tracey D. Arnell, MD, was the author of this chapter in the second edition.

Table 33-1. Gastrointestinal bleeding: vital signs and blood loss.

Finding	% Blood Loss
Shock	20-25%
Postural hypotension	10-20%
Normal	<10%

Modified from Feldman M et al: *Slisenger and Fordtran's Gastrointestinal and Liver Disease*. Philadelphia: Saunders, 2003, p. 212.

patient triage and timely resuscitation. Syncope or lightheadedness, when associated with GI bleeding, are classic signs of hemodynamic compromise. Unstable vital signs or postural hypotension indicates significant blood volume loss (>10%), pointing to possibly massive bleeding (Table 33-1).

Following hemodynamic assessment, a focused history and physical examination should be performed. Timing, amount, and color of the blood; potential risk factors for GI bleeding; and confounding comorbidities are the main points to be elicited.

Repeated bleeding episodes or passage of bright red blood or large blood clots indicates clinically significant bleeding. In trying to identify potential risk factors, a detailed medication history is particularly important. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) are the most common causes of UGI bleeding. The risk appears to be dose-related, but even patients taking low-dose (75 mg) aspirin are at increased risk for bleeding. The risk is further amplified when NSAIDs are taken along with corticosteroids or bisphosphonates. Although data are limited, bleeding risk also appears to be increased with clopidogrel. Chronic anticoagulation itself does not increase the risk for GI bleeding but is thought to unmask preexisting causes of bleeding.

Particular attention should be paid to associated comorbidities. Confounding medical problems, in particular coronary artery disease (CAD), chronic obstructive pulmonary disease (COPD), and liver disease, affect subsequent resuscitative and treatment decisions. Moreover, with recent advances in GI bleeding management, mortality mostly results from decompensation of associated illnesses caused by bleeding rather than from the bleeding itself.

Physical examination of a patient with GI bleeding should focus on signs of hemodynamic instability and volume loss. Rectal examination should be performed with attention to stool color and presence of frank blood or melena. Stool occult blood testing is not helpful in the acute setting.

Another important goal of the examination is to assess the severity of comorbid medical conditions. For example, ascites, spider angiomas, and abdominal wall collateral veins indicate significant liver disease. Respiratory status should be

checked in all patients, particularly those with in COPD, to determine sedation risk and the need for endotracheal intubation prior to therapeutic interventions.

After initial resuscitation, physical examination usually is followed by NG aspiration. Presence of blood in NG aspirates confirms an upper GI source of bleeding, but a 10–15% false-negative rate of NG aspiration has been reported, mostly in patients with postpyloric bleeding lesions. Some experts consider NG aspiration redundant if endoscopy is planned within a few hours. However, finding of bright red blood in the aspirate has been shown to correlate strongly with GI bleeding mortality and is an independent predictor of rebleeding. NG lavage also helps to clear blood and blood clots from the stomach prior to endoscopy, improving diagnostic yield. To clear the stomach prior to endoscopy, some experts also recommend administration of a promotility agent such as erythromycin (3 mg/kg intravenously). Cold water or saline lavage is no longer recommended because it does not facilitate hemostasis. Testing of NG aspirate for occult blood is notoriously unreliable and should be discouraged.

The initial evaluation concludes with focused laboratory tests, including hemoglobin, prothrombin time (PT) or international normalization ratio (INR), platelet count, and assessment of renal and liver function. In patients with CAD (or high risk for CAD), an ECG should be obtained. If chest pain or significant ECG changes are present, cardiac biomarkers need to be checked. Initial hemoglobin values often underestimate the extent of blood loss because hemodilution can take up to 72 hours to occur. Thus initial hemoglobin can be misleading in risk stratification decisions. A blood urea nitrogen (BUN):creatinine (Cr) ratio of more than 36 may be seen in UGI bleeding. Blood proteins are degraded by bacteria in the upper intestinal tract and are absorbed as urea, thus increasing BUN. The sensitivity of a BUN:Cr ratio of more than 36 for UGI bleeding is about 90%, but specificity is quite low (~30%).

The results of the initial evaluation should provide answers to two main questions: (1) Is bleeding moderate or massive, based on the degree of hemodynamic compromise, and (2) is there exacerbation of a comorbid illnesses by the bleeding?

Resuscitation

Resuscitation has a dual goal: (1) aggressively restore intravascular volume and (2) optimize comorbid conditions in order to decrease bleeding and minimize treatment-related complications. The degree of hemodynamic instability and associated illnesses determines the extent of resuscitative measures and monitoring. Older patients and patients with significant cardiopulmonary disease or hemodynamic compromise should be monitored in the ICU. For these patients, endoscopy should be performed at the bedside in the ICU to optimize monitoring. Patients with altered mental status or massive bleeding should be electively intubated for airway protection. All patients need two large (at least 18 gauge) intravenous catheters placed or central venous access obtained.

Initial volume resuscitation should be done with normal saline or lactated Ringer's. Colloids can be given. In patients

with cardiopulmonary, renal, or liver disease, central venous monitoring can be helpful to monitor volume status closely.

Concurrently with intravascular volume resuscitation, any hemostatic abnormalities need to be corrected. A target level for INR of less than 1.5 and platelet count greater than 50,000/ μ L should be sought when active GI bleeding is occurring. Appropriate clotting factors, usually in the form of fresh-frozen plasma, are given to achieve rapid reversal of coagulopathy. Even if deficient, vitamin K typically does not correct a coagulopathy fast enough and should be used only as an adjunct to clotting factors.

Transfusion of packed red blood cells is usually considered when hemoglobin is less 10 g/dL, especially in patients with cardiopulmonary disease. Clinical data supporting this threshold value are limited. However, maintaining the hemoglobin level above 10 g/dL showed a trend toward improved survival in critically ill patients with CAD. Aiming at a hemoglobin level of greater than 8 g/dL appears to be safe for young, healthy patients without comorbidities.

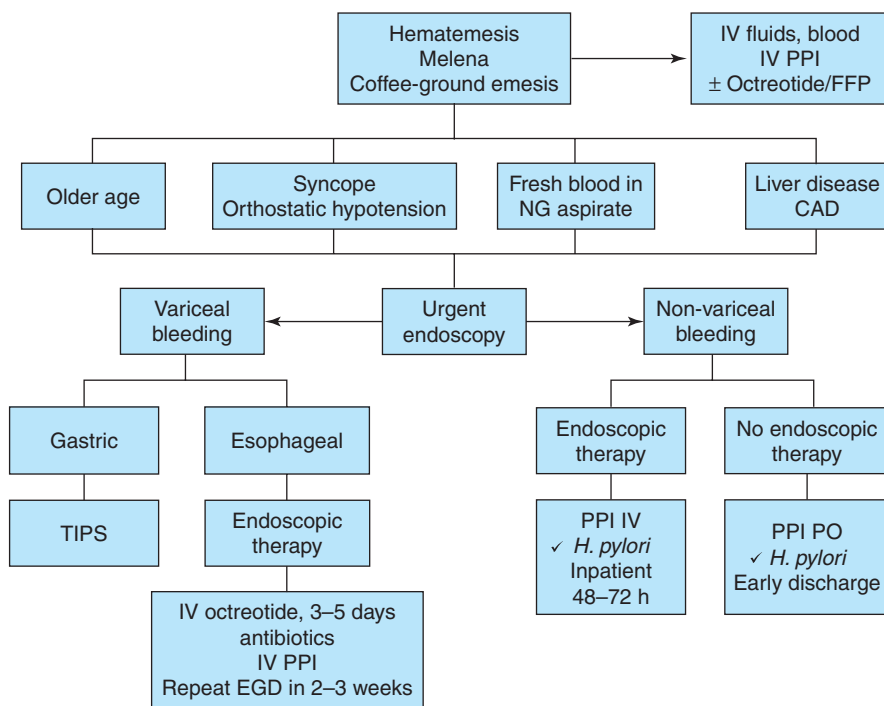

Risk Stratification

Initial evaluation and the patient's response to resuscitation determine patient risk, and patients can be stratified into high- or low-risk categories for rebleeding and mortality. Indeed, 80% of patients with UGI bleeding stop bleeding without treatment. It is crucial to identify the remaining 20% who are at increased risk for continued bleeding and mortality.

Multiple scoring systems have been proposed based on both clinical and endoscopic criteria. Because physicians typically determine risk prior to endoscopy, risk stratification schemes based on clinical parameters alone are most practical.

Predictors of rebleeding and mortality are age greater than 65 years, shock, comorbid illnesses, bright red blood per rectum or in the emesis, low initial hemoglobin, and high transfusion requirements. For example, a scoring system that has been prospectively validated recently includes initial vital signs, presence of syncope or melena, hemoglobin, BUN, and presence of hepatic or cardiac disease. This system correctly identified up to 99% of patients with serious bleeding and more than 20% of low-risk patients who were further managed as outpatients. However, because such risk stratification schemes mostly come from cohort studies, concerns remain about their prospective validity.

We use a simple risk stratification system based on patient age, orthostatic changes in blood pressure or heart rate or syncope, history of cardiopulmonary or liver disease, and fresh blood in emesis or NG aspirate. Patients with these clinical predictors are considered to be at high risk for continued bleeding and mortality. Such patients require ICU monitoring and endoscopy in the ICU immediately after resuscitation is completed (Figure 33-1). In life-threatening hemorrhage, when patients fail initial resuscitation, we perform endoscopy in the operating room with surgical service backup rather than delaying endoscopy with repeated resuscitation attempts.

▲ Figure 33-1. Management of upper gastrointestinal bleeding.

Causes of UGI Bleeding

Causes of acute UGI bleeding can be grouped into six main categories based on anatomic and pathophysiologic parameters: ulcers or erosions, portal hypertension, vascular lesions, trauma, tumors, and miscellaneous (Table 33–2). For decades, peptic ulcer disease has been the most common cause of UGI bleeding, followed by esophageal varices. Recently, the trends have changed (Table 33–3). The latest review of the Clinical Outcomes Research Initiative (CORI) database showed that peptic ulcer disease accounts for fewer than 21% of UGI bleeding episodes. Nowadays, the most

Table 33–2. Causes of upper gastrointestinal bleeding.

Ulcerative erosive	Peptic ulcer disease Infectious (<i>H. pylori</i> , CMV) NSAIDs, ASA Stress-induced Zollinger-Ellison syndrome
	Esophagitis Peptic Infectious (<i>Candida</i> , HSV, CMV) Pill-induced (alendronate, ASA, NSAIDs, tetracycline)
Portal hypertension	Varices Esophageal Gastric Portal hypertensive gastropathy
Vascular malformation	Arteriovenous malformations Idiopathic angiomas Osler-Weber-Rendu syndrome Dieulafoy's lesion Radiation-induced telangiectasia Gastric antral vascular ectasia
Traumatic, postoperative	Mallory-Weiss tear Foreign body Aortoenteric fistula
Tumors	Benign Leiomyoma Gastrointestinal stromal tumors Lipoma Polyps (adenomatous, inflammatory) Malignant Adenocarcinoma GI stromal tumor Sarcomas Lymphoma Carcinoid Melanoma Kaposi's sarcoma
Miscellaneous	Hemobilia Hemosuccus pancreaticus Meckel's diverticulum

Table 33–3. Common causes of upper gastrointestinal bleeding.

Cause	Relative Frequency
Mucosal abnormalities	37%
Peptic ulcer disease	21%
Esophagitis	15%
Varices	12%
AVM	6%
Mallory-Weiss tear	5%
Tumors	4%

common cause is nonspecific mucosal abnormalities (such as erosions), responsible for 42% of UGI bleedings. This changing dynamic is most likely brought about by widespread use of NSAIDs and by increased recognition and treatment of *Helicobacter pylori* infection.

A. Peptic Ulcer Disease—Peptic ulcer disease can be a result of *H. pylori* infection, NSAID use, stress, or excess gastric acid exposure. *H. pylori* is a spiral gram-negative bacterium found in 90% of duodenal ulcers and 70% of gastric ulcers. It is thought to be transmitted via the fecal-oral route and is commonly acquired in early childhood. *H. pylori* does not typically invade mucosa but makes mucosa more susceptible to gastric acid damage. It also stimulates host immune response, resulting in chronic inflammation (gastritis) and further mucosal damage. Most infected individuals are asymptomatic, but in some, chronic inflammation and increased gastric acid secretion lead to ulcer formation.

NSAIDs are another common cause of gastroduodenal ulceration. Aspirin and NSAIDs are prescribed very often, and their use is particularly widespread in the elderly because of aspirin's cardioprotective effects and the role of NSAIDs in osteoarthritis management. Until recently, NSAID-related injury was thought to be limited primarily to the stomach and duodenum. Later reports showed that NSAIDs are also a common cause of distal small bowel and even colonic ulceration. NSAID-induced mucosal injury results from both direct topical and systemic effects of prostaglandin inhibition. NSAIDs also can be a contributing factor to nonhealing ulcers from other causes. Although erosions and small ulcerations are found frequently in NSAID users, most patients are asymptomatic. The risk of clinically significant ulceration and bleeding with chronic NSAID treatment is about 1%.

Peptic ulceration also commonly occurs with severe stress, including major trauma, burns, sepsis, and multiorgan system failure. The injury is likely the result of impaired mucosal defense mechanisms secondary to decreased mucosal blood flow. Over the past decade, the incidence of stress-induced ulcer bleeding has been declining, with the recently reported rate in critically ill patients only 1.5%. The

decrease in incidence is probably due to wide use of stress-ulceration prophylaxis in ICU patients.

B. Portal Hypertension—Varices are a hallmark of portal hypertension, most commonly caused by liver cirrhosis. The lifelong risk of variceal bleeding is about 50% in cirrhotic patients. For patients with variceal bleeding, prognosis is poor. Without treatment, the risk of rebleeding is 70%. Each episode of variceal bleeding carries 30% mortality rate.

The size, location, and endoscopic appearance of varices and the Child-Pugh score are the most important independent predictors of variceal bleeding. Varices that are larger than 6 mm or that occupy more than a third of the lumen portend the highest risk of bleeding. Esophageal varices are responsible for most cases of variceal bleedings, whereas gastric varices account for fewer than 30%. Usually, gastric varices are found in combination with esophageal varices, but isolated gastric varices should prompt evaluation for splenic vein thrombosis. If isolated splenic vein thrombosis is present, splenectomy is the therapy of choice. Gastric varices, and in particular, isolated fundic varices, tend to produce severe and difficult-to-control bleeding. Endoscopic appearance of varices is also a bleeding risk predictor. Red streaks or “cherry” or cystic spots (“blood blisters”) are high bleeding risk endoscopic stigmata.

Development of varices parallels the progression of liver disease. Thus patients with higher Child-Pugh scores are more likely to have varices and are at higher risk for variceal bleeding. As an example of these factors put together, a Child’s C cirrhotic patient with large varices and endoscopic red streaks has a 76% yearly risk of variceal bleeding, whereas the risk drops to 10% for a Child’s A patient without other risk factors.

UGI Bleeding Diagnosis and Treatment

Over the past decade, significant advances have been made in the diagnosis and treatment of UGI bleeding. Endoscopy has evolved from a merely diagnostic technique into a commonly used therapeutic modality. Endoscopic therapy

decreases mortality and the need for surgery and reduces rebleeding rates, length of hospital stay, and transfusion requirements. Endoscopy also plays an important role in patient risk stratification, allowing for significant cost savings. The armamentarium of available diagnostic techniques has further expanded with the invention of capsule endoscopy. A small camera/capsule is swallowed by the patient and transmits 360-degree pictures throughout the UGI tract. In particular, capsule endoscopy significantly improves localization of small bowel bleeding lesions. Another new endoscopic technique is double-balloon enteroscopy, which allows for endoscopic examination of the entire small bowel. It is still under development and has limited availability.

A combination of endoscopic and pharmacologic therapies is successful in great majority of UGI bleeding patients. Currently, 95% of UGI bleeding patients respond to combined endoscopic and pharmacologic therapy. Therefore, surgery and interventional radiology techniques are reserved for patients who fail endoscopic management. Below we focus on endoscopic and pharmacologic approaches to the two main types of UGI bleeding: peptic ulcer and variceal bleeding.

Peptic Ulcer Disease

A. Endoscopic Diagnosis and Treatment of Peptic Ulcer Bleeding

Endoscopic findings determine the need for endoscopic therapy and guide further decisions on hospitalization and the extent of follow up (Table 33–4). Active bleeding, a visible vessel, and adherent clot are considered high-risk endoscopic signs. Endoscopic therapy is recommended for such patients, and they need to be monitored closely for signs of rebleeding. Indeed, without endoscopic therapy, an ulcer found to be actively bleeding during the endoscopy has a 90% rebleeding rate after bleeding stops spontaneously. On the other hand, no endoscopic therapy is indicated for clean base ulcers (low-risk finding). Such patients can be discharged safely after endoscopy with close outpatient follow-up.

Table 33–4. UGI bleeding: endoscopic stigmata and risk of rebleeding without and with endoscopic therapy.

	Endoscopic Stigmata	Prevalence	Rebleeding Risk without Endoscopic Therapy	Rebleeding Risk after Endoscopic Therapy
High risk	Active arterial bleeding	10%	90%	18%
	Nonbleeding visible vessel	25%	40–50%	10–15%
	Adherent clot	10–14%	25–35%	0–5%
	Oozing without visible vessel	10%	10–20%	<1%
Low risk	Flat spot	10%	7%	N/A
	Clean-base ulcer	35%	3–5%	N/A

Modified from Katschinski B et al: *Dig Dis Sci* 1994;39:706; and from Center for Ulcer Research and Education: Digestive Disease Research Center, Hemostasis Research Group, UCLA School of Medicine and the West Los Angeles VA Medical Center.

Modern endoscopic therapeutic techniques include injection of vasoconstrictive agents, thermal therapy, and use of mechanical devices. Injection therapy employs a needle with retractable tip, with epinephrine the most commonly used agent. Injections are frequently combined with thermal therapy. A bipolar coagulation or heater probe is physically compressed against the bleeding vessel, and thermal energy then seals the vessel wall. More recently, mechanical devices, in particular endoscopic clips, are being used increasingly in ulcer hemostasis. A number of studies have shown significantly decreased rebleeding rates with the combination of endoscopic clips and injection therapy compared with injection therapy alone. However, clips are difficult to place in a scarred-down ulcer, and they also are more likely to fall off in this situation. Overall, clip application is more operator- and position-dependent than other modalities.

B. Pharmacologic Therapy for Peptic Ulcer Bleeding—

Pharmacologic therapy by acid suppression is the cornerstone of peptic ulcer bleeding management. Indeed, clot lysis occurs at pH less than 6, and platelet aggregation is enhanced at pH greater than 6. Proton pump inhibitors (PPIs) are the main acid suppressive agents. A high-dose PPI bolus followed by continuous infusion is particularly efficacious after endoscopic therapy. A recent large double-blind, randomized trial showed 6.7% versus 22.5% rebleeding rates in patients on continuous intravenous PPIs after endoscopic therapy compared with placebo. PPIs also decreased rebleeding and surgery rates compared with histamine-2 (H_2) blockers. Data also support the use of empirical high-dose PPI therapy prior to endoscopy.

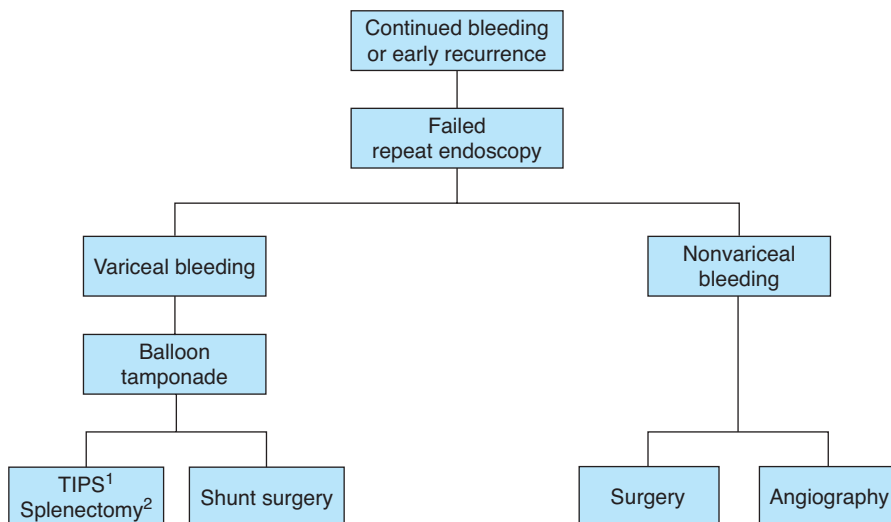

H. pylori eradication is important in peptic ulcer bleeding management, in particular for prevention of ulcer recurrence. *H. pylori* serology and antral biopsy are the preferred tests in acute bleeding. *H. pylori* eradication should be confirmed after treatment with a urea breath test.

Intravenous octreotide has been studied in nonvariceal acute UGI bleeding, but its effectiveness remains undetermined.

C. Recurrent Peptic Ulcer Bleeding and Endoscopic Therapy Failures—

Effective hemostasis is attained endoscopically in more than 95% of ulcers that are actively bleeding or have high-risk endoscopic stigmata. However, high-risk ulcers have a 15% risk of rebleeding, usually in the first 72 hours after index bleed. Active spurting of blood and large (>2 cm) ulcers were independent risk factors for endoscopic therapy failure in a recent prospective study. Therefore, a “second look” endoscopy is usually indicated in case of rebleeding, with a 73% rate of long-term hemostasis.

Failure of the second endoscopic therapy attempt should initiate consideration for alternative treatments, in particular surgery (Figure 33–2). According to a recent large registry of UGI bleeding cases, 6.5% of patients with bleeding peptic ulcers underwent surgery for continued bleeding or rebleeding. With the effective medical therapies available, the goal of surgery is no longer ulcer cure but control of hemorrhage in these patients. The choice of surgical procedure includes simple oversewing of the ulcer (with or without vessel ligation), ulcer excision, or radical surgery (ie, depending on ulcer location, vagotomy with antrectomy or gastrectomy). In a recent review of surgical options, conservative therapy

¹Treatment of choice for gastric varices

²Treatment of choice for isolated splenic vein thrombosis & gastric varices

▲ **Figure 33–2.** Upper gastrointestinal bleeding: failures of endoscopic therapy.

with oversewing of the ulcer had rates of morbidity and mortality comparable with those of more radical surgery. However, rebleeding rate was somewhat higher. Current recommendations are for ulcer excision in patients with a bleeding gastric ulcer, but gastric resection should be performed for a large penetrating ulcer. Duodenal ulcers should be oversewn and vessel ligation performed.

Patients who are not surgical candidates can be considered for a third endoscopic therapy attempt or for therapeutic angiography. The latter showed a 50–90% success rate in management of large gastroduodenal ulcers. Intraarterial vasopressin infusion and embolization with microcoils, gelatin, or polyvinyl alcohol particles are the main angiographic techniques in ulcer hemostasis. With selective catheterization, complications of embolization such as bowel ischemia, perforation, abscess formation, and hepatic infarction are rare.

Variceal Bleeding

A. Endoscopic Diagnosis and Treatment of Variceal Bleeding—Endoscopy is critical in all aspects of variceal bleeding management: to identify the patients at risk, to prevent a first bleed, to treat active bleeding, and to decrease the risk of rebleeding. Both esophageal and gastric (near the cardia) varices can be treated endoscopically, with overall success rates of about 90% (see Figure 33-1). However, gastric varices often require additional treatment modalities to prevent rebleeding.

Two endoscopic techniques are applied most often for variceal bleeding hemostasis: sclerotherapy, which has been in use for 60 years, and more recently, band ligation. In sclerotherapy, a sclerosant (routinely 5% ethanolamine) is injected via a retractable-tip needle into the varix and/or surrounding tissues, leading to coagulation necrosis and variceal thrombosis. Repeated sclerotherapy can be performed until there is complete eradication of esophageal varices. However, sclerotherapy has been associated with 2–5% mortality and up to a 20% major complication rate. Major complications include deep ulcerations, stricture formation, esophageal perforation, and mediastinitis. Transient bacteremia is common during sclerotherapy, and antibiotics should be given to at-risk patients prior to sclerotherapy.

In recent years, band ligation has replaced sclerotherapy as the primary endoscopic treatment of variceal bleeding, and it is equally efficacious but much safer. In this procedure, a rubber band is placed on the varix via a device attached to the endoscope. The band effectively strangulates the varix, resulting in varix thrombosis. Multiple bands can be deployed in one setting. The effect of the band is local, and systemic complications are rare. In several studies, band ligation was compared with sclerotherapy for the prevention of esophageal varices recurrence. Rebleeding rate and number of sessions needed for variceal obliteration were significantly lower with band ligation (6% and four sessions compared with 21% and five sessions for sclerotherapy). On the other hand, recurrence of varices at 1 year was less with sclerotherapy

(8% versus 29% for band ligation). Some experts recommend combining band ligation and sclerotherapy at the final therapy session to improve long-term eradication of varices.

B. Pharmacologic Therapy of Variceal Bleeding—Pharmacologic therapy is a necessary component of variceal bleeding management. Octreotide, a long-acting analogue of somatostatin, is used most commonly owing to its safety and ease of administration. Octreotide is thought to work, at least in part, by decreasing splanchnic blood flow. Octreotide typically is given as a bolus followed by continuous infusion. Optimal duration of therapy is not well defined, but 3–5 days of administration after the bleeding episode is typically recommended. Octreotide, used in combination with endoscopic therapy, has been shown to significantly improve short-term hemostasis rate (66% versus 55% for band ligation alone).

Prophylactic use of antibiotics in cirrhotic patients with UGI bleeding is another important aspect of variceal bleeding management. Indeed, bacterial infections are found in up to 20% of cirrhotic patients with UGI bleeding. Antibiotic prophylaxis not only reduces infectious complications but also has shown a trend toward improved mortality. The choice of antibiotic and duration of therapy are not well established. An oral quinolone is used commonly for 7–10 days after the bleeding episode.

Several uncontrolled studies suggest that acid suppression (ie, with a PPI) might be another useful addition to endoscopic therapy, in particular in healing of postsclerotherapy or post-band ligation ulcers. Nonselective β -blockers and nitrates have a limited role in acute variceal bleeding setting and should be reserved for outpatient rebleeding prevention.

C. Recurrent Variceal Bleeding and Endoscopic Therapy Failures—In 10–20% of patients, combined endoscopic and pharmacologic therapy fails to achieve long-term hemostasis. The highest risk for rebleeding is in the first 48 hours, as well as up to 6 weeks after the index bleed. Generally, repeat endoscopy is recommended in early hemostasis failure. Alternative endoscopic therapeutic modality should be applied in these cases, such as sclerotherapy if initial band ligation was unsuccessful.

Surgery and transjugular intrahepatic portosystemic shunting (TIPS) are the two main treatment options for patients who have failed endoscopic therapy (see Figure 33-2). Balloon tamponade usually is attempted to address acute severe bleeding until one of these options is chosen. The Sengstaken-Blakemore tube, with both esophageal and gastric balloons, is used most commonly for tamponade. Short-term hemostasis rates vary from 30–90%, and rebleeding usually occurs after balloon deflation. Balloon tamponade is associated with a number of significant complications, in particular esophageal rupture and aspiration. To prevent these complications, the esophageal balloon should not be inflated for more than 24 hours, and tamponade should be performed only in patients with an endotracheal tube in place.

Surgery is effective in variceal bleeding. Unfortunately, most variceal bleeding patients present with decompensated cirrhosis, making them poor surgical candidates. Nowadays, both nonselective (ie, portocaval) and selective (ie, splenorenal) shunts are used for variceal bleeding control. Nonshunting operations, such as gastroesophageal devascularization (Sugiura procedure), are performed rarely. Perioperative morbidity and mortality are quite high for emergent shunt operations, and management is further complicated by a 40–50% incidence of encephalopathy. Surgical shunting also significantly alters vascular anatomy, making future liver transplantation more challenging.

In recent years, TIPS has emerged as a safer and easier-to-perform alternative to surgical shunting. TIPS is done by an interventional radiologist and requires only local anesthesia or light sedation. The stent is passed via the transjugular route and connects the hepatic vein with an intrahepatic portion of the portal vein, thus creating a portosystemic shunt. TIPS is effective in more than 90% of variceal bleeds. It is the treatment of choice for gastric variceal bleeding because endoscopic therapy usually does not prevent rebleeding of gastric varices. As with surgical shunts, post-TIPS encephalopathy is common (~30% incidence). Another limitation of TIPS is frequent stent stenosis or thrombosis leading to multiple revisions and restenting.

▶ Lower Gastrointestinal Bleeding

ESSENTIALS OF DIAGNOSIS

- ▶ Hematochezia (bright red or maroon stools).
- ▶ Initial evaluation is similar for lower and upper GI bleeding patients.
- ▶ Patients younger than 50 years of age with self-limited mild lower intestinal bleeding (most likely owing to internal hemorrhoids) can be further evaluated with colonoscopy or flexible sigmoidoscopy as outpatients.
- ▶ Urgent colonoscopy is indicated in the presence of unstable vital signs, continued bleeding, or more than two comorbid conditions.
- ▶ Life-threatening lower intestinal bleeding require consideration of emergent angiography or surgery without delaying for bowel preparation/colonoscopy.

General Considerations

Lower intestinal bleeding is characterized by a lesion location distal to ligament of Treitz. Most often the source of bleeding is colonic. Hematochezia (ie, bright red or maroon colored stools) is the classic clinical presentation. Although severe lower intestinal bleeding is less common than UGI bleeding, it is a frequent GI emergency. On average, a full-time gastroenterologist sees more than 10 severe lower intestinal bleeding cases per year.

Initial Approach, Resuscitation, and Risk Stratification

The main principles of initial evaluation and resuscitation of UGI bleeding apply equally to lower intestinal bleeding. The goals are the same: to assess bleeding severity based on the degree of hemodynamic compromise, to evaluate comorbid illnesses, and to optimize the patient's condition prior to treatment. Syncope or postural hypotension is indicative of

potentially massive bleeding. In such cases, NG aspiration should be performed to exclude an upper bleeding source. In hematochezia without hemodynamic compromise, severe UGI bleeding is unlikely, and NG tube placement might not be necessary. After assessing bleeding severity, attention should be paid to exacerbation of comorbid illnesses. In particular, evaluation for cardiac ischemia is important because lower intestinal bleeding is frequent in elderly patients.

Resuscitation of lower and upper GI bleeding patients involves similar approaches. As described earlier for UGI bleeding, resuscitation aims to quickly restore intravascular volume with crystalloids, colloids, and blood and to correct hemostatic abnormalities, if present. Patients with severe bleeding should be admitted to an ICU, and surgical consultation should be obtained early in the course of hospitalization.

In most patients, lower intestinal bleeding stops spontaneously. Thus it is crucial to identify patients who are at high risk for continued bleeding. Commonly reported clinical predictors are hypotension and tachycardia, continued rectal bleeding during the first 4 hours of hospitalization, absence of abdominal pain, use of aspirin, and presence of at least two comorbid conditions. Prospective validation of this risk stratification scheme showed 0% rebleeding in a low-risk group compared with 77% in a high-risk group.

► Causes of Lower Intestinal Bleeding

Diverticulosis, colitis (ie, ischemic, infectious, or postradiation), cancer, and angiodysplasia are the main causes of severe lower intestinal bleeding (Table 33–5). Hemorrhoids are a frequent cause of rectal bleeding, especially in patients younger than 50 years. However, hemorrhoidal bleeding is rarely severe.

Diverticulosis is responsible for more than 30% of lower intestinal bleeding. Colonic diverticula are mucosal and submucosal herniations through the muscle layer, thought to develop owing to increased intraluminal pressure or decreased colonic wall muscle tone. They are found in half the adult population in the Western hemisphere, and the incidence increases with age. Bleeding occurs in only 5–15% of patients with diverticular disease. However, lower GI bleeding can be massive in a third of those patients. Painless hematochezia is the classic clinical presentation of diverticular bleeding. In 75%, diverticular bleeding stops spontaneously, but the risk of rebleeding is 25–38% in the following 4 years.

Colitis (inflammation of the colon) is another common cause of severe lower intestinal bleeding. Of note, mortality rates as high as 20–50% have been reported in hospitalized patients with ischemic colitis bleeding. Hematochezia in ischemic colitis is typically accompanied by mild abdominal pain, differentiating it from painless diverticular bleeding. The mechanism of mucosal ischemia is thought to be hypoperfusion of small intramural vessels rather than large vessel occlusion. Ischemic colitis can occur throughout the colon, but watershed areas such as at the splenic flexure or rectosigmoid junction are affected most frequently. Ischemic colitis

Table 33–5. Severe lower gastrointestinal bleeding: causes.

		Relative Frequency
Anatomic	Diverticulosis	33%
Vascular malformations	Arteriovenous malformations Idiopathic angiomas Osler-Weber-Rendu syndrome Radiation-induced telangiectasia	Angiodysplasia, 8%
Inflammatory	Ischemic colitis Infectious colitis Inflammatory bowel disease Radiation colitis	18%
Neoplasm	Polyps Carcinoma	19%
Other	Hemorrhoids Ulcer Postbiopsy, postpolypectomy	18%

sometimes occurs after extensive surgical procedures or as a result of systemic hypotension.

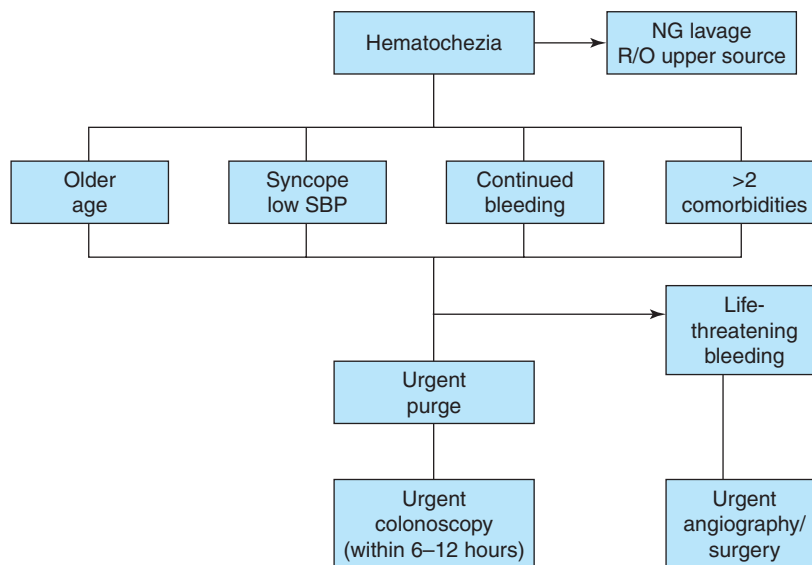

Infectious and inflammatory colitis rarely cause severe lower intestinal bleeding. However, infectious colitis, in particular secondary to *Clostridium difficile*, can mimic ischemic colitis and should be excluded as part of the workup for hematochezia and colitis.

Angiodysplasias (arteriovenous malformations) account for about 8% of severe lower intestinal bleeding, but its incidence has been decreasing in recent years. Angiodysplasia is associated with renal failure and hereditary hemorrhagic telangiectasia syndrome (Osler-Weber-Rendu syndrome). An association with aortic stenosis is less clear.

Colon cancer typically presents with occult blood loss rather than overt hematochezia. Severe lower intestinal bleeding usually is caused by cancer ulceration, signifying an advanced stage.

Diagnosis of Lower Intestinal Bleeding

Colonoscopy is typically the first step in evaluation of lower intestinal bleeding (Figure 33–3). Its main advantage is that both diagnosis and treatment can be accomplished in one procedure. However, downsides are the requirement for bowel preparation and the small, albeit identifiable, risk of sedation. Notably, management of severe life-threatening lower intestinal bleeding (ie, angiography or surgery) should not be delayed for bowel preparation/colonoscopy. Some gastroenterologists perform colonoscopy on unprepared bowel because blood is cathartic.

▲ **Figure 33-3.** Management of lower gastrointestinal bleeding.

Occasionally, flexible sigmoidoscopy on unprepared bowel is sufficient, in particular as a quick check for ischemic or infectious colitis. In most cases, we recommend urgent bowel purge with polyethylene glycol (4–6 L) over 3–5 hours via NG tube or orally. Metoclopramide can be used in conjunction with the purge to improve gastric emptying and decrease nausea. Sodium phosphate preparations should not be used in the acute setting because of high phosphate and sodium loads. Radiographic studies should be obtained prior to the bowel preparation to rule out perforation or intestinal obstruction.

The overall diagnostic yield of colonoscopy in lower intestinal bleeding is between 48% and 90% (mean 68%). There are conflicting data on the optimal timing for colonoscopy. One recent report suggests that diagnostic yield improves with urgent colonoscopy. We usually perform colonoscopy for severe lower intestinal bleeding within 6–12 hours of hospitalization, after resuscitation and bowel preparation.

Treatment of Lower Intestinal Bleeding

Although surgery is the most common treatment modality for lower intestinal bleeding, endoscopic therapeutic options have been expanding in recent years. In particular, bipolar coagulation is used successfully for angiodysplasia bleeding. In diverticular hemorrhage, a visible bleeding vessel or clot (high-risk stigmata) can be treated with sclerotherapy and bipolar coagulation similar to peptic ulcer bleeding. Use of endoscopic clips in diverticular bleeding is currently under investigation. Significantly decreased short- and long-term rebleeding rates have been reported for endoscopic therapy of diverticular bleeding. However, urgent colonoscopy and

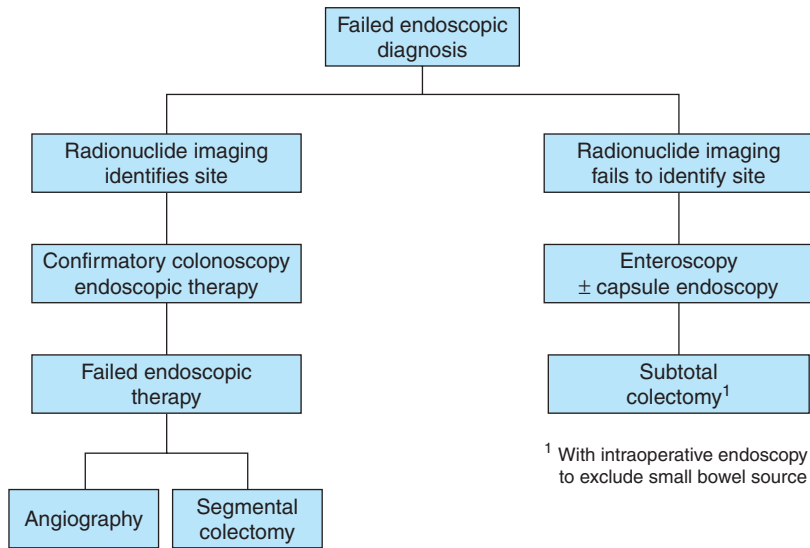

experience in advanced endoscopic techniques are needed to achieve high hemostasis success rates.

Failure of Endoscopic Diagnosis and Treatment

Radionuclide imaging typically is the next step in the localization of a bleeding site after unsuccessful colonoscopy (Figure 33-4). Radiolabeled red blood cells are injected intravenously, and focal collections of radiolabeled material are detected by scintigraphy. A 78% accuracy rate has been reported, and bleeding as slow as 0.1–0.5 mL/min can be identified. However, confirmatory colonoscopy is recommended in the case of a positive radionuclide test owing to rather high false-positive rates, typically a result of blood from a UGI source collecting in the right colon.

Angiography is another diagnostic and therapeutic modality used in case of colonoscopic failure. Angiography is highly specific, but its sensitivity is significantly lower than that of radionuclide imaging or colonoscopy. For angiography to be positive, bleeding must be brisk, at a rate of more than 1–1.5 mL/min. Since most lower GI bleeding stops spontaneously, the timing of the angiography procedure is particularly important. The overall diagnostic yield varies widely from 12–69%. Some experts recommend radionuclide imaging prior to angiography to increase sensitivity. However, this would further delay angiography and potentially decrease its diagnostic yield.

After the bleeding site is identified angiographically, vasopressin can be infused or a vessel can be selectively embolized to stop the bleeding. Hemostasis rates of 91% have been reported after intraarterial vasopressin in diverticular and angiodysplasia bleeding. However, the rebleeding rate can be

▲ **Figure 33-4.** Lower gastrointestinal bleeding: failures of endoscopic diagnosis.

as high as 50%. Angiography also has a fairly significant (up to 9%) rate of major complications, including intestinal ischemia, contrast-induced renal failure, femoral artery thrombosis, and transient ischemic attack.

Surgical Treatment

Surgery is recommended for continued bleeding (~10% of all patients presenting with lower intestinal bleeding; see Figure 33-4). If bleeding has been localized preoperatively, segmental resection is performed with or without a stoma. Reported surgical mortality is about 10%, mostly because of comorbid conditions.

In the case of bleeding that cannot be localized, enteroscopy and, if available, capsule endoscopy should be performed as a final attempt to identify the bleeding site. If the bleeding lesion is still not identified, a thorough surgical exploration is performed, with examination and palpation of the entire small intestine. If there is a significant amount of blood in the small intestine, intraoperative endoscopy can be performed. Exploratory laparotomy leads to localization of the bleeding site in 78% of patients without preoperative diagnosis.

In the absence of an identified source of bleeding, subtotal colectomy is undertaken with ileorectal anastomosis or ileostomy with Hartmann's pouch. Emergent subtotal colectomy carries significant morbidity (37%) and mortality (11%). However, segmental colectomy without a definitive source of bleeding is associated with an unacceptably high 30% rebleeding rate.

Hepatobiliary Disease

Hernan I. Vargas, MD

Liver disease is the ninth leading cause of death in the United States, resulting in approximately 30,000 deaths each year. Cirrhosis represents the final common pathway for a wide variety of chronic liver diseases. Cirrhosis is defined as a diffuse fibrotic process in the liver. Grossly abnormal nodules replace the normally smooth hepatic parenchyma.

Patients with cirrhosis often develop complications from their underlying liver disease such as upper GI bleeding, renal insufficiency, ascites, or encephalopathy and require critical care. In other circumstances, cirrhotic patients may require critical care owing to unrelated problems such as trauma, cancer, or major surgery. The physician caring for patients in the ICU therefore should be knowledgeable about disorders of liver function.

▶ Acute Hepatic Failure

ESSENTIALS OF DIAGNOSIS

- ▶ Acute onset.
- ▶ Jaundice.
- ▶ Encephalopathy.

General Considerations

Acute hepatic failure is a rapid-onset, severe impairment of liver function. The natural history is that of progressive deterioration with multiple-system organ failure. Prior to the availability of liver transplantation, the mortality was as high as 80%.

The interval between the development of jaundice and the onset of encephalopathy has been used to classify hepatic failure as hyperacute (0–7 days), acute (8–28 days), and subacute (28 days–12 weeks).

Acute viral hepatitis (ie, hepatitis B [HVB], and hepatitis A [HVA]) and acetaminophen toxicity are the most common

causes of acute hepatic failure in the United States. Other causes are as listed in [Table 34–1](#).

Clinical Features

A. Symptoms and Signs—The onset of symptoms is usually abrupt, characterized by malaise, fatigue, and loss of appetite. Less frequently, patients complain of abdominal pain and fever. The physical examination is significant for the presence of jaundice, hepatomegaly, and right upper quadrant tenderness.

Signs of developing encephalopathy range from mild personality change to confusion and deep coma. The presence of encephalopathy is a precondition for a diagnosis of acute hepatic failure. The severity of encephalopathy is measured in four stages ([Table 34–2](#)).

Patients with encephalopathy stage III or stage IV commonly suffer from cerebral edema and increased intracranial pressure. Cerebral edema is a common finding in patients who die from acute hepatic failure. The pathogenesis of cerebral edema has not been clearly elucidated. However, investigators have proposed a breakdown of the blood-brain barrier as an important mechanism. Sodium accumulation in the brain cells secondary to inhibition of Na^+, K^+ -ATPase also has been proposed. Cerebral edema causes an acute rise in the intracranial pressure that decreases perfusion pressure and cerebral blood flow. Autoregulation of cerebral blood flow is lost.

Oliguria and generalized edema occur commonly and are associated with higher mortality. They are typically caused by hypovolemia, acute tubular necrosis, or hepatorenal syndrome.

Late in the course, patients may develop upper GI bleeding and blood loss from the airways, puncture sites, and soft tissues.

The clinical course of acute hepatic failure is frequently complicated by bacterial and fungal infections. Infectious complications are a major contributor to increased morbidity and are the immediate cause of death in nearly half of

Table 34-1. Causes of acute hepatic failure.

Most common causes in USA
Acute viral hepatitis (HBV, HAV, HC)
Acetaminophen toxicity
Less common causes
Hepatitis D and E
Herpes simplex virus
Epstein-Barr virus
Drug toxicity
Antimicrobials (eg, ampicillin-clavulanate, ciprofloxacin, erythromycin, isoniazid, tetracycline)
Sodium valproate
Lovastatin
Phenytoin
Tricyclic antidepressants
Halothane
Other toxins

Amanita phalloides (mushrooms)
Organic solvents
Herbal medicines (eg, ginseng, pennyroyal oil, <i>Teucrium polium</i>).
Miscellaneous causes
Acute fatty liver of pregnancy
Autoimmune hepatitis
Budd-Chiari syndrome
Reye's syndrome
Wilson's disease
Indeterminate

fatal cases. The immune system is impaired by decreased function of the reticuloendothelial system and complement deficiency.

Coagulopathy may occur as a consequence of decreased production of coagulation factors by the liver, as a consequence of increased fibrinolysis, and from consumption, as in disseminated intravascular coagulation. Thrombocytopenia and platelet dysfunction are common.

Predictors of poor outcome are summarized in the King's College criteria (Table 34-3).

Treatment

Acute liver failure constitutes a medical emergency given the high incidence of multisystem organ failure and the high mortality. Patients with mild hepatic injury require maintenance therapy with adequate hydration, euglycemia, and electrolyte balance. Because the condition of patients with more severe liver damage may deteriorate rapidly, respiratory support is often needed—particularly when cerebral edema ensues.

A. Support Measures—

1. ENCEPHALOPATHY AND INTRACRANIAL HYPERTENSION—

Cerebral herniation is a major cause of death if cerebral edema and hypertension are untreated. Intracranial pressure measurement is used for diagnosis of intracranial hypertension and monitoring of intracranial pressure dynamics. The techniques for intracranial pressure monitoring are discussed in Chapter 31. Other monitoring techniques are measurements of cerebral blood flow (with xenon) and cerebral oxygen consumption (by calculating the arterial-jugular venous oxygen content difference).

The head of the bed is typically elevated 20–30 degrees to reduce intracranial pressure, although the cerebral perfusion pressure should be monitored to avoid an adverse impact from a decrease in systemic pressure. Patients being maintained on ventilatory support are subjected to mild hyperventilation to decrease cerebral hyperemia. Patient stimulation must be minimized by premedication prior to suctioning or postural changes in patients with severe intracranial hypertension. A number of other measures may decrease cerebral edema, such as mannitol (1 g/kg). Serum osmolarity should be monitored. Mannitol is contraindicated if the serum osmolarity is greater than 320 mOsm/L.

The use of barbiturates has been proposed as a means of lowering intracranial pressure in combination with hypothermia. Barbiturates decrease cerebral metabolism and further

Table 34-2. Stages of encephalopathy.

Stage	Mental Status	Tremor	Electroencephalography
I	Euphoria, occasionally depression; fluctuating mild confusion; slowness of mentation and affect; slurred speech; disorder in sleep rhythm	Slight	Normal
II	Drowsiness; inappropriate behavior.	Present	Generalized slowing
III	Sleeps most of the time but is arousable, confused; incoherent speech.	Present	Abnormal
IV	Unarousable	Absent	Abnormal

Table 34-3. Predictors of poor outcome in patients with acute hepatic failure (King's College criteria).

Acetaminophen toxic patients

Blood pH <7.30 (irrespective of grade of encephalopathy) or—
A combination of: encephalopathy stage III or IV, prothrombin time >100 s (INR >6.5), and serum creatinine >3.4 mg/dL

Nonacetaminophen toxic patients

Prothrombin time >100 s (INR >6.5) (irrespective of stage of encephalopathy) or—
Any three of the following five variables (irrespective of stage of encephalopathy):

1. Age <10 years or >40 years
2. Etiology: hepatitis C, halothane hepatitis, idiosyncratic drug reactions
3. Duration of jaundice before onset of encephalopathy of >7 days
4. Prothrombin time >50 s (INR >3.5)
5. Serum bilirubin level of >17.5 mg/dL

decrease cerebral blood flow and pressure. They also prevent seizures. Barbiturate use is controversial, however, because of their delayed metabolism owing to liver insufficiency.

2. CARDIOVASCULAR SUPPORT—Patients with acute liver insufficiency experience arteriovenous shunting and vasodilation that causes tachycardia and hypotension. The decreased clearance of vasoactive metabolites causes decreased systemic vascular resistance and increased cardiac output. Therefore, volume resuscitation and vasoactive drugs may be necessary as support measures. With this hemodynamic profile, an important differential diagnosis is sepsis.

3. COAGULOPATHY—Transfusion therapy is in general reserved for patients with active bleeding. It is indicated also prior to invasive procedures such as the placement of intracranial pressure monitoring.

4. RENAL FAILURE—Renal failure is common in patients with acute liver insufficiency. Maintenance of euolemia is critical. Avoidance of nephrotoxic drugs (ie, aminoglycosides) is important. If renal azotemia ensues, dialysis may be needed. Continuous venovenous dialysis or arteriovenous dialysis methods are preferred to avoid hemodynamic changes and hypotension associated with standard hemodialysis.

5. RESPIRATORY FAILURE—Airway intubation and mechanical ventilation are frequently used as the encephalopathy progresses to stage III. Acute respiratory distress syndrome (ARDS) occurs in one-third of patients, causing hypoxemia.

B. Liver Transplantation—The mortality of severe acute liver insufficiency in the absence of liver transplantation approaches 80%. Survival after orthotopic liver transplantation has improved in recent years from 50% to more than 80% in selected series. Unfortunately, only 40–60% of patients actually undergo transplantation owing to the shortage of available organ donors.

Contraindications to liver transplantation are malignancy, extrahepatic sepsis, irreversible brain injury from intracranial hemorrhage, and unresponsive cerebral edema.

Bioartificial liver support is being investigated in selected centers as a bridge to transplantation. Reports of hemoperfusion, plasmapheresis, and extracorporeal perfusion exist, but there has been limited success. Most recently, the development of hybrid bioartificial support systems using hepatocytes from human or xenogeneic sources has shown some promise.

▶ Acute Gastrointestinal Bleeding from Portal Hypertension

ESSENTIALS OF DIAGNOSIS

- ▶ Hematemesis, melena.
- ▶ Stigmata of chronic liver disease.
- ▶ Endoscopic evidence of bleeding varices.

General Considerations

Esophagogastric varices occur in 90% of patients with cirrhosis. Approximately one-third of these patients will experience GI bleeding, and between 30% and 50% of them will die during each episode. It is not unexpected that bleeding from esophagogastric varices accounts for one-third of all deaths in patients with cirrhosis.

Esophagogastric varices are dilated intramural veins associated with an extensive and tortuous capillary network. They are alternative pathways of venous flow around the increased vascular resistance in the intrahepatic and portal system. They occur as a consequence of portal hypertension. The development of varices is facilitated by systemic vasodilation and decreased vascular resistance present in cirrhotics.

Clinical Features

A. Symptoms and Signs—Patients with acute bleeding present with hematemesis. Patients with more chronic bleeding present with melena and symptoms of anemia, such as fatigue and weakness. Anemia may cause pallor and tachycardia.

B. Laboratory Findings—Anemia occurs frequently. Decreases in hemoglobin levels may not be detectable in an early assessment of the bleeding. Evidence of chronic hepatic dysfunction such as elevated serum aminotransferases, bilirubin, and alkaline phosphatase is commonly present.

Differential Diagnosis

Patients with cirrhosis may experience an upper GI bleed from other causes such as gastritis, peptic ulcer disease, esophageal ulceration, or mucosal tears (Mallory-Weiss syndrome). Endoscopy is essential for diagnosis.

Treatment

Initial management is based on restoring blood volume through intravenous hydration and transfusion. Coagulopathy should be corrected as appropriate with fresh-frozen plasma. In patients with significant bleeding or with altered sensorium, endotracheal intubation for protection of the airway may be necessary.

A. Medical Treatment—Vasoactive drugs may be started as soon as the diagnosis is suspected. These drugs have proven value in nonesophageal sites of bleeding, such as portal hypertensive gastropathy and gastric varices. Vasoconstrictors decrease portal flow and pressure by decreasing splanchnic arterial flow. Vasodilators decrease hepatic vascular resistance and cause peripheral vasodilation, resulting in reflex splanchnic vasoconstriction.

Vasopressin's main role is as a temporizing measure. An infusion of 0.2–0.4 units/min successfully controls acute variceal bleeding in half of patients. It is often used for 48–72 hours. However, recurrent episodes of bleeding are common (approximately 50%). By decreasing the rate of bleeding, it facilitates initial resuscitation and the performance of endoscopy for local definitive therapy of the bleeding varices. Secondary effects are significant vasoconstriction with hypertension, bradycardia, and risk of myocardial infarction. Vasopressin generally is used in conjunction with nitroglycerin. The combination, which reduces cardiac ischemia, is superior to vasopressin alone in controlling acute variceal bleeding. Nitroglycerin is also delivered via continuous infusion at a dose of 0.2 µg/kg per minute.

Somatostatin is an effective hormone in the control of acute variceal bleeding. An intravenous infusion of 25–50 µg/h has been found to be as effective as vasopressin, balloon tamponade, and sclerotherapy in prospective randomized trials. Octreotide, the longer-acting form of somatostatin, is the agent of choice in the initial management of acute variceal bleeding because it is at least as effective as vasopressin but has fewer side effects. Octreotide has been found to be as effective as balloon tamponade of the esophagus in a clinical trial.

B. Endoscopic Management—Sclerotherapy is the treatment of choice in the management of acute variceal bleeding. Sclerotherapy is successful in 60–90% of patients during initial management and is superior to vasopressin and balloon tamponade. Complications of sclerotherapy are esophageal ulceration, bleeding, perforation, bacteremia, and mediastinitis. Complications can occur in 10–30% of patients.

Variceal ligation is an alternative to sclerotherapy. The efficacy is high and comparable with that of sclerotherapy. There seems to be a trend toward fewer complications with ligation.

Balloon tamponade is used less frequently as a temporizing measure, showing an efficacy of approximately 60–70%, comparable with that of vasopressin and sclerotherapy but associated with a high complication rate. In a Sengstaken-Blakemore tube, the gastric balloon is passed into the stomach

and inflated; the esophageal balloon is inflated only if bleeding is not controlled by the gastric balloon to 35–50 mm Hg of pressure using manometer control. The lowest pressure possible that will control hemorrhage should be used. Serious complications, with a 5% mortality, include aspiration pneumonia, esophageal rupture, and mucosal ulceration. The risk of complications increases with prolonged use. However, use of a Blakemore-Sengstaken tube or a Linton tube can be a lifesaving maneuver if medical and endoscopic measures fail to stop bleeding.

C. Nonsurgical Shunts (Transjugular Portosystemic Shunt [TIPS])—This technique is used widely in the setting of acute variceal bleeding because it offers a rapid decompressive shunt that does not require laparotomy. It is used as primary treatment for patients with bleeding gastric varices and for patients with hypertensive portal gastropathy—mainly because of the difficulty and poor results with endoscopic management.

D. Surgical Treatment—Surgery plays a role in the management of patients who fail medical, endoscopic, and TIPS management of acute variceal bleeding. The surgical options are either shunt or nonshunt operations.

Shunt procedures are either total (eg, portacaval shunt, mesocaval shunt, and central splenorenal shunt) or selective (eg, distal splenorenal shunt). These procedures are so named because they *theoretically* divert all (total) or only part (selective) of the portal blood flow. The most commonly used operation in the emergency setting is a portacaval shunt. It is very effective in controlling acute bleeding and preventing rebleeding, but the mortality rate is as high as 50%. All surgical procedures have some undesirable side effects, including encephalopathy and/or ascites. The selective procedures lose their selective nature over time and also have undesirable side effects.

Gastroesophageal devascularization (Sugiura operation) is a nonshunt operation. It has fallen into disfavor because the recurrence rate of bleeding is high, but it is indicated in a selected subset of patients with portal vein thrombosis or segmental portal hypertension with an acute bleeding episode.

▶ Ascites

ESSENTIALS OF DIAGNOSIS

- ▶ History: abdominal distention.
- ▶ Physical examination: fluid wave, shifting dullness, and dullness to percussion.
- ▶ Abdominal ultrasound may detect up to 100 mL of ascitic fluid; ultrasound is useful in the diagnosis of patients with minimal ascites.
- ▶ Paracentesis; serum ascites albumin gradient >1.1 g/dL.

General Considerations

A typical circulatory dysfunction characterized by arterial vasodilation and high cardiac output coupled with increased sinusoidal pressure and hepatic insufficiency is the cause of ascites in cirrhotic patients. In addition, there is renal sodium and water retention caused by stimulation of the renin-angiotensin-aldosterone axis and activation of antidiuretic hormone (ADH) secretion by the relative underfilling of the arterial vascular compartment.

Over 50% of patients with cirrhosis will develop ascites. It is therefore one of the most common complications of cirrhosis. Once ascites develops, the median survival is approximately 1 year.

Clinical Features

A. Symptoms and Signs—Patients with large-volume ascites complain of increasing abdominal girth and abdominal pressure. Some patients complain of anorexia, early satiety, and nausea or flank pain. Clinical findings of abdominal distention and shifting dullness and demonstration of a fluid wave support the diagnosis of ascites. Other stigmata of liver disease that aid in diagnosis are jaundice, spider angiomas, and large periumbilical collateral veins in the abdominal wall (caput medusae).

B. Laboratory Findings—Diagnostic paracentesis is essential in the evaluation and management of patients with ascites. Inspection of the fluid in patients with portal hypertension reveals clear, straw-colored fluid. Laboratory evaluation includes cell count, cytologic examination, albumin and protein concentrations, and bacteriologic analysis. The serum-to-ascites albumin gradient, calculated by subtracting the ascitic fluid albumin level from the serum albumin level, has been shown to be effective in differentiating portal hypertensive from nonportal hypertensive ascites. Patients with a gradient of more than 1.1 g/dL can be diagnosed as having portal hypertension with a reliability of 97%. A gradient of less than 1.1 g/dL suggests nonportal hypertensive etiology. Further differentiation of the ascitic fluid as a transudate or exudate provides insight into the origin of ascites.

C. Imaging Studies—Ultrasonography may be helpful in the detection of small volumes of ascitic fluid. Duplex ultrasound of the portal and hepatic venous system is indicated if portal vein thrombosis or hepatic vein thrombosis is suspected. CT scanning is also helpful in the detection of small volumes of ascites, usually as an incidental finding when x-rays are requested for evaluation of intraabdominal pathology.

Differential Diagnosis

Cirrhosis and chronic liver disease are the most common causes of ascites (approximately 70–80% of patients). The differential diagnosis of ascites is set forth in [Table 34-4](#).

Table 34-4. Differential diagnosis of ascites.

Organ System	Cause
Hepatic	Cirrhosis Veno-occlusive disease
Cardiac	Right ventricular failure Constrictive pericarditis
Renal	Nephrotic syndrome Renal failure
Malignancy	Ovarian Gastric Colorectal Pancreatic
Immunologic	Tuberculosis
Pancreas	Pancreatitis
Lymphatic	Congenital anomaly Trauma
Digestive	Malnutrition
Endocrine	Myxedema

Spontaneous bacterial peritonitis is a frequent complication of cirrhotic patients with ascites. It has a 1-year mortality of 40% despite treatment with antibiotics. Because its inception can be subclinical, bacteriologic analysis should be done on every patient with new-onset ascites. Culture of ascitic fluid in blood culture bottles is more reliable and is successful in approximately 80% of patients.

Treatment

The treatment of ascites is directed at the underlying pathogenesis.

A. Medical Treatment—Patients with mild ascites may be managed with fluid (1.5 L/day) and sodium restriction (88 meq/day). Addition of an inhibitor of aldosterone (eg, spironolactone) provides a slow sodium loss with preservation of potassium. Initial doses are 100 mg/day but may be elevated progressively up to 400 mg/day. Monitoring of weight and electrolytes is important so that adjustments can be made to the initial therapy.

Patients with moderate ascites should, in addition, receive loop diuretics (eg, furosemide). An initial dose of 40 mg/day generally is well tolerated and may be increased up to 160 mg/day in adults. Careful monitoring of weight, electrolytes, and serum creatinine may prevent complications from diuretic therapy. Any rise in serum creatinine or urea nitrogen warrants reduction of the diuretic dosage. An initial daily weight loss of 500 g/day is acceptable in patients with moderate ascites. If patients have peripheral edema, a weight loss of approximately 1 kg/day is acceptable.

Patients with tense ascites in addition should be treated with paracentesis. Up to 4–5 L may be removed safely.

Attention to salt and water restriction is also a critical component of management. Patients who require large-volume paracentesis may develop rapid contraction of the intravascular space after fluid shifting. Clinical trials have documented a better outcome after large-volume paracentesis with the simultaneous infusion of intravenous albumin. Intravenous salt-poor albumin should be used routinely in patients undergoing large-volume paracentesis. As a rule of thumb, salt-poor albumin (~10 g/L of ascitic fluid) is infused concomitantly intravenously. Spontaneous bacterial peritonitis must be suspected in patients with known liver disease who present with fever, leukocytosis, and abdominal pain. Cell count of the ascitic fluid is diagnostic if the polymorphonuclear neutrophil count is 250 in the absence of a visceral source of infection. Treatment should be initiated empirically on diagnosis. A third-generation cephalosporin such as ceftriaxone or cefotaxime generally is the first-line therapy until a specific organism has been selected on the basis of ascitic fluid culture. A 5-day course generally is therapeutic. Most common organisms are *Escherichia coli*, *Klebsiella*, and *Streptococcus pneumoniae*. Other organisms are *Enterococcus*, *Bacteroides*, and *Enterobacter*. Antibiotics with a nephrotoxic profile, such as aminoglycosides, should be avoided if at all possible.

B. Surgical Treatment—Ten percent of patients develop intractable ascites. Refractory ascites may be treated by the placement of a transjugular intrahepatic portosystemic shunt. Transjugular intrahepatic portosystemic shunt insertion lowers the rate of ascites recurrence and the risk of developing hepatorenal syndrome compared with paracentesis plus albumin administration in patients with refractory ascites. However, a recent meta-analysis documented increased encephalopathy and absence of improvement in survival. Transjugular intrahepatic portosystemic shunt insertion is also recommended in the treatment of patients with severe ascites and imminent rupture of umbilical/ventral hernia or hepatic hydrothorax.

Operative therapy with placement of a peritoneovenous shunt may be considered in patients with mild, stable liver dysfunction who are otherwise refractory to less invasive therapies. Although shunting is a simple surgical procedure, the incidence of postoperative complications is high, related to infection, coagulopathy, congestive heart failure, and early shunt occlusion.

Patients with severe or rapidly deteriorating liver dysfunction should be considered for liver transplantation.

▶ Hepatorenal Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Chronic liver disease.
- ▶ Renal failure.
- ▶ Circulatory abnormalities (low systemic vascular resistance and blood pressure).

General Considerations

Hepatorenal syndrome is a clinical condition that occurs in patients with chronic liver disease, advanced hepatic failure, and portal hypertension characterized by impaired renal function. The prevalence of hepatorenal syndrome in patients with end-stage cirrhosis ranges between 7% and 15%. It is associated with marked abnormalities in the arterial circulation and activity of the endogenous vasoactive system. Severe renal vasoconstriction causes a low glomerular filtration rate (GFR), whereas in the extrarenal circulation there is predominance of arterial vasodilation, which results in reduction of total systemic vascular resistance and arterial hypotension.

Hepatorenal syndrome is caused by severe vasoconstriction of the renal circulation. A number of vasoactive mediators are implicated in the development of vasoconstriction, such as angiotensin II, norepinephrine, neuropeptide Y, endothelin, adenosine, and cysteine leukotrienes. The most commonly accepted explanation is the arterial vasodilation theory, which proposes that renal hypoperfusion represents the extreme manifestation of underfilling of the arterial circulation secondary to massive vasodilation of the splanchnic circulation. Splanchnic vasodilation is caused by nitric oxide, prostaglandins, and vasodilator peptides. In the early phase, urine output and renal function are maintained by renal vasodilator factors. Hepatorenal syndrome develops later, when vasoconstriction ensues from relative hypovolemia.

Hepatorenal syndrome may be precipitated by concomitant illnesses or may occur spontaneously. Spontaneous bacterial peritonitis is the most common precipitating factor of hepatorenal syndrome in patients with cirrhosis.

Clinical Features

A. Symptoms and Signs—Hepatorenal syndrome occurs as a complication of cirrhosis, more commonly in patients with ascites. Two types are recognized. Type I is characterized by rapid and progressive impairment of renal function. Dominant features are marked renal failure, oliguria or anuria, and high levels of urea and creatinine. Most patients have hyperbilirubinemia, coagulopathy, and encephalopathy. The median survival is only 2 weeks. Type II consists of mild and stable reduction in renal function. These patients typically present with diuretic-resistant ascites.

Four major criteria must be present to establish the diagnosis of hepatorenal syndrome: (1) low GFR (creatinine clearance <40 mL/min or serum creatinine >1.5 mg/dL), (2) absence of shock with ongoing bacterial infection, fluid loss, and current treatment with nephrotoxic drugs, (3) no improvement in renal function after withdrawal of diuretics, and (4) no evidence of obstructive uropathy and absence of proteinuria (<500 mg/day).

B. Laboratory Findings—Laboratory findings in hepatorenal syndrome include a creatinine clearance of less than 40 mL/min or a serum creatinine concentration of more than 1.5 mg/dL, a urine sodium concentration of less than 10 meq/L, a urine

Table 34-5. Child-Turcotte-Pugh estimate of surgical risk.

Clinical Variable	1 Point	2 Points	3 Points
Encephalopathy	None	Stage 1-2	Stage 3-4
Ascites	Absent	Slight	Moderate
Bilirubin (mg/dL)	<2	2-3	>3
Albumin (g/dL)	3.5	2.8-3.5	<2.8
Prothrombin time (seconds prolonged or INR)	<4 s or INR <1.7	4-6 s or INR 1.7-2.3	>6 s or INR >2.3

Interpretation: Child class A = 5–6 points, Child class B = 7–9 points, Child class C = 10–15 points.

osmolality that is greater than plasma osmolality, urine red blood cells fewer than 50/hpf, and a serum sodium concentration of less than 130 meq/L.

Differential Diagnosis

Other causes of renal failure that must be excluded prior to making a diagnosis of hepatorenal syndrome include hypovolemia causing prerenal failure (eg, use of diuretics or bleeding), acute tubular necrosis (eg, following hypotension or sepsis), drug-induced nephrotoxicity (eg, NSAIDs or aminoglycosides), and glomerulonephritis (commonly associated with proteinuria) secondary to autoimmune disease.

Treatment

Initial management requires volume replacement and reaching a euvolemic state. Once hepatorenal syndrome is suspected, medical management is difficult and more often than not unsuccessful. Basic management requires monitoring of urine output, patient weight, blood pressure, evaluation and replacement of electrolytes, and possibly dialysis.

Intravenous clonidine has been shown to lower renal vascular resistance and increase the GFR by as much as 25%. Dopamine has been proposed as a selective vasodilator of the renal circulation in selected reports, but the literature suggests that there is only a very mild effect in increasing GFR.

Liver transplantation causes a dramatic improvement in renal function. Recovery of renal function typically is seen within 48–72 hours of transplantation. Long-term survival after transplantation is very good—approximately 60% after 3 years. The perioperative phase may be more complicated owing to a 30% requirement of temporary hemodialysis and the higher incidence of morbidity and mortality than in patients transplanted without hepatorenal syndrome.

▶ Preoperative Assessment & Perioperative Management of Patients With Cirrhosis

There is high perioperative morbidity and a high mortality risk in patients with cirrhosis undergoing abdominal surgery for any indication. Liver function may deteriorate from general

anesthesia. Anesthesia reduces cardiac output, induces splanchnic vasodilation, and causes a 30–50% reduction in hepatic blood flow.

The 30-day mortality for patients with cirrhosis undergoing celiotomy is 30%. A 60% major complication rate also was reported. The risk depends on a number of factors.

A. Physiologic Status—The Child-Turcotte-Pugh classification of surgical risk is summarized in Table 34–5. This classification was first proposed (by Child) as a means of predicting the operative mortality associated with portacaval shunt surgery. The presence of ascites, encephalopathy, and coagulopathy predicts mortality. There is a 10% mortality rate for patients with Child class A cirrhosis, 30% for Child class B, and 75% for Child class C.

Another model predictive of outcomes in patients with cirrhosis is the Model for End-Stage Liver Disease (MELD), which is a numerical scale based on the etiology of cirrhosis, bilirubin, creatinine, and international normalization ratio (INR). Scores range from 6 (less ill) to 40 (gravely ill), and the model is used for liver transplant candidates aged 12 and older.

B. Type of Surgery—The overall hospital mortality rate was estimated at 21% for biliary surgery, 35% for peptic ulcer disease, and 55% for colectomy. Newer techniques such as laparoscopy and better patient selection have contributed to a reduced mortality rate in recent reports of laparoscopic cholecystectomy and appendectomy.

C. Other Factors—Active infection, a higher number of blood transfusions, pulmonary complications, GI bleeding, and the need for emergency surgery have a negative impact on the outcome of surgery in patients with cirrhosis.

▶ Liver Resection in Patients with Cirrhosis

Hepatectomy is a major operation that induces a severe catabolic response and immunosuppression. Cirrhotic patients already suffer from underlying catabolism and immunosuppression. Liver resection in patients with underlying liver

insufficiency carries the risk of postoperative liver failure. In experienced hands, the mortality rate after hepatectomy ranges from 5–50%.

Other postoperative complications are common, such as the development of ascites (5%), encephalopathy (20%), renal failure (15%), and upper GI bleeding (5%). Factors that contribute to this great variability are the extent of resection and the patient's underlying physiologic status. Preoperative patient selection and perioperative management are critical to successful outcome after liver resection in patients with cirrhosis.

Preoperative Evaluation

Prior to operation, attention is directed to identification of patients in whom the complication rate or mortality risk is prohibitive. Numerous methods of identification have been proposed. The clinical classification of patients according to their Child score is a time-tested approach and is used most commonly. Patients with Child A liver function have a hospital mortality risk for major hepatectomy of 3–15%. Patients with Child B or C liver function tolerate liver resection poorly, and that procedure should be withheld except in highly selected individuals who require minimal surgery. Others have proposed the use of the indocyanine green clearance test, the lidocaine clearance test, and measuring the degree of fibrosis in the unaffected liver as predictors of morbidity and mortality. Another factor that must be considered in selection of patients is the volume of remaining liver estimated by CT scan.

As before any other major surgery, a good clinical history and examination should alert the clinician to the presence of any significant pulmonary, cardiac, hematologic, or renal disorders. Screening of hematologic, biochemical, renal, pulmonary, and cardiac function is essential.

Operative Management

Metabolic and hematologic derangements must be corrected prior to surgery. Intraoperative monitoring of blood loss, hemodynamics, and urine output is crucial. Patients with hepatic dysfunction suffer from peripheral vasodilation and are less responsive to catecholamines. It is therefore important to maintain the circulatory volume. Maintaining liver perfusion during surgery is critical to the prevention of any further impairment of hepatic function. Therefore, anesthetic agents that do not impair hepatic perfusion and oxygenation should be selected.

Liver transection must be performed with two issues in mind, minimizing blood loss and having adequate hemostasis and securing biliary radicles to avoid postoperative biliary leakage, which is a cause of postoperative morbidity and sepsis.

Postoperative Care

Postoperative monitoring should include hemodynamics, oxygen saturation, vital signs, fluid balance, electrolytes, and blood glucose. Postoperative pain must be controlled to

avoid cardiopulmonary complications. Careful fluid management is a critical component of postoperative care. Maintaining euvolemia is a priority. Owing to alterations in the renin-angiotensin-aldosterone axis, cirrhotic patients have a propensity for salt retention and third spacing of extracellular water. This, in turn, manifests as ascites. When salt restriction is required, 0.25% saline solution should be used instead of 0.5%.

Parenteral nutritional support is provided in the form of branched-chain amino acids because they reduce the catabolic response and promote hepatic protein synthesis and liver regeneration in cirrhosis. Adequate calories and fatty acids are also provided. Perioperative nutritional support reduces overall postoperative morbidity by decreasing septic complications, the incidence of ascites, and deterioration of liver function.

Potassium phosphate is used in the parenteral solution to avoid hypophosphatemia, which occurs commonly after hepatectomy. Phosphate is necessary for production of ATP in the liver.

At least one study supports the use of salt-poor albumin in septic cirrhotic patients as a means of reducing renal complications and mortality.

Hyperbilirubinemia occurs commonly and generally is transient, but progressive hyperbilirubinemia is an ominous sign. Decreased sensorium, hypoglycemia, and acidosis are present in severe hepatic failure and portend a poor prognosis. Hepatic failure is complicated by a noncorrectable coagulopathy and sepsis. Use of the bioartificial liver is potentially a life-saving measure, but this resource is not yet widely available. Liver transplantation is the only option (see Chapter 35).

Burns

35

David W. Mozingo, MD
William G. Cioffi, Jr., MD
Basil A. Pruitt, Jr., MD*

Burns represent particularly challenging and difficult management problems. This chapter addresses the most common causes, including thermal, electrical, and chemical burns. Because of the far-reaching implications for care, additional aspects of electrical injuries such as lightning strikes and electrocution are discussed further with environmental injuries in Chapter 37.

I. THERMAL BURN INJURY

Approximately 1.25 million burn injuries occur each year in the United States. House and structure fires account for 81% of the 3600 burn- and fire-related deaths that occur each year. Flame injury following a house fire or ignition of clothing is the most common burn injury in patients admitted to burn centers. Scald burns, the most common burn injury in children, are responsible for about 30% of patients requiring hospitalization for burns. Most burn injuries are treated adequately on an outpatient basis; however, approximately 60,000 patients per year require hospital care because of the extent of their injury, the presence of comorbid factors, or extremes of age. Approximately 20,000 patients have injuries of such significance that care is best undertaken in a designated burn care facility. The American Burn Association has developed criteria to identify patients who require treatment in a burn center. These criteria assess the severity of injury and the need for specialized burn center treatment based on the age of the patient; the extent, depth, and location of the burn; the type of injury; and the presence of preexisting comorbid factors or associated injuries (Table 35-1).

Thermal burn injury initiates a deleterious pathophysiologic response in every organ system, with the extent and duration of organ dysfunction proportionate to the size of the burn. Direct cellular damage is manifested by

coagulation necrosis, with the magnitude of tissue destruction determined by the temperature to which the tissue is exposed and the duration of contact.

▶ Histopathologic Characteristics of Burned Tissue

Following thermal injury, the region of the burn in which protein coagulation and cell death has occurred has been referred to as the *zone of necrosis*. In full-thickness injury, all dermal elements are destroyed, whereas partial-thickness burns are characterized by a variable and incomplete dermal necrosis. Extending radially from the zone of necrosis are areas of cellular damage referred to as the *zones of stasis* and *hyperemia*. The zone of stasis is characterized by a decreased microvascular blood flow, which may be restored to normal with successful resuscitation or converted to necrosis following inadequate perfusion, desiccation, or infection. Minimal thermal injury induces a zone of hyperemia characterized by an immediate inflammatory response and increased microvascular blood flow. These early histopathologic changes are depicted as concentric tissue zones about the point of thermal contact. Coagulation necrosis of the skin and skin appendages results in loss of normal skin functions; the antimicrobial barrier is destroyed, control of water evaporation is lost, and regulation of body temperature is impaired.

▶ Mechanisms of Edema Formation

Following thermal injury, edema formation in the burn wound and in unburned tissues is greatest in the first 6 hours following injury and continues to a lesser extent for the first 24 hours postburn. Postcapillary venular constriction results in a marked increase in capillary hydrostatic pressure and the production of interstitial edema in the early postinjury phase. In an animal model of burn injury, a strongly negative interstitial fluid hydrostatic pressure has been shown to occur within 30 minutes of injury. The duration and

*The views of the authors do not purport to reflect the position of the Department of the Army and the Department of Defense.

Table 35-1. American Burn Association burn center referral guidelines.

Partial-thickness burns greater than 10% total body surface area
Burns that involve the face, hands, feet, genitalia, perineum, or major joints
Third-degree burns in any age group
Electrical burns, including lightning injury
Chemical burns
Inhalation injury
Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
Any patients with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality. In such cases, if the trauma poses the greater immediate risk, the patient may be initially stabilized in a trauma center before being transferred to a burn unit. Physician judgment will be necessary in such situations and should be in concert with the regional medical control plan and triage protocols.
Burned children in hospitals without qualified personnel or equipment for the care of children
Burn injury in patients who will require special social, emotional, or long-term rehabilitative intervention

TBSA=total surface area.

magnitude of the negative hydrostatic pressure change were proportional to the size of the burn. An early increase in the interstitial fluid colloid osmotic pressure following burn injury resulting in a reversal of the transcapillary osmotic pressure gradient also has been reported. Following initial changes in the physical characteristics of burn tissue, subsequent edema formation generally has been attributed to an increase in microvascular permeability owing to the effects of humoral factors liberated from burned tissue and cytokines produced by activated leukocytes. The plasma concentration of histamine, a potent regulator of vascular permeability present in abundance in mast cells, rises in proportion to burn size immediately following injury. Many inflammatory mediators, including activated proteases, prostaglandins, leukotrienes, fibrin degradation products, and substance P, have been reported to increase microvascular permeability following burn injury. Specific antagonists to these agents have been shown to decrease but not eliminate edema formation when administered prior to burn injury. The efficacy of inflammatory mediator antagonists in decreasing microvascular permeability when administered following burn injury has not been demonstrated conclusively.

Leukocyte activation results in the production of cytokines and other factors capable of increasing microvascular permeability. Lysosomal enzymes, increased xanthine oxidase activity, products of complement activation, and oxygen radicals are generated following thermal injury and are capable of increasing microvascular permeability and burn wound edema. Interleukin 2 (IL-2)-activated human killer lymphocytes have been shown to increase albumin flux

across monolayers of cultured endothelial cells in vitro. Even though neutrophil depletion has been reported to protect against postburn lung injury, it did not reduce burn wound edema formation. The response of the leukocyte appears to depend on the agent of injury, the proximity to the site of injury, and exposure to humoral mediators.

Edema formation also occurs in unburned tissues following a major burn. Conflicting reports exist concerning the mechanism of this edema formation. In animal studies, an increase in the ratio of lymph to plasma protein measured in uninjured extremities following burn injury, as well as an increase in extravasation of radiolabeled albumin into uninjured tissue, has been described. Others were unable to demonstrate a change in ratios of lymph to serum protein from an uninjured sheep extremity following burn injury, implying that no change in vascular permeability in the uninjured extremity had occurred. Edema accumulation may be massive in unburned tissue following thermal injury, and despite the conflicting reports, it is most likely due to changes in oncotic pressure and the dilutional effects resulting from the infusion of large volumes of crystalloid fluid required for burn resuscitation. Edema formation is characterized by a shift of fluid and protein from the intravascular into the extravascular compartment. Volume shifts occur in proportion to the extent of burn, resulting in decreased blood volume and decreased cardiac output, which, if untreated, progress to hypovolemic shock.

► Organ System Responses to Burn Injury

The magnitude and duration of the prototype organ response to thermal injury of early hypofunction and later hyperfunction depend on the extent of injury.

Cardiovascular System

During the resuscitative phase, the initial cardiovascular response to thermal injury is manifested by decreased cardiac output and increased peripheral vascular resistance followed by a progressive increase in cardiac output and decrease in peripheral vascular resistance during the hypermetabolic flow phase. The fall in cardiac output is proportional to the size of the burn and attributable to the loss of fluid and protein from the intravascular into the extravascular compartment. There is a corresponding reflex increase in peripheral vascular resistance as a consequence of the neurohumoral response to hypovolemia. A myocardial depressive factor has been implicated as the cause of initial impaired myocardial performance; however, this factor has not been identified. Clinical studies have demonstrated that in the absence of heart disease, the ventricular ejection fraction and velocity of myocardial fiber shortening were increased following thermal injury and that hypovolemia, as measured by decreased left ventricular end-diastolic volume, was the cause of depressed cardiac output. Fluid resuscitation following burn injury improves cardiac performance as hypovolemia is corrected.

As microvascular permeability decreases, the plasma volume deficit is replenished in the second 24 hours, and cardiac output increases to supranormal levels. Peripheral vascular resistance decreases below normal, and the postburn hypermetabolic state, which peaks in the second postburn week and slowly recedes thereafter, is established. Studies have demonstrated that the postresuscitation increase in cardiac output is directed primarily toward the burn wound; that is, the blood flow to a burned extremity is significantly increased compared with an unburned extremity in the same patient, and the increase is proportional to the extent of burn on the involved extremity. As a consequence, a decrease in cardiac output secondary to hypovolemia or pharmacologic intervention may reduce the flow of oxygen and nutrients to the wound and impair wound healing.

Lungs

Following thermal injury, even in the absence of associated smoke inhalation, physiologic changes in pulmonary function occur. Immediately postburn, minute ventilation is unchanged or slightly increased as a result of anxiety- and pain-induced hyperventilation. With the initiation of fluid resuscitation, respiratory rate and tidal volume increase progressively, resulting in a minute ventilation that may be two to two and one-half times normal. The magnitude of this increase is proportional to the extent of burn and is considered to reflect postinjury hypermetabolism. In patients with circumferential burns of the thorax, the unyielding eschar and underlying edema may restrict ventilation to the point of requiring escharotomy incisions to relieve the restrictive ventilatory defect.

Pulmonary vascular resistance increases immediately following thermal injury, and the increase is more prolonged than the increase in peripheral vascular resistance. The release of vasoactive amines and other mediators following thermal injury may be responsible for the increased pulmonary vascular resistance, and this process may exert a protective effect during fluid resuscitation by decreasing pulmonary capillary hydrostatic pressure and thus prevent pulmonary edema. Lung lymph flow studies have demonstrated no change in pulmonary capillary permeability following cutaneous thermal injury. Complement activation and generation of the chemotactic peptide C5A have been shown to be temporally related to neutropenia, aggregation of leukocytes in pulmonary capillaries, and intraalveolar hemorrhages. In other laboratory studies, preburn depletion of complement, neutrophils, and platelets was protective of postinjury lung dysfunction. Preinjury treatment with catalase and superoxide dismutase also improve postburn pulmonary function, implicating toxic oxygen products produced by activated neutrophils as mediators of the postburn pulmonary dysfunction.

Whether or not the infusion of large volumes of crystalloid solution associated with burn resuscitation causes postburn pulmonary changes remains controversial. The

accumulation of chest wall edema, exacerbated by infusion of large volumes of resuscitation fluid, decreases total lung compliance and promotes atelectasis and hypoxemia. Furthermore, overzealous initial fluid resuscitation may result in florid pulmonary edema as the edema fluid is resorbed during the third to fifth postburn days. Consequently, the smallest volume of resuscitation fluid that maintains adequate organ perfusion should be administered to avoid secondary pulmonary complications.

Kidneys

The renal response following thermal injury parallels the cardiovascular response. In the immediate postburn period, renal blood flow and the glomerular filtration rate are reduced in proportion to the size of the burn and the magnitude of the intravascular volume deficit. Delayed or inadequate fluid resuscitation may cause inadequate renal perfusion and lead to acute tubular necrosis and renal failure. Following a successful resuscitation phase, cardiac output and renal blood flow are increased as edema fluid is resorbed. A diuretic response is observed during the period of edema resorption; however, this response may be modified by a large evaporative loss of fluids through the wound surface and slow rates of edema resorption in patients with large-surface-area burns. Despite the markedly increased cardiac output and renal plasma flow seen in the flow phase of burn injury, the blood volume of patients measured by ^{51}Cr red blood cell labeling was only 81% of predicted values. Plasma renin activity and antidiuretic hormone levels are elevated, as predicted by the decreased blood volume, despite the findings of increased blood flow to the kidney. This may explain in part the propensity for sodium retention to occur during the course of treatment for thermal injury. As in other organ systems, the duration of changes in renal physiology is related to the timing of wound closure by primary healing or autografting. Owing to the increased renal blood flow, drugs excreted by the kidneys tend to have markedly shortened half-lives, and appropriate dosing adjustments of these drugs are necessary.

Gastrointestinal Tract and Liver

GI and hepatic dysfunction are also related to the magnitude of thermal injury. In patients with burns of more than 25% of the total body surface, ileus, resulting from the combined effects of hypovolemia and neurohumoral changes, is a prominent feature. Nasogastric intubation for gastric decompression is usually required. Following resuscitation, normal GI motility commonly returns by the third to fifth postburn day. Focal ischemic mucosal lesions of the stomach and duodenum may be observed as early as 3–5 hours following burn injury, and in the absence of stress ulcer prophylaxis, these early lesions may progress to frank ulceration. Intestinal bacterial translocation following thermal injury has been studied extensively in the laboratory, and increased intestinal permeability to low-molecular-weight sugars has been identified as

a prodrome to the onset of infection in thermally injured patients. However, the clinical significance and therapeutic implications of these findings are yet to be fully elucidated.

As the magnitude of a burn increases, so does the likelihood of early postburn hepatic dysfunction. An initial increase in hepatic aminotransferase is common following burns of more than 50% of the body surface area. This is most likely due to the acute reduction in cardiac output, increased blood viscosity, and associated splanchnic vasoconstriction that occur immediately following thermal injury. Following successful fluid resuscitation, the hepatic enzymes promptly return to normal in most patients. The magnitude of initial enzyme derangements has not been predictive of outcome; however, the early onset of jaundice following thermal injury is associated with a poor prognosis, probably indicating preinjury hepatic dysfunction or severely compromised hepatic perfusion during the resuscitative phase. The onset of hepatic dysfunction later in the postburn period usually is manifested by hyperbilirubinemia and elevation of liver enzymes in a cholestatic pattern. These changes are most often associated with sepsis or multiple-organ failure.

Nervous System

Nonspecific neurologic changes such as increased anxiety and disorientation are observed commonly in patients with extensive thermal injury and are most likely due to the neurohumoral stress response and ICU isolation. Specific neurologic changes are observed more commonly in patients with high-voltage electrical injury or mechanical trauma. Changing neurologic symptoms and signs, manifested by increasing disorientation, obtundation, or seizures, may be the earliest indications of hypoxemia, electrolyte or fluid imbalance, sepsis, or the toxic effects of medications. Changes in neurologic findings require prompt intervention to identify and correct such abnormalities.

Endocrine System

The metabolic response to thermal injury is also proportionate to the extent of burn and follows the typical biphasic response documented in other organ systems. Immediately following burn injury, during the period of hypovolemia, the metabolic rate decreases; however, as resuscitation progresses, a catabolic or hypermetabolic hormonal pattern emerges. Serum levels of catecholamines, glucagon, and cortisol increase, whereas insulin and triiodothyronine levels are decreased. There is an increase in net glucose flow, with relative peripheral insulin resistance and a markedly negative nitrogen balance. As the burn wounds heal or are closed by autografting, the catabolic hormone response dissipates, an anabolic state is eventually attained, and restoration of lean body mass ensues. Septic complications superimposed on thermal injury initially exaggerate the hypermetabolic response, but if the septic state persists, progressive deterioration and multisystem organ failure, characterized by hypometabolism, may occur.

Hematopoietic System

Destruction of red blood cells following thermal injury occurs to an extent proportional to the size and depth of burn. In areas of full-thickness burn, red blood cells are immediately coagulated in the involved microvasculature. There is a continuing red blood cell loss in patients with extensive burns of 8–12% of the red blood cell mass per day caused by the continued lysis of cells damaged by heat, microvascular thrombosis in zones of ischemia that subsequently become necrotic, and repeated blood sampling. In the early postburn period, platelet number and fibrinogen levels are depressed, with a corresponding rise in fibrin split products. Following resuscitation, platelets and serum levels of fibrinogen and factors V and VIII rapidly increase to supranormal levels. Erythropoietin levels are increased coincident with the anemia following thermal injury. Recent studies have suggested that the rate of erythropoiesis may be further increased by the administration of recombinant erythropoietin and iron. However, a decrease in transfusion requirements has yet to be demonstrated.

Immunologic Response

Infection remains the major cause of death among burn patients. Following injury, dysfunction of the cellular and humoral immune response occurs that is related to the extent of injury. Destruction of the normal skin barrier results in loss of mechanical protection from microbial proliferation and allows microbial invasion into normal tissues. Modern burn care—with emphasis on effective topical antimicrobial agents, infection control policies, and timely excision with autograft closure of burn wounds—has significantly decreased the incidence of burn wound infection. Other infectious complications, principally pneumonia, remain the major source of morbidity and mortality, and treatment may be made difficult by the generalized immune system dysfunction following thermal injury.

During the first postburn week, the total white blood cell count is elevated, although peripheral blood lymphocyte counts are reduced. Burn injury also causes apoptosis of lymphocytes in various solid organs following burn injury. This process is glucocorticoid-mediated and can be blocked experimentally by the administration of glucocorticoid receptor antagonists. This process is not TNF- α - or Fas ligand-dependent and may represent a counterregulatory mechanism to reduce inflammatory stimuli. Delayed hypersensitivity reactions and peripheral blood lymphocyte proliferation in the mixed lymphocyte reaction are both inhibited following thermal injury. Alterations in lymphocyte subpopulations have been described that normalize over the second postburn week in patients whose course is uncomplicated. Further alterations occur prior to and during the onset of septic complications. Alterations in IL-2 production and IL-2 receptor expression by lymphocytes have been measured following burn injury, and direct correlation has been established between the extent of burn and the decrease in IL-2

production by peripheral blood lymphocytes. Septic complications result in a further decrement in IL-2 production.

Serum IgG levels are decreased following burn injury and gradually return to normal over 2–4 weeks as the patient recovers. Restoration of IgG levels to normal by exogenous administration has not been shown to affect morbidity or mortality. Many investigators, using a number of experimental approaches, have demonstrated immunosuppressive factors present in the serum of thermally injured patients. Similar immunosuppressive properties have been detected in burn blister fluid. Immunosuppressive polypeptides have been the most commonly invoked agents; however, other factors, including complement degradation products, immunoglobulin fragments, prostaglandins, and endocrine secretions, occur in the serum following thermal injury.

Alterations in granulocyte chemotaxis, degranulation, adherence, oxygen free-radical production, and complement receptor expression have been observed following thermal injury. Granulocytes from burned patients exhibit an increase in cytosolic oxidase activity, suggesting *in vivo* activation. They also exhibit greater than normal oxidase activity after *in vitro* stimulation. This increase suggests that neutrophils from burned patients have an increased oxidative burst potential that, if activated, could cause increased tissue and organ injury. A marked and sustained increase in neutrophil expression of the complement opsonin receptors CRT and CR3 has been described following burn injury. The increase in receptor expression correlated with decreased chemotaxis in response to zymosan-activated serum, suggesting that C5A was responsible for inducing systemic neutrophil activation. Recent investigations have demonstrated significant elevation of F-actin content and decreased ability to polymerize and depolymerize F-actin in the granulocytes of burn patients when compared with controls. These alterations may be partly responsible for the observed changes in chemotaxis and migration following thermal injury.

Almost every aspect of immunoregulation is affected following burn injury. At present, no effective immunomodulatory treatment has been identified; however, the development of new immunomodulatory drugs and recombinant lymphokines and their antagonists may prove beneficial in correcting immune dysfunction following burn injury.

INITIAL CARE OF THE BURN PATIENT

Prehospital Treatment

The primary concern at the accident scene is to stop the burning process. Burning and smoldering clothing should be extinguished. Patients with electrical injury should be separated from points of electric contact, taking all necessary care

to avoid injuring oneself. If the burn was caused by a chemical agent, all contaminated clothing should be removed and copious water lavage initiated.

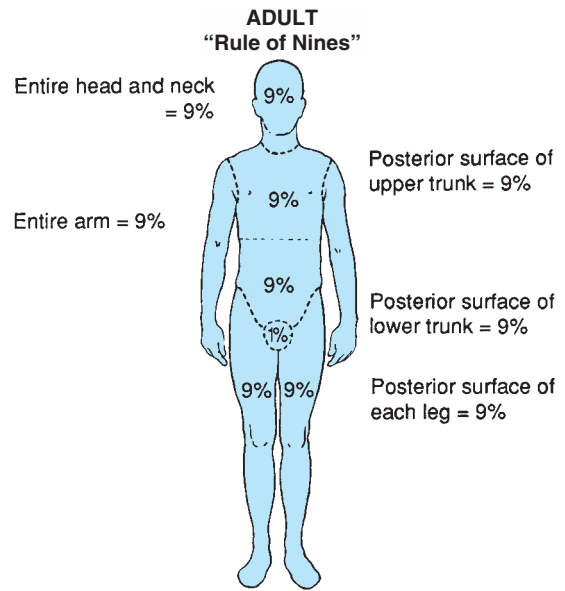

As with all trauma patients, the primary concern during initial assessment is maintenance of cardiopulmonary function. Airway patency and adequacy of ventilation must be maintained and supplemental oxygen administered as necessary. In the absence of associated mechanical trauma or need for cardiopulmonary resuscitation, placement of an intravenous cannula is not necessary if transport to a treatment facility can be accomplished in less than 45 minutes. The application of ice or cold water soaks will relieve pain in areas of second-degree burn. If the cold therapy is initiated within 10 minutes of burning, tissue heat content is also reduced, and the depth of thermal injury may be lessened. If cold therapy is used, care must be taken to avoid causing hypothermia. Cold soaks or ice should only be used on patients with burns of less than 10% of the body surface and only for the time required to produce analgesia. After the ice or cold soak is removed, the patient should be covered with a clean sheet and blanket to conserve body heat and minimize contamination of the burn wounds during transport to the hospital.

► Emergency Management

On arrival at the hospital, the patency of the airway and adequacy of breathing should be reassessed and endotracheal intubation performed if necessary. Intravenous fluid resuscitation is initiated by infusing a physiologic salt solution, for example, lactated Ringer's solution, through a large-bore intravenous cannula. The order of preference for the site of intravenous cannulation is a peripheral vein underlying unburned skin, a peripheral vein underlying burned skin, and lastly, a central vein.

A history should be obtained, paying special attention to the circumstances of the injury, the presence of preexisting disease, allergies and medications, and the use of illicit drugs or alcohol prior to injury. A complete physical examination should be performed and associated injuries identified. Baseline laboratory data should include an arterial blood gas and pH analysis, serum electrolytes, urea nitrogen, creatinine, and glucose, and a complete blood count. If available, continuous transcutaneous pulse oximetry determination of oxygen saturation should be initiated in patients with suspected inhalation injury or extensive burns.

Since all currently used resuscitation formulas are based on body weight and the percentage of total body surface area burned (TBSB), the patient should be weighed and the depth and extent of burn estimated. The extent of body surface area burned can be estimated easily using the "rule of nines," which recognizes that specific anatomic regions represent 9% or 18% of the total body surface area (Figure 35-1). Since the area of one surface of the patient's hand (palm and digits) represents 1% of that person's total body surface, one can use that relationship in estimating the extent of irregularly distributed burns. Infants and children have a different body surface area

▲ **Figure 35-1.** Rule of nines showing distribution of body surface area (BSA) by anatomic parts in the adult.

distribution, with relatively larger heads and smaller lower extremities. When estimating the body surface burn area for children under age 10, the Lund and Browder burn diagram (Figure 35-2) or other similar diagram should be used to determine the body surface area burned with greater precision.

The depth of burn is classified as partial- or full-thickness with respect to the extent of dermal destruction by coagulation necrosis (Figure 35-3). First- and second-degree burns are considered partial-thickness injuries and third-degree burns full-thickness injuries. Superficial partial-thickness burns heal spontaneously by epithelial migration from preserved dermal appendages. Full-thickness injuries have complete destruction of all epithelial elements and require skin grafting for wound closure. Deep partial-thickness burns may heal over a long period of time, but grafting is frequently performed to decrease time to wound closure, reduce scar formation, improve functional outcome, and shorten the hospital stay. The clinical criteria in Table 35-2 permit initial differentiation among the different depths of burn injury. Only the total percentage of skin surface area involved in second- and third-degree burns is calculated or estimated for resuscitation purposes. First-degree burns do not cause significant edema formation or metabolic alteration and are not considered in the calculation of burn size for estimation of resuscitation requirements. Differentiation between second- and third-degree burns is more important in the later post-burn course because it has implications for the duration of hypermetabolism, the need for autograft closure of the burn wound, and the anticipated functional result.

BURN ESTIMATE AND DIAGRAM

▲ **Figure 35-2.** The use of a burn diagram permits a more exact estimation of the extent of burn. Note that the surface areas of the head and lower extremities change significantly with age.

The presence of associated mechanical trauma may affect the resuscitation requirements of the thermally injured patient. Soft tissue trauma and bleeding from any injury will increase the fluid required to establish adequate urine output. The presence of thermal injury should not delay or alter the evaluation and subsequent treatment, including operative intervention, of mechanical trauma. An indwelling

urethral catheter should be inserted in all patients requiring intravenous fluid therapy, and the urinary output should be measured and recorded hourly. Vital signs and the patient's general condition should be monitored and recorded frequently on a flowsheet. The rectal temperature should be measured hourly, providing a guide for maintenance of core temperature. In patients with high-voltage electrical injury,

▲ **Figure 35-3.** Diagram of the skin and subcutaneous tissues demonstrating the depth of burn and relationship to the location of the cutaneous adnexa. First- and second-degree burns are considered partial-thickness. Preservation of the hair follicles and sweat glands permits spontaneous healing by epithelial cell migration. Full-thickness (third-degree) burns will not reepithelialize and require skin grafting for closure.

electrocardiographic monitoring should be initiated in the emergency department.

The tetanus immunization status of the patient should be determined in the emergency department. The burn patient who has been immunized against tetanus previously should be given a booster dose of tetanus toxoid if the last dose was administered more than 5 years previously. Patients with no history of active immunization should receive tetanus immune globulin in addition to an initial dose of tetanus toxoid. Active immunization is completed subsequently according to the routine dosage schedule.

PRINCIPLES OF BURN TREATMENT

▶ Fluid Resuscitation

Fluid resuscitation should be started as soon as possible following thermal injury. Generally, burns involving more than 25% of the body surface area require intravenous fluid resuscitation because ileus precludes oral resuscitation. Patients with smaller burns in whom ileus does not develop should have liberal access to electrolyte-containing fluids such as fruit juices or milk, but excessive intake of electrolyte-free water should be avoided to prevent hyponatremia. Many formulas have been proposed for calculation of intravenous fluid resuscitation of thermally injured patients (Table 35-3). The central theme is that the volume of fluid required depends on the patient's weight and the extent of burn. Most often it is recommended that half the calculated requirement be infused over the first 8 hours following injury, that is, at the time of maximal vascular permeability; the remainder of the first 24-hour resuscitation volume is delivered over the next 16 hours. Certain subgroups of patients require a significantly greater resuscitation volume than that estimated by the formulas. A delay in starting fluid resuscitation, inhalation injury, and ethanol intoxication frequently are associated with greater than predicted fluid requirements. Patients with high-voltage electrical injuries frequently require more resuscitation fluid than that predicted based on the extent of cutaneous injury. One must recognize that any resuscitation formula serves only to guide the initiation of fluid therapy. The actual amount of resuscitation fluid is tailored to each patient's physiologic responses, with frequent reassessment and adjustment of infusion rates as needed to preserve vital organ perfusion.

The various burn formulas in Table 35-3 differ considerably with respect to the volume and composition of the resuscitation fluids; however, each formula has been found to be clinically effective. The general use of burn formulas has decreased the frequency of burn-induced hypovolemic shock and organ dysfunction, which were secondary to inadequate

Table 35-2. Characteristics of first-, second-, and third-degree burns.

	First-Degree	Second-Degree	Third-Degree
Cause	Exposure to sunlight, very brief exposure to hot liquid, flash, flame, or chemical agent.	Limited exposure to hot liquid, flash, flame, or chemical agent.	Prolonged exposure to flame, hot object, or chemical agent. Contact with high-voltage electricity.
Color	Red	Pink or mottled red	Pearly white, charred, translucent, or parchment-like. Thrombosed vessels may be visible.
Surface	Dry or very small blisters	Bullae or moist, weeping surface	Dry and inelastic
Sensation	Painful	Painful	Insensate surface

Table 35-3. Commonly used resuscitation formulas.

Formula	Electrolyte-Containing Solution	Colloid-Containing Solution	5% Glucose in Water
First 24 Hours Postburn			
Parkland	Lactated Ringer's, 4 mL/kg per % burn.		
Hypertonic sodium resuscitation	Volume of fluid containing 250 meq of sodium/L to maintain hourly urinary output of 30 mL.		
Modified Brooke	Lactated Ringer's, 2 mL/kg per % burn.		
Consensus*	Lactated Ringer's, 2-4 mL/kg per % burn.		
Second 24 Hours Postburn			
Parkland		20-60% of calculated plasma volume.	As necessary to maintain urinary output.
Hypertonic sodium resuscitation	33% isotonic salt solution up to 3500 mL limit.		
Modified Brooke		0.3-0.5 mL/kg per % burn†	As necessary to maintain urinary output.
Consensus*		0.3-0.5 mL/kg per % burn†	As necessary to maintain urinary output.

*American Burn Association: Advanced Burn Life Support Course.

†Administered as a plasma equivalent (eg, 5% albumin in 0.9% sodium chloride solution.)

resuscitation. Failure to reevaluate the patient's response to resuscitation frequently on a scheduled basis may lead to over- or underresuscitation. This is frequently observed when the volume of fluid administered is based solely on the initial estimate. With overzealous administration of intravenous fluids, pulmonary, cerebral, and excessive burn wound edema may result. These complications are most evident from the third to sixth postburn days, when vascular permeability has returned to "normal," vascular resistance has decreased, and burn wound edema is being resorbed.

Laboratory and clinical studies evaluating transcapillary fluid movement and the physiologic response to resuscitation have failed to demonstrate a benefit from the use of colloid-containing solutions during the first 24 hours of resuscitation. Extravascular lung water has been shown to remain essentially unchanged during the first postburn week in patients who received only crystalloid-containing fluids in the first 24 hours following injury. However, extravascular lung water increased progressively in patients who received colloid-containing fluids as part of the initial resuscitation. During the latter half of the first week following injury, capillary permeability normalizes and fluid requirements decrease. As this occurs, the use of colloid-containing fluids

repletes the intravascular volume deficit more efficiently and with a lesser volume than with crystalloid fluids alone.

The use of hypertonic saline has been proposed as a means of reducing resuscitation fluid volume requirements. Although the initial volume of fluid administered when using hypertonic fluid is clearly less, the proposed benefits of a decreased need for escharotomy, decreased incidence and duration of ileus, and decreased fractional sodium retention have not been found in all studies. Potential problems with hypertonic saline resuscitation include hypernatremia, which, if of sufficient magnitude to require infusion of hypotonic fluid, negates the potential benefits of this resuscitation strategy. The cellular dehydration induced by hypertonic saline infusion of sufficient magnitude (15%) may cause cellular and organ dysfunction necessitating correction with hypotonic fluid administration. Subsequent evaporative water loss from the burn wound may worsen the expected hypernatremia from hypertonic saline resuscitation, requiring additional hypotonic fluid infusion. Occasionally, some patients with markedly reduced cardiac reserve may benefit from resuscitation protocols employing hypertonic saline; however, isotonic fluid resuscitation formulas provide adequate resuscitation in most patients. Caution should be

observed when implementing hypertonic saline resuscitation because increases in early acute renal failure and mortality have been reported.

Adjuvant administration of high-dose ascorbic acid during the first 24 hours after thermal injury has been shown to reduce the resuscitation fluid volume required significantly during this period in burn patients. Wound edema and body weight gain also were decreased. Infusion of ascorbic acid has been shown to attenuate postburn lipid peroxidation as a known antioxidant. It is uncertain as to the exact mechanism by which vitamin C seems to confer these benefits during burn resuscitation. Additional study of this treatment should be performed.

The modified Brooke formula (see Table 35–3), which is recommended by the authors, employs a physiologic salt solution during the first 24 hours without the addition of colloid or electrolyte-free crystalloid solutions. Lactated Ringer's is the preferred solution because of its more nearly physiologic concentration of chloride ions than normal saline. Fluid needs are estimated as 3 mL (children) or 2 mL (adults) per kilogram body weight per percent TBSA of lactated Ringer's solution. Children have a greater body surface area per unit of body mass and require more resuscitation fluid than adults. One-half the calculated estimate is administered in the first 8 hours and the second half over the subsequent 16 hours postburn. If initiation of fluid resuscitation is delayed, that amount of fluid calculated to be administered in the first 8 hours should be infused at a rate such that half the estimated 24-hour fluid requirement will be delivered by 8 hours postburn.

In the second 24 hours following burn injury, 5% albumin solution in physiologic saline is administered in an amount proportional to body weight and the extent of burn to aid in correction of the plasma volume deficit (Table 35–4). During the second 24 hours, lactated Ringer's infusion is stopped, and 5% dextrose and water is delivered to maintain adequate urine output.

Monitoring Resuscitation

The objective of fluid resuscitation following thermal injury is maintenance of organ perfusion and function. The adequacy of resuscitation may be assessed by the hemodynamic response, the status of mental function, indicating the adequacy of cerebral perfusion, and the volume of urine output, indicating effective renal perfusion.

Table 35–4. Estimation of colloid replacement during second 24 hours postburn.

30–50% burn:	0.3 mL/kg body weight per % burn
50–70% burn:	0.4 mL/kg body weight per % burn
>70% burn:	0.5 mL/kg body weight per % burn

Patient disorientation, anxiety, and restlessness may be early signs of hypovolemia or hypoxemia that require immediate assessment and correction. Sphygmomanometric monitoring of blood pressure in patients with extensive burns can be misleading. In a burned limb—or in an unburned extremity in which massive edema develops—Korotkoff sounds may be progressively attenuated, falsely implying hypoperfusion. Blood pressure measurements, even when obtained by use of an indwelling peripheral arterial cannula, may not reflect true hydration status because markedly elevated circulating levels of catecholamines and other vasoactive materials may cause severe vasospasm. A resting tachycardia between 100 and 120 beats/min is common following thermal injury. Rates above this level may reflect inadequate pain control or inadequate fluid resuscitation. A more objective indication of the adequacy of resuscitation is the rate of production of urine, which reflects the adequacy of renal perfusion. In the absence of osmotically driven diuresis, a urinary output of 30–50 mL/h indicates adequate resuscitation in most adult patients, and 1 mL/kg per hour indicates adequate resuscitation in patients weighing less than 30 kg.

Routine use of flow-directed pulmonary artery catheters during burn resuscitation is unnecessary. Even with extensive injury, healthy young adults usually respond to fluid resuscitation in a predictable manner. The previously discussed indicators of adequacy of resuscitation may be used to guide fluid infusion rates. Fluid infusion rates should be adjusted if the hourly urine output is below or above the desired urinary output by more than 33% for 2 consecutive hours. Only patients who do not respond to fluid resuscitation as expected—or whose fluid administration in the first 6 hours exceeds that volume which will result in a 6 mL/kg per percent burn resuscitation—should be monitored with a flow-directed pulmonary artery catheter. If the pulmonary artery occlusion pressure or measurements of right ventricular end-diastolic volume indicate an adequate intravascular volume, this type of patient may benefit from the use of a cardiac inotropic agent to augment cardiac output.

Occasionally, patients manifest a diminished cardiac output with a markedly elevated systemic vascular resistance when pulmonary artery wedge pressures indicate adequate fluid resuscitation. In these patients, administration of a short-acting afterload-reducing agent may result in a decrease in the systemic vascular resistance and an increase in the hourly urinary output. Administration of small doses of hydralazine (0.5 mg/kg) has been shown to be effective when used in this manner. In animal models of burn injury, sodium nitroprusside and verapamil administered during the resuscitation period reduced peripheral vascular resistance and increased cardiac output. This therapy should be administered cautiously and only to patients who have received adequate fluid loading. If used inappropriately, the resulting vasodilation will exacerbate the hypovolemia and further depress cardiac output and organ perfusion.

Excessive fluid administration during resuscitation may result in pulmonary edema, increased need for escharotomy, and even the need for fasciotomy in unburned limbs. Recently, the occurrence of intraabdominal compartment syndrome has been recognized as a complication of excessive fluid resuscitation. An increase in intraabdominal pressure to greater than 25 mm Hg may impair venous return and decrease cardiac output. This is often associated with elevated peak and mean airway pressures and high pulmonary artery wedge and central venous pressures. It is prudent to monitor intraabdominal pressure routinely using an indwelling bladder catheter in patients with extensive burns who receive fluid volumes of more than 25% of preburn total body weight during the resuscitation phase. More important, strict attention to the rate of fluid administration and reduction of excessive resuscitation fluid volumes should be emphasized.

Continuous monitoring of arterial blood pressure with indwelling arterial cannulas is not required in uncomplicated burn resuscitations. In patients with inhalation injury or those who do not respond as expected to fluid resuscitation, frequent monitoring of arterial blood gases should be performed, and a distal extremity artery should be cannulated to decrease the risk of complications associated with repetitive arterial puncture. Femoral arterial cannulation also has a low complication rate and may be employed if distal arterial cannulation is not possible.

Other measures of perfusion such as serum lactate, base deficit, and intramucosal pH, commonly followed during resuscitation of various shock states, may be difficult to interpret when used to monitor burn resuscitation. An elevation of plasma lactate concentration is observed frequently in severely burned patients and may in part reflect increased circulating levels of catecholamines. Glucose administration increases the rate of glucose oxidation with a subsequent increase in plasma lactate and pyruvate concentrations following thermal injury. Thus caution must be used in interpreting elevated serum lactate levels as related to the adequacy of burn resuscitation and systemic oxygen delivery. Similarly, measurement of the arterial base deficit during burn resuscitation often will yield values as low as -6 even though other measures of resuscitation, such as urinary output, are at normal levels. This may reflect a relative deficit in systemic oxygen delivery; however, the excessive fluid administration required to reverse the base deficit will result in complications of overresuscitation. Measurement of gastric intramucosal PCO_2 changes using a gastric tonometer may be used to detect intestinal ischemia during burn resuscitation. Patients with significant gastric acidosis have a mortality rate twice that of patients without acidosis. The deaths in this group were predominantly from multiple-organ dysfunction occurring several weeks after injury. This suggests that intestinal ischemia still may occur in some patients despite apparently adequate fluid resuscitation after thermal injury, inflicting persistent deleterious effects on distant organ function. Conversely, Venkatesh and colleagues have reported

depression of gastric mucosal pH in the presence of "normal" indices of systemic circulation and attributed this disparity to selective GI vasoconstriction and the development of tissue edema.

At the beginning of the second postburn day, when colloid replacement is initiated and infusion of lactated Ringer's solution is discontinued, the volume of 5% dextrose in water infused per hour should be equal to 25–50% of the preceding hour's volume of lactated Ringer's solution. If the urinary output remains greater than 30 mL/h, that infusion rate should be maintained for the next 3 hours, at which time the rate of infusion of 5% dextrose in water should be further reduced in a similar manner.

Pulmonary function must be reassessed continually throughout the resuscitative phase. Tachypnea may indicate metabolic acidosis from underresuscitation, hypoxemia, or restriction of chest wall motion owing to circumferential burns or massive edema. Evaluation must include auscultation, chest x-rays, and arterial blood gas analyses if a significant tachypnea occurs. Thermally injured patients in the ICU should be monitored with a pulse oximeter. In most patients, hemoglobin saturation by arterial blood gas analysis matches that obtained by pulse oximetry; however, patients with severely burned digits may be difficult to monitor using this method. In addition, a decrease in intensity of the pulsed signal detected in an extremity monitored by pulse oximetry may reflect inadequate distal perfusion from underresuscitation, constricting circumferential burn wounds, or arterial spasm owing to high levels of circulating catecholamines. Low oxygen saturation, as measured by pulse oximetry, also may indicate circulating levels of carboxyhemoglobin or methemoglobin as a consequence of the inhalation of carbon monoxide or cyanide, respectively.

In thermally injured patients requiring endotracheal intubation and mechanical ventilation, end-tidal CO_2 monitoring should be used to detect early changes in ventilation owing to inhalation injury or restriction of chest wall motion. This method of monitoring is particularly useful in pressure-controlled modes of mechanical ventilation. Chest radiographs should be obtained at least daily during resuscitation and the period of edema absorption. Subsequent x-rays are ordered as clinically indicated.

Serum chemistry profiles, complete blood count, arterial blood gases, and other baseline blood studies are obtained on admission, with further tests depending on the clinical situation. The patient's weight should be measured on admission and followed daily as an indicator of fluid balance.

Evaporative water loss from the wound typically peaks on the third postburn day and persists until the burn wound is healed or grafted. Insensible water losses may be estimated according to the following formula:

$$\text{Insensible water loss (mL/h)} = (25\% + \% \text{ BSA burned}) \times \text{total BSA (m}^2\text{)}$$

This formula, like the initial resuscitation formulas, is only an estimate, and replacement of evaporative water loss should be guided by assessing the adequacy of hydration by monitoring the patient's weight, serum osmolality, and serum sodium concentrations. Following elimination of the resuscitation-related salt and water load, salt-containing fluids should be administered in the amount needed to maintain a normal serum sodium concentration.

► Escharotomy & Fasciotomy

Edema formation beneath the inelastic eschar of circumferential full-thickness burns of the extremities may impair the circulation to the distal and underlying tissues. To prevent secondary ischemic necrosis of those tissues, an escharotomy may be necessary to reduce the elevated tissue pressure. To identify the need for escharotomy, the adequacy of circulation must be assessed at no less than hourly intervals. The most reliable determination is made with a Doppler flowmeter to detect pulsatile blood flow in the palmar arch, digital vessels in the upper limbs, and pedal vessels in the lower

limbs. Absence or progressive decrease of pulsatile flow on sequential examination is an indication for escharotomy. Clinical indicators of impaired extremity perfusion, including distal cyanosis, impaired capillary refilling, neurologic deficits, and deep tissue pain, are less precise in determining true impairment of blood flow and should be used only as indications for escharotomy when a Doppler flowmeter is unavailable. Fascial compartment pressure monitoring also has been described following thermal injury. Fascial compartment pressures often exceed 30 mm Hg following circumferential extremity burns, and escharotomy based on compartment pressures has been proposed. A greater sensitivity of direct compartment pressure measurements in detecting critically low-flow states and preserving threatened tissues has not been confirmed by direct comparison with Doppler flowmeter assessments. This technique is associated with a risk of infection arising in the pressure cannula tract, but the magnitude of the risk is undefined.

The escharotomy procedure may be performed in the ICU without the use of general or local anesthesia. Since only insensate, full-thickness burn is incised, the use of anesthetic agents is unnecessary. The first escharotomy incision is placed in the midlateral line of the involved extremity. If this does not improve distal blood flow, a second escharotomy incision is made in the mid-medial line of that limb (Figure 35–4). The escharotomy incision should be performed along the entire length of the full-thickness burn to

▲ **Figure 35–4.** The dashed lines show the preferred sites for escharotomy incisions. The solid segments of the lines demonstrate the importance of extending the incisions across joints with full-thickness burns.

ensure adequate release of vascular and neural compression. The incision must cross involved joints because the relative lack of subcutaneous tissue in these areas permits ready compression of vessels and nerves. The escharotomy incision should only penetrate the eschar and immediately subjacent thin connective tissue to permit expansion of the edematous subcutis. When performed at this level, loss of blood from the escharotomy incision is minimal and readily controlled by electrocoagulation or application of pressure. When incisions are carried into the subcutaneous tissues, excessive bleeding often occurs. The consumptive coagulopathy that may occur in the early postburn period may contribute to excessive blood loss when escharotomy incisions are made too deep.

Fasciotomy is rarely required to restore circulation in a thermally injured limb. However, in patients with high-voltage electrical injury, fasciotomy is often necessary. Patients with very deep burns involving fascia and muscle or patients with associated traumatic injuries may require fasciotomies to restore adequate limb circulation.

Escharotomies also may be required in patients with circumferential truncal burns to relieve restriction of chest wall movement by the unyielding eschar and restore more effective ventilation. The escharotomy incision is made in the anterior axillary line in the area of full-thickness burn. An incision along the lower margin of the rib cage may be necessary in patients with deep burns extending onto the upper abdominal wall (see Figure 35–4). Patients may become restless, agitated, and tachypneic despite having an adequate airway, indicating the need for chest escharotomy. In mechanically ventilated patients, the need for escharotomy is manifested by a progressive increase in peak inspiratory pressure, decreased tidal volumes in pressure-controlled ventilation, and an increase in the end-tidal CO₂ fraction. Once chest escharotomy is performed, these changes promptly revert toward normal.

CARE OF THE BURN WOUND

► Debridement

Only after respiratory and hemodynamic stability have been achieved should care of the burn wound be addressed. During transport of the patient from the accident scene or from the initial care facility to a burn center, the burns should be covered with clean sheets or blankets and no attempt made to debride or dress them. In the absence of gross contamination, burn wounds may be managed safely without topical antimicrobial agents for the first 24–48 hours. When the patient arrives at the definitive care facility, general anesthesia is not necessary for initial burn wound

debridement; intravenous analgesia is sufficient for pain control during this procedure. The burns are gently cleansed with a surgical soap solution, and nonviable epidermis is debrided. Bullae are excised, and body hair is shaved from the area of thermal injury beyond the margin of normal skin. The patient is placed in a clean bed, and bulky dressings may be placed beneath the burned parts to absorb the serous exudate. These dressings should be changed as they become saturated. Patients should be turned frequently to prevent maceration of burned and unburned skin.

► Topical Antimicrobial Therapy

The development and clinical use of effective topical antimicrobial agents has decreased the incidence of invasive burn wound infection and subsequent sepsis significantly. This has been associated with improved survival of burn patients and nearly eliminated invasive bacterial burn wound infection as a cause of death. Mafenide (Sulfamylon), silver sulfadiazine (Silvadene), and silver nitrate are the three topical antimicrobial agents employed most commonly for burn wound care. Each agent has specific advantages and limitations with which the physician must be familiar to ensure optimal benefit and patient safety. Mafenide acetate and silver sulfadiazine are available as topical creams to be applied directly to the burn wound. Silver nitrate is applied as a 0.5% solution in occlusive dressings.

Mafenide burn cream is an 8.5% by weight suspension of mafenide acetate in a water-soluble base. Mafenide is very water-soluble and diffuses freely into the eschar. Mafenide is the preferred agent if the patient has heavily contaminated burn wounds or has had burn wound care delayed by several days. Mafenide has the added advantage of being highly effective against gram-negative organisms. The limitations of mafenide burn cream include hypersensitivity reactions in 7% of patients, pain or discomfort of 20–30 minutes' duration when applied to partial-thickness burns, and carbonic anhydrase inhibition. The latter may produce an early bicarbonate diuresis and increase postburn hyperventilation. This metabolic acidosis may develop into significant acidemia if respiratory complications occur and the compensatory hyperventilation is impaired. Carbonic anhydrase inhibition rarely persists for more than 7–10 days, and the severity of acidosis can be minimized if mafenide is applied once per day followed by an application of silver sulfadiazine cream 12 hours later.

Silver sulfadiazine burn cream is a 1% suspension of silver sulfadiazine in a water-miscible base. Unlike mafenide acetate, silver sulfadiazine has limited solubility in water and thus limited penetration into the eschar. The agent is most effective when applied to burns immediately after injury to minimize bacterial proliferation on the wound's surface. This agent has the advantage of being painless on application and has no effect on serum electrolytes or acid-base balance. Silver sulfadiazine burn cream may induce neutropenia, which usually subsides after discontinuation of the agent.

Hypersensitivity is uncommon and is manifested by an erythematous maculopapular rash on unburned skin. The sulfadiazine component of silver sulfadiazine is ineffective against certain strains of *Pseudomonas* and virtually all *Enterobacter* species; however, the sensitivity of microorganisms colonizing burn wounds to the silver ion of this compound maintains its effectiveness as a topical antimicrobial agent.

Either cream is applied in an $\frac{1}{8}$ -inch layer to the entire burn wound in an aseptic manner following initial debridement and is reapplied at 12-hour intervals to ensure continuous topical chemotherapy. Once each day, all the topical agent should be cleansed from the patient using a surgical detergent or disinfectant solution and the wounds inspected by the attending physician.

Silver nitrate solution (0.5%) delivered in multilayered occlusive gauze dressings may provide an effective antimicrobial barrier to the burn wound surface. This agent is employed most commonly when a history of allergy to sulfonamide drugs is elicited or when the patient develops a hypersensitivity reaction to one of the burn creams. The dressings are changed two or three times daily and moistened every 2 hours to prevent evaporation from increasing the silver nitrate concentration to cytotoxic levels within the dressings. Transeschar leaching of sodium, potassium, chloride, and calcium should be anticipated and replaced appropriately. Because silver nitrate precipitates on contact with the proteinaceous exudate of the burn wound and does not penetrate the eschar, it is not effective for treatment of burn wound infection or for prophylactic treatment of heavily contaminated wounds. A common use of silver nitrate is for topical antimicrobial prophylaxis in patients with toxic epidermal necrolysis syndrome, a disorder caused by idiosyncratic drug reactions resulting in significant epidermal sloughing. Hypersensitivity to silver nitrate has not been described.

Acticoat is a new burn wound dressing. It consists of a urethane film onto which nanocrystalline elemental silver is deposited. When moistened, application of this dressing to the wound results in a sustained release of elemental silver, which is bactericidal and fungicidal. The mechanism of action is probably much like that of silver nitrate dressings; however, Acticoat does not cause transeschar leaching of electrolytes. The silver does not penetrate the eschar, limiting its use on infected or heavily contaminated wounds. Transient mild pain may be noted occasionally after application. The use of Acticoat is currently limited to partial-thickness burns.

Aquacel Ag hydrofiber (ConvaTec, a Bristol-Myers Squibb Company, Skillman, NJ) is another dressing containing elemental silver, although at a much lower concentration. When compared with silver sulfadiazine on partial-thickness burns, this dressing was associated with an increased rate of reepithelization and was a slightly more cost-effective. This study was limited owing to sample size; however, the replacement of burn cream pharmaceuticals with silver-containing barrier dressings is occurring in certain settings, namely, those of superficial burns.

All these agents are effective in the prevention of invasive burn wound infection. However, because of their lack of eschar penetration, silver nitrate soaks and silver sulfadiazine burn cream are most effective in the treatment of full-thickness burns when applied immediately following burn injury.

▶ Burn Wound Infection (See Figure 35-5)

ESSENTIALS OF DIAGNOSIS

- ▶ Hypo- or hyperthermia.
- ▶ Tachycardia and tachypnea.
- ▶ Glucose intolerance.
- ▶ Disorientation.
- ▶ Ileus.
- ▶ Change in appearance of the burn wound.

General Considerations

Inherent characteristics of the microorganisms and the burn wound they colonize influence the rate of microbial penetration of and proliferation in the eschar. The moist, protein-rich, avascular eschar serves as an excellent culture medium from which white blood cells and systemically administered antibiotics are excluded. The density of bacterial colonization of the eschar influences the likelihood of burn wound infection. Bacterial invasion is uncommon unless the number of microorganisms exceeds 10^5 per gram of tissue. Bacterial strain-specific factors such as enzyme production

▲ **Figure 35-5.** The frequency of infection by site expressed as a percentage of all infections complicating thermal injury.

(eg, collagenase, protease, etc.), bacterial motility, and antibiotic resistance may be important in the pathogenesis of eschar penetration and invasion of viable tissues.

Although the use of topical chemotherapeutic agents and the timely excision and grafting of the burn wound have decreased the incidence of invasive burn wound infection in most U.S. burn centers, this problem has not been eliminated entirely. Invasive burn wound infection is uncommon in second-degree burns and in patients with burns of less than 30% of the body surface. Extremes of age and increasing size of burn strongly influence the risk of developing invasive burn wound infection.

Clinical Features

A. Symptoms and Signs—Clinical signs of invasive burn wound infection are often indistinguishable from those observed in uninfected hypermetabolic burn patients or burn patients with other sources of sepsis and include hyper- or hypothermia, tachycardia, tachypnea, ileus, glucose intolerance, and disorientation. Tinctorial and physical changes in the appearance of the burn wound are more reliable signs of invasive burn wound infection (Table 35-5). The development of clinical signs and symptoms of sepsis in the thermally injured patient should prompt a thorough examination of the burn wound to identify areas suspicious for invasive infection.

B. Laboratory Findings—Surface cultures of the eschar cannot distinguish colonization from invasive infection. Quantitative bacteriologic cultures of burn wound tissue correlate poorly with the presence of invasive burn wound infection. Quantitative bacteriologic counts less than 10^5 per gram of biopsy tissue correlate with absence of invasive burn wound infection; however, even when quantitative counts exceed 10^5 organisms per gram of biopsy tissue, histologic examination confirms invasive infection in less than half of biopsy specimens.

Histologic examination of a biopsy of the burn wound and underlying viable tissue is the most rapid and reliable method for differentiating microbial colonization of nonviable eschar from microbial invasion of viable subeschar tissue. The latter defines invasive burn wound infection. A burn wound biopsy is performed as an ICU procedure. A 500-mg elliptical biopsy (0.5×1.0 cm) including subjacent unburned

Table 35-5. Clinical signs of burn wound infection.

Conversion of second-degree burn to full-thickness necrosis
Focal dark brown or black discoloration of wound
Degeneration of wound with "neoeschar" formation
Unexpectedly rapid eschar separation
Hemorrhagic discoloration of subeschar fat
Erythematous or violaceous, edematous wound margin
Metastatic septic lesions in unburned tissue

Table 35-6. Histologic staging of burn wound infection.

Stage I: Colonization

- A. Superficial: Sparse microbial population on burn wound surface.
- B. Penetration: Microorganisms present in variable thickness of eschar.
- C. Proliferation: Dense population of microorganisms at interface of nonviable and viable tissue.

Stage II: Invasion

- A. Microinvasion: Microscopic foci of microorganisms in viable tissue immediately subjacent to subeschar space.
- B. Generalized: Widespread penetration of microorganisms deep into viable subcutaneous tissues.
- C. Microvascular: Involvement of lymphatics and microvasculature.

tissue is obtained by scalpel dissection from the area of the burn wound identified as suspicious for infection. Hemostasis is achieved by application of direct pressure or by electrocoagulation. Half the specimen is cultured for organism identification and antibiotic sensitivities, and the other half is submitted for histologic analysis. The presence of microorganisms in viable tissue confirms the diagnosis of invasive burn wound infection. The histologic staging scheme for burn wound colonization and infection is presented in Table 35-6. If only colonization (stage 1A to stage 1C) is present, no specific change in antimicrobial therapy is indicated unless serially obtained specimens document a progression of colonization stage. If stage 2 (invasion) is reported, prompt treatment for invasive burn wound infection should begin.

Treatment

When the diagnosis of invasive burn wound infection is made, local and systemic antimicrobial therapy is initiated. In the case of bacterial burn wound invasion, topical chemotherapy should be in the form of twice-daily applications of mafenide acetate because of its superior eschar penetration. Systemic antibiotic therapy is initiated based on prior surface cultures or burn center organism prevalence. Further refinements in therapy are based on biopsy, culture, and sensitivity results. Customary critical care supportive measures are employed to maintain hemodynamic and respiratory stability. Subeschar antibiotic clysis of the infected area with a broad-spectrum penicillin is recommended at 12 hours and immediately prior to operation to minimize the risk of hematogenous seeding and florid septic shock at the time of eschar excision. Half the daily dose of a broad-spectrum penicillin (eg, piperacillin or ticarcillin) delivered in 1 L of normal saline is infused into the subeschar tissues by means of a no. 20 spinal needle. Excision of the burn wound to the level of the investing fascia is employed to ensure removal of all nonviable tissue. The wound is usually treated with moist dressings of 5% mafenide acetate, 0.5% silver nitrate, or a biologic dressing. The patient is returned to the operating room in 24–48 hours for wound inspection and debridement or split-thickness skin grafting as needed.

In addition to bacteria, fungi and yeasts also cause invasive burn wound infection and have become the predominant organisms causing burn wound infection because topical therapy and early excision have reduced the incidence of bacterial infection. *Candida* species commonly colonize wounds but rarely cause invasive burn wound infection. *Aspergillus*, the most common filamentous fungus that causes invasive burn wound infection, usually remains confined to subcutaneous tissues and seldom transverses fascial planes. Wounds colonized by *Candida* or *Aspergillus* can be treated with topical application of clotrimazole, but histologic evidence of invasion requires surgical burn wound excision and initiation of systemic amphotericin B therapy. The Phycomycetes often behave in a manner similar to *Aspergillus*; however, these organisms may spread rapidly along tissue plains, invade blood vessels, and penetrate fascia. Aggressive wide debridement, including amputation, may be necessary to control these infections.

► Burn Wound Excision & Grafting

Technique

The current operative management of burns employs tangential excision of eschar to viable dermis or fat and scalpel excision to the level of the investing fascia for burn wound removal. Burn wound excision may be performed early in the postburn course once the patient is hemodynamically stable and resuscitation is complete.

The operative procedure should be limited to excision of 20% of the body surface area, an area of excision producing a blood loss equal to the patient's blood volume, or 2 hours of operative time. Careful anesthetic management is imperative to avoid hypotension and hypothermia. Hypotension may impair blood flow to areas of second-degree burn, resulting in ischemia of the wound and conversion to full-thickness injury. The depth of excision in tangential and sequential burn wound removal is governed by the appearance of healthy tissue and punctate bleeding from dermal beds. Scalpel excision of burns involves removal of the wound and underlying subcutaneous tissue to the level of the investing muscle fascia. This may be accomplished more rapidly and with significantly less blood loss than tangential or

sequential wound excisions. Once a viable wound surface is obtained, wound coverage is accomplished with autograft or biologic dressings.

Conventional skin grafting is achieved with cutaneous autografts 0.008–0.012 inches thick. These grafts may be employed as a sheet graft or meshed to provide expansion ratios ranging from 1.5:1 to 9:1. Expansion ratios of 4:1 or greater require a prolonged time for interstitial closure, have a greater propensity for scar formation, and are used only in patients with massive burns and limited donor sites. Following grafting, occlusive dressings moistened with topical antibiotic agents are applied. The wounds are kept moist to prevent desiccation until the interstices of the graft have epithelialized.

Skin Substitutes and Biologic Dressings

In massively burned patients, the disparity between donor-site area and burn-wound area requires the use of temporary skin substitutes or biologic dressings to effect wound closure while awaiting donor-site availability. Biologic dressings prevent desiccation of the wound bed, decrease protein and fluid losses, promote angiogenesis of granulation tissue, and reduce pain. Viable cadaver allograft currently provides the best temporary wound coverage. Allograft becomes vascularized from the underlying wound bed and usually remains adherent until surgically excised or immunologically rejected by the patient. As a result of the immunosuppression associated with thermal injury, the allograft may remain intact, vascularized, and viable for several weeks following application. The same theoretical risks of disease transmission (eg, hepatitis, HIV infection, etc.) associated with organ donation apply to the use of cadaveric allografts. Appropriate tissue banking measures are imperative. In addition to fresh cadaver allograft, frozen and lyophilized allograft is available from many sources.

Porcine xenograft is also available as a fresh, frozen, or lyophilized preparation. Advantages include an abundant supply and lower cost. This biologic dressing, however, does not become vascularized and adheres to the wound bed by fibrin bonding. The underside of the graft is nourished by the plasma circulation, and desiccation and necrosis of the outer surface usually occur within 1 week. Application of porcine cutaneous xenografts to superficial partial-thickness wounds facilitates healing and decreases pain. Porcine xenografts are of limited usefulness in the coverage of excised wounds because of their lack of vascularization and the limited time until desiccation and necrosis occur.

Several synthetic skin substitutes have been developed in an attempt to avoid the problems of disease transmission and storage requirements common to biologic dressings. The most successful materials have been of a bilaminated configuration with an outer layer mimicking epidermis that allows water vapor transmission and prevents bacterial contamination. The inner dermal layer is designed to promote adherence and fibrovascular ingrowth from the wound bed. Biobrane is currently the most commonly used synthetic skin

substitute. The epidermal layer is composed of pliable Silastic, and the dermal component is derived from porcine collagen. This product is available with a variety of pore sizes, and its elastic nature allows freedom of motion and is well adapted to body contours. Biobrane promotes healing of second-degree burns and usually provides adequate short-term coverage for excised wounds, although submembrane suppuration and lack of adherence cause difficulties. Integra is a synthetic dermal substitute that is unique in that a neodermis is formed by fibrovascular ingrowth into a glycosaminoglycan matrix dermal analogue. The epidermal component is Silastic and is removed once the dermal analogue is vascularized, allowing definitive closure of the wound with ultrathin split-thickness autografts. This permits more rapid healing of donor sites for repeated autograft harvesting. Incomplete adherence, submembrane suppuration, and technical problems with the application of ultrathin autografts have been observed.

TransCyte is a bilaminated biosynthetic skin substitute used as a temporary dressing on second-degree burns or excised full-thickness burns. This product is composed of Biobrane on which human foreskin-derived neonatal dermal fibroblasts are seeded and grown to confluence in culture. The fibroblasts secrete matrix proteins and growth factors that remain active after the product is frozen. Application of TransCyte to the wound surface is similar to that of Biobrane. It also carries the same limitations.

The availability of commercial laboratories capable of carrying out skin culture techniques has led to the recent evaluation of cultured autologous keratinocytes for coverage of wounds in massively burned patients. Current culture techniques require 3 or more weeks of preparation for a product six to eight epidermal cells in thickness. These grafts are quite fragile and susceptible to bacterial colonization of the recipient wound bed and minimal shear forces. The use of cultured autologous keratinocytes to effect wound closure in massively burned patients was studied recently. In a series of 16 patients with an average burn size greater than 60% of BSA, definitive final engraftment covered only 4.7% of the body surface area at a cost of over \$9000 per percent of BSA closed. Wound bed microbial colonization, lack of dermal elements, and patient age may be significant factors relating to the failure of culture-derived cells as a definitive form of burn wound coverage. This technology has the potential for providing timely coverage of large surface areas but is presently limited by the aforementioned problems.

▶ Inhalation Injury

ESSENTIALS OF DIAGNOSIS

- ▶ Facial burns.
- ▶ Intraoral burns or carbonaceous sputum.
- ▶ Edema, erythema, mucosal ulcerations on laryngoscopy.
- ▶ Increased ¹³³Xe retention.
- ▶ Decreased Pao₂ and expiratory flow rates.

General Considerations

Pulmonary injury from smoke inhalation is frequently observed in patients with thermal injury who require admission to a burn center. In a recent series, 33% of patients had concomitant inhalation injury. The injury caused by the inhalation of smoke or toxic gases may include chemical damage to the respiratory system, carbon monoxide toxicity, and infrequently, direct thermal injury to the tracheobronchial tree. Patients most likely to have inhalation injury are those with burns sustained in a closed space and those who were burned during a period of depressed consciousness secondary to head trauma or drug intoxication.

Direct thermal injury to the airway is encountered rarely in patients who survive a fire and are hospitalized for treatment. However, autopsy series of patients dying at the scene of a fire frequently reveal devastating direct thermal injury to the airways. The effective cooling capabilities of the nasopharynx and oropharynx prevent significant heat exposure of the lower respiratory system; however, direct thermal injury to the supraglottic airway does occur and may lead to upper airway obstruction. An exception is burns caused by exposure to steam because water has a heat-carrying capacity 4000 times greater than that of air.

Smoke inhalation—particularly when the injury occurred in a closed space—may be associated with carbon monoxide poisoning, which may impair tissue oxygenation. The presence of carboxyhemoglobin or the chemical alteration of the cytochrome system by carbon monoxide does not affect the amount of dissolved oxygen in the blood; thus the Pao₂ will remain normal. However, saturation of hemoglobin by oxygen may be markedly reduced, impairing oxygen delivery.

The inhalation of smoke (incomplete products of combustion) is manifest by deleterious effects on both the airway and

the pulmonary vasculature. The anatomic location of pulmonary injury depends on the size of the inhaled particle. When the particle diameter is less than 0.05 μm , the larger, endoscopically visible airways may appear normal in the presence of severe alveolar and terminal bronchiolar inflammatory damage. Alternatively, the larger airways may be severely inflamed, leading to mucosal ulceration or necrosis in the presence of relatively normal gas exchange and alveolar function.

In various animal models of inhalation injury, increased pulmonary microvascular permeability and peribronchial edema have been reproduced. Thromboxane A_2 levels have been found to increase within 5 minutes of inhalation injury, with levels correlating with increases in lung lymph flow and extravascular lung water. The role of the neutrophil in the pathophysiology of smoke inhalation is currently under investigation. Both the preinjury induction of a neutropenic state by administration of mechlorethamine and postinjury treatment with pentoxifylline have been reported to attenuate pulmonary artery hypertension, reduce pulmonary vascular resistance, and decrease the severity of pulmonary insufficiency following smoke exposure in animals. Although alterations in surfactant function have been described following smoke inhalation, surfactant replacement has not been shown to improve pulmonary function in animal models of inhalation injury.

Clinical Features

A. Symptoms and Signs—Smoke inhalation should be suspected in patients with facial burns, singed facial hair and nasal fibrillae, intraoral burns or carbonaceous deposits in the oropharynx, or a history of being burned in a closed space.

B. Bronchoscopy—The diagnosis of inhalation injury is made by examination of the upper airway and tracheo-bronchial tree by fiberoptic bronchoscopy. Direct laryngoscopy also may be used to visualize the upper airway. The presence of carbonaceous material, edema, erythema, or mucosal ulcerations below the vocal cords confirms the diagnosis. An endotracheal tube of appropriate size should be placed over the fiberoptic bronchoscope before the examination so that intubation may be readily achieved if the appearance of upper airway edema threatens airway patency. False-negative bronchoscopic examinations occur occasionally and usually are secondary to the failure to observe inflammation and erythema in the hypovolemic patient with impaired tracheal mucosa perfusion.

C. Radionuclide Studies— ^{133}Xe ventilation-perfusion lung scans may be performed in patients in whom the clinical suspicion of inhalation injury is high yet the bronchoscopic examination appears relatively normal. After intravenous injection of 10 μCi of ^{133}Xe , serial chest scintigraphs are obtained. Retention of the gas in the lungs for over 90 seconds following injection or an unequal distribution of radiation density is considered diagnostic of inhalation injury. The false-negative and false-positive rates from this study are 5% and 8%,

respectively. False-negatives result from marked hyperventilation and false-positives from preexisting chronic obstructive pulmonary disease (COPD), bronchitis, or atelectasis.

D. Respiratory Function Studies—Measurements of pulmonary function also may be helpful in establishing the diagnosis of inhalation injury. Burn patients with inhalation injury may have a decreased PaCO_2 and peak expiratory flow and an increased ventilation-perfusion gradient, airway resistance, and nitrogen washout slope. Static and dynamic compliance tends to be normal in the early phase of inhalation injury. The complexity of some pulmonary function tests and the requirement for full patient cooperation often limit their clinical usefulness as aids to the early diagnosis of inhalation injury.

The diagnosis of inhalation injury can be made with 96% accuracy when the results of fiberoptic bronchoscopy, ventilation-perfusion scanning, and pulmonary function testing are combined. Overdiagnosis of inhalation injury accounts for the 4% error.

Treatment

A. General Measures—The current treatment of inhalation injury is primarily supportive because no specific agent has been identified that minimizes the severity of the insult. The aim of treatment, therefore, is to correct the underlying pulmonary insufficiency while minimizing further iatrogenic pulmonary insults. The amount of intervention required is guided by the severity of pulmonary insufficiency.

B. Respiratory Support—Patients with mild disease require only administration of humidified oxygen-enriched air (usually 40%) and noninvasive pulmonary physiotherapy. Severe injury may require maximal mechanical ventilatory support and frequent flexible fiberoptic or rigid bronchoscopy to clear the airways of sloughed mucosal debris and secretions. Small-airways disease may produce significant atelectasis requiring increased oxygen administration and institution of positive end-expiratory pressure. Systemic administration of steroids has not decreased morbidity or mortality rates in patients with inhalation injury, and such treatment has been reported to increase infectious complications.

A recent clinical trial of the prophylactic use of high-frequency percussive ventilation in patients with inhalation injury demonstrated significant improvements in morbidity and mortality rates compared with conventional volume ventilation. Fifty-four burn patients with documented inhalation injury were managed by this type of ventilation within 24 hours of intubation. Fourteen patients (25.9%) developed pneumonia, compared with a predicted historical frequency of 45.8%. The observed mortality rate was 18.5% compared with a historical frequency of 35%. Only 4 of the 10 deaths were attributable to pulmonary failure. Although the exact mechanism by which high-frequency percussive ventilation improves outcome is not known, the ability to maintain ventilation and oxygenation at lower peak

airway pressures and inspired oxygen concentrations may reduce the iatrogenic injury associated with the use of volume-controlled ventilators. The high frequency percussive breaths also improve clearance of secretions—similar to results obtained with high-frequency oscillators and jet ventilators.

C. Antimicrobial Therapy—Bronchopneumonia is the most common cause of morbidity and death in patients with inhalation injury. The daily chest roentgenograph should be examined carefully. Appropriate antimicrobial therapy is initiated based on the presence of pulmonary infiltrates and sputum leukocytosis. Pneumonia occurring after inhalation injury usually is caused by gram-positive organisms. Gram-negative pneumonias, which now occur infrequently, usually develop later in the hospital course. Therapy is initiated based on the results of the sputum Gram stain, with refinements of antibiotic choice depending on endobronchial culture and microbial sensitivity testing.

Prognosis

Smoke inhalation, in the absence of cutaneous thermal injury, is almost always treated successfully by supportive measures. The tracheobronchial mucosa typically heals completely in 2–3 weeks. However, when smoke inhalation occurs in the presence of moderate to severe cutaneous burn, mortality rates are increased by as much as 20% over those predicted by the age of the patient and the extent of injury. When pneumonia complicates inhalation, the mortality rate may rise to 60% above the predicted level.

POSTRESUSCITATION PERIOD

► Prevention & Treatment of Complications

1. Infection Control

Infectious complications always have been the predominant determinant of outcome in thermally injured patients.

Improved care of critically ill patients and the control of burn wound sepsis through effective topical antimicrobial agents and timely excision and grafting have resulted in the salvage of more burn patients who previously would have died in the early postburn period. The hospital course of nonsurvivors also has been prolonged. Since infection continues as the leading cause of morbidity and death in burn patients, prolonged hospitalization increases the risk of colonization and infection by nosocomial organisms that are predominantly true fungi, yeasts, and multiply-antibiotic-resistant bacteria.

A strict infection control program can minimize the clinical impact of exposure to nosocomial pathogens during a prolonged hospital stay in an immunocompromised patient. Such a program might employ scheduled microbial surveillance, an actively functioning infection control committee, environmental monitoring procedures, biopsy monitoring of the burn wound, and cohort patient care as deemed necessary. The surveillance program includes thrice-weekly cultures of sputum and the burn wound surface and twice-weekly culturing of urine and stool. Multiple antibiotic sensitivities are determined for all *staphylococci* as well as all *Pseudomonas* species and other gram-negative organisms recovered from routine cultures. Reports are provided on a daily basis, enabling initial empirical selection of antibiotics to be made more precisely should an infection be diagnosed.

Cohort patient care is initiated if a patient is admitted and found to be colonized or infected with an organism of broad antibiotic resistance or if this resistance pattern develops during broad-spectrum antibiotic therapy.

Cross-contamination is minimized by strict enforcement of hand washing, gowning, and gloving policies. The establishment of patient care teams to provide care for only one specific patient or a limited number of patients and restriction of the traffic of convalescing patients (often colonized with resistant organisms) are imperative in reducing cross-contamination and eradicating endemic microorganisms.

The infection control committee monitors infections occurring in the burn unit to identify changes in microbial prevalence, the incidence of infection, and evidence of cross-contamination. Strict criteria for the definition and identification of infections that occur in burn patients are necessary to avoid unnecessary and inappropriate antibiotic administration. Antibiotics are used only for specific indications to minimize the emergence of microbial resistance. Effective infection control policies require continual reevaluation of surveillance culture results and correlation with the sites and treatment of infections.

2. Infectious Complications: Prevention, Diagnosis, & Treatment

With the decrease in fatal burn wound sepsis and improved survival of patients with massive burns, infections in other sites have shown a relative increase as principal causes of

death. Dense bacterial colonization of the burn wound and the presence of immunosuppression associated with burn injury increase the likelihood of development of infectious complications.

Pneumonia

Pneumonia is the most frequent septic complication following thermal injury. As the occurrence of invasive burn wound infection has decreased, bronchopneumonia has surpassed hematogenous pneumonia as the predominant form. The increase in airborne pneumonia also may be attributable to improved survival in patients with severe inhalation injury. Atelectasis is often present prior to the development of infection. The appearance of an ill-defined irregular infiltrate on chest x-ray mandates Gram stain, culture, and sensitivity testing of endobronchial secretions. Empirical antibiotic treatment is begun as determined by microbiologic surveillance and Gram stain of the secretions. Subsequent antibiotic therapy is adjusted on the basis of sensitivity testing.

Compared with bronchopneumonia, hematogenous pneumonia usually occurs later in the hospital course. Remote septic foci such as invasive wound infection, endocarditis, and suppurative thrombophlebitis are common causes. The radiographic hallmark is a solitary nodular pulmonary infiltrate, but progression to multiple nodular infiltrates throughout the lungs may occur. All possible sites of infection must be evaluated if a characteristic nodular pulmonary infiltrate appears. The primary infection must be identified and treated. The pneumonic process is treated by systemic administration of antibiotics directed against the causative organism and ventilatory support as needed. Aggressive pulmonary toilet to prevent atelectasis may help to decrease the occurrence of pneumonia, although most routine measures have little proved benefit.

Suppurative Thrombophlebitis

The loss of skin integrity, the presence of dense bacterial colonization of the burn wound, and the frequent need for long-term venous access increase the likelihood that suppurative thrombophlebitis will develop in burn patients. Limiting the duration of cannulation of a vein to 3 days or less in patients with thermal injury has reduced the incidence of this complication from 4.3% to less than 1.4% in recent years. Local signs of thrombophlebitis are present in less than half of patients with this complication because of the presence of the overlying burn wound and the systemic immunosuppression accompanying burn injury. With the increased use of central venous cannulation, these patients are also at risk for development of central vein suppurative thrombophlebitis.

The diagnosis of peripheral vein suppurative thrombophlebitis is made by operative exploration, excision, histologic

analysis, and culture of the suspected phlebotic vein. Identification of bacteria within the vein necessitates excision of the entire length of involved vein to a level of patent normal vein and the administration of systemic antibiotics to which the causative microorganism is sensitive. The diagnosis of central venous thrombophlebitis is more difficult. Indium-111-labeled leukocyte scanning, CT scanning, and contrast venography may help to establish the diagnosis. This rare complication is treated with systemic antibiotics directed against the organism isolated by blood culture and anticoagulation with heparin. The efficacy of thrombolytic therapy in the treatment of central venous thrombosis is unclear. The failure of antibiotics and anticoagulation to eradicate the infectious focus mandates surgical exploration and vein excision.

The true incidence of intravascular catheter-related bacteremia in thermally injured patients is unknown. Vascular access through a densely colonized wound in those with extensive surface area burns limits the use and effectiveness of standard catheter care policies employed for other critically ill patients. Presumably, as a result of contamination by removal through colonized eschar and skin, catheter tip cultures frequently are positive even in the absence of sepsis or bacteremia. Exchanging catheters over guidewires, an accepted practice in most ICUs, is discouraged because the catheters and guidewires often transverse heavily contaminated open wounds or intact eschar. Consequently, central venous and pulmonary artery catheters are removed and a new catheter inserted at a different site every 3 days. This policy has resulted in a low incidence of bacteremia and sepsis clinically attributable to catheter-related infections.

Endocarditis

Acute infective endocarditis is an infrequent but consistent source of morbidity and mortality in burn patients (1.3%) owing to the bacteremias associated with wound manipulation, prolonged intravenous cannulation, and septic thrombophlebitis. Preventive measures include effective topical antimicrobial therapy, timely excision and closure of the burn wound, and early discontinuation or frequent replacement of intravenous cannulas.

Staphylococcus aureus is the most common causative organism, and the right side of the heart is affected most frequently. Recurrent staphylococcal bacteremia in a burn patient with sepsis and no other apparent identifiable source of infection should suggest the diagnosis. Heart murmurs are difficult to detect in hyperdynamic, tachycardiac patients. Transesophageal echocardiography is the preferred examination to detect valvular lesions, but small vegetations may remain undetected. On occasion, cardiac catheterization—to identify valvular vegetations or valvular incompetence—may be required for definitive diagnosis if echocardiographic findings are equivocal. Systemic maximal-dose antibiotic therapy is directed against the causative organism. Antibiotic therapy is continued for 6 weeks after the last positive blood culture.

Sinusitis

The true incidence of sinusitis in burn patients is unclear, but patients requiring prolonged transnasal intubation of both the airway and stomach are at increased risk. One study reported an incidence of 36% in transnasally intubated ICU burn patients. Sinusitis is most often clinically undetectable and requires radiographic examination by plain films or CT scanning to establish the diagnosis. These studies help to direct sinus aspiration to differentiate between congestion and infection. Treatment involves topical mucosal vasoconstrictors to improve patency of the sinus ostia and removal of transnasal tubes. Appropriate systemic antibiotic therapy should be initiated. Surgical drainage is required in cases not responsive to these procedures. Tracheostomy or gastrostomy may be necessary if prolonged ventilatory support and enteral nutrition are required.

Other Complications

A. Ocular—Thermal injury of the ocular adnexa is common in patients sustaining facial burns, but actual injury to the cornea and globe is uncommon because of the blepharospasm induced by heat, noxious gases, and smoke. Exceptions occur in patients with altered sensoria at the time of burning and incomplete protection of the globe. Shortly after admission, fluorescein staining of the cornea and examination with a Wood's lamp should be performed to detect loss of epithelial integrity. If epithelial defects are noted, prophylactic topical antibiotic therapy, for example, bacitracin zinc-neomycin sulfate-polymyxin B sulfate ophthalmic ointment, should be initiated. Ophthalmologic consultation should be obtained and the defects examined daily to document resolution or progression of the epithelial defects, the major hazard of which is bacterial infection. Minor corneal abrasions that become infected may progress rapidly to corneal ulceration and globe perforation. Infections caused by *Pseudomonas* species are particularly prone to this complication.

Frequent ocular examination, adequate eye lubrication, prophylactic and therapeutic use of topical antibiotics, and timely performance of eyelid releases are paramount in the prevention of ocular complications. With severe burns of the eyelids, ectropion or loss of lid margin may occur. If the cornea is no longer protected, operation is indicated in the form of an eyelid release with split-thickness skin grafting. Release of one or both lids may be required, and in severe cases, repeated release of the same lid may be made necessary by progressive skin graft contracture. A temporary tarsorrhaphy is sometimes useful to protect the cornea from exposure, but severe ectropion or loss of the lid margin limits the usefulness of this technique.

B. Gastrointestinal—Many GI complications have been documented following thermal injury and include pancreatitis, acalculous cholecystitis, gastroduodenal stress ulceration,

and Ogilvie's syndrome. Stress ulceration of the upper GI tract has been controlled effectively by prophylactic antacid or H₂-receptor antagonist therapy. Hemorrhage or perforation requiring operative management occurred in only five patients (0.1%) during a 14-year series. In a recent study, the prophylactic administration of sucralfate has been found equally effective in stress ulcer prevention. Gastric colonization with gram-negative organisms occurred later among patients receiving sucralfate than among those receiving antacids, but this did not change the incidence or type of pneumonia occurring following burn injury.

Superior mesenteric artery syndrome may occur in patients who sustain profound weight loss during their hospital course. This condition results in compression and obstruction of the transverse duodenum by the superior mesenteric artery from weight loss–induced changes in the anatomic position of this vessel. Current nutritional practices have nearly eliminated this complication. If diagnosed, initial management should be directed toward nutritional repletion and nasogastric decompression. Nasoenteral feeding tubes may be guided past the obstruction under fluoroscopic guidance and are preferred over parenteral alimentation. Operation is rarely necessary.

The management of GI complications in thermally injured patients is the same as in other critically ill patients. If operation is required, retention sutures should be used in closing any abdominal incision in burn patients owing to the increased risk of postoperative wound infection and fascial dehiscence.

NUTRITION

▶ Postburn Hypermetabolism

Extensive thermal injury may cause metabolic rates to rise to levels one and one-half to two times normal, far exceeding the hypermetabolism observed in other critically ill patients. The hypermetabolic response is linearly related to the extent of burn, and the actual physiologic response is influenced by environmental temperature, the patient's age, physical activity, pain and anxiety, and the presence of infection. The hypermetabolic response to burn injury, common to other forms of critical illness and trauma, is partially driven by the neurohumoral milieu produced by

the hypothalamic-pituitary and autonomic nervous system responses. Activation of the former results in increased release of antidiuretic hormone, adrenocorticotrophic hormone (ACTH), and β -endorphins, whereas stimulation of the latter results in the release of catecholamines, glucagon, and cortisol. Postburn hypermetabolism is manifested by increased oxygen consumption, a hyperdynamic circulation, increased core temperature, wasting of lean body mass, and increased urinary nitrogen excretion. An increase in CO_2 production follows that parallels oxygen consumption. Hypermetabolism is temperature-sensitive in patients with burns involving over 50% of the BSA, and a 10% decrease in metabolic rate may be achieved by maintaining ambient temperatures above 30°C. Blood flow to the burn wound is markedly increased compared with the blood flow to other organs and tissues. This explains to some extent the relationship of extent of burn to hypermetabolism.

► Substrate Utilization

Glucose metabolism is altered following thermal injury. Hepatic gluconeogenesis and total glucose flow increase. However, owing to relative insulin insensitivity, glucose uptake by insulin-dependent tissues is decreased. An exaggerated fraction of nutrient flow is directed to the burn wound. Through anaerobic, insulin-independent means, large quantities of glucose are required to support the immune cellular functions of necrotic tissue removal and microbial containment and destruction. Cellular proliferation and wound healing are also glucose-dependent. The predominance of anaerobic metabolism in the burn wound results in increased lactate production with subsequent hepatic conversion of lactate to glucose via the Cori cycle.

Marked catabolism resulting in muscle protein breakdown and loss of lean body mass is observed following thermal injury. Catabolism of muscle protein provides amino acid gluconeogenic precursors (converted to glucose by liver and gut) and supplies amino acid substrates for synthesis of acute-phase

proteins. Significant nitrogen loss occurs, with 80–90% excreted as urea. The metabolism of glutamine, a preferred substrate for gut metabolism and a precursor for renal ammonia production, is also increased during the hypermetabolic phase. Glutamine is converted by the gut into alanine, which subsequently enters the gluconeogenic pathway.

The ability to oxidize fat as a source of nonprotein calories depends on the extent of injury and the degree of hypermetabolism. In patients with relatively small burns, carbohydrate and fat may be used interchangeably as effective nonprotein calorie sources. In patients with larger burns, carbohydrate is more effective than fat in maintaining body protein stores when each is used as a sole energy source.

► Estimation of Caloric Needs

Many formulas exist for the estimation of caloric needs in thermally injured patients. Some of the more common ones based on body size, age, and sex are presented in Table 35–7. The increase in calories required to support the metabolic demand following burn injury is computed by either adding predetermined stress or injury factors to standard formulas or by incorporating the measured extent of burn into those formulas specifically derived for burn patients. The use of formulas to predict caloric requirements in individual patients may result in overestimation or underestimation of caloric needs. Since most formulas are derived by patient measurements in the resting state, activity factors are customarily applied and range from 10–50%. Serial measurements by indirect calorimetry provide the most accurate determination of energy requirements for patients with major burns; however, there is no current consensus regarding the most appropriate formula to use when requirements must be estimated.

The best method to calculate the protein requirements of thermally injured patients remains controversial; however, supplying 12–18 g of nitrogen per square meter of body surface area or 1.5–2 g of protein per kilogram of body weight

Table 35–7. Formulas for estimating energy requirements in thermally injured patients.

Based on Harris-Benedict equation	Basal metabolic rate \times Activity factor \times Injury factor BMR male = $66.47 + 13.75 (\text{kg BW}) + 5.00 (\text{cm ht}) - 6.76 (\text{age yr})$ BMR female = $65.51 + 9.56 (\text{kg BW}) + 1.85 (\text{cm ht}) - 4.68 (\text{age yr})$ Activity factor = 1.2 bed rest, 1.3 out of bed Injury factor = 2.1 for severe burn
Curreri	$(25 \text{ kcal} \times \text{kg BW}) + 40 \text{ kcal} \times \% \text{ burn}$
Shriner's (Galveston)	$1800 \text{ kcal/m}^2 \text{ BSA} + 2200 \text{ kcal/m}^2 \text{ of burn}$
USAISR	Basal in $\text{kcal/m}^2 \text{ BSA per hour} \times \text{Factor}$ Factor = $2.33764 - (1.33764)^{[-0.0286 \times \% \text{ burn}]}$

USAISR = U.S. Army Institute of Surgical Research.

has been recommended. Nonprotein kilocalorie-to-nitrogen ratios of 100:1 to 150:1 are acceptable. Only enough fat to prevent essential fatty acid deficiency is required. Some burn patients may tolerate up to 9 mg/kg per minute of carbohydrate administration. However, carbohydrate delivery exceeding 5 mg/kg per minute occasionally results in hepatic fat deposition and excessive CO₂ production. This may cause CO₂ retention in patients unable to compensate by increasing minute ventilation.

Once the optimal delivery rate of carbohydrates is determined, balancing the remainder of the caloric requirements with fat may be achieved safely if the fraction of calories delivered as fat does not exceed one-third of the total. Triglyceride clearance usually is increased following thermal injury, but triglyceride levels should be followed weekly in patients whose nutritional regimens contain a significant percentage of calories supplied as fat. Hypertriglyceridemia, usually from parenteral infusion of fat emulsions, may result in coagulation abnormalities, hepatic dysfunction, and altered pulmonary diffusion capacity. Triglyceride levels above 200 mg/dL should prompt a decrease in lipid administration. The combination of medium- and long-chain triglycerides provided in most enteral formulas is the preferred form of dietary fat supplementation and rarely results in hypertriglyceridemia.

► Delivery of Nutritional Support

Administration of nutrition by the enteral route is preferred to preserve enterohepatic delivery of substrates and maintain mucosal function and integrity. Enteral intake may be initiated safely when the ileus associated with thermal injury has resolved. Patients with burns exceeding 30–40% of BSA may not be capable of meeting nutritional goals by oral intake alone, and supplementation with any of the commercially available enteral formulas with an appropriate calorie-to-nitrogen ratio may be used. Nasogastric and nasojejunal feedings are commonly employed based on institutional preference. Nasojejunal feedings have the added advantage of providing continuous nutrition throughout the perioperative and intraoperative periods with a low risk of aspiration.

Parenteral nutrition is reserved for patients with prolonged ileus or conditions prohibiting effective GI motility or absorption. Glucose intolerance is a more common complication of parenteral nutrition and necessitates frequent monitoring of blood glucose levels.

► Monitoring Nutritional Therapy

Careful monitoring of nutritional therapy is imperative if the high metabolic demand associated with thermal injury is to be met and adequate nutrition maintained throughout the hospital course. Useful indices include body weights, calorie counts, nitrogen balance studies, and measurement of

respiratory quotients. In other critically ill patients, measurement of serum albumin, transferrin, prealbumin, and retinol-binding protein are commonly employed to monitor the adequacy of nutritional support; however, these biochemical markers have been shown to be poor predictors of temporal changes in nitrogen balance in thermally injured patients, and their use is not recommended. Nitrogen balance calculations based on urinary urea nitrogen (UUN) excretion measurements should be modified to include wound losses and other nonurea protein losses. Wound losses, in grams per day, may be estimated as $0.1 \times \text{BSA}$ in $\text{m}^2 \times \text{percent BSA}$ of unhealed burn wound. Total urinary nitrogen excretion exceeds UUN in thermally injured patients. Increasing the measured 24-hour UUN by 25% will provide an accurate estimate of total urinary nitrogen losses. The daily nitrogen loss is increased by adding 2 g to account for stool and normal integumentary losses. The formula derived for daily nitrogen loss following thermal injury is as follows:

$$\text{Total nitrogen loss (g/day)} = 24\text{-hour UUN} \\ \times 1.25 + [0.1 \times \text{BSA (m}^2)] + 2$$

If indirect calorimetric measurements are available, monitoring the respiratory quotient (RQ) provides useful information regarding substrate utilization. An RQ of greater than 1.0 indicates carbohydrate oxidation and overfeeding, which may result in hepatic fat deposition. An RQ of less than 0.7 indicates fat oxidation and is consistent with the delivery of insufficient carbohydrate calories. Routine serum chemistries, liver function tests, and serum calcium, phosphorus, magnesium, and triglyceride determinations should be monitored once or twice a week during nutritional therapy. Most metabolic complications can be avoided by appropriate adjustment of the elemental and nutrient composition of the formula administered.

► Complications

The mechanical, septic, and metabolic complications associated with enteral and parenteral nutrition in thermally injured patients are the same as those common to all critically ill patients. However, the quantity and duration of nutritional supplementation required in thermally injured patients are such that strict attention to the amount, composition, and safe delivery of nutrition is required to avoid complications.

Current Controversies & Unresolved Issues

Postburn Hemodynamics

Resuscitation of patients to provide supranormal levels of oxygen delivery in states of severe illness or injury has been popularized recently. At present, this goal is impractical in the acute resuscitation of thermally injured patients. Even though large volumes of fluid may be required to maintain urine output, burned patients have decreased oxygen delivery and consumption during the initial phase of resuscitation. Attempts to improve oxygen delivery would result in massive fluid administration leading to excessive edema formation and subsequent morbidity. The goal of fluid resuscitation in thermally injured patients is to maintain vital organ function at the lowest physiologic cost. A more physiologic restoration of intravascular volume and oxygen delivery would seem beneficial.

Several approaches to reduction of edema formation and restoration of circulatory integrity are under investigation. Early intervention to block production of or to scavenge superoxide and oxygen free radicals has been shown to decrease edema formation. Administration of a soluble complement receptor that blocks the classic and alternative complement pathways has attenuated postburn edema formation in animals. Fluid resuscitation with deferoxamine has been shown to diminish the systemic effects of burn-induced oxidant injury, and an inositol phosphate derivative, 1,2,6-D-myoinositol triphosphate, has been shown to decrease burn wound edema and resuscitation fluid requirements by an unknown mechanism. Vitamin C, which has been shown in various animal models to reduce burn wound edema and resuscitation volume, was administered to burn patients in a prospective, randomized, controlled manner. The patients were resuscitated according to the Parkland formula. The 24-hour total fluid infusion volumes were 5.5 mL/kg per percent burn in the control group and 3.0 mL/kg per percent burn in the vitamin C group. The vitamin C group had an initial weight gain of 9.2% of pretreatment weight compared with a 17.8% weight increase in controls. The results of this initial small study are encouraging. Urinary outputs were maintained between 0.5 and 1.0 mL/kg per hour during the first 24 hours postburn, and total 24-hour urine volumes were

not different between groups. Inhibition of lipid peroxidation accomplished by antioxidant administration may be an important adjunct in limiting fluid resuscitation volume and edema formation following burn injury.

The inclusion of osmotically active macromolecules, such as pentafractan, that have a decreased propensity for transcapillary leakage during resuscitation also could improve early circulatory integrity. Until mechanisms of edema formation are better understood and means of limiting transvascular fluid loss are developed, “supranormal” resuscitation is neither appropriate nor feasible for burn patients.

Inhalation Injury

The mechanism by which inhalation of smoke and products of incomplete combustion injure the tracheobronchial mucosa, distal airways, and lung parenchyma is not completely understood. In part, injury is governed by particle size, which determines the anatomic region where injury will occur. Toxicities of noxious gases produced by combustion of synthetic and natural materials also contribute to the tissue injury of smoke inhalation but are at present impossible to quantify in patients following exposure. Most animal models used to study the effects of smoke inhalation fail to reproduce the clinical and histologic changes associated with inhalation injury in humans. Problems with smoke composition, carbon monoxide poisoning, and smoke delivery systems are common. In a recent study of smoke inhalation injury in non-human primates, high-frequency percussive ventilation was found to be superior to conventional volume ventilation and high-frequency oscillatory ventilation in decreasing barotrauma and the histopathologic severity of injury.

Pharmacologic intervention to modulate the response to smoke inhalation may prove beneficial in decreasing pulmonary vascular changes and improving lung aeration. Recent studies in sheep have shown improved alveolar ventilation and diminished inflammatory response to smoke inhalation following postexposure treatment with pentoxifylline. The use of inhaled nitric oxide—which does not alter the normal inflammatory response—to ameliorate pulmonary artery hypertension following smoke inhalation is also being studied. Other treatments, including complement depletion and antioxidant therapy, are being investigated and may prove beneficial. Any attempt to modulate the host response to inhalation injury must proceed with caution to avoid impairing the normal mechanisms of cellular repair and immunologic defense.

A nebulized cocktail of heparin and a mucolytic agent, N-acetylcystine, has been shown to reduce pulmonary failure and ameliorate airway cast formation in both an animal model and a case-controlled human study in 47 children. A blinded, randomized study or studies in adults have not been reported; however, decreases in reintubation rates and mortality rates for patients treated with this regimen were noted when compared with historical controls. Further information is also needed in this arena; however,

this may represent a potentially beneficial active intervention as opposed to supportive care and good pulmonary toilet that represents the mainstay of current care of smoke inhalation injury.

Infection

The immune dysfunction following burns, for which a specific cause is unknown, also may be a potential site of pharmacologic intervention. Granulocyte-macrophage colony-stimulating factor (GM-CSF; sargramostim), in addition to stimulating proliferation of granulocyte and macrophage progenitor cells, increases macrophage phagocytic and cytotoxic activity, granulocyte RNA and protein synthesis, granulocyte oxidative metabolism, and antibody-dependent cytotoxic killing in mature cells *in vitro*. In a small cohort of burn patients, sargramostim therapy increased granulocyte counts by 50%. Administration of sargramostim reduced granulocyte cytosolic oxidative function and myeloperoxidase activity to control levels without changing superoxide production. However, following cessation of treatment, superoxide activity was subsequently increased compared with untreated burn patients. These findings caution against clinical extrapolation of *in vitro* results. A reduction in myeloperoxidase activity actually may be detrimental because bactericidal capability may be compromised. Increased superoxide production could potentiate endothelial cell damage leading to increased capillary permeability. The inability of immunomodulatory drugs to significantly alter the postburn changes in immune function simply may represent the inability of single agents to alter the complex cascade of pathophysiologic events occurring in extensively burned patients.

The concept that the gut plays a central role in maintenance of a persistent catabolic state in severely injured patients has gained substantial popularity. Many animal studies support this hypothesis; however, the lack of clinically significant bacteremia and endotoxemia in humans makes the meaning of these findings unclear. Intestinal permeability is increased preceding and during episodes of sepsis in burn patients. Whether alterations in intestinal permeability result in infection or represent only an epiphenomenon remains to be proved. In a recent clinical study, the administration of prophylactic enteral polymyxin B to burn patients resulted in a decrease in endotoxemia; however, no correlation with illness severity score or outcome was observed.

Wound Closure

Excision of the burn wound with subsequent split-thickness skin grafting is now common practice in most institutions. Some clinicians advocate complete excision of the burn wound within the first several days of hospitalization. The postulated benefits of this treatment include decreasing the extent and duration of hypermetabolism and immunosuppression, shortening the length of the hospital stay, and improving survival. Prompt excision and closure of the burn

wound has been shown to ameliorate the hypermetabolic response in laboratory animals, provided that the entirety of the excised wound is closed by grafting. Similar reversal of the immunosuppressive effects of burning also has been documented. Such findings have yet to be observed in humans probably because the entirety of the full-thickness wound is seldom removed, partial-thickness wounds are not excised, and definitive closure of large wounds cannot be accomplished in a single operation. In several reports dealing exclusively with early wound excision in burned children, the duration of hospital stay was clearly shortened, intraoperative blood loss was decreased, and survival was reported to be improved. The duration of hospitalization has decreased for adult burn patients in many centers because excisional therapy is employed routinely, but a favorable impact of early complete excision of the burn wound on pathophysiologic changes and outcome has not been documented. Moreover, the deleterious hemodynamic and pulmonary effects of general anesthesia during the early postburn period speak for cautious use of such procedures during the resuscitation period in the severely burned patient. Such excisions should be performed on carefully selected patients and only by experienced operating teams and anesthesiologists.

The identification and availability of various growth factors have stimulated interest in the potential for accelerating the healing of burns, skin grafts, and skin graft donor sites. An effective agent could produce more rapid healing of burns (hastening return to work), permit more frequent harvesting of donor sites in massive burns, and shorten healing time of skin grafts (reducing periods of immobility). The topical application of epidermal growth factor has been shown to enhance healing of split-thickness skin graft donor sites by reducing the time to complete healing by 1.5 days. Although the decrease in healing time was statistically significant, the clinical benefit would be minimal. A 50% reduction in skin graft donor-site healing time would be required to be clinically effective. The systemic administration of human growth hormone also has been reported to decrease the time of skin graft donor-site healing in children, but the same effect was not observed routinely in adult patients. The ability of growth factors to improve healing in burn patients continues to be an area of active research and debate.

Hypermetabolism

The hypermetabolic response to thermal injury is well described, and in addition to the classic hormonal mediators, cytokines may play an important role in maintenance of the hyperdynamic state. Circulating levels of tumor necrosis factor, IL-1, and IL-6 are increased at various times following thermal injury and sepsis; however, the effect of pharmacologic or immunologic blockade of these cytokines is not clearly established following burn injury. In a series of extensively burned patients, blood levels of TNF- α , IL-1, and IL-6, although frequently elevated, had no correlation with the patients' clinical courses.

The hypermetabolic response to thermal injury can be attenuated by β -adrenergic blockade. Administration of propranolol has been effective in decreasing metabolic rate and cardiac work in burned children and adults; however, increased nitrogen loss was induced presumably from peripheral β -receptor blockade. Cardioselective β -adrenergic blockers are currently being studied that may circumvent the nitrogen-wasting effects of nonselective agents. Attempts to decrease catabolism and protein wasting also have been studied. The selective β_2 -adrenergic agonist clenbuterol increased resting energy expenditure and normalized muscle protein content, muscle mass, and body weight gain in burned rats. Administration of insulin-like growth factor 1 (IGF-1) to burn patients, decreased protein oxidation and protein breakdown only in patients in whom an insulin-like effect also occurred. Similar responses in burn patients were demonstrated with the administration of low-dose exogenous insulin and glucose. Testosterone analogues also have been used to reduce postinjury catabolism. Oxandrolone, a weakly androgenic testosterone analogue, has been shown recently to decrease net daily nitrogen loss and weight loss in seriously burned patients. This study also described a decrease in healing time of standardized donor sites from 13 ± 3 days to 9 ± 2 days. Complications were similar between groups, and no side effects directly attributed to the drug were identified. Herndon and colleagues evaluated the effect of β -adrenergic blockade using orally administered propranolol on resting energy expenditure and muscle-protein catabolism in severely burned children. After 2 weeks of treatment, a dose sufficient to decrease the resting heart rate by 20% resulted in a 24% decrease in resting energy expenditure in the propranolol group compared with a 5% increase in a matched control group. The net muscle-protein balance increased by 82% over baseline values in the propranolol group, whereas it decreased by 27% in the control group.

Further studies are required to determine if the apparent benefits of blockade of the hypermetabolic response result in decreased morbidity and mortality for the severely burned patient or whether they merely reflect short-term changes in protein metabolism.

II. CHEMICAL BURN INJURY

The severity of injury caused by chemical exposure is related to the amount and concentration of the agent and the duration of contact with the tissues. Strong alkalis and acids found in common household cleaners are responsible for the majority of minor chemical injuries. More extensive injuries often result from industrial and laboratory accidents or from assaults. The amount of tissue damage incurred also depends on the nature of the specific agent. Strong alkalis react with tissues to produce saponification and liquefaction necrosis. Acids are water-soluble and penetrate easily into subcutaneous tissue and cause coagulation necrosis soon after contact. The exothermic reaction produced by contact with strong acids or bases also contributes to the depth of injury. Organic solvents and petroleum products, which are highly lipid-soluble, injure tissues by delipidation. Cutaneous absorption of certain chemical agents may cause systemic toxicity, which complicates subsequent therapy and makes identification of the causative agent imperative.

► Initial Care of Chemical Burns

Chemical injuries, unlike other thermal injuries, require immediate care of the burn wound. The caustic agent must be washed from the skin surface as soon as possible. All clothing, including shoes and gloves, must be removed and the wounds copiously irrigated with water. If possible, lavage of chemical injuries should continue for at least 30 minutes. In the case of alkali burns, this treatment should continue for a minimum of 1 hour. If ocular injury is suspected, prompt and prolonged irrigation with saline or water should begin. A search for specific antidotes is unnecessary and may only delay the initiation of adequate water lavage. Assessing the depth of injury in chemical burns is difficult because many agents may produce a tanned or bronzed appearance of the skin, which remains pliable to the touch but may represent extensive full-thickness tissue necrosis. With the exception of the initial attention given to the burn wound, the resuscitation and later treatment of skin injury follow that of thermal burns.

► Specific Chemical Agents & Systemic Toxicities

In general, the use of antidotes for specific chemicals is condemned, and copious water lavage is considered the appropriate form of initial therapy. However, several specific chemical agents exist for which treatment with a specific antidote has proved beneficial. Injury owing to hydrofluoric acid exposure is an occupational hazard of petroleum refinery workers, etchers, and those employed in the cleaning of air-conditioning equipment. Following contact with this agent, there is usually a pain-free interval followed by

pallor in the area of contact in association with severe tissue pain. Fluoride ion continues to penetrate the tissues until inactivated by calcium salt formation. Immediately after exposure, the area should be copiously irrigated with water. Topical treatment with a calcium gluconate gel should be instituted, and if the pain does not subside, local injection of 10% calcium gluconate into the damaged tissue may provide prompt pain relief. Intraarterial infusion of calcium gluconate also has been used to limit tissue damage and relieve pain, but surgical excision of the damaged tissue may be necessary for complete pain control. Hypocalcemia may occur following extensive hydrofluoric acid burns.

Phenol

Phenol is an aromatic acid alcohol with high lipid solubility. Initial treatment consists of copious water lavage; however, owing to the poor water solubility of phenol, a lipophilic solvent such as polyethylene glycol (50% solution in water) may be more effective at removing the residual agent. Sufficient systemic absorption of phenol produces CNS depression, hypothermia, hemolysis, renal failure, and hypotension. Maximal ICU support may be required. No specific antidote is available.

Hydrocarbons

Cutaneous injury from immersion in gasoline and other hydrocarbons is often overlooked in victims of motor vehicle accidents who sustain prolonged exposure during extrication. Skin necrosis results from lipid dissolution. Partial- and full-thickness injuries have been described, and systemic toxicity, similar to that produced by ingestion or inhalation, may occur. The pulmonary excretion of hydrocarbons may produce chemical pneumonitis and bronchitis. Systemic lead poisoning from cutaneous absorption of leaded gasoline also has been described.

Inhalation of Aerosolized Chemicals

Inhalation of aerosolized chemicals may produce pulmonary injury and systemic toxicity, thus requiring accurate diagnosis and aggressive treatment. Varying degrees of pulmonary insufficiency may be agent-specific and manifested by severe airway edema formation, mucosal sloughing, and bronchospasm. Systemic toxicity through pulmonary absorption may occur; thus the causative agents must be clearly identified to ensure appropriate diagnostic and treatment strategies. The degree of pulmonary support required is determined by the severity of pulmonary insufficiency.

Ocular Injury

If chemical eye injury is suspected, prompt and prolonged irrigation of the eye with water or saline should ensue. A specially designed scleral contact lens with an irrigating sidearm

is useful when prolonged irrigation is necessary. Epithelial defects may be identified by fluorescein stain. Ophthalmology consultation should be obtained on all suspected chemical eye injuries.

Mozingo DW et al: Chemical burns. *J Trauma* 1988;28:642–7. [PMID: 3367407]

III. ELECTRICAL BURN INJURY

Tissue damage from electrical injury results from heat generated by the passage of electric current through the body as well as direct thermal injury caused by the ignition of clothing. The severity of the injury depends on the voltage, the type of current (alternating or direct), the path of the current through the body, and the duration of contact. High- and low-voltage injuries are arbitrarily defined as those above and below 1000 V.

Tissue damage from electrical injury may be obvious at the cutaneous contact site or sites but also may involve underlying tissues and organs along the path of the current. The amount of heat generated is proportionate to tissue resistance; however, the differences in tissue resistance (eg, bone, fat, nerve, etc.) are so small that the body acts as a volume conductor. Current density then predominates as the main determinant of tissue damage, with severity of injury being inversely proportional to the cross-sectional area traversed by current. Thus severe injuries to the extremities are often encountered, and significant injuries to the torso are rare. Superficial tissues in a limb may be normal, whereas tissues near bone may be nonviable owing to longer duration of heating because of the slower heat dissipation from bone. Alternating current injuries may initiate ventricular fibrillation, whereas high-voltage injury and lightning injury are associated with asystolic cardiopulmonary arrest.

Treatment

Cardiac arrest often occurs following an electrical contact and requires immediate cardiopulmonary resuscitation. Patients with electric injury are more likely to have associated injuries owing to falls or tetanic skeletal muscle contractions from the electric current; therefore, the patient's spine should be immobilized until cervical, thoracic, and lumbar radiographs exclude the presence of spinal fractures. In patients not sustaining an initial cardiac arrest, cardiac dysrhythmias occur in a small percentage of patients. All patients should have continuous electrocardiographic monitoring for at least 24 hours, and functionally significant dysrhythmias should be treated promptly if they occur.

The estimation of resuscitation fluid requirements in patients sustaining electrical injury is difficult owing to

extensive subcutaneous or deep tissue involvement with only limited areas of cutaneous injury. This “iceberg” effect may require the performance of fasciotomy—rather than escharotomy—to ensure adequate perfusion of the distal extremity and to evaluate the viability of the underlying subcutaneous tissue and muscle. With extensive muscle necrosis, hemochromogens may be liberated, resulting in the appearance of those pigments in the urine. Intravenous fluids are administered to achieve a urine output of 100 mL/h in adults. If the hemochromogenuria does not clear with an adequate urine output, 50 meq sodium bicarbonate should be added to each liter of intravenous fluid to promote alkalization of the urine and prevent pigment precipitation in the renal tubules. If after aggressive fluid resuscitation the renal output does not reach 100 mL/h, an osmotic diuretic such as mannitol also may be administered (a bolus dose of 25 g with 12.5 g added to each liter of IV fluid until pigment clearing occurs) to force an increased urine output. When urine production is increased by the use of diuretics, invasive hemodynamic monitoring with a pulmonary artery catheter should be considered because urine output is no longer a reliable measure of intravascular volume and organ perfusion.

Complications

Associated injuries are more common in patients sustaining electrical injury than those injured by thermal burns. Owing to the titanic contractions of the paraspinal musculature induced by the electric current, compression fractures of the lumbar and thoracic spine may occur. Furthermore, many electrical injuries involve workers who fall from heights. Blunt traumatic injuries should be suspected and appropriate diagnostic measures initiated.

A complete neurologic examination must be performed on admission and at scheduled intervals in all patients sustaining electrical injury. Neurologic changes may be of early or late onset. Immediate peripheral deficits owing to the damaging effects of electric current may be irreversible; however, early deficits in a distribution where there is no clear tissue damage are likely to resolve. Neurologic symptoms of delayed onset, often mimicking upper motor neuron disease, tend to be progressive and permanent. Progressive thrombosis of nutrient vessels of the spinal cord or nerve trunks may play a role in the pathogenesis of the late-occurring upper motor neuron deficits.

Direct electrical injury to the viscera is rare; however, liver necrosis, intestinal perforation, focal pancreatic necrosis, and gallbladder necrosis have been reported in patients with high-voltage electric injury and truncal contact points. An increased occurrence of cholelithiasis has been reported in convalescent patients following electric injury.

Delayed hemorrhage from moderate-sized to large blood vessels has been described following electrical injury and attributed by some to an “arteritis” produced by the electric current. The actual mechanism of this complication is unclear, but inadequate initial wound debridement and subsequent

exposure and desiccation of the involved vessel appear to be causative factors.

In patients in whom the electrical contact point involved the head or neck, the development of cataracts up to 3 years or more following injury has been described. Ophthalmologic slit-lamp examination should document the presence or absence of cataracts during the initial hospitalization. Additional information on electrical injuries is presented in Chapter 37.

Poisonings & Ingestions*

Diane Birnbaumer, MD

An integral part of the practice of critical care is treating the patient who either intentionally or inadvertently ingests or is exposed to a potentially toxic substance. The magnitude of this problem is staggering. In 2002, the American Association of Poison Control Centers documented 2,112,774 episodes of toxin exposure resulting in poison center notification. This number actually underrepresents the true number of poisonings because 70% are never reported to poison control centers.

Treating these patients requires a working understanding of the principles of stabilization and supportive care, decontamination, drug elimination, use of antidotes, and the pathophysiologic features specific to the poisons or toxins involved. This chapter will cover the general principles involved in caring for these patients and will discuss the details of treating the specific poisons typically encountered in the practice of critical care.

EVALUATION OF POISONING IN THE ACUTE CARE SETTING OR ICU

The pathophysiologic consequences following an exposure are poison-specific, and adequate treatment requires an understanding of these individual differences. However, there are several general guidelines for the evaluation and treatment of a patient with a potential ingestion or toxic exposure.

► Diagnosis of Poisoning

History

Obtaining a history from a patient with a potential ingestion or toxic exposure may be difficult if the patient is too young to communicate, is obtunded, or is reluctant to cooperate. It may be helpful to question the patient's relatives, friends, or coworkers to obtain additional historical information in these cases. When getting the patient's history, several points

require particular attention: the drugs or toxins involved, the route of exposure (ie, oral, dermal, inhalation, etc.), and the time of the exposure or ingestion. It is important to remember, however, that the history may be unreliable in patients who intentionally ingest toxins. Careful physical examination is key, and laboratory evaluation and close observation are frequently required.

Symptoms and Signs

The physical examination can provide a wealth of information, even in patients unable to provide a useful history. An abbreviated physical examination, which could be called the *toxidrome-oriented physical examination*, focuses on the physical findings observed in patients exposed to particular types of poisons and offers rapid assessment and guides testing and treatment. This physical examination should include vital signs, a brief neurologic examination emphasizing level of consciousness and pupillary and motor responses, palpation of the skin for moisture and inspection for cyanosis and rashes, auscultation and percussion of the lungs, and auscultation of bowel sounds (Table 36–1). Table 36–2 summarizes the physical findings associated with the major groups of poisons and lists several examples of each.

Laboratory Studies

A rapid bedside serum glucose concentration should be checked in all patients with altered mental status, and if it is found to be low, intravenous glucose should be administered. Serum electrolytes, blood urea nitrogen (BUN), serum creatinine, arterial blood gas, serum osmolality, calculated osmolar gap, and a urinalysis (ie, crystals, myoglobinuria or hemoglobinuria) are the basic laboratory tests in the evaluation of patients with overdoses (Table 36–3). Other tests (eg, drug levels, methemoglobin level, and carboxyhemoglobin level) may be helpful in specific patients and will be discussed later in this chapter.

As a general rule, toxicology screens are of limited value in evaluation of these patients and are expensive and

*Envenomation (snakebite, etc.) is discussed in Chapter 37.

Table 36-1. The toxidrome-oriented physical examination.

Vital signs
Temperature
Blood pressure

Motor responses
Skin examination: moisture, rash, cyanosis
Lung examination
Auscultation for bowel sounds

time-consuming. In some specific situations, however, screening may be helpful. These tests can be useful in narrowing the differential diagnosis in patients who present with altered mental status or abnormal vital signs; in such

cases, a directed toxicology screen should be ordered that tests for agents consistent with the patient's presentation and physical findings. A toxicology screen also may be helpful in patients with mixed-drug ingestions or those who present with signs of major toxicity. Finally, a sample of blood may be saved for future toxicology evaluation in patients in whom the diagnosis is unclear.

Serum concentrations of some drugs are helpful in guiding management decisions (Table 36-4). Salicylate, acetaminophen, barbiturates, digoxin, ethanol, iron, lithium, and theophylline serum levels are available in most hospital laboratories on an urgent basis. (Methanol and ethylene glycol levels often need to be sent out; positive tests are often used to confirm a suspected case, but management must begin before levels are available.) Salicylate serum drug levels are not necessary in all ingestion cases, an acetaminophen level should be sent in virtually all cases. This drug is found in many prescription and over-the-counter medications, and patients may ingest potentially lethal amounts but show minimal or nonspecific signs of toxicity.

Table 36-2. Toxidromes.

Physical Examination	Sedative-Hypnotic	Cholinergic	Anticholinergic	Sympathomimetic	Sympatholytic
Temperature	N/-	N	N/+	N/+/**	N/-
Respiratory rate	N/-/-	+/-	N/-	+/-	-
Heart rate	N/-	+ or -	+/**	**	N/-

Electrocardiography

An ECG should be ordered in all patients with potential drug ingestions. The heart rate, evidence of dysrhythmias, vector axes, and interval measurements are helpful in determining the presence or severity of several ingestions, and serial electrocardiographic evaluation can, in some cases, help to follow the progression of toxicity.

Imaging Studies

A plain abdominal film may be helpful in patients who ingest radiopaque medications such as iron tablets or some enteric-coated medications. These films also may be helpful in visualizing drug packets in “body packers”—individuals who ingest wrapped packets of illicit drugs to transport them. Although the packages themselves are often not radiopaque, they still may be visualized by the changes caused in bowel gas patterns by their presence.

► Differential Diagnosis of Poisoning

The differential diagnosis of the toxin-exposed patient is extensive and varies with the agent involved. In general, however, infectious processes (eg, meningitis, encephalitis, and sepsis), metabolic disorders (eg, hypo- or hyperthyroidism, hypo- or hyperglycemia, hypo- or hypercalcemia, and hypo- or

hypernatremia), and environmental disorders (eg, heat stroke) are the most common other causes of the clinical syndromes found in toxic exposures. Head trauma or hypoxemia also may cause findings similar to those observed following toxin exposure.

Lai MW et al: 2005 Annual Report of the American Association of Poison Control Centers' national poisoning and exposure database. *Clin Toxicol (Phila)* 2006;44:803–932. [PMID: 17015284]

TREATMENT OF POISONING IN THE ICU

General Measures

The first priority in treating any patient with a toxic exposure is resuscitation and stabilization; assessing the patient's airway, breathing, and circulation are the initial goals. This may require establishing an airway, ventilating and oxygenating the patient, and supporting circulation by normalizing and maintaining an adequate heart rate and blood pressure. These measures should be taken regardless of the toxin involved; more specific interventions can be made after stabilization is completed. All overdose or toxin-exposed patients should be placed on a cardiac monitor and given supplemental oxygen if hypoxic. Intravenous access should be established.

Airway Management

Endotracheal or nasotracheal intubation is indicated in all patients who are inadequately ventilating, those who have significant hypoxemia, those who cannot protect their airway because of obtundation or a poor gag reflex, or those with an anticipated clinical course of deterioration. Intubation for airway protection also should be considered in patients who need gastric lavage, although this once frequently used practice is now indicated in only rare instances.

There are two potential situations where an obtunded patient may not need intubation. Altered patients whose rapid blood glucose is low may respond sufficiently to intravenous dextrose to obviate the need for intubation. (In patients with suspected alcohol abuse or those who appear significantly malnourished, administration of dextrose should be preceded by a 100-mg dose of thiamine intravenously or intramuscularly.) Obtunded patients taking narcotics or benzodiazepines may respond to administration of naloxone or flumazenil (see “Antidotes” below).

Hemodynamic Support

Abnormal blood pressure, heart rate, and temperature should be managed in the usual fashion; more specific interventions

Table 36-4. Drug levels helpful in guiding management.

Salicylates	Ethylene glycol
Acetaminophen	Iron
Barbiturates	Isopropyl alcohol
Digoxin	Lithium
Ethanol	Theophylline
Methanol	

or modifications of treatment can be addressed when more information regarding the toxin involved is available.

Control of Seizures

Benzodiazepines should be used initially for the management of seizures; phenytoin or barbiturates may be needed if benzodiazepines are not effective. In cases of refractory seizures, general anesthesia or the use of paralytic agents may be required; in this case, electroencephalographic monitoring should be instituted to determine if the patient continues to have electrical seizure activity. It is important to note that normalization of vital signs and control of seizures may require interventions specific to the toxin involved (eg, pyridoxine for treating isoniazid ingestion).

Opioid and Benzodiazepine Antagonists

Comatose patients should receive naloxone, particularly if they are hypoventilating and have miotic pupils. The usual dose is 0.8 mg intravenously in both adults and children; if there is a suspicion that the patient may be narcotic-addicted, the dose should be titrated in increments of 0.2–0.4 mg to prevent abrupt withdrawal symptoms. Certain opioid ingestions, particularly propoxyphene, may require larger doses of naloxone to be effective. If this ingestion is suspected, 2 mg naloxone should be administered.

Flumazenil—a benzodiazepine antagonist—may be indicated in patients who present with obtundation or coma suspected to be due to benzodiazepine ingestion. Since use of this agent in the benzodiazepine-dependent patient may precipitate withdrawal seizures, this agent should be used with extreme care in these patients if it is used at all. The initial dose of flumazenil is 0.2 mg intravenously given over 30 seconds; if, after observation for 30 seconds, the patient does not respond, an additional dose of 0.3 mg should be given over 30 seconds. If additional doses are needed, 0.5 mg should be given over 30 seconds at 1-minute intervals to a total dose of 3–5 mg; if the patient does not respond to this maximum dose, the primary cause of altered mental status is unlikely to be due to benzodiazepines. Because the half-life of flumazenil is approximately 1 hour (shorter than the half-life of all currently available benzodiazepines), re sedation occurs in 50–65% of patients with benzodiazepine overdose. When it occurs, the re sedation is usually within 1–3 hours of flumazenil administration; this necessitates close observation of these patients.

Decontamination

After stabilization and initial basic therapeutic interventions have been completed, decontamination should be addressed.

A. External Exposures—Patients who have dermal exposure to a toxin should be undressed and copiously irrigated with tepid water. Health care personnel must take appropriate measures to ensure that they are not exposed to the agent while caring for the patient. Irrigation also should be used in

patients with eye contamination, particularly with alkali or acid substances.

B. Ingestions—Since the vast majority of poisonings occur by ingestion, gastric emptying and gut decontamination have been a mainstay of management. Studies have shown, however, that these interventions are of little benefit in most cases.

1. SYRUP OF IPECAC—In the past, syrup of ipecac was used extensively to induce gastric emptying in patients with toxic ingestions, particularly children, but studies question the role of ipecac in these situations. Ipecac is no longer recommended for the treatment of most ingestions (see “Current Controversies and Unresolved Issues” below).

2. GASTRIC LAVAGE—Gastric lavage is a relatively effective means of accomplishing gastric emptying, decreasing drug absorption by as much as 50%. Studies of its impact on clinical outcome in poisoned patients, however, have reported conflicting results. Gastric lavage should not be used routinely in all poisoned patients but may have a role in specific clinical situations. Gastric lavage should be considered in patients who present within 1 hour of ingesting a potentially lethal amount of a toxin. Another possible indication is in poisonings with agents that decrease gastric motility (eg, anticholinergic agents), although utility in these cases is questionable. Gastric lavage may be useful when patients ingest agents that bind poorly to activated charcoal and in life-threatening poisonings with agents such as theophylline, tricyclic antidepressants, and cyanide. [Table 36–5](#) summarizes these indications.

When gastric lavage is performed, the patient should be placed in the head-down lateral position. Owing to the risk of aspiration, gastric lavage *never* should be performed with the patient supine, particularly if the patient is in restraints and cannot be turned quickly if emesis occurs. Suction equipment should be available at all times. A large-bore gavage tube (ie, 36–42F in adults and 16–32F in children) should be used to remove large pill fragments and whole pills. Some authors recommend that extra holes be cut along the sides of the distal end of the tube to facilitate pill removal. Since these tubes are large, they should not be passed through the nose; oral passage is better tolerated and has fewer complications. Once gastric tube position is confirmed, aspiration of the stomach should be performed to remove as much of the

Table 36–5. Indications for gastric lavage.

Recent ingestion (<1 hour) of a potentially life-threatening poison
Ingestion of a substance that slows gastric emptying (eg, anticholinergic medications)
Ingestion of a poison that is slowly absorbed from the gastrointestinal tract
Ingestion of a substance that does not bind well to activated charcoal (eg, iron, lithium)
Ingestion of specific life-threatening poisons (eg, tricyclic antidepressants, theophylline, cyanide)

poison as possible before irrigation is instituted. Once aspiration is complete, tepid tap water should be used for gastric lavage. In patients under age 5, normal saline should be used to prevent electrolyte disturbances. Using 150–300-mL aliquots (50–150 mL in children), the fluid should be alternatively instilled down the tube and then allowed to efflux from the stomach by gravity; amounts in excess of 300 mL increase the risk of emesis and aspiration. Lavage should be continued until the effluent fluid is clear of pill fragments. If activated charcoal and a cathartic is to be used, it can be placed down the lavage tube before it is withdrawn.

Several complications are associated with gastric lavage. Aspiration and subsequent pneumonitis can occur; therefore, it is critical that patients who cannot protect their airways be intubated prior to gastric lavage. Esophageal perforation has been reported, as has inadvertent tracheal tube placement (with subsequent instillation of lavage fluid into the lungs). Children under the age of 5 years may develop electrolyte imbalances if normal saline is not used as the lavage fluid. Laryngospasm and cardiac dysrhythmias also have been described.

Gastric lavage has only one absolute contraindication—it should not be used in caustic ingestions because it may cause the patient to vomit, leading to more extensive esophageal and oral burns.

3. CHARCOAL—Activated charcoal is an odorless, tasteless powder that is beneficial in many types of ingestions and is the cornerstone of therapy for most cases. In the gut, it binds the toxin and prevents its absorption. Although it binds many compounds, there are several potentially life-threatening poisons that do not bind well to charcoal (Table 36–6). When used in repeated doses, activated charcoal can both interrupt enterohepatic circulation and enhance the elimination of some drugs that have already been absorbed from the GI tract (Table 36–7); this is referred to as *gastrointestinal dialysis*. When used in this fashion, the dose of activated charcoal should be 25–50 g orally every 2–4 hours; in children, it is 0.25–1 g/kg every 2–4 hours.

Activated charcoal is administered as a slurry of water and charcoal. Although the initial dose is 50–100 g orally in adults and 1–2 g/kg in children, when the amount of ingested

Diazepam
Digitalis
Phenobarbital
Phenytoin
Salicylates
Theophylline
Tricyclic antidepressants

agent is known, the optimal dosing of activated charcoal is in a ratio of 10:1, charcoal to ingested agent.

The only relative contraindication to giving charcoal is in patients with caustic ingestions; the charcoal accumulates in burned areas of the GI tract and interferes with endoscopy. The most common complication of charcoal administration is constipation. This problem can be addressed by adding a cathartic to the charcoal. If repeat-dose activated charcoal therapy is to be used, the cathartic should be added only to the first dose of charcoal because the every 2–4-hour dosing of the repeat-dose activated charcoal regimen can lead to excessive cathartic administration and possible electrolyte imbalances from the resulting diarrhea. In addition, some children have become hypermagnesemic when magnesium citrate was used as the cathartic. The most common cathartics used in this situation are 70% sorbitol (1 g/kg), magnesium citrate (4 mL/kg), and 10% magnesium sulfate (250 mg/kg).

4. BOWEL IRRIGATION—Whole bowel irrigation is a method of removing ingested toxins from the gut by forcing the toxin rapidly through the GI tract. Indications for whole bowel irrigation are limited; the most common use of this technique is in patients who intentionally ingest packets of illicit compounds such as cocaine or heroin in order to transport them without detection. The other indication for this therapy is in patients who ingest potentially lethal toxins that are difficult to remove from the stomach and do not bind well to charcoal (eg, iron).

The technique for whole bowel irrigation involves administration of 1–2 L of polyethylene glycol electrolyte solution per hour, either orally or via a nasogastric tube. In children under the age of 5 years, the solution should be given at a rate of 150–500 mL/h. The goal is to produce a rectal discharge with the same appearance as the administered oral solution, which indicates complete cleansing of the gut. Effective whole bowel irrigation usually takes 6–12 hours. The patient must be able to cooperate and sit either on a toilet or a bedside commode during the procedure.

The only contraindications to this procedure are the presence of ileus, GI perforation, and bleeding. It should not be used in patients who are uncooperative or combative or in those with CNS depression or respiratory distress. The complications associated with whole bowel irrigation are abdominal

Table 36–6. Poisons not well bound by activated charcoal.

Isopropyl alcohol
Lithium
Methanol

cramping and vomiting. Emesis can be treated with antiemetics and a slowed administration rate of the solution. Hyperchloremia has been reported and requires repeated serum chloride determinations during the procedure. It is also important to note that activated charcoal, if indicated, should be given before the initiation of whole bowel irrigation. Repeat-dose activated charcoal is not effective when given during whole bowel irrigation.

5. ION TRAPPING—Once a drug has been absorbed from the GI tract, gut decontamination measures become relatively ineffective. Ion trapping is a method to enhance elimination of an already absorbed drug by “trapping” it in the urine. Drugs that acidify urine (eg, salicylates) ionize in alkaline urine and then cannot be reabsorbed by the kidney and are therefore excreted. This treatment is most helpful in salicylate and phenobarbital ingestions.

The simplest method for ion trapping uses 1 L of 0.45% saline solution to which 2 ampules of sodium bicarbonate have been added. The solution is infused intravenously at a rate of 150–250 mL/h. Urine pH is monitored, with the goal being a pH of 7.0–8.0. Potassium deficits need to be replaced because alkalization of the urine is difficult to achieve in the hypokalemic patient. Complications of urinary alkalization are volume overload and hypokalemia.

6. HEMODIALYSIS AND HEMOPERFUSION—In some situations, hemodialysis or hemoperfusion may be required to eliminate the toxin. Indications include patients refractory to supportive care alone, those who have a potentially toxic drug level or highly toxic dose of the ingestant, and those in whom other routes of elimination are impaired (eg, by renal failure). Few toxins are amenable to this type of therapy; cases in which hemodialysis or hemoperfusion may be useful are listed in [Table 36–8](#).

► Current Controversies & Unresolved Issues

Administration of activated charcoal has become the primary means for decontamination of the gut in most cases of toxic ingestion. Gastric lavage was once a mainstay for decontamination of the gut and removal of the ingested agent. Recent studies, however, have shown little change in outcome for most patients who undergo gastric lavage. In

addition, this method has the potential for causing serious side effects such as aspiration. Gastric lavage should be limited to patients who ingest a potentially lethal amount of an agent poorly adsorbed to charcoal or those who present less than 1 hour after ingesting a potentially significant amount of a toxic agent—and it should be done with care.

Ipecac, a central- and peripheral-acting agent used to induce vomiting in patients with toxic ingestions, was once a common method of gastric decontamination. However, this agent is no more effective than gastric lavage, and vomiting after ipecac can persist for several hours, precluding the use of oral activated charcoal. Its use is contraindicated in caustic and hydrocarbon ingestions and in infants under 6 months of age. At this point, syrup of ipecac has little, if any, role in the management of toxic ingestions.

In the past, forced diuresis was recommended in the treatment of several drug ingestions. Studies have shown that forced diuresis does not enhance elimination significantly and that the relatively large volumes of intravenous crystalloid needed can lead to pulmonary edema, particularly in patients with cardiac dysfunction. Forced diuresis is therefore no longer recommended as a modality in treating drug ingestions.

MANAGEMENT OF SPECIFIC POISONINGS

► Sedative-Hypnotic Overdose

ESSENTIALS OF DIAGNOSIS

- Dysarthria.
- Ataxia.
- Emotional lability.
- Altered sensorium.
- Horizontal and vertical nystagmus.
- Respiratory, cardiovascular, and renal failure.

General Considerations

Sedative-hypnotic abuse is common, particularly among patients who began using the drugs therapeutically for sleep or as anxiolytics. Other patients may use these drugs orally or intravenously because of the disinhibition and euphoria they produce. In the past, short-acting barbiturates such as amobarbital, pentobarbital, and secobarbital were used commonly; these agents are used much less frequently because benzodiazepines are now prescribed more commonly. Their use is frequently combined with other drugs or with alcohol.

Continued abuse of sedative-hypnotics is more likely to cause mental and physical impairment when compared with narcotics. When administered intravenously, the alkaline barbiturate solutions cause sclerosis of the veins and may result in profound ischemia if intraarterial injection occurs.

Withdrawal from sedative-hypnotics produces a characteristic syndrome that may be fatal. Although a period of initial improvement may occur after 8–16 hours of abstinence, rapid deterioration with agitation, altered mental status, and seizures frequently follows. ICU admission is mandatory for any patient suspected of having barbiturate withdrawal symptoms.

Clinical Features

A. Symptoms and Signs—An overdose of these drugs results in findings similar to those of intoxication with alcohol: ataxia, altered sensorium, and dysarthria. Both horizontal and vertical nystagmus may be present. When intoxication is severe, respiratory and cardiovascular compromise may occur. Ventilation is usually slow and shallow, and pulmonary edema or pneumonitis may develop. Centrally mediated vasomotor depression results in a decrease in blood pressure. If perfusion is not maintained, renal failure may follow. Tissue hypoxia may develop as a result of decreased respiratory function, and pupillary dilation may be seen. Deep tendon reflexes also may be depressed.

B. Laboratory Findings—Routine laboratory studies should include electrolytes and an arterial blood gas determination. A sample of blood should be obtained and sent for barbiturate concentration determination. Lethal levels vary widely depending on patient factors and the presence of coingestants. An acetaminophen level should be determined in case this agent was coingested.

C. Imaging Studies—A chest x-ray is advisable to evaluate the extent of atelectasis and pneumonitis present at the time of admission.

Differential Diagnosis

Ingestions of nonbarbiturate sedatives such as chloral hydrate, ethchlorvynol, glutethimide, methypylon, and

methaqualone are the considerations when treating a barbiturate overdose. Coingestion of alcohol, benzodiazepines, or opioids also must be considered.

Treatment

A. General Measures—When cardiovascular and respiratory parameters are normal and stable, supportive care generally is all that is required. However, when intoxication is severe, hypoventilation and depressed cough and gag reflexes are indications for intubation to protect the airway, prevent aspiration, and allow for mechanical ventilation as needed.

B. Decontamination—Lavage generally should be considered if ingestion has been within the preceding 45 minutes. Food in the stomach decreases absorption and may prolong the time during which lavage is useful; however, if obtundation is a concern, the risks of lavage may not outweigh any potential benefits of this procedure.

C. Diuresis—Although believed to be useful in the past, forced diuresis is no longer felt to be useful. Sodium bicarbonate to alkalinize the urine prevents tubular reabsorption of phenobarbital and supplemental potassium chloride should be given to ensure alkalinization of the urine. Careful serum electrolyte monitoring is mandatory.

D. Cardiovascular Support—Hypotension usually responds to the administration of balanced salt solutions such as normal saline or lactated Ringer's solution, although vasopressors may be required. If large amounts of fluid are necessary for resuscitation, fluid administration should be guided by central venous or pulmonary artery catheter monitoring to prevent pulmonary edema.

E. Hemodialysis—When renal failure occurs, hemodialysis may be necessary. Most of the barbiturates are dialyzable, although the short-acting forms have the lowest percentage of removal.

Withdrawal

Withdrawal from sedative-hypnotics may be fatal. Symptoms of withdrawal typically occur after 8–16 hours of abstinence and include anxiety, tremulousness, weakness, and insomnia. GI symptoms include abdominal cramping, anorexia, nausea, and vomiting. As withdrawal progresses, neurologic findings become predominant and are characterized by twitching, coarse tremors, increased startle response, and hyperactive deep tendon reflexes. After 2–3 days, grand mal seizures may occur. As the seizures subside, improvement usually is noted, although some patients develop organic brain syndrome with disorientation, visual and auditory hallucinations, and delusions. Hyperthermia may lead to cardiovascular collapse and death.

When withdrawal is suspected, the patient should be given an intravenous dose of pentobarbital or phenobarbital based on an estimate of the most recent consumption. This dose then can be reduced by about 10% per day until the patient is drug-free.

Mohammed Ebid AH, Abdel-Rahman HM: Pharmacokinetics of phenobarbital during certain enhanced elimination modalities to evaluate their clinical efficacy in management of drug overdose. *Ther Drug Monit* 2001; 23:209–16. [PMID: 11360027]

Palmer BF: Effectiveness of hemodialysis in the extracorporeal therapy of phenobarbital overdose. *Am J Kidney Dis* 2000;36:640–3. [PMID: 10977799]

▶ Opioids

ESSENTIALS OF DIAGNOSIS

- ▶ Decreased level of consciousness.
- ▶ Depressed respiration.
- ▶ Miosis.
- ▶ Pulmonary edema.

General Considerations

Narcotic abuse is a major problem worldwide. Although the drugs of choice traditionally have been morphine and heroin, the shorter-acting agents such as fentanyl have come into vogue, especially among health care workers. Most narcotics are administered intravenously because of the rapid euphoria they produce. Methadone, a long-acting oral agent, is used commonly in narcotic addiction treatment/maintenance programs. Pentazocine is a synthetic analgesic with both agonist and antagonist properties. When given to a narcotic-dependent patient, pentazocine may cause withdrawal symptoms. In high doses, it can cause visual hallucinations and dysphoria.

Immediate care of the narcotic overdose or withdrawal patient focuses on resuscitation, stabilization, and use of antidotes. Critical care of patients suffering from narcotic overdose and withdrawal may include the treatment of conditions caused by narcotic use and the sharing of injection needles. These include pulmonary hypertension (presumably from cotton fiber emboli), endocarditis (from bacterial contamination), necrotizing fasciitis, and tetanus. Other reported complications include hepatitis, AIDS, cutaneous abscesses, and Guillain-Barré syndrome. Many patients will use other intoxicants concurrently, such as alcohol or cocaine, which complicates their care.

Clinical Features

A. Symptoms and Signs—Patients with opioid overdoses present most commonly with decreased level of consciousness, depressed respiration, and miotic pupils. In severe cases, such as cases of attempted suicide, respiratory depression may be pronounced. Pulmonary edema may be seen, particularly in heroin overdose. Other common findings include hypo- or hyperthermia, emesis, hypoxia, hypotension, and depression of deep tendon reflexes.

B. Laboratory Findings—A blood sample should be sent for toxicology screen and alcohol level and to check for other CNS depressants. Routine electrolytes, a complete blood count, and liver function tests should be obtained. In cases of pulmonary edema, pulse oximetry and/or an arterial blood gas analysis will help to assess severity. In patients with oral opioid ingestions, an acetaminophen level should be determined. If the patient is febrile and uses opioids by injection blood cultures should be sent.

C. Imaging Studies—A chest x-ray should be obtained in patients suspected to have pulmonary edema or other indications of pulmonary compromise. A head CT scan may be useful in patients with depressed level of consciousness who do not respond appropriately to naloxone to exclude the presence of a mass lesion or intracranial bleed.

Treatment

A. General Measures—Most patients transferred to the ICU will already have been stabilized and intravenous access established. Patients should be reassessed on arrival to the ICU because those with significant narcotic overdose are at high risk for respiratory depression and airway compromise. If indicated by either a low blood glucose determination or in the obtunded patient in whom this measurement cannot be made, 50 mL of 50% dextrose should be given intravenously along with 100 mg thiamine.

Mechanical ventilation may be required both for decreased respiratory drive and for management of pulmonary edema. Hypotension usually responds to volume infusion and correction of hypoxia. Pulmonary edema caused by narcotic overdose usually does not respond to the customary regimen of diuretics and preload and afterload reduction, and intubation is often required.

B. Decontamination—If the use of coingestants is suspected, administration of activated charcoal is advisable; this can be done either orally or via a nasogastric (NG) tube. If there is a risk of aspiration, however, charcoal should be used only if it has a high likelihood of improving the patient's outcome.

C. Narcotic Antagonists—Several narcotic antagonists have been used—naloxone, naltrexone, nalmefine, nalorphine, and levallorphan; the latter two also have agonist properties. Although naltrexone is longer-acting than naloxone, its use in the acute setting has been disappointing, and naloxone is the drug of choice in this situation. An initial dose of 0.2–0.8 mg should be administered intravenously for heroin and morphine overdoses, titrating to response. When the abused drug is codeine, pentazocine, or propoxyphene, an initial dose of up to 2 mg naloxone may be required. When effective, an improvement in respiration and mental status typically occurs in less than 2 minutes, often in seconds. If no response to a total dose of 2 mg is seen, the diagnosis of narcotic

overdose should be questioned. Because the half-life of naloxone is substantially shorter than that of most narcotic agents, repeat dosing may be required to prevent recurrence of respiratory and mental status depression. Continuous administration of naloxone intravenously may be required in some cases to prevent relapse of respiratory depression.

D. Other Modalities—Because of the complications associated with narcotic abuse, additional therapy in the ICU may be required for pulmonary edema, pneumonitis, cardiac valvular compromise, or infectious complications. Overdosage with meperidine may cause hyperactive reflexes and convulsions. Rhabdomyolysis may occur, particularly in patients who have been obtunded for a significant amount of time; if not treated, patients may develop renal failure from the myoglobinuria seen in this condition.

Withdrawal

Withdrawal from narcotics produces autonomic disturbances, hyperexcitability, and personality changes characterized by drug-seeking behavior. Within the first 8 hours of withdrawal, lacrimation, rhinorrhea, diaphoresis, and sneezing are common. This is followed by nausea and vomiting, diarrhea, and abdominal cramping. Patients may exhibit tremors and twitching in association with myalgias. Pilomotor erection produces the “cold turkey” appearance of the skin. All the symptoms are relieved by the administration of narcotic.

► Sympathomimetics

ESSENTIALS OF DIAGNOSIS

- ▶ Agitation, anxiety, hallucinations, psychosis.
- ▶ Seizures.
- ▶ Coma, stroke, encephalopathy.
- ▶ Hypertension, tachycardia.

General Considerations

Sympathomimetics are a category of drugs that induce a physiologic state similar to that caused by catecholamine release. Many different prescription, over-the-counter, and recreational or abuse drugs fall into this category. Examples include amphetamine and its derivatives, over-the-counter products for appetite control, cold remedies, and stimulants (eg, phenylpropanolamine, caffeine, ephedrine, and pseudoephedrine).

Overuse of sympathomimetics causes toxicity by inducing excessive release of neurotransmitters, including epinephrine and norepinephrine, and the subsequent α - and β -adrenergic effects they produce. α -Adrenergic effects are primarily vasoconstriction, diaphoresis, and dilated pupils; β_1 -adrenergic effects lead to tachycardia, and β_2 -adrenergic effects cause bronchodilation and vasodilation. The clinical effects that result from any specific sympathomimetic drug depend on the relative α - or β -adrenergic actions of that drug (eg, phenylpropanolamine is an α -selective drug that causes hypertension, diaphoresis, and mydriasis).

Duration of toxicity is usually limited; however, patients may demonstrate prolonged toxicity if they ingest bags containing the drug for illicit transport or if they use “Ice,” a long-acting, smokable form of methamphetamine.

Clinical Features

A. Symptoms and Signs—Sympathomimetic toxicity causes a toxic syndrome that includes primarily CNS and cardiovascular effects (see Table 36–2). Both illicit drug users and those who use excessive amounts of over-the-counter medications (eg, diet aids, stimulants, and cold medications) may present with sympathomimetic poisoning.

CNS toxicity is manifested as agitation, anxiety, delusions, hallucinations, paranoia, and seizures. Sympathomimetics may cause a psychotic state indistinguishable from that seen in schizophrenia; although almost always temporary, this psychosis may take weeks to months to resolve. Less common but more severe effects include coma, strokes (ischemic and hemorrhagic), hypertensive encephalopathy, and focal neurologic deficits.

Cardiovascular effects include hypertension and sinus tachycardia. Hypertension may be of rapid onset and severe. Because these patients often do not have underlying hypertension, they have no CNS autoregulation at these excessively high blood pressures. As a result, they are much more likely to suffer serious CNS sequelae such as hemorrhagic strokes or encephalopathy from acute hypertension. Sinus bradycardia or atrioventricular block occurs mainly after ingestion of drugs with primarily α -agonist properties. Patients may suffer tachydysrhythmias, cardiac ischemia, and rarely, infarction.

Other findings include rhabdomyolysis with or without renal failure, diarrhea, intestinal cramping, and hyperthermia. Pupils typically are dilated if the patient ingests an agent

with α -adrenergic properties; by the same mechanism, these patients also may be diaphoretic.

B. Laboratory Findings—Laboratory abnormalities are variable and not diagnostic. Toxicology screening may be positive for sympathomimetic drugs, but it is by no means comprehensive of the wide array of available agents; therefore, a negative screen does not exclude sympathomimetic toxicity. Leukocytosis is common as a result of demargination caused by catecholamine stimulation. Patients should have a creatine kinase (CK) determination to evaluate for rhabdomyolysis. Serum electrolytes (especially potassium) and blood pH should be tested.

C. Imaging Studies—CT scanning is indicated in patients with altered mental status or seizures.

Differential Diagnosis

Thyrotoxicosis may present in a manner identical to sympathomimetic overdose. A history of thyroid disease is suggestive of the diagnosis, as is the presence of goiter or physical findings suggestive of hyperthyroidism. CNS infections may cause similar clinical findings. Drug withdrawal (eg, ethanol and benzodiazepines) also presents with agitation and cardiovascular abnormalities. Similar clinical findings result from toxic effects of theophylline, tricyclic and SSRI antidepressants, anticholinergics, isoniazid, phencyclidine, and salicylates, and from interaction between monoamine oxidase inhibitors and other drugs. The agitation and paranoia seen in these patients may mimic psychiatric disorders such as schizophrenia.

Treatment

A. General Measures—After initial assessment and stabilization, treatment should be individualized to the drug involved and the toxic clinical effects manifest. If the drug was ingested, gastric lavage should be considered if presentation is within 1 hour of ingestion or if the patient is transporting the drugs as a body packer. Care must be taken to protect the airway because these patients may seize as a result of their ingestion. Activated charcoal should be administered to all patients with an oral ingestion. Repeat-dose activated charcoal is helpful in enhancing caffeine elimination. Forced diuresis, hemodialysis, and hemoperfusion are not helpful in these poisonings.

B. Hypertension—Hypertension is a medical emergency in these patients because of the risk of hemorrhage or encephalopathy. Patients with evidence of end-organ dysfunction from hypertension (eg, headache, renal compromise, cardiac ischemia, and heart failure) should be treated with antihypertensive agents. Nitroprusside is a good choice because it is easily titratable and doses can be adjusted rapidly. Phentolamine may be used in patients who overdose on

pure α -agonists such as phenylpropanolamine. Although nifedipine is a potent antihypertensive agent, it is not easily titrated, and cases of prolonged hypotension from its use have been reported. Labetalol may be a good choice in patients with significant tachycardia.

C. Arrhythmias—Sinus tachycardia rarely requires intervention. Supraventricular tachycardia is usually benign; however, when the patient suffers compromise from the rapid ventricular response, verapamil or adenosine may be used to control the rhythm. Esmolol may be used to treat both supraventricular tachycardia and ventricular dysrhythmias. Esmolol and other β -adrenergic blockers may worsen hypertension because of unopposed α -adrenergic activity.

D. Seizures—Seizures and agitation should be treated with benzodiazepines. Status epilepticus may develop and may require treatment with phenobarbital and phenytoin. If these medications are ineffective, paralysis may be required to prevent rhabdomyolysis, acidosis, and hyperthermia. Continuous electroencephalographic monitoring is required in these patients because they may continue to have electrical seizure activity despite chemical paralysis.

E. Psychosis—Benzodiazepines may be used to treat psychosis associated with sympathomimetic overdoses. Although neuroleptics have been used in the past, they can lower the seizure threshold and alter thermoregulation; their use probably should be avoided in this situation.

F. Myocardial Ischemia—Although actual myocardial infarction is rare, patients with angina pectoris should be managed with aspirin, nitrates, and heart rate control. Patients usually respond to this treatment and should be monitored for elevation of cardiac enzymes or changes in the ECG consistent with myocardial infarction.

G. Hyperthermia—Hyperthermia can be severe and life-threatening. When present, aggressive treatment is warranted. Patients with agitation or seizures should receive benzodiazepines. Antipyretics are rarely helpful. All clothing should be removed and patients sprayed with a mist of water or covered with damp sheets to increase evaporation, and a fan is helpful. Those with excessive agitation or seizures who do not respond to benzodiazepines may need paralysis to control heat production.

▶ Phencyclidine

ESSENTIALS OF DIAGNOSIS

- ▶ Nystagmus.
- ▶ Hypertension.
- ▶ Tachycardia.
- ▶ Agitation, psychosis, violent behavior.
- ▶ Seizures.

General Considerations

Phencyclidine (PCP), pharmacologically related to ketamine, is an illicit hallucinogen used as a recreational drug. The usual method of consumption is by smoking cigarettes that have been soaked in a solution of PCP. PCP also can be used via the intranasal route or by ingestion. Some patients have become intoxicated from percutaneous exposure by handling the drug. Absorption is rapid by any route; effects are seen within a few minutes to half an hour. The drug is highly lipid-soluble, and inconstant release from adipose tissue may lead to waxing and waning findings that are predominantly due to CNS effects. Metabolism is primarily in the liver. The half-life varies from 7 hours to over 3 days.

Clinical Features

The clinical presentation of PCP intoxication is extremely variable, ranging from confusion to agitation. Alterations in mental status are erratic, and violent behavior often occasions transport to a hospital. Concurrent use of other drugs of abuse is common, and the treating physician must be aware of this possibility when evaluating these patients. In addition, phencyclidine is an analgesic agent. These patients may suffer significant traumatic injuries with minimal findings on examination.

A. Symptoms and Signs—The most common findings (>50% of patients) are nystagmus (horizontal, vertical, or rotatory) and hypertension. Although hypertension is common, medical complications are rare. Tachycardia is also common, but rates over 130 beats/min are unusual. The level of consciousness may vary from comatose to agitated to fully alert. Mental status may wax and wane, and unpredictable and precipitous violent outbursts may occur. These patients may require physical and chemical restraints to prevent them from hurting themselves or the medical personnel caring for them. Hallucinations, frank psychosis, and seizures are common. Most symptoms resolve spontaneously within hours; however, some patients may remain symptomatic for several days or even a week. The psychosis may last months, and in these cases, recovery may be gradual. Rhabdomyolysis is a relatively common complication of PCP intoxication and may lead to renal failure in up to 2.5% of cases.

B. Laboratory Findings—Urine for PCP level may be sent to confirm the diagnosis. Quantitative levels are not necessary and do not correlate with clinical effects. If patients who appear to be PCP-intoxicated have negative urine results, they need to be evaluated for other causes of their symptoms (see “Differential Diagnosis” below).

Elevated creatine kinase levels are found in up to 70% of cases and can occur even in the absence of excessive muscle activity. Although usually positive for blood, initial urine dipstick may be negative despite a significant elevation in CK, so all patients with PCP intoxication should have a serum sample sent for CK measurement.

C. Concealed Injuries—Because PCP has anesthetic properties, patients may suffer significant trauma in the prehospital setting that may not be manifested in the usual fashion. All patients should undergo a thorough physical evaluation for trauma and be reevaluated several times during the hospital stay, particularly as their mental status improves.

Differential Diagnosis

Lethargic patients may have consumed other intoxicants, including sedative-hypnotic drugs or barbiturates. Patients who are agitated or violent must be evaluated for possible sympathomimetic use or a withdrawal syndrome. Other causes include head trauma, infection (eg, meningitis or encephalitis), metabolic derangements, and psychiatric disorders.

Treatment

A. Decontamination—Gastric lavage is rarely indicated because PCP is typically inhaled. If patients ingest the agent, activated charcoal should be used.

B. Supportive Measures—Most patients respond to minimal measures such as being placed in a quiet, darkened room with minimal stimulation. Benzodiazepines may be useful to decrease agitation. In some cases, however, specific treatment measures may be necessary.

Patients with hypertension or tachycardia rarely need intervention for these problems; end-organ dysfunction should be managed in the usual manner. Hyperthermia requires treatment with antipyretics and cooling measures as necessary. Seizures should be treated with benzodiazepines. If the patient develops refractory seizures, phenytoin may be used, but neuromuscular blockade may be required to prevent acidosis, hyperkalemia, and rhabdomyolysis. Continuous electroencephalographic monitoring is required in this situation.

In the past, urinary acidification was advocated to cause urinary ion trapping of the drug and enhance elimination. Because only a small amount of the drug is excreted unchanged in the urine, and because induction of aciduria is difficult to achieve and may lead to renal dysfunction owing to rhabdomyolysis, this treatment is no longer recommended.

C. Hydration—If serum CK is elevated, vigorous hydration is required, and intravenous crystalloid is the mainstay of therapy. Normal saline should be used until the patient is volume-repleted and has a good urine outflow; the goal is a urine output of 150 mL/h. Adequate urine output is the mainstay of therapy, but additional therapy with intravenous mannitol and bicarbonate also may be used. Follow serial CK levels to ensure that levels decrease. BUN and creatinine levels should be measured to monitor renal function, and potassium levels and blood gases should be followed to evaluate hyperkalemia and acidosis.

D. Restraints and Sedation—Patients who are agitated or violent may require physical or chemical restraints. The use of physical restraints alone may exacerbate rhabdomyolysis as the patient fights against the restraints. Restrained patients should be placed in a quiet room to avoid stimulation. Benzodiazepines or haloperidol may be used for sedation.

Cocaine

ESSENTIALS OF DIAGNOSIS

- ▶ Hypertension.
- ▶ Tachycardia and other dysrhythmias.
- ▶ Headache.
- ▶ Myocardial infarction.
- ▶ Transient ischemic attacks, stroke.
- ▶ Seizures.

General Considerations

Cocaine is available as cocaine hydrochloride, a water-soluble crystalline salt that can be used intranasally or dissolved and injected intravenously. Cocaine is also available in an alkaloid form that is not water-soluble and can be smoked in a free-base form or mixed with baking soda and water and smoked

as the “crack” form. Absorption from all sites is rapid. The half-life varies with the route of administration; intravenous use or smoking leads to a half-life of 60–90 minutes, whereas intranasal or oral use has a half-life of several hours.

Cocaine has several effects. It causes CNS release of neurotransmitters, including dopamine; acts as a local anesthetic; blocks neuronal catecholamine reuptake; and inhibits serotonin reuptake. The end result of these mechanisms is a spectrum of clinical findings primarily involving the central nervous and cardiovascular systems. Respiratory and metabolic effects also may be noted.

Clinical Features

A. Symptoms and Signs—Hypertension occurs frequently and can be severe. It can lead to intracranial bleeding, aortic dissection, and cardiac ischemia. Tachycardia is also common, as are dysrhythmias, including atrial fibrillation, atrial tachycardia, ventricular tachycardia, and rarely, asystole.

Cocaine is a potent vasoconstrictor that may result in organ ischemia. Myocardial infarction, bowel ischemia, renal infarction, and limb ischemia all have been reported. A combination of vasospasm, enhanced platelet aggregation, and enhanced workload caused by an excessive demand for oxygen produces end-organ dysfunction. In addition to organ ischemia, cocaine can cause a myocarditis manifested by elevated CK-MB enzymes and diffuse ST-segment elevations or T-wave inversions on ECG.

There are many CNS manifestations of cocaine toxicity. Headache is common in chronic abusers. In patients who develop CNS complications owing to cocaine, cerebral infarction occurs in about one-fourth, subarachnoid hemorrhage in another one-fourth, and intraparenchymal hemorrhage in the remainder.

Patients who abuse cocaine also may present with depressed mental status or frank coma, a condition known as *cocaine abstinence syndrome*. This phenomenon is likely due to CNS depletion of neurotransmitters. These patients characteristically have been using large amounts of cocaine for over a week and present either after a seizure or when they are found obtunded. They may be frankly comatose or extremely difficult to arouse, often prompting extensive medical evaluation of their altered mental status. Typically, they awaken completely within 24 hours.

Seizures occur in up to 2% of cocaine abusers, and although they usually occur soon after cocaine use, they may not present until several hours later. Transient ischemic attacks have been described and may lead to stroke; cocaine use should be considered in the differential diagnosis of a young patient with a stroke. Strokes are independent of the route of administration and may occur as late as 24 hours after use. They can present in first-time users but are more common in chronic abusers.

Pulmonary complications include pneumothorax and pneumomediastinum in patients who smoke or snort cocaine. Pulmonary edema is rare in most cases of cocaine

toxicity but is a common finding in patients who die of cocaine intoxication.

Rhabdomyolysis may occur with excess muscle activity and hyperthermia. Hyperthermia, when present, is often severe.

B. Laboratory Findings—Laboratory evaluation of patients with serious intoxication should include an ECG and measurements of serum electrolytes, total CK levels, and a urine test for myoglobin. Blood for cardiac markers may be indicated by the patient's clinical presentation. Toxicology screens for cocaine may focus the diagnosis.

C. Imaging Studies—CT head scanning should be performed in any patient with a concerning headache or in those with neurologic findings or altered mental status. Plain films of the abdomen may reveal packets in the intestines of patients who swallow containers of the drug for the purpose of transport (“body packers”).

Differential Diagnosis

Other stimulants, including sympathomimetics, SSRIs, theophylline, phencyclidine, and anticholinergic drugs, can cause a similar clinical picture. Withdrawal from ethanol or benzodiazepines may present similarly, as can thyrotoxicosis and CNS infection. Psychiatric disorders are also in the differential diagnosis.

Treatment

A. Supportive Measures—Basic supportive measures such as intravenous access, fluid administration, and supplemental oxygen should be initiated as indicated by the clinical situation. Gastric decontamination is not indicated in most cases; however, patients who have ingested packets of the drug are candidates for whole bowel irrigation.

B. Hyperthermia—When hyperthermia is present, the patient should be undressed completely and sprayed with a cool mist or draped with a wet sheet. A fan can be used to facilitate evaporation. Ice packs should be placed at the neck, axillae, and groin. Care should be taken not to overcool the patient. Antipyretic agents are not effective.

C. Seizures—Initial treatment of agitation and seizures should be with benzodiazepines. Neuroleptics may be effective, but since they lower the seizure threshold, their use is discouraged. Seizures refractory to benzodiazepines can be treated with phenobarbital or phenytoin. Status epilepticus unresponsive to this therapy should be treated with pharmacologic paralysis and mechanical ventilation; continuous EEG monitoring is necessary in these cases to ensure that the paralyzed patient is not seizing.

D. Hypertension—Mild hypertension usually does not require intervention. Severe hypertension or labile hypertension should be treated with intravenous nitroprusside. Labetalol is another alternative, especially in the tachycardiac patient.

Tachydysrhythmias that require treatment may respond to β -blockers such as esmolol or metoprolol, but the patient must be observed carefully for the development of worsening hypertension from the unopposed α -adrenergic stimulation and β -adrenergic blockade. Concurrent use of nitroprusside with β -blockers is often necessary. Patients suspected of having a myocardial infarction should receive standard therapy, but may or may not have classic arteriosclerotic coronary artery disease.

E. Rhabdomyolysis—Rhabdomyolysis should be treated with isotonic fluids to ensure a urine output of over 150 mL/h. The addition of mannitol or alkalinization also may be useful.

▶ Tricyclic Antidepressants

ESSENTIALS OF DIAGNOSIS

- ▶ Tachycardia, arrhythmias.
- ▶ Seizures.
- ▶ Sensorium may range from awake and alert to comatose.
- ▶ Mydriasis.
- ▶ Dry skin.
- ▶ Ileus.
- ▶ Urinary retention.

General Considerations

Tricyclic antidepressants (TCAs) such as amitriptyline, doxepin, and trimipramine work therapeutically by blocking reuptake of norepinephrine into adrenergic nerves, but they also have significant toxic effects related to their anticholinergic and α -adrenergic blocking properties. When ingested, they are absorbed rapidly; in overdose situations, owing to the slowed intestinal motility from the anticholinergic effects, absorption may be prolonged, increasing the half-life to as much as 3–4 days.

Clinical Features

A. Signs and Symptoms—Patients with TCA overdose may deteriorate rapidly, progressing from awake with normal vital signs to having seizures or cardiac arrest within less than an hour of significant ingestion. Mental status may range from awake and alert to having seizures to frankly comatose.

Patients with suspected TCA ingestion need immediate medical evaluation and close observation. Evaluation often reveals both central and peripheral anticholinergic effects: tachycardia, mydriasis, dry skin, urinary retention, ileus, elevated temperature (usually mild), altered mental status (eg, agitation, anxiety, delirium, and coma), seizures, and occasionally, respiratory depression. Cardiovascular effects are usually the cause of death and can include sinus tachycardia, dysrhythmias, atrioventricular blockade, and hypotension (decreased contractility and α -adrenergic blockade). This ingestion should be suspected in any patient who presents with seizures, anticholinergic signs (including coma), and cardiovascular abnormalities, particularly if the ECG is abnormal.

B. Electrocardiography—The single most valuable initial test in patients suspected of having a TCA overdose is the ECG. Common findings include sinus tachycardia, PR-interval and QT-segment prolongation, and nonspecific ST-segment changes. QRS complex prolongation suggests a serious overdose. Rightward and superior terminal QRS forces (a wide, prominent S wave in leads I, aVF, and V_6 , with a prominent R wave in aVR) are very suggestive of TCA overdose.

C. Laboratory Findings—General laboratory evaluation is rarely helpful. Drug levels correlate poorly with toxic effects and can vary widely in an individual patient.

D. Imaging Studies—Since some TCAs are radiopaque, a plain film of the abdomen may show tablets in the stomach or intestines.

Differential Diagnosis

The combination of altered mental status, seizures, and cardiovascular abnormalities suggests several diagnoses. Toxicologic causes include phenothiazines, anticholinergics, and theophylline; less commonly, β -blockers, calcium channel blockers, and local anesthetic drug overdose (eg, lidocaine) can cause these findings. Nontoxicologic causes include meningitis, sepsis, hypoglycemia (severe), anaphylaxis, and head trauma.

Treatment

A. Initial Management—General measures aimed at stabilization, monitoring, and intravenous access should be instituted rapidly. A urinary catheter should be placed to monitor urine output and provide easy determination of urine pH. Syrup of ipecac should be avoided because these patients may deteriorate rapidly and become obtunded before vomiting begins, placing them at risk for aspiration. Gastric lavage should be considered in patients presenting within 1 hour of ingestion

of a large amount of TCAs. If gastric lavage is performed, suction and airway management equipment must be readily available in the event the patient develops seizures. Activated charcoal, 100 g, should be placed down the lavage tube (if used) or given to the patient via NG tube. There is some evidence that a repeated-dose activated charcoal regimen (every 2–4 hours) may be helpful in significant ingestions.

TCA overdose patients need to be admitted to the ICU if they have any of the following: persistent tachycardia (>120 beats/min); dysrhythmias, including premature ventricular contractions; QRS >100 ms; hypotension; or evidence of CNS toxicity. Patients admitted should be monitored until they are free of toxicity for 24 hours. Patients who present with none of the preceding and do not develop any of the listed admission criteria after 6 hours of observation may be discharged; a psychiatric evaluation before discharge is prudent and is mandatory in cases of attempted suicide.

B. Bicarbonate Therapy—Alkalinization of the blood is a mainstay in the therapy of TCA ingestion. It effectively treats most of the major adverse effects of the drug, including hypotension, cardiac conduction abnormalities, and dysrhythmias. Alkalinization has varying efficacy in the treatment of seizures and coma. Optimal blood pH is 7.50, and the urine pH should be over 7.0. Alkalinization is achieved by intravenous sodium bicarbonate therapy; in intubated patients, transient hyperventilation will alkalinize the blood until intravenous therapy can be initiated.

Supportive care and alkalinization therapy usually are adequate to manage patients with TCA overdose. In some cases, additional measures will be needed to stabilize the patient. Those with severe agitation, delirium, or seizures may require benzodiazepines or barbiturates for control. Dysrhythmias refractory to alkalinization can be treated with lidocaine or cardioversion. Class Ia antiarrhythmic agents should be avoided in this patient population because they can exacerbate dysrhythmias. Hypotension that does not respond to alkalinization can be managed with fluid boluses or with vasopressors; since the hypotension is often due to α -adrenergic blockade, α -adrenergic agonists (eg, phenylephrine or methoxamine) are a good choice. Dopamine may be ineffective or may exacerbate hypotension owing to its β -agonist effects (peripheral β_2 -adrenergic stimulation produces vasodilation). Hemodialysis and hemoperfusion are relatively ineffective in these patients because the TCAs are highly protein-bound and not easily removed by these measures.

Current Controversies and Unresolved Issues

In the past, physostigmine was recommended for treatment of TCA overdose. As an acetylcholinesterase inhibitor, physostigmine increases acetylcholine availability at receptor sites and reverses central and peripheral anticholinergic effects. It has not been proven to be effective in treating hypotension, ventricular dysrhythmias, and conduction disturbances, which are the major causes of fatal toxicity in TCA overdoses. Significant adverse effects such as atrioventricular

blockade, bradycardia, and asystole may occur with physostigmine. Therefore, use of physostigmine is not recommended in the treatment of TCA overdose.

▶ Serotonin Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Coma, somnolence, confusion, agitation, or seizures.
- ▶ Autonomic instability, including fever, diaphoresis, tachycardia, hyper- or hypotension, mydriasis.
- ▶ Clonus (may be spontaneous), especially ocular clonus, rigidity, hyperreflexia.
- ▶ History of use of serotonin-based antidepressants or other drugs associated with serotonin release.

General Considerations

The serotonin syndrome historically has been associated with cocaine, amphetamines, and other drugs that cause increased release of serotonin, such as a drug of abuse, 3,4-methylenedioxymethamphetamine (MDMA or “ecstasy”), or dextromethorphan, bromocriptine, and linezolid. With the increased use of selective serotonin reuptake inhibitors (SSRIs) as antidepressants, overdose of these agents is responsible for a number of cases of serotonin syndrome.

Clinical Features

A. Symptoms and Signs—The serotonin syndrome shares many symptoms and signs with overdose of sympathomimetics (eg, tachycardia and mydriasis) and with the

neuroleptic malignant syndrome (eg, rigidity, hyperthermia, and alterations of mental status). In fact, distinguishing serotonin syndrome from these may be difficult. Most cases of serotonin syndrome are mild and self-limited, but severe complications can include diaphoresis with severe fluid loss, rhabdomyolysis, marked hyperthermia, and death. Diagnostic criteria have been proposed, but these are somewhat nonspecific.

B. Laboratory Findings—Laboratory evaluation in patients with serious intoxication should include an ECG and measurements of serum electrolytes, total CK levels, and urinary myoglobin. There are no specific tests for this syndrome, although toxicology studies may demonstrate the presence of concomitant cocaine, amphetamines, or other drugs.

Differential Diagnosis

The differential diagnosis includes sympathomimetic overdose, including amphetamines and cocaine, both of which also can trigger the serotonin syndrome. A more confusing clinical picture is the neuroleptic malignant syndrome, in which muscular rigidity, altered mental status, and hyperthermia are key features. Some authors have suggested that dilated pupils with clonus and hyperreflexia rather than severe muscle rigidity make it more likely to be the serotonin syndrome. A key differential feature is evidence of an overdose of an SSRI or other drug. While neuroleptic malignant syndrome may occur at any time after a neuroleptic is prescribed, it is not more likely after an overdose. Other possible syndromes include thyroid storm and withdrawal from benzodiazepines or ethanol.

Treatment

A. Supportive Measures—Basic supportive measures such as intravenous fluid administration and supplemental oxygen should be initiated as indicated by the clinical situation. When hyperthermia is present, the patient should be undressed completely and sprayed with a cool mist or draped with a wet sheet. A fan can be used to facilitate evaporation. Ice packs should be placed at the neck, axillae, and groin. Care should be taken not to overcool the patient. Antipyretic agents are not effective.

B. Specific Treatment—Potential drugs precipitating the serotonin syndrome should be discontinued. Benzodiazepines generally are considered useful for the serotonin syndrome. They are anticonvulsants, are not associated with serotonin release, and are anxiolytic and sedating. Dantrolene uncouples excitation-contraction in skeletal muscles and has been used in malignant hyperthermia, neuroleptic malignant syndrome, and serotonin syndrome. There are case reports of benefit from dantrolene in serotonin syndrome but no controlled trials.

C. Current Controversies—A number of authors have commented on the approach when it is not clear whether a

patient has severe serotonin syndrome or neuroleptic malignant syndrome. Cyproheptadine and chlorpromazine potentially antagonize serotonin in the CNS, but there are no controlled trials of these agents. However, chlorpromazine may be contraindicated in neuroleptic malignant syndrome because of its antidopaminergic properties. On the other hand, bromocriptine, a central dopaminergic agonist thought to be useful in neuroleptic malignant syndrome, may cause the serotonin syndrome and therefore is contraindicated.

One approach is to treat with benzodiazepines as necessary while carefully supporting the patient and considering the need for dantrolene and cyproheptadine. When the clinical picture becomes clearer, then other treatment may be added.

▶ Antihypertensives

ESSENTIALS OF DIAGNOSIS

β-Blockers:

- ▶ Bradycardia.
- ▶ Conduction blocks.
- ▶ Hypotension.
- ▶ Cardiogenic shock.
- ▶ Depressed mental status.

Calcium channel blockers:

- ▶ Bradycardia.
- ▶ Hypotension.
- ▶ Heart block.
- ▶ Drowsiness.

General Considerations

Acute overdose of β-blockers and calcium channel blockers can be potentially life-threatening and poses significant treatment challenges for the intensivist. Clinical manifestations of β-blocker overdose are due to the effects of systemic β-adrenergic blockade. Toxic effects involve mainly the cardiovascular system, but CNS effects are seen as well. β-Blockers are absorbed rapidly from the GI tract, and clinical effects may appear as rapidly as 20–60 minutes after ingestion. Half-life depends on the specific drug but ranges from 2–12 hours; excessive overdose may prolong this half-life.

Clinical effects of calcium channel blocker overdose are caused by actions on the myocardium and on the smooth muscle of blood vessels. This produces vasodilation and negative inotropic, dromotropic, and chronotropic activity. The most commonly used calcium channel blockers are verapamil, diltiazem, and nifedipine, and each has slightly different effects. All are well absorbed from the GI tract, but diltiazem and verapamil both undergo a significant hepatic first-pass effect. Metabolism is primarily in the liver.

Clinical Features

Although toxicity is seen most frequently with oral ingestion, significant β-blocker toxicity also can be seen in patients being treating with β-blocker eyedrops for conditions such as glaucoma. Patients with significant β-blockade toxicity present with bradycardia, conduction blocks, hypotension, decreased cardiac output, and cardiogenic shock; depressed mental status also may be seen. Bradycardia can be severe and appears to be more common with ingestions of propranolol than with other drugs. Overdose with atenolol, nadolol, carvedilol, and metoprolol tend to present with hypotension and a heart rate that may be within normal limits. Pindolol and practolol overdoses may present with tachycardia owing to their partial agonist activity. First-degree atrioventricular block is common with propranolol overdoses, and junctional rhythms, bundle branch block, complete atrioventricular block, and asystole all have been observed with β-blocker ingestions. Hypotension is common and may be profound. Depressed mental status is also seen frequently and is more common in patients with significant hypotension. Seizures are uncommon but do occur with propranolol ingestion. Significant bronchospasm is surprisingly rare.

Significant calcium channel blocker overdose commonly presents with bradycardia, hypotension, and significant heart block (including third-degree heart block), which can be life-threatening. Hypotension is due to both decreased cardiac output and peripheral vasodilation. These patients also may be somewhat drowsy, although markedly altered mental status is rare.

Differential Diagnosis

β-Blocker overdoses present with bradycardia and hypotension; these findings also can occur with barbiturate intoxication and in cases of ingestion of some antiarrhythmics such as mexiletine.

Treatment

A. Decontamination—In both β-blocker and calcium channel blocker overdoses, patients who present soon after ingestion of a significant amount of the drug should be considered for gastric lavage. Activated charcoal should be given; repeat doses may be helpful. Patients who are initially stable and who remain so need only be observed and monitored for 12–24 hours.

B. Specific Therapy—

1. β -BLOCKER OVERDOSE—

a. Glucagon—Glucagon has been used with significant success in patients with symptomatic overdoses of β -blockers and is considered to be the drug of choice. It is effective because its effects are independent of β -receptors, and it has both inotropic and chronotropic effects. The dose used is higher than that used for stimulating gluconeogenesis. The recommended initial dose is 0.05 mg/kg intravenously, followed by an infusion of up to 0.07 mg/kg per hour as needed. It is important to be certain that the preparation used for these doses does not contain phenol as a diluent because even small amounts of phenol may be toxic. The most common side effects of this dose of glucagon are nausea and vomiting.

b. β -Agonists— β -Adrenergic agonists have been used to treat β -blocker overdoses with varying success. Since use of these agents requires quantities sufficient to overcome the competitive blockade at the receptor, the necessary doses may be prohibitively high. Agonists may be tried empirically, but if excessive doses are used with minimal effect, the drug should be discontinued.

c. Atropine—Atropine, the agent usually first used to treat symptomatic bradycardia, may have little effect in cases of β -blocker toxicity because these rhythms are not vagally mediated. When used, a dose of not more than 1 mg intravenously should be administered. Use of external or transvenous pacing has been reported, but the heart is often refractory to normal pacing potentials, and the pacemaker may not capture despite the use of high voltage settings.

2. CALCIUM CHANNEL BLOCKER OVERDOSE—

a. Calcium—Calcium channel blocker overdoses have been treated with a variety of medications with varying success. Calcium intuitively would seem to be appropriate therapy, but its use has been disappointing. This result is not surprising, however, because the calcium channels are blocked, and this effect is not easily overcome with additional calcium. Calcium is relatively nontoxic, however, and administration of calcium chloride, 5–10 mL of a 10% solution, is probably indicated in most cases of symptomatic calcium channel blocker toxicity.

b. Glucagon—As with β -blocker overdoses, glucagon is useful in managing patients with calcium channel blocker ingestion, although results have been less impressive. Dosing is the same as that used in treating β -blocker toxicity.

c. Atropine—Atropine has been used to treat bradyarrhythmias and heart block but has proved to be relatively ineffective. If the patient does not respond to 1 mg intravenously, use of atropine should be discontinued. Transvenous pacing may be necessary and may require high voltage settings outputs for capture.

d. Pressors—Dobutamine and dopamine infusions have been used in these ingestions with varying results. These agents may be tried in patients whose hypotension does not respond to fluid administration and use of glucagon. Norepinephrine also may be used.

▶ Digoxin

ESSENTIALS OF DIAGNOSIS

- ▶ Weakness, fatigue.
- ▶ Palpitations.
- ▶ Nausea, anorexia.
- ▶ Visual complaints.

General Considerations

Digitalis is found in commercially prepared medications and is also naturally occurring in plants such as oleander; toxicity may be seen in patients exposed to medications or with plant toxicity.

Digitalis preparations (eg, digoxin and digitoxin) have two therapeutic effects. The first is to increase vagal tone, which leads to conduction blockade at the atrioventricular node and results in decreased chronotropy. The second is to inhibit the myocardial Na^+, K^+ -ATPase pump, which normally pumps calcium and sodium out of the cell and potassium into it. Inhibition causes the intracellular calcium concentration to rise, resulting in increased contractile force (ie, positive inotropic effect). In the patient suffering from digitalis toxicity, inhibition of the pump leads to excessive extracellular potassium and intracellular sodium and calcium, causing exaggerations of the therapeutic effects of the drug. Toxicity is manifested by cardiac, GI, neurologic, and electrolyte abnormalities.

Many of the symptoms of digitalis toxicity are nonspecific. Patients may develop digitalis toxicity even when they have normal blood levels of the drug if they have an underlying condition that sensitizes them to its effects (eg, hypokalemia). Conversely, patients with elevated levels may show no evidence of toxicity. The diagnosis of digitalis toxicity, therefore, often requires that the treating physician know the patient groups at risk and suspect the diagnosis in the appropriate setting. Table 36–9 summarizes the factors that predispose to the development of digitalis toxicity. Patients with any of these factors who are also taking digitalis

Table 36–9. Predisposing factors in digitalis toxicity.

Diuretics	

should be evaluated for possible digitalis toxicity when the clinical setting is suggestive.

Clinical Features

A. Symptoms and Signs—Over 80% of patients with digitalis toxicity will complain of weakness, nausea, anorexia, fatigue, and visual complaints. The visual complaints may be a clue to making this diagnosis. The patient may complain of yellow or green vision or of halos around objects—in addition to other visual disturbances such as photophobia or transient amblyopia. Other complaints include vomiting, headache, diarrhea, and dizziness.

B. Electrocardiography—Patients with significant cardiac toxicity may not manifest either GI or neurologic effects. Cardiac toxicity is due both to the increased vagal effects of the drug and to the effects on the Na^+, K^+ -ATPase pump. In general, cardiac toxicity results from depression of impulse formation or conduction (vagally mediated) and from enhancement of automaticity (caused by blocking the Na^+, K^+ -ATPase pump). Virtually any rhythm disturbance can be observed in digitalis-toxic patients.

Effects on the sinus node lead to bradycardia, sinoatrial block, and sinus arrest. Increased irritability and automaticity in the atria cause atrial tachycardia and can produce atrial fibrillation or flutter. The ventricular rate is often normal or slow as a result of the conduction block caused by the drug. Digitalis effect in the atrioventricular node can cause atrioventricular block or junctional rhythm. In fact, patients with digitalis toxicity may show “regularized” atrial fibrillation—that is, a regular junctional rhythm with a background of atrial fibrillation owing to the high degree of atrioventricular block. The effect in the ventricles may cause premature ventricular contractions (the most common digitalis toxic rhythm), ventricular tachycardia, and ventricular fibrillation.

C. Laboratory Findings—Hyperkalemia may be observed in acute ingestions owing to the effect of digitalis on the Na^+, K^+ -ATPase pump and the resulting shift of potassium to the extracellular space. This effect is not prominent in patients who are maintained on digitalis on a chronic basis and develop toxicity.

Evaluation of the patient with suspected digitalis toxicity includes a serum digitalis level, serum electrolytes (including magnesium and calcium), BUN, and serum creatinine. An arterial blood gas analysis or pulse oximetry should be performed to ensure that the patient is not hypoxic. An ECG also should be obtained.

Differential Diagnosis

Symptoms of digitalis intoxication are nonspecific and are not infrequently misdiagnosed as gastroenteritis or a viral syndrome. The bradydysrhythmias may be associated with other medications, including β-blockers and calcium channel blockers. The observed ectopy also can occur with electrolyte disorders, particularly hypokalemia, and in patients who are hypoxic or in those with cardiac ischemia.

Treatment

A. Decontamination—In the patient with suspected digitalis toxicity, it is crucial to determine whether the toxicity is acute, chronic, or acute on chronic. Although the same general care principles apply to all three situations, patients with an acute overdose may need several additional measures such as gastric emptying, which should be considered if the patient presents within 1 hour of the ingestion. If performed, lavage should be done carefully because all gastric emptying techniques cause increased vagal tone and may lead to worsening of any bradydysrhythmias or blocks. Pretreatment with atropine may have minimal effect owing to digoxin’s blocking effect on the atrioventricular node. Whether lavage is performed or not, charcoal, 50–100 g orally, should be given to adsorb any digitalis remaining in the GI tract. Repeat-dose activated charcoal may be effective in enhancing elimination of the drug. Cholestyramine, which binds digitalis in the gut, also has been used for this purpose in doses of 4–8 g orally, but it has no particular advantage over charcoal. Drug levels should not be drawn until at least 6 hours after the acute ingestion because it takes that long for the drug level to equilibrate, and levels obtained sooner may be misleadingly high.

In most cases of chronic toxicity, withdrawal of the drug and a period of observation are all that are required for treatment. In cases of both acute and chronic toxicity, forced diuresis, hemoperfusion, and hemodialysis have been shown to be ineffective in removing digitalis owing to its high degree of protein binding.

B. Management of Electrolyte Abnormalities—Patients who develop hyperkalemia should be treated with the standard treatment regimen. It is important to note, however, that some of these measures may be ineffective in the presence of digitalis toxicity. Use of bicarbonate and the

administration of glucose and insulin intravenously require an intact Na^+, K^+ -ATPase pump to reduce the elevated potassium and may not produce the desired effect of lowering the potassium level. Intravenous calcium is contraindicated because it sensitizes the patient further to the toxic effects of the digitalis. Sodium-potassium exchange resins are effective and probably constitute the first choice in treating hyperkalemia from digitalis toxicity (polystyrene sulfonate, 15 g in 20–100 mL of syrup orally one to four times daily or 30–50 g in 100 mL of water per rectum every 6 hours). Dialysis is also effective and can be used if hyperkalemia is life-threatening or refractory to exchange-resin treatment. Digitalis antibodies (see below) are also effective in treating hyperkalemia. A serum potassium level over 5 meq/L in the setting of an acute overdose is an indication for treatment with antidigitalis antibodies.

C. Treatment of Arrhythmias—The major and most life-threatening toxicity associated with digitalis is cardiotoxicity. Bradydysrhythmias, owing to the increased vagal tone, should be treated with atropine starting with doses of 0.5 mg intravenously. Doses can be repeated at 5-minute intervals as necessary to a total dose of about 2 mg (0.3 mg/kg). If the bradydysrhythmias are refractory to atropine, electrical pacing may be necessary.

Tachydysrhythmias or rhythms resulting from increased automaticity should be treated in a stepwise approach. First, if the patient is hypokalemic (serum potassium <3.5 meq/L), particularly if the patient is suffering from chronic toxicity, potassium should be gently replenished, with frequent monitoring of the serum potassium level. Magnesium should be given to virtually all patients with tachydysrhythmias except those with elevated magnesium levels or those with renal failure. The optimal dose is unknown, but 2 g of magnesium sulfate intravenously over 20–30 minutes appears effective. In patients whose tachydysrhythmia does not respond to electrolyte replacement or who have contraindications to electrolyte replacement, lidocaine should be used. If the patient's tachydysrhythmias persist despite adequate lidocaine dosing, phenytoin poses an effective alternative, aiming for a therapeutic level of 10–20 $\mu\text{g}/\text{mL}$. Cardioversion is safe when used in patients who have normal digitalis levels and no evidence of toxicity. However, cardioversion in patients with digitalis toxicity can lead to refractory ventricular tachycardia, ventricular fibrillation, or asystole. It should be avoided if possible in this group of patients, and all attempts should be made to treat dysrhythmias medically. However, in some cases, cardioversion may be necessary to regain a perfusing rhythm. If needed, it is critical that the lowest possible energy level be used to achieve cardioversion. If possible, pretreatment with lidocaine may be prudent.

D. Antibodies—Digoxin-specific antibodies (digoxin immune Fab [ovine]) are a vital addition to the armamentarium for treating digitalis toxicity, but their use should be limited to very specific situations. These antibodies are sheep serum Fab fragments that have a high affinity for digoxin—higher than the

Table 36–10. Indications for therapy with digoxin antibodies.

Life-threatening dysrhythmias
Serum potassium >5 meq/L
Acute ingestion of >10 mg of digoxin (>4 mg in children)
Steady-state digoxin level >10 ng/mL

affinity of digoxin for Na^+, K^+ -ATPase. They circulate in the intravascular space and diffuse into the extracellular space, where they bind to free digoxin. The complex formed has no biologic activity and is excreted in the urine. The intracellular-to-extracellular gradient produced by the binding of extracellular free digoxin causes intracellular digoxin to diffuse from within the cells to be bound to the antibody and subsequently excreted. Indications for use of these antibodies are listed in Table 36–10. In general, digitalis-specific antibody should be used when there are life-threatening dysrhythmias that do not respond to conventional therapy, in patients with an initial potassium level of greater than 5 meq/L (particularly in acute ingestions), in patients who have ingested more than 10 mg of digoxin (4 mg in children), and in those who have a steady-state digoxin level of greater than 10 ng/mL.

Dosing of digoxin antibodies is based on the fact that each vial contains 40 mg antibody and will bind 0.6 mg digoxin or digitoxin. The formula for calculating the dose of antibody in a particular patient is shown below:

CALCULATION OF DOSE OF DIGOXIN ANTIBODY

1. Calculation of body load of digoxin:
 - a. Based on amount ingested:
 - Digoxin tablets: Amount ingested (mg) \times 0.8
 - Digoxin elixir or capsules: Amount ingested (mg) \times 1.0
 - b. Based on serum level (measure 6–8 hours after ingestion)

$$\frac{\text{Serum concentration (ng / mL)} \times 5.6 \times \text{weight (kg)}}{1000}$$

2. Calculation of dose of digoxin antibodies:

$$\frac{\text{Body load of digoxin (mg)}}{0.6 \text{ mg / vial}} = \text{Number of vials of antibody}$$

3. If ingested amount is unknown or the level not available and the patient has indications for antibody use:
 - Administer 20 vials (800 mg)

In patients with life-threatening complications who have ingested an unknown amount, or if the blood level is unavailable, a dose of 20 vials (800 mg) should be given.

Dysrhythmias are treated successfully with these antibodies in about 70% of patients. The rhythms usually respond within 20–60 minutes of administration of the antibody. Side effects are generally mild. Up to 15% of patients may develop minor allergic reactions, and some patients with preexisting congestive heart failure may have an exacerbation owing to the volume of fluid used to infuse the antibodies. It is important to note that measuring digoxin levels after giving antibodies is unreliable for up to 7 days after their administration. Levels tend to rise to alarming levels because so much of the drug ends up in the circulation bound as the inactive antibody complex.

Current Controversies and Unresolved Issues

The treating physician must understand the indications for digoxin antibodies and use them appropriately. Patients who have minor manifestations of digitalis toxicity such as GI complaints or visual changes and those with evidence of cardiac toxicity that does not need intervention or responds to conventional therapy do not need this treatment. In addition, patients with elevated digitalis levels but without evidence of toxicity do not need treatment unless their levels are over 10 ng/mL at steady state. The levels should be measured at least 6–8 hours after the ingestion or the last dose of the medication.

▶ Acetaminophen

ESSENTIALS OF DIAGNOSIS

- ▶ Nausea and vomiting.
- ▶ Jaundice.
- ▶ Right upper quadrant pain.
- ▶ Asterixis.
- ▶ Lethargy and coma.
- ▶ Bleeding.
- ▶ Hypoglycemia.

General Considerations

Acetaminophen is an antipyretic and analgesic medication available over the counter generically and in several brand-name preparations. It is also used commonly in many combination medications, both over the counter and available by prescription. Overdose may occur inadvertently or intentionally. Patients may ingest excessive doses of acetaminophen in an attempt to treat their own pain, being unaware of the potential for toxicity. In the intentional overdose, treating physicians must be aware that many medications contain acetaminophen as a component of a combination preparation, and what might otherwise be a relatively benign ingestion from the other active ingredients in the medication becomes a potentially lethal one in light of the amount of acetaminophen consumed.

Acetaminophen is normally metabolized by the liver to non-toxic compounds. If these pathways are saturated, a toxic intermediate (N-acetyl-p-benzoquinoneimine) is formed that is detoxified by glutathione. Excessive amounts of acetaminophen deplete glutathione stores, leading to accumulation of high levels of these toxic metabolites. The major toxicity is hepatotoxicity, with hepatocyte necrosis and, in severe cases, frank liver failure. *N*-Acetylcysteine, the antidote for this toxicity, acts by enhancing glutathione stores and providing a glutathione substitute to allow for detoxification of the toxic metabolites.

Susceptibility to toxicity is variable. Patients with liver disease or severe malnutrition are more sensitive, whereas children under 9–12 years of age are more resistant than their adult counterparts. Toxic doses vary; in adults, doses of less than 125 mg/kg are rarely toxic unless the patient has preexisting liver disease or malnutrition. Doses of 125–250 mg/kg produce variable toxicity, with some patients developing significant liver damage at these levels. Doses over 250 mg/kg commonly place the patient at risk to develop massive hepatic necrosis and liver failure. Patients with severe hepatotoxicity eventually die from massive liver failure 4–18 days after ingestion. Among patients who recover, liver enzymes begin to normalize 5 days after ingestion, and full recovery occurs within 3 months. Chronic liver disease after acetaminophen ingestion is extremely rare in patients who were healthy prior to ingestion.

Clinical Features

A. History—The treating physician must be aware of the potential for acetaminophen toxicity in virtually all patients with intentional overdoses because of the widespread availability of this compound in combination preparations. In addition, patients may unintentionally take excessive amounts of acetaminophen to treat themselves for painful conditions, not knowing that this drug may be toxic.

B. Symptoms and Signs—Despite ingesting potentially lethal amounts of the agent, patients with acetaminophen overdose often are asymptomatic or minimally symptomatic

in the first 24 hours. GI complaints such as nausea and vomiting are common in large overdoses but may not be seen in all serious overdoses. Patients also may be somewhat lethargic and diaphoretic. Twenty-four to forty-eight hours after ingestion, the patient feels well; however, hepatotoxicity begins during this time, and levels of hepatic enzymes begin to rise. Three to four days after significant ingestion, the patient presents with progressive hepatic damage, nausea, vomiting, jaundice, right upper quadrant pain, asterixis, lethargy, coma, and bleeding, and hypoglycemia may develop.

C. Laboratory Findings—The single most important laboratory test in patients who present after acetaminophen ingestion is the acetaminophen level. A serum sample should be drawn at least 4 hours after an acute single ingestion; levels drawn before this 4-hour time delay are unreliable in predicting toxicity. The acetaminophen treatment protocol nomogram (Figure 36–1) is used to ascertain patient risk. In general, patients who have a 4-hour level of over 150 $\mu\text{g}/\text{mL}$ should be regarded as toxic and treated accordingly.

Patients with significant ingestions should have their liver enzymes and coagulation studies checked at least once every 12–24 hours and should be monitored closely for hypoglycemia, which is common among those with hepatotoxicity.

▲ Figure 36–1. Acetaminophen treatment protocol. (Adapted from Rumack BH et al: Acetaminophen overdose: 662 cases with evaluation of oral acetylcysteine treatment. *Arch Intern Med* 1981;141:382 [PMID: 7469629].)

Differential Diagnosis

Liver failure may be caused by a number of other toxins, most commonly chronic ethanol abuse. Acute ingestions such as cyclopeptide toxicity following mushroom ingestion also cause liver damage. Shock liver and massive hepatic necrosis from hepatitis also may produce a similar clinical picture.

Treatment

A. Decontamination—All patients who present within 1 hour of ingesting a potentially lethal amount of acetaminophen-containing medications should be considered for gastric emptying. Use of activated charcoal is somewhat controversial because activated charcoal binds and prevents the absorption of both acetaminophen and its antidote, acetylcysteine (*N*-acetylcysteine). The charcoal may bind up to 40% of the acetylcysteine. However, increasing the acetylcysteine dose can provide adequate absorption despite the use of charcoal. Therefore, if charcoal is used, the acetylcysteine dose should be adjusted accordingly.

Patients who present more than 4–6 hours after ingestion already have absorbed the acetaminophen, making gastric decontamination and charcoal administration relatively ineffective. It should be noted, however, that patients may have ingested other medications along with the acetaminophen that may respond to repeated-dose charcoal treatment if the ingested agent is one that can be recovered in this way.

B. Acetylcysteine—To date, there are no reliably effective methods for enhancing the elimination of acetaminophen already absorbed from the gut. Therefore, antidote therapy is the mainstay of treatment for patients with potentially toxic ingestions. Acetylcysteine is indicated in patients who have toxic levels, as determined by the treatment nomogram, and in those who may have ingested toxic amounts of acetaminophen and present 8 hours or more after ingestion (see Figure 36–1). Acetylcysteine is most effective when given within the first 8 hours after ingestion; after that time, efficacy decreases with increasing delay. There is no benefit to giving acetylcysteine in the first 4 hours after ingestion, so treating the patient with acetylcysteine can wait until the acetaminophen level is known if this information will be available within 8 hours of ingestion. If the result will be delayed beyond the 8-hour window and the patient ingested a significant amount of acetaminophen, acetylcysteine therapy should be started empirically and can be discontinued if the level obtained falls in the non-toxic range.

Acetylcysteine usually is given orally. The loading dose is 140 mg/kg, and subsequent doses of 70 mg/kg then are given every 4 hours, typically for a total of 17 doses. A 2-day regimen also has been used successfully in selected patients. Patients with acetaminophen toxicity may have significant nausea and vomiting, which may make oral administration of acetylcysteine difficult. As a rule, patients who vomit

within 1 hour of receiving their oral acetylcysteine dose should have that dose repeated. In addition, several measures can be taken to minimize this difficulty. Antiemetics (eg, prochlorperazine, metaclopramide, or ondansetron) should be used. If they prove inadequate, the acetylcysteine may be administered via an NG tube.

Some patients with toxic acetaminophen levels may have persistent vomiting despite the preceding measures, precluding enteric administration of acetylcysteine. In this situation, intravenous acetylcysteine is indicated and can be lifesaving. Recently, an intravenous formulation of *N*-acetylcysteine was approved for use in the United States. Dosing is the same as for the oral route.

Common complications of intravenous acetylcysteine treatment are rashes and urticaria. Serious reactions are rare. Complications are minimized when acetylcysteine is delivered in at least 250 mL of diluent and infused over 1 hour.

C. Other Measures—Supportive care, including administration of vitamin K and lactulose, is indicated in patients with coagulopathy or encephalopathy, respectively. In severe cases refractory to supportive care, liver transplantation may be necessary.

Current Controversies and Unresolved Issues

Administration of acetylcysteine beyond 24 hours after acetaminophen ingestion has been shown to have little effect. Despite this information, and because there are few treatment options other than supportive care and liver transplantation in severely toxic cases, acetylcysteine probably should be used in these situations. The duration of treatment is also controversial. Currently, a 72-hour course is considered the standard of care, but studies have shown that a 48-hour course may be just as effective.

Salicylates

ESSENTIALS OF DIAGNOSIS

- ▶ Nausea and vomiting.
- ▶ Tinnitus.
- ▶ Diaphoresis.
- ▶ Hyperventilation.
- ▶ Confusion and lethargy.
- ▶ Convulsions and coma.
- ▶ Cardiovascular failure.

General Considerations

Salicylates are used widely as antipyretics, analgesics, antiplatelet agents, and anti-inflammatories; salicylates are also found in topical preparations used to treat sore joints and muscles. Not only are they available as aspirin preparations, but they also constitute a common component of other combination medications readily available over the counter. Another source of salicylates is oil of wintergreen; this formulation contains very large amounts of the drug, with concentrations as high as 7 g per teaspoon (compared with 325–650 mg per tablet in most aspirin preparations).

When taken orally, salicylates are absorbed rapidly from both the stomach and the small bowel. Peak blood levels occur 2 hours after ingestion of a normal dose. In therapeutic doses, salicylates undergo hepatic metabolism and renal excretion with a half-life of 4–6 hours. In the event of an overdose, the hepatic enzymes become saturated, and metabolism changes from first-order (concentration-dependent) to zero-order (concentration-independent) kinetics. Under these circumstances, the drug's half-life increases dramatically to 18–36 hours. In the event of an overdose, renal excretion of the unchanged salicylate becomes the major pathway of drug elimination.

Salicylates produce respiratory alkalosis by directly stimulating the CNS respiratory center and by increasing its sensitivity to changes in CO₂ and oxygen concentrations. Salicylates also uncouple oxidative phosphorylation, which leads to an increased metabolic rate with a resulting increase in glucose utilization, oxygen consumption, and heat production. Clinical effects of this uncoupling include hypoglycemia and fever. Inhibition of enzymatic components of the Krebs cycle occurs, leading to an increase in pyruvate and lactate that causes an elevated anion gap metabolic acidosis. As a result of their stimulatory effects on lipid metabolism, salicylates increase ketone formation.

Clinically, it is important to divide patients with salicylate toxicity into two groups: those who take the medication on a chronic basis and those who have taken an acute overdose. Patients who use aspirin chronically, such as the elderly or

patients with arthritis, may present with unintentional overdose, and because they may have subtle clinical findings, these patients are often misdiagnosed. As a result of this misdiagnosis, serious sequelae may develop, such as pulmonary and CNS complications, with a mortality rate that approaches 25%. The acute overdose group, on the other hand, ingests this drug intentionally, and the acutely elevated levels cause these patients to be more symptomatic and therefore easier to diagnose. Acute ingestions of over 150 mg/kg are commonly associated with symptoms of toxicity. Pulmonary and neurologic complications are less common in this group, and the mortality rate is only 2%.

Clinical Features

A. Symptoms and Signs—Patients with mild to moderate salicylate toxicity present with nausea, vomiting, tinnitus, diaphoresis, and hyperventilation (eg, hyperpnea or tachypnea), confusion, and lethargy. In cases of severe poisoning, convulsions, coma, and respiratory or cardiovascular failure may occur. These symptoms of coma, seizures, hyperventilation, and dehydration are more common in patients with chronic poisoning and are observed at lower salicylate levels (35–50 mg/dL). Pulmonary edema, cerebral edema, gastritis with hematemesis, and hyperpyrexia are observed occasionally.

B. Laboratory Findings—Salicylate levels are important in the management of these patients. Peak levels after overdose occur 4–6 hours after ingestion. This peak may be delayed or prolonged if the patient ingested enteric-coated preparations or if the patient develops gastric concretions of aspirin after a massive ingestion. The Done nomogram (Figure 36–2) estimates the severity of *acute* salicylate toxicity; it does *not* apply in the patient with chronic toxicity. Levels obtained 6 hours or more after an acute ingestion can be plotted on the nomogram and extrapolated to obtain the level of severity.

Common laboratory findings in a patient suffering from salicylism are an elevated anion gap metabolic acidosis and respiratory alkalosis. Other laboratory abnormalities may include a prolonged prothrombin time, thrombocytosis, hypernatremia, hyper- or hypoglycemia, ketonemia, lactic acidemia, hypokalemia, and elevated liver transaminases. A urine Phenistix test is usually positive, as is the ferric chloride test (5–10 drops of 10% ferric chloride solution added to urine that has been boiled for 1–2 minutes will turn the solution a burgundy color). Because coingestions are common, an acetaminophen level should be obtained.

Differential Diagnosis

Because salicylism often presents with altered mental status and an increased metabolic state, other entities that cause this combination should be considered in the differential diagnosis. Stimulants are the primary toxicologic cause, and meningitis, sepsis, or encephalitis are possible infectious sources. Pneumonia, renal failure, diabetic ketoacidosis, and alcoholic ketoacidosis also should be considered.

▲ Figure 36–2. Nomogram for determining severity of salicylate intoxication. Absorption kinetics assume acute (one-time) ingestion of non-enteric-coated preparation. (Redrawn and reproduced, with permission, from Done AK: Salicylate intoxication: Significance of measurement of salicylate in blood in cases of acute ingestion. *Pediatrics* 1960;26:800 [PMID: 13723722].)

Treatment

A. Decontamination—Gastric lavage should be performed in any patient with an ingestion of over 100 mg/kg within 1 hour before presentation. Gastric lavage also should be considered in patients who have ingested massive amounts of salicylates because they are prone to develop intragastric or intractable concretions; lavage may be helpful as late as 12–24 hours after ingestion in these cases. Activated charcoal should be given to all patients with salicylate ingestion. Repeated-dose activated charcoal administration should be considered in patients with a significant exposure.

B. Alkaline Therapy—Alkalinization is the mainstay of therapy for salicylate poisoning. It is indicated for patients with significant acidemia and for those with blood salicylate levels of over 35 mg/dL. In an alkaline environment, salicylates remain in an ionized form and do not easily diffuse into tissues. Alkalinization of the urine leads to trapping of the salicylates in the renal tubules and facilitates excretion. The goal of treatment is to achieve and maintain the urine pH at 8.0 or above. An adequate serum potassium level is required before urinary alkalization can be achieved, and patients

Table 36–11. Indications for hemodialysis in salicylate therapy.

Acute ingestion with levels over 120 mg/dL if drawn <6 hours after ingestion, or over 100 mg/dL if drawn ≥6 hours after ingestion
Chronic toxicity with a salicylate level of 60–70 mg/dL
Deterioration despite conventional therapy
Significant central nervous system toxicity
Renal failure
Hepatic failure
Pulmonary edema
Rising salicylate levels despite attempts at decontamination and elimination

may require potassium supplementation to ensure adequate blood levels. Patients receiving bicarbonate therapy should be evaluated serially for the possible development of cerebral or pulmonary edema.

C. Hemoperfusion and Hemodialysis—Hemoperfusion and hemodialysis effectively remove salicylates from the blood (Table 36–11). Hemodialysis may be preferable because it also can be used to manage fluid and electrolyte imbalances. Hemodialysis is specifically indicated for patients who are deteriorating despite supportive and conventional therapy, those with acute levels over 120 mg/dL if drawn less than 6 hours after ingestion or 100 mg/dL if drawn at 6 hours after ingestion despite the clinical presentation, those with chronic toxicity and levels of 60–70 mg/dL, those with rising salicylate levels despite attempts at elimination, those with significant CNS effects, and those with pulmonary edema or renal or hepatic failure.

D. Other Measures—Patients who develop seizures should be treated with benzodiazepines or phenobarbital. Hypotension should be treated with fluids and vasopressors. Pulmonary edema may develop as a result of capillary damage from salicylates and can be exacerbated by aggressive fluid therapy. Development of pulmonary edema may require intubation and mechanical ventilation with positive end-expiratory pressures. Hemodialysis is frequently required in these instances.

▶ Theophylline

ESSENTIALS OF DIAGNOSIS

- ▶ Nausea and vomiting.
- ▶ Tachycardia with atrial or ventricular dysrhythmias.
- ▶ Hypotension.
- ▶ Agitation, hyperreflexia, seizures.
- ▶ Hypokalemia.

General Considerations

Although inhalational agents are now the first-line therapy for reactive airways disease, theophylline is a phosphodiesterase inhibitor that is still used for the treatment of this disorder. It comes in several forms, including an elixir and tablets that are absorbed rapidly. Drug levels usually peak 2–4 hours after ingestion. Theophylline is also available as a sustained-release preparation whose serum level peaks anywhere from 6–24 hours after ingestion.

As a phosphodiesterase inhibitor, theophylline produces an increase in intracellular cAMP, a mediator of β -adrenergic effects. In addition, at toxic levels, theophylline causes catecholamine release from the adrenal medulla. Therefore, the result of toxic levels of theophylline is excessive β -stimulation, and most of the toxic effects are a result of this excessive catecholamine activity. Theophylline toxicity also causes CNS effects, the mechanism of which is unclear.

Theophylline toxicity, like that of salicylates, causes two distinct clinical entities depending on whether the toxicity results from acute ingestion or chronic intake. Acute toxicity usually results from an intentional overdose in a patient not already taking the medication. Chronic toxicity is usually an inadvertent overmedication in a patient already maintained on this drug. Patients with acute intoxications more commonly have metabolic abnormalities and tolerate higher levels of the drug, often not demonstrating serious toxic effects until the levels reach 80–100 mg/L. Patients with chronic toxicity, on the other hand, often do not demonstrate metabolic abnormalities but may manifest serious toxicity at levels as low as 40 mg/L. It is also important to note that in the patient with chronic toxicity, the serum levels often do not correlate with the severity of toxicity—that is, the patient with what may appear to be a mildly elevated drug level may have life-threatening toxic effects. This is particularly true in elderly patients with chronic theophylline toxicity.

Clinical Features

A. Symptoms and Signs—Theophylline toxicity causes GI, cardiovascular, CNS, and metabolic abnormalities. As a result of local gastric irritation and central effects, patients often complain of nausea and vomiting. This is not universal,

however, and patients may have other life-threatening toxic effects without GI complaints.

Owing to the excessive β -stimulation, patients are often tachycardic and prone to ventricular tachydysrhythmias. Atrial dysrhythmias, including atrial fibrillation and multifocal atrial tachycardia, are also seen. As a result of the stimulation of peripheral β_2 -adrenergic receptors and vasodilation, these patients may develop hypotension. Decreased diastolic pressure may be a warning sign that severe vasodilation is developing.

Patients with theophylline toxicity demonstrate agitation, hyperreflexia, and tremulousness. Seizures may develop and are often the first CNS sign of toxicity; this is frequently the case in patients with chronic toxicity. Seizures may be focal or generalized and are often prolonged; status epilepticus is not uncommon. Seizures may be refractory to anticonvulsant therapy and can result in permanent brain damage or death.

B. Laboratory Findings—Hypokalemia is common with acute ingestions; it occurs as a result of a theophylline-induced intracellular shift of potassium. Theophylline toxicity also causes hyperglycemia, metabolic acidosis, respiratory alkalosis, and leukocytosis.

Differential Diagnosis

In addition to theophylline, toxic causes of altered mental status, seizures, and cardiovascular abnormalities include tricyclic antidepressants, anticholinergic agents, and phenothiazines. Rarely, calcium channel blockers, β -blockers, and overdoses of local anesthetic agents cause these findings. Nontoxic causes include meningitis, sepsis, anaphylaxis, head trauma, and hypoglycemia.

Treatment

A. General Measures—Basic supportive measures such as intravenous access, hemodynamic monitoring, oxygen administration, and airway management (as needed) should be the first priority.

B. Correction of Hypotension—Hypotension should be treated initially with infusion of crystalloid as a bolus of 250–500 mL over several minutes, repeated as necessary. If infusions of balanced salt solution do not correct the hypotension, or if the patient cannot tolerate the volume, pressors may be necessary. Pure α -agonists such as phenylephrine are preferable to pressors with beta-effects that may exacerbate theophylline toxicity. Propranolol also may be used to treat the hypotension in patients who do not have contraindications to using this drug. The mechanism for the efficacy of propranolol lies in the fact that it blocks the peripheral β_2 -adrenergic receptors that participate in the peripheral vasodilation of theophylline toxicity.

C. Antiarrhythmics—Patients who have severe supraventricular dysrhythmias from theophylline toxicity (eg, severe sinus tachycardia, supraventricular tachycardia, or multifocal

atrial tachycardia) may be treated with verapamil or β -blockers if there are no contraindications to using these drugs. Ventricular dysrhythmias should be treated by correcting hypokalemia and administering lidocaine.

D. Anticonvulsants—Seizures should be treated with benzodiazepines, phenobarbital, or phenytoin singly or in combination. Seizures accompanying theophylline toxicity are frequently refractory to treatment. It may be necessary to either place the patient under general anesthesia or use neuromuscular blockade to prevent acidosis and rhabdomyolysis and to facilitate ventilation. Patients still may have electrical seizure activity despite being anesthetized or paralyzed. Electroencephalographic monitoring should be used to make this determination.

E. Decontamination—Once the patient is stabilized hemodynamically, prevention of further absorption of the drug is the next goal. Patients who present within the first hour after ingestion should be considered for gastric lavage; because seizures may be precipitous, intubation is often indicated before lavage if the patient manifests signs of significant toxicity. If the patient ingested a sustained-release form of theophylline, lavage should be considered as long as 3–4 hours after ingestion.

Charcoal administration is pivotal in treating patients with theophylline toxicity. All patients, regardless of the time since ingestion, should receive activated charcoal, in a dose of either 1–2 g/kg or 10 g of charcoal for every gram of theophylline ingested. This can be given orally or via the lavage tube. For patients who cannot drink the charcoal slurry, an NG tube should be placed and the charcoal delivered directly into the stomach. Serial charcoal dosing is a mainstay in the treatment of theophylline toxicity. Charcoal avidly binds theophylline, making this treatment akin to “gastrointestinal dialysis.” Doses of 0.5–1 g/kg of charcoal every 2 hours dramatically decrease the half-life of theophylline. To prevent GI fluid and electrolyte losses, it is essential *not* to give cathartics with each dose of the charcoal. Cathartics should be given with the first dose of charcoal only, and subsequent doses should be a slurry of the charcoal only. If the serial charcoal needs to be continued for more than 24 hours, cathartics can be given once or twice daily as needed. If the patient has persistent vomiting that precludes charcoal administration, metoclopramide or ondansetron can be given intravenously. In these patients, the charcoal may be better tolerated when given as a continuous administration of 0.25–0.5 g/kg per hour via an NG tube.

Despite appropriate treatment, some patients with theophylline toxicity continue to have dysrhythmias, hypotension, and seizures. Following an acute ingestion, serum levels of more than 90–100 mg/L are associated with more serious toxic effects. After chronic intoxication, this toxic level is approximately 60 mg/L. When drug concentrations reach these levels, hemoperfusion or hemodialysis may be indicated. [Table 36–12](#) lists the major indications for initiating hemodialysis or hemoperfusion therapy in patients with

Table 36-12. Indications for hemoperfusion or hemodialysis in theophylline toxicity.

Refractory dysrhythmias, hypotension, or seizures
Acute ingestion with level >90–100 mg/L
Chronic ingestion with—
Level 60–90 mg/L
Level 40–60 mg/L and—
Age <6 months or >60 years
Congestive heart failure
Liver disease
Unable to tolerate oral charcoal
Patient not tolerating current level

theophylline toxicity. Of the two procedures, hemoperfusion is the method of choice. It is important to initiate these procedures early because if hemodynamic instability develops, hemodialysis may not be possible.

▶ Methanol & Ethylene Glycol

ESSENTIALS OF DIAGNOSIS

Methanol:

- ▶ Visual disturbances.
- ▶ Nausea, vomiting, abdominal pain.
- ▶ Lethargy and confusion.
- ▶ Seizures and coma.
- ▶ Abdominal tenderness.

Ethylene glycol:

- ▶ Stage I: intoxication, slurred speech, ataxia, stupor, hallucinations, seizures, coma.
- ▶ Stage II: hypertension, tachycardia, high-output renal failure, myositis.
- ▶ Stage III: costovertebral angle tenderness; oliguria or anuria.

General Considerations

Methanol and ethylene glycol are CNS depressants that are found most commonly in antifreeze and deicing products. Ingestions of these compounds occur sporadically in alcoholic patients seeking an ethanol substitute, as an accidental ingestion, or epidemically in groups of patients seeking CNS effects. Both methanol and ethylene glycol are absorbed rapidly from the GI tract. Methanol blood levels peak 30–90 minutes after ingestion, whereas ethylene glycol levels peak 1–4 hours after ingestion. Although the parent compounds are relatively benign, both are metabolized in the liver by alcohol dehydrogenase to toxic metabolites. Formic acid is the major toxic metabolite of methanol; glycolic acid and oxalic acid are the predominant metabolites of ethylene glycol. The half-lives of methanol and ethylene glycol are 14–18 and 3–8 hours, respectively. When ethanol is ingested at the same time as either compound, the half-life can more than double because alcohol dehydrogenase preferentially metabolizes ethanol. Ingestions as small as 30–60 mL of these compounds have been fatal in adults. Even very small amounts may cause significant morbidity.

Clinical Features

A. Symptoms and Signs—If presentation is soon after ingestion, apparent intoxication may be the only finding. Because toxicity is from metabolites rather than from the parent compound, specific toxic clinical effects may not be noted for many hours after ingestion. The delay is increased when ethanol is ingested at the same time.

1. METHANOL—The latent period from ingestion of methanol to manifestations of toxicity is 12–24 hours. At that time, about half of patients will complain of visual disturbances, which include cloudy, blurred, or misty vision. Scotomas are common. The patient typically appears intoxicated and often complains of a headache. Nausea, vomiting, and abdominal pain are common. Ophthalmologic examination may reveal multiple eye abnormalities, including dilated and fixed pupils, constricted visual fields, retinal edema, and hyperemia of the optic disk. However, some patients may have a completely normal eye examination despite having subjective visual complaints. Patients may be lethargic or confused. Seizures and coma may occur. Abdominal tenderness is common. Death may follow abrupt respiratory arrest without warning, so careful monitoring is mandatory.

2. ETHYLENE GLYCOL—Ethylene glycol ingestion presents in three stages. Stage I, known as the *CNS stage*, occurs 30 minutes to 12 hours after ingestion. It is characterized by intoxication, slurred speech, ataxia, stupor, hallucinations, seizures, and coma. The patient may complain of nausea and vomiting and may be mildly hypertensive and tachycardic. Stage II, the *cardiopulmonary stage*, manifests 12–24 hours after ingestion. Patients become significantly hypertensive and tachycardic and may develop high-output cardiac failure. Some patients also develop diffuse myositis with muscle tenderness.

Stage III, the *renal stage*, occurs 24–72 hours after ingestion. Patients complain of flank pain and costovertebral angle tenderness. Oliguria, frank renal failure, and anuria develop.

B. Laboratory Findings—Laboratory evaluation of these patients is notable for an elevated osmolal gap (Table 36–13). Most patients with ethylene glycol ingestion have crystalluria at presentation. The crystals can be either envelope-shaped calcium oxalate crystals or needle-shaped calcium oxalate monohydrate crystals. Leukocytosis and hypocalcemia occur in up to 85% of patients who ingest ethylene glycol. Metabolic acidosis with an increased anion gap is sometimes the first clue to ingestion of these toxic alcohols.

Treatment

A. General Measures—Supportive care should be initiated as described rapidly. Gastric lavage is rarely effective after ingestion of these compounds.

B. Specific Treatment—Specific treatment of these intoxications is the mainstay of therapy and is similar for both methanol and ethylene glycol.

Any patient with a history, clinical presentation, or laboratory findings suggestive of methanol or ethylene glycol

ingestion should be treated. There are three major goals: (1) to correct the metabolic acidosis, (2) to block the production of metabolites, and (3) to remove the parent compound and toxic metabolites.

1. ACIDOSIS—Acidosis is treated with intravenous sodium bicarbonate. Bicarbonate therapy should be initiated when the pH drops below 7.2, with therapy directed at maintaining the pH above that level. Massive doses of bicarbonate may be required because the toxic metabolites are inorganic acids that are being produced continuously. Blood pH should be measured frequently. Iatrogenic hyponatremia may develop if large doses of bicarbonate are needed.

2. METABOLITES—Production of toxic metabolites can be blocked by administering either ethanol or fomepizole, both of which alter metabolism of the parent compounds to toxic metabolites by alcohol dehydrogenase. Ethanol can be administered either orally or intravenously. The loading dose of ethanol for an average adult is 0.6 g/kg (1.2 mL/kg of 50% ethanol orally or 6 mL/kg of 10% ethanol intravenously over 30 minutes). Intravenous solutions should be at concentrations of 10% or less to decrease toxicity. Infusion should provide blood ethanol levels of 100–150 mg/dL to ensure

Table 36–13. Use of the osmolal gap in toxicology.

The osmolal gap (Δosm) is determined by subtracting the calculated serum osmolality from the measured serum osmolality.

$$\text{Calculated osmolality (mosm/kg)} = 2[\text{Na}^+ \text{ (meq/L)}] + \frac{\text{Glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8}$$

$$\Delta\text{osm} = \text{Measured osmolality} - \text{Calculated osmolality}$$

Serum osmolality may be increased by contributions of circulating alcohols and other low-molecular-weight substances. Since these substances are not included in the calculated osmolality, there will be a gap proportionate to their serum concentration and inversely proportionate to their molecular weight:

$$\text{Serum concentration (mg/dL)} = \Delta\text{osm} \times \frac{\text{Molecular weight}}{10}$$

	Molecular Weight	Toxic Concentration	Approximate Corresponding ΔGosm (mosm/kg)
Ethanol	46	300	65
Methanol	32	50	16
Ethylene glycol	62	100	16
Isopropanol	60	150	25

Note: Most laboratories use the freezing point method for calculating osmolality. If the vaporization point method is used, alcohols are driven off and their contribution to osmolality is lost.

Note: A normal osmolar gap may be present in the face of a potentially lethal methanol or ethylene glycol ingestion. Modified from Saunders CE, Ho MT (editors): *Current Emergency Diagnosis & Treatment*, 4th ed. Originally published by Appleton & Lange. Copyright © 1992 by The McGraw-Hill Companies, Inc.

Table 36-14. Ethanol doses* for treatment of methanol poisoning in a 70-kg adult.

		Loading Dose	Infusion Rate During Dialysis	Infusion Rate After Dialysis	Total Over 36 Hours
Amount of ethanol	Chronic drinker	42 g	18.0 g/h	10.8 g/h	474 g
	Nondrinker	42 g	11.8 g/h	4.6 g/h	251 g
Volume of IV 10% ethanol	Chronic drinker	530 mL	228 mL/h	137 mL/h	6010 mL
	Nondrinker	530 mL	149 mL/h	58 mL/h	3010 mL
Volume of oral 43% ethanol	Chronic drinker	125 mL	54 mL/h	32 mL/h	1410 mL
	Nondrinker	125 mL	35 mL/h	14 mL/h	749 mL
Volume of oral 90% ethanol	Chronic drinker	60 mL	26 mL/h	15 mL/h	666 mL
	Nondrinker	60 mL	17 mL/h	7 mL/h	359 mL

*Calculated to achieve and maintain blood ethanol concentration of 100 mg/dL, assuming ethanol dialysance of 120 mL/min and a 6-hour dialysis period.

From McCoy HG et al: Severe methanol poisoning: An application of a pharmacokinetic model for ethanol therapy and hemodialysis. *Am J Med* 1979;67:806.

preferential metabolism of ethanol over the toxic alcohol. Since alcohol dehydrogenase has a higher affinity for ethanol and will preferentially metabolize ethanol rather than the toxic alcohols, the goal is to maintain a blood ethanol level of 100–150 mg/dL, which saturates the enzyme (Table 36-14).

Fomepizole (4-methylprazole) may be preferred over ethanol for the treatment of methanol and ethylene glycol ingestions. This agent blocks the metabolism of the toxic alcohols by alcohol dehydrogenase. It offers the benefit of not needing to maintain a blood level as with ethanol treatment, but it is expensive. Fomepizole is extremely effective, but dialysis remains necessary to definitively remove the alcohols and their metabolites.

3. DECONTAMINATION—Once bicarbonate and ethanol or fomepizole therapy have been instituted, hemodialysis is begun to remove the parent compound and toxic metabolites. This has the additional benefit of correcting severe acidosis refractory to intravenous bicarbonate therapy. However, hemodialysis also removes ethanol. Patients with methanol ingestion also should receive folic acid, 50 mg intravenously every 4 hours. Those with ethylene glycol ingestion should be given thiamine, 100 mg intramuscularly, and pyridoxine, 100 mg orally.

▶ Isopropyl Alcohol

ESSENTIALS OF DIAGNOSIS

- ▶ Headache, dizziness, confusion.
- ▶ Intoxication with poor coordination.
- ▶ Abdominal pain, nausea, vomiting.
- ▶ Tachycardia.
- ▶ Miosis and nystagmus.

General Considerations

Isopropyl alcohol is a clear and colorless liquid found in rubbing alcohol, skin and hair products, and antifreeze. It is ingested occasionally as a substitute for ethanol. Up to 80% of the volume ingested is absorbed from the GI tract within 30 minutes. Half the isopropyl alcohol is excreted unchanged by the kidney, with the remainder metabolized in the liver to acetone. Both isopropyl alcohol and acetone are CNS depressants. Isopropyl alcohol ingestion is usually relatively benign, with patients surviving after ingestions of up to 1 L. Some patients develop serious toxicity with doses as low as 2–4 mL/kg. Although uncommon, dermal exposure can cause toxicity.

Clinical Features

A. Symptoms and Signs—GI and CNS effects predominate. Patients often complain of headache, dizziness, confusion, intoxication, and poor coordination. Abdominal pain, nausea, and vomiting are also common. Because isopropyl alcohol is a gastric irritant, it may cause gastritis, which can result in hematemesis. Massive upper GI bleeding from hemorrhagic gastritis is a rare but potentially fatal complication of this ingestion.

Examination of these patients is usually normal except for evidence of intoxication. Mild sinus tachycardia may be seen. Hypotension can occur following severe ingestions. Patients may have miosis, nystagmus, and decreased deep tendon reflexes.

B. Laboratory Findings—Serum ketosis without acidosis is the hallmark of isopropyl alcohol ingestion. The metabolism of isopropyl alcohol produces acetone, which is a ketone without acidic properties. Since isopropyl alcohol increases serum osmolality, an osmolal gap also may be present. For every 1 mg/dL of isopropyl alcohol in the blood, there is a rise in serum osmolality of 0.18 mOsm/kg. Hypoglycemia is frequently present.

Differential Diagnosis

Patients who appear intoxicated may have ingested ethanol, methanol, ethylene glycol, or isopropanol. All these alcohols can cause an elevated osmolal gap, but ethylene glycol and methanol also cause a metabolic acidosis not observed with isopropyl alcohol ingestions. Other causes of metabolic abnormalities such as hyperglycemia, hyperosmolar states, infections (eg, sepsis and meningitis), and head trauma also should be considered.

Treatment

A. General Measures—Intravenous fluid resuscitation, oxygen administration, and hemodynamic monitoring should be initiated. If the patient presents more than 30 minutes after ingestion, gastric decontamination is not effective. Activated charcoal does not bind alcohols well and should only be given if coingestion of another substance is suspected.

Patients with hematemesis should have blood sent for typing in case bleeding becomes clinically significant and the patient requires transfusion. Hypotension should be managed with crystalloid infusion; if necessary, vasopressors may be added.

B. Glucose Supplementation—Since hypoglycemia is common with significant isopropyl alcohol ingestion, frequent evaluation of the blood glucose with administration of supplemental intravenous glucose as needed is mandatory. Hourly rapid glucose determinations should be followed with more frequent monitoring if patients have symptoms typical of hypoglycemia.

C. Dialysis—Dialysis is rarely necessary following isopropyl alcohol ingestion. The only indication for hemodialysis is in the patient who remains hypotensive despite crystalloid and vasopressor administration.

► Mushroom Poisoning

ESSENTIALS OF DIAGNOSIS: CYCLOPEPTIDES

Early:

- Colicky abdominal pain.
- Watery diarrhea, nausea, vomiting.

Late:

- Right upper quadrant pain.
- Hepatomegaly, asterixis, jaundice, encephalopathy, liver failure.

ESSENTIALS OF DIAGNOSIS: GYROMITRIN

Early:

- Dizziness, bloating, nausea, vomiting.
- Headache.

Late:

- Hepatic failure.
- Seizures and coma.

ESSENTIALS OF DIAGNOSIS: OTHERS

- Findings related to specific ingestion.

General Considerations

Severe mushroom poisoning is rare in the United States, with only 200–350 cases and 50 deaths reported each year. Children account for half of these ingestions, which occur most commonly in the spring, summer, and fall. Of the 500 species of mushrooms in the United States, 100 are toxic, and only 10 are potentially fatal when ingested. The toxicity of any particular mushroom is variable and depends on the climate, the amount of rainfall, and the maturity of the plant.

Toxic mushrooms are divided into eight categories grouped by the effects of the toxin and the time to manifestation of effects. Table 36–15 summarizes these categories. Half the reported mushroom ingestions and 95% of the fatal cases result from the cyclopeptide group. Mushrooms harboring this toxin are found chiefly along the northwest Pacific Coast region of North America, including California. Ingestions occur most commonly in the summer and fall. Toxicity is due to GI irritation and hepatic failure. Mortality rates are as high as 50%, with death often owing to hepatorenal syndrome, which occurs 6–16 days after ingestion.

The remainder of the fatal ingestions result from consumption of mushrooms in the gyromitrin group, also known as *false morels*. Found in California woodlands, these poisonings occur most commonly in the early spring. Gyromitrins are hydrolyzed in the liver to monomethylhydrazine, which causes toxicity by inactivating pyridoxal phosphate.

Both cyclopeptide and gyromitrin toxins have delayed symptom onset from time of ingestion; this characteristic

serves as an important clue that the patient may have ingested a potentially lethal mushroom.

Mushrooms that contain toxins that affect the autonomic nervous system are found virtually everywhere, often growing alongside other nontoxic mushrooms. Two types of autonomic syndromes occur in this category. Ingestion of mushrooms that contain significant amounts of muscarine produces stimulation of postganglionic parasympathetic muscarinic effectors, causing a cholinergic toxidrome. Ingestion of the coprine group of mushrooms (“inky caps”) is usually nontoxic, and these mushrooms often are considered a delicacy. Coingestion of ethanol with these mushrooms, however, leads to a disulfiram-like reaction probably owing to blocking of aldehyde dehydrogenase in the liver. If the ethanol is ingested before or concurrently with the mushrooms, this toxicity does not occur. Instead, sensitivity to ethanol begins 2 hours after ingestion of the mushrooms and lasts up to 5 days.

Ingestion of mushrooms that affect the CNS often constitutes a form of recreational drug use. Inadvertent consumption

Table 36–15. Classification of mushroom toxicity.

Poison	Symptoms	Onset	Examples
Rapid-Onset Toxicity			
Poisons affecting the autonomic nervous system			
Muscarine	Cholinergic toxidrome	1–2 hours	<i>Clitocybe</i> species
Coprine	“Nature’s disulfiram”: flushing, nausea, vomiting, diaphoresis	30 minutes after ethanol	<i>Coprinus</i> species
Poisons affecting the central nervous system			
Ibotenic acid, muscimol	Dizziness, incoordination, myotonic jerks, spasms, hallucinations	30 minutes to 2 hours	<i>Amanita muscaria</i>
Psilocybin, psilocin	Euphoria or dysphoria, lethargy, deep sleep, hallucinations (visual)	30 minutes to 1 hour	<i>Psilocybe</i> species
Poisons affecting the gastrointestinal system			
Multiple	Nausea, vomiting, diarrhea, abdominal pain	30 minutes to 2 hours	“Little brown mushrooms,” widespread
Delayed-Onset Toxicity			
Poisons causing cellular destruction			
Cyclopeptides	Abdominal pain, nausea, vomiting, diarrhea, delayed jaundice, coma	6–24 hours	<i>Amanita phalloides</i> , <i>Galerina marginata</i>
Gyromitrin, monomethylhydrazine	Nausea, vomiting, diarrhea, incoordination, seizures, coma	6–12 hours	<i>Gyromitra</i> species
Poisons affecting the renal system			
Orelline, orellanine	Gastritis, delayed renal failure	3–14 days	<i>Cortinarius</i> species (especially Japan, Europe)

of mushrooms in this category also occurs because they are often found along the Pacific Coast in the spring, summer, and fall. Although these mushrooms rarely produce serious toxicity in adults, children may develop lethal complications.

Clinical Features

A. History—Mushroom toxicity presents with a wide array of symptoms depending on the type of mushroom ingested. Patients who present with mushroom toxicity may or may not relate a history of ingestion. They may not connect their consumption of the mushrooms with their illness, or if they are using mushrooms for recreational purposes, they may be hesitant to give medical personnel this information. In clinical settings suggestive of mushroom ingestion, clinicians should ask specifically about this possibility.

One of the most important historical pieces of information that should be sought from the patient is the time from ingestion to the onset of symptoms; mushrooms that are potentially lethal (those containing cyclopeptides and gyromitrins) have a time delay of at least 4–6 hours from ingestion to symptoms, a very important clinical clue in determining the potential for serious toxicity. Any patient who presents with symptoms that occur more than 6 hours after ingesting a potentially toxic mushroom should be considered to have a possibly fatal ingestion. It should be kept in mind, however, that patients may ingest several different types of toxic mushrooms, and a rapid onset of symptoms does not exclude concurrent ingestion of a potentially lethal one.

B. Symptoms and Signs—Cyclopeptides, the most commonly lethal mushroom toxin, cause a three-phase illness. The GI phase begins abruptly 6–12 hours after ingestion and is characterized by severe colicky abdominal pain, profuse watery diarrhea, nausea, and vomiting. These symptoms last up to 24 hours and then resolve. The patient feels well during a latent phase of 3–5 days, but hepatic toxicity is occurring. At the end of this phase, the patient presents with findings typical of liver failure, including right upper quadrant pain, hepatomegaly, asterixis, jaundice, or frank encephalopathy.

Gyromitrin-containing mushrooms (false morels) cause gastritis with an onset 6–12 hours after ingestion. The patient complains of dizziness, bloating, nausea, vomiting, and severe headache. Hepatic failure may occur in severe cases, usually 3–4 days after ingestion. Seizures and coma are also described.

The *Cortinarius* species of mushrooms, found most commonly in Japan and Europe, contains orelline, which results in a delayed presentation 24–36 hours after ingestion with a self-limited gastritis-like illness. Three to fourteen days after ingestion, the patient presents with night sweats, anorexia, headache, chills, and a severe burning thirst. Oliguria and flank pain also may be present. These patients may develop renal failure.

The remainder of the toxic mushrooms cause symptoms soon after ingestion. Toxins that affect the autonomic nervous system include muscarine and coprine. Fifteen minutes to 1 hour after ingestion of muscarine-containing mushrooms, the

patients will complain of headache, nausea, vomiting, and abdominal pain and may develop cholinergic symptoms of salivation, lacrimation, urination, defecation, and diaphoresis. In severe cases, bronchospasm, bronchorrhea, bradycardia, and shock may occur. In most cases, however, symptoms are usually mild and resolve in 2–6 hours. Coprine-containing mushrooms alone do not cause toxicity; however, when ethanol is ingested 2 hours to 5 days after ingestion of these mushrooms, the patient may develop a disulfiram-like syndrome. Fifteen to twenty minutes after drinking ethanol, the patient complains of a severe headache, facial flushing, paresthesias, lightheadedness, orthostatic hypotension, vomiting, palpitations, and tachycardia. Although the patient feels ill, these symptoms rarely cause significant compromise and abate after several hours.

Mushrooms that affect the CNS contain one of several toxins, including ibotenic acid, muscimol, and psilocybin. Symptoms usually begin 30 minutes to 4 hours after ingestion. Patients complain of drowsiness, incoordination, waxing and waning mental status, and formed or unformed visual hallucinations. Psilocybins are renowned for causing alterations in perceptions of shapes, sounds, and colors. Ibotenic acid and muscimol may cause anticholinergic effects that are rarely severe except in children; these effects are seizures, coma, tachycardia, and hypertension. Most of these patients resolve their symptoms within several hours without sequelae.

The final group of toxic mushrooms are those known as “little brown mushrooms” and cause primarily a self-limited GI illness characterized by rapid onset of malaise, nausea, vomiting, and diarrhea within 1–3 hours of ingestion. These symptoms usually resolve within 24–48 hours.

C. Laboratory Findings—Laboratory results are related specifically to the type of ingestion.

1. CYCLOPEPTIDES—Laboratory evaluation may reveal hypoglycemia, elevated aminotransferases, metabolic acidosis, and coagulopathy.

2. GYROMITRIN—Laboratory evaluation may show elevated liver function tests and coagulopathy; these patients also may have methemoglobinemia.

3. ORELLINE—Laboratory evaluation may reveal red blood cell casts, elevated BUN, serum creatinine, proteinuria, and hematuria.

Differential Diagnosis

Owing to the wide range of symptoms caused by toxic mushrooms, the differential diagnosis depends on the type of mushroom ingested. Most of the toxic mushrooms cause a GI syndrome that may be confused with gastroenteritis, infectious diarrhea, or other GI diseases. Liver failure (associated with the cyclopeptides and gyromitrins) can be caused by other toxins, particularly acetaminophen, as well as entities such as shock liver, severe hepatitis, and alcoholism. CNS effects of mushroom toxicity also can be observed in patients who ingest anticholinergics, LSD, peyote, and other hallucinogens. The cholinergic

syndrome that occurs with muscarine-containing mushrooms is also found in organophosphate poisoning.

Treatment

Treatment of patients with toxic mushroom ingestions depends on the type of mushroom ingested and the symptoms. If there is any possibility that the patient may have ingested a potentially lethal mushroom—even if it cannot be confirmed—the patient should be treated aggressively.

A. Decontamination—In general, all patients who may have ingested potentially lethal mushrooms should have gastric emptying if they present as long as 4 hours after ingestion. Repeated-dose activated charcoal should be given to these patients and those presenting after this 4-hour time period.

B. Antidotes—Although several potential antidotes have been used to treat patients who may have ingested cyclopeptide-containing mushrooms, none have been proved to be effective. These patients need supportive care and ultimately may need liver transplantation if liver failure becomes severe.

C. Renal Dialysis—*Cortinarius* mushroom toxicity that results in renal failure should be managed with dialysis as needed. These patients may need dialysis for weeks to months but usually will recover renal function eventually.

D. Other Measures—If significant methemoglobinemia (metHb >30% or symptomatic hypoxia or ischemia and metHb <30%) develops in a patient who ingests gyromitrin-containing mushrooms, one should give methylene blue, 0.1–0.2 mL/kg of a 1% solution intravenously over 5 minutes. Such patients who develop intractable seizures refractory to standard therapy may respond to pyridoxine, 25 mg/kg intravenously given over 25–30 minutes.

Patients with cholinergic symptoms from muscarine-containing mushrooms usually need observation only. However, if they develop bronchospasm, bronchorrhea, bradycardia, or shock, they should be treated with atropine, 0.5–1 mg intravenously, repeated as needed for recurrence of symptoms. This dose should be repeated every 10–20 minutes until the symptoms resolve.

Patients who ingest hallucinogenic mushrooms do not need specific medical interventions. They should be placed in a dark, quiet room and observed until the effects subside. If patients manifest significant anticholinergic signs, they should be monitored closely and receive specific treatment for anticholinergic toxicity if indicated.

Current Controversies and Unresolved Issues

Several antidotes have been used to treat cyclopeptide toxicity. Thioctic acid, a coenzyme in the Krebs cycle, has been used in a dose of 50–150 mg intravenously every 6 hours with variable results. Its only major side effect is hypoglycemia, which requires close monitoring. Since this poisoning can be life-threatening, use of thioctic acid should be considered

with the understanding that its effects have not been validated. Other treatments, including high-dose penicillin, silibinin, high-dose steroids, hyperbaric oxygenation, and pyridoxine, have been used with inconclusive results.

▶ Organophosphates

ESSENTIALS OF DIAGNOSIS

Muscarinic effects:

- ▶ Bronchospasm, bronchorrhea.
- ▶ Salivation, lacrimation, urination, defecation, gastric emesis (SLUDGE) syndrome.
- ▶ Blurred vision.

Nicotinic effects:

- ▶ Muscle fasciculations, weakness, paralysis.
- ▶ Ataxia.

CNS effects:

- ▶ Headache.
- ▶ Slurred speech.
- ▶ Confusion.
- ▶ Seizures, coma.
- ▶ Depression of the respiratory center.

General Considerations

Organophosphates are found most commonly in herbicides and insecticides and are in the form of organophosphates or carbamates. They also can be used in chemical warfare or terrorism events. They act by causing irreversible inactivation of acetylcholinesterase, resulting in an accumulation of acetylcholine at cholinergic receptors. The toxicity results from excessive muscarinic, nicotinic, and CNS effects of the excess acetylcholine. Toxicity may develop after oral or dermal exposure.

Patients with organophosphate toxicity may be exposed accidentally at work, often by dermal exposure. Alternatively, patients may accidentally or intentionally ingest these compounds. The diagnosis often is made clinically because there are no laboratory tests immediately available to detect these compounds.

Clinical Features

A. Symptoms and Signs—Patients present with a myriad of symptoms. Peripheral muscarinic effects include bronchospasm, bronchorrhea, nausea, vomiting, diarrhea, miosis, blurred vision, urinary incontinence, salivation, diaphoresis, and lacrimation. The combination of salivation, lacrimation, urination, defecation, and gastric emesis is known as the SLUDGE syndrome and is very suggestive of organophosphate poisoning. Nicotinic effects consist primarily of skeletal muscle symptoms, particularly muscle fasciculations, weakness, ataxia, and frank paralysis. Blood pressure and heart rate effects vary depending on whether muscarinic or nicotinic effects predominate. Patients may be tachycardic or bradycardic and hypertensive or hypotensive. Elevated CNS acetylcholine concentrations cause headache, slurred speech, confusion, seizures, and coma, as well as depression of the respiratory centers. Respiratory failure is the usual cause of death, often owing to a combination of central respiratory depression, respiratory muscle weakness, bronchospasm, and increased bronchial secretions.

B. Laboratory Findings—There are no laboratory tests immediately available that characterize this ingestion, and the diagnosis is often made on the basis of a potential for exposure to the toxin combined with a suggestive clinical presentation. Laboratory testing for cholinesterase activity will show decreased activity of this enzyme and often confirms the diagnosis. However, this test is usually not performed on an emergent basis, and several days may pass before results become available. Definitive diagnosis is made by appropriate response to treatment (eg, atropine or pralidoxime) and decreased cholinesterase activity in the blood.

Differential Diagnosis

The combination of salivation, lacrimation, urination, and defecation strongly suggests organophosphate poisoning. This diagnosis is of particular importance if the patient is

diaphoretic and has bronchospasm, with excessive pulmonary secretions and muscle weakness. Patients with myasthenia gravis in cholinergic crisis present with a similar clinical picture.

Treatment

A. Decontamination—Medical personnel should wear gowns and gloves when treating patients with organophosphate poisoning because they may become contaminated and symptomatic from either the patient's clothing or secretions and body fluids. Patients with dermal exposure need copious irrigation in a protected area. Gastric lavage should be attempted if the ingestion was less than 1 hour before presentation and the patient is not already vomiting. After lavage, activated charcoal should be given through the NG tube before it is removed. Intubation and ventilatory support should be considered early.

B. Atropine—Atropine antagonizes the peripheral muscarinic effects of the excess acetylcholine and may moderate some of the CNS effects, but it does nothing to alter the skeletal muscle nicotinic effects, nor does it restore acetylcholinesterase to an active state. Indications for the use of atropine are suspected organophosphate poisoning in a patient who has muscarinic symptoms and signs. The drug can be used both diagnostically and therapeutically. Diagnostically, a dose of 1 mg (or 0.015 mg/kg) intravenously should dilate the pupils and increase the heart rate within 10 minutes. If there is no response to this dose, cholinergic toxicity is suggested. At that point, 2–4 mg (or 0.02–0.05 mg/kg) of atropine should be given intravenously every 10–15 minutes, with the endpoint being a drying of secretions, particularly bronchial secretions. Pupillary dilation and tachycardia should not be used as endpoints because these effects may be seen before drying of bronchial secretions is achieved. Massive doses of atropine may be needed to achieve full effect.

C. Pralidoxime—Pralidoxime reverses phosphorylation of acetylcholinesterase and therefore restores its activity. This drug will reverse the nicotinic effects of muscle weakness and also reverses some of the CNS effects of the poison. Because pralidoxime is more effective in reversing the nicotinic than the muscarinic effects, it should be used in conjunction with atropine. Indications for pralidoxime include the nicotinic effects of organophosphate poisoning (eg, fasciculations and weakness) or CNS effects (eg, altered mental status). Blood should be drawn and sent for cholinesterase activity before the drug is administered. The dose is 1–2 g (or 25–50 mg/kg) intravenously over 5–15 minutes. End-organ effects are seen in 15–45 minutes and are manifested by increased muscle strength. Dosing can be repeated in 1–2 hours if weakness and fasciculations persist. Pralidoxime can be repeated every 4–12 hours as needed. Its side effects (eg, nausea, headache, and tachycardia) are rare and usually result from too rapid injection.

In moderate to severe poisoning, atropine and pralidoxime should be continued for at least 24 hours; in severe poisonings, therapy may need to be continued for days to weeks. Treatment with antidotes can be discontinued when clinical response indicates that they are no longer needed—that is, when there is an absence of clinical improvement with therapy and a lack of recurrence of signs and symptoms of toxicity when the antidotes are withheld.

Care of Patients with Environmental Injuries

James R. Macho, MD
William P. Schecter, MD

Patients with injuries owing to environmental hazards and toxic exposure may require admission to an ICU for resuscitation, stabilization, and definitive treatment. This chapter reviews the essentials of diagnosis and treatment of heat stroke, hypothermia, frostbite, near-drowning, envenomation, electric shock (and lightning injury), and radiation injury.

▶ Heat Stroke

ESSENTIALS OF DIAGNOSIS

- ▶ Core body temperature approaching 41°C.
- ▶ Confusion, stupor, coma.
- ▶ Hypotension and tachycardia.
- ▶ Muscle stiffness.
- ▶ Hot, dry skin.
- ▶ Elevated hematocrit and hyperkalemia.

General Considerations

The three major manifestations of heat illness are heat cramps, heat exhaustion, and heat stroke. The syndromes usually occur in warm, humid environments after strenuous physical exertion. However, elderly persons with medical problems or infants may be affected under less severe conditions.

Heat cramps and *heat exhaustion* result from the depletion of fluid and electrolytes. Complete recovery occurs after removal of the patient from the stressful environment and the institution of replacement therapy. *Heat stroke* results from the failure of thermoregulatory mechanisms. *It is a medical emergency*, and prompt reduction of body temperature is necessary to prevent morbidity and mortality.

To maintain a constant body temperature, heat loss must equal heat production. Cutaneous vasodilation allows for heat

loss through the processes of radiation, conduction, and convection. Evaporative heat loss occurs from sweating and to a lesser extent from the airway. When the environmental temperature exceeds body temperature, the only effective means of heat loss is through sweating. Although significant amounts of heat can be dissipated through this mechanism, sweating becomes less efficient under conditions of high humidity.

Heat stress syndromes develop as a result of processes that attempt to maintain normal body temperature. Heat stroke results from failure of thermoregulatory mechanisms. Heat cramps and heat exhaustion commonly occur after excessive sweating in a hot environment. Heat cramps are painful spasms of voluntary muscles that occur as a result of electrolyte depletion. Depletion of fluid and electrolytes contributes to the weakness and mental status changes associated with heat exhaustion.

Heat stroke occurs when the core body temperature exceeds 41°C. Heat stroke may occur in otherwise healthy people after extreme exertion in a hot climate, particularly in unacclimatized individuals. In this setting, heat production exceeds heat loss, resulting in failure of thermoregulatory mechanisms. Once these mechanisms have failed, body temperature may rise quite rapidly. Signs and symptoms can develop suddenly. A rise in core body temperature above 42°C is associated with protein denaturation and cellular lipid membrane dissolution. Hypovolemia owing to dehydration may exacerbate the direct organ injury. Nonexertional heat stroke is often called *classic heat stroke* and commonly affects elderly or debilitated individuals with impaired thermoregulation owing to disease or medications. The volume status of a patient with nonexertional heat stroke is unpredictable. In both exertional and nonexertional heat stroke, myocardial dysfunction may occur as a result of direct damage to the myocytes.

The neurologic abnormalities associated with heat stroke range from confusion and stupor to coma and seizure disorders. Cerebral and cerebellar neurons may be destroyed by the increased temperature. Intracerebral hemorrhage and

cerebral edema can occur in severe cases. Although many patients recover without neurologic sequelae, residual cerebellar symptoms, quadriplegia, hemiparesis, and memory loss may be present.

Hypovolemia results from dehydration, intracellular volume shifts, decreased peripheral vascular resistance, or poor myocardial function. Myocardial depression follows heat-induced myocardial necrosis.

Disseminated intravascular coagulation can result from heat stroke. Denaturation of the proteins involved in the coagulation cascade may produce prolongation of the prothrombin time and partial thromboplastin time. Direct thermal injury may result in platelet dysfunction. Megakaryocytes in the bone marrow also may show thermal damage. Coagulation abnormalities cause hemorrhage within the CNS resulting in secondary neurologic deterioration.

Thermal injury results in direct muscle damage and necrosis. It may occur in nonexertional heat stroke as well as in heat stroke associated with exertion. Rhabdomyolysis results in the release of large amounts of myoglobin and muscle enzymes.

Renal failure may result from direct thermal damage to the tubules. Hypoperfusion of the kidneys results in acute tubular necrosis. Myoglobinuria may exacerbate renal failure owing to direct toxic effects.

Death in heat stroke can occur from direct heat injury to the brain. Other causes of death and morbidity include cerebral hemorrhage, aspiration pneumonia, cardiac failure, renal failure, and hepatic failure.

Clinical Features of Heat Stroke

A. Symptoms and Signs—Heat stroke can develop suddenly, with loss of consciousness, and need not be preceded by prodromal symptoms such as headache, dizziness, muscle cramps, nausea, and fainting. Although hot, flushed skin is associated with heat stroke, about half of patients exhibit sweating. Depression of neurologic status is present in nearly all cases, and most patients are unconscious at presentation. Signs of cerebellar dysfunction and seizures also may occur. Sinus tachycardia and hypotension are common in patients with heat stroke. Hypovolemia with dehydration causes these changes in most cases, but cardiac dysfunction also may occur as a result of direct injury or acidosis. In the later stages of heat stroke, acute respiratory failure, renal failure, and severe coagulation disorders may develop.

B. Laboratory Findings—Serum concentrations of sodium, potassium, phosphate, calcium, and magnesium are usually low during the early stages of heat stroke. Hematocrit is usually elevated as a result of hemoconcentration. In the later stages of heat stroke, hyperkalemia may develop as a result of rhabdomyolysis. This also results in serum enzyme elevations of creatine kinase (CK), lactate dehydrogenase (LDH), and aspartate aminotransferase (AST). Coagulation studies may be abnormal in the later stages of the syndrome. Elevation of fibrin split products suggests disseminated

intravascular coagulation and is associated with a poor prognosis. Arterial blood gases usually reveal a mixed disorder, with respiratory alkalosis owing to hyperventilation and a profound metabolic acidosis. Arterial blood gases should be interpreted without temperature correction to avoid misinterpretation.

Differential Diagnosis

The diagnosis of exertional heat stroke is usually straightforward and based on a history of strenuous physical activity in a hot environment. In the elderly patient presenting with fever, hypotension, tachycardia, and mental status changes, sepsis must be considered. A thorough physical examination should be performed and appropriate cultures obtained to exclude this possibility. Heat stroke also must be differentiated from neuroleptic malignant syndrome. In this syndrome, hyperthermia is triggered by major antipsychotic medications such as phenothiazines, thioxanthenes, and the butyrophenones. Neuroleptic malignant syndrome occurs in as many as 1% of patients receiving these medications, and its recognition is important because effective treatment is available with the nondepolarizing muscle relaxants and dantrolene.

It is important to differentiate between fever and the hyperthermia of heat stroke. In the febrile patient, the regulatory set point is increased owing to endogenous or exogenous pyrogens, and body temperature is balanced at a new set point. Heat stroke represents a failure of thermoregulatory mechanisms. Therefore, antipyretics are ineffective in patients with heat stroke, and the peripheral cooling used to lower body temperature in these patients generally is not effective in treating patients with fever.

Treatment of Heat Stroke

A. Prompt Lowering of Body Temperature—The patient should be placed in a cool environment. If the patient is unconscious, endotracheal intubation should be performed and mechanical ventilation with supplemental oxygen instituted to maintain adequate gas exchange. Fluid resuscitation is required to reverse hypovolemia. In almost all cases, central venous pressure monitoring will be necessary to evaluate fluid status. In the elderly patient with evidence of cardiac dysfunction, pulmonary artery catheterization may be required. After rapid resuscitation, the rapid reduction of body temperature is the major priority. The optimal method for cooling the patient remains controversial. Immediate treatment usually consists of surface cooling with immersion in ice water or cold water or the use of cooling blankets. Cold water immersion has been shown to be as effective as ice water immersion and may be less uncomfortable for the patient. The disadvantages of ice water immersion include peripheral vasoconstriction and shivering. Shivering is undesirable because of increased heat production and metabolic demand. In this setting, shivering can be abolished by the administration of nondepolarizing muscle relaxants. The use

of phenothiazines should be avoided because of the risk of toxicity and the possibility of a decrease in the seizure threshold. Other techniques for cooling include cold intravenous fluids, cold water gastric or rectal lavage, peritoneal dialysis with cold fluids, and the use of external cooling with circulatory bypass. Once the temperature has been reduced to 39°C, cooling efforts should be discontinued to prevent the development of hypothermia. The use of antipyretics such as aspirin or acetaminophen is ineffective for the reasons previously stated, and their use is contraindicated because they may worsen an existing coagulopathy or exacerbate hepatic injury. The use of alcohol sponge baths is also contraindicated because of the risk of systemic absorption and resulting toxicity.

B. Physiologic Monitoring—Continued monitoring in the ICU is essential because many of the complications of hyperthermia, such as pulmonary failure, renal failure, and coagulopathy, may take 24–48 hours to develop. Electrolytes should be monitored frequently to detect life-threatening electrolyte disorders. If rhabdomyolysis develops, osmotic diuresis and alkalization of the urine may help to prevent renal damage from myoglobinuria. Organ system dysfunction may necessitate continued mechanical ventilation or hemodialysis.

Current Controversies and Unresolved Issues

Investigations continue to focus on the relationship between heat stroke and malignant hyperthermia and the role of inflammatory mediators in the pathogenesis of heat stroke. Clinical heat stroke may be associated with an underlying inherited abnormality of skeletal muscle similar to that of malignant hyperthermia. Skeletal muscle biopsies performed in patients who developed heat stroke have shown abnormal responses similar to those seen in malignant hyperthermia. Such an association might suggest that certain patients are more susceptible to heat stroke than others. Several authors have suggested that dantrolene may be effective in the treatment of heat stroke patients. However, the scant data available are still inconclusive.

There is evidence that inflammatory mediators may have a role in the pathogenesis of heat stroke and subsequent organ-system dysfunction. Patients with heat stroke have been found to have elevated levels of tumor necrosis factor and interleukin-1 α . These elevated levels persisted even after cooling was completed. Heat stroke also has been associated with excessive nitric oxide (NO) production, the magnitude of which is proportional to the severity of illness. It has been suggested that NO may be an important mediator and integral part of the pathophysiologic processes resulting in heat stroke and may be a central factor linking the observed neurologic and cardiovascular abnormalities. If a role is established for these mediators, new management strategies may be possible by modulation of the inflammatory response or specific blocking agents.

▶ Hypothermia

ESSENTIALS OF DIAGNOSIS

- ▶ History of events.
- ▶ Early hypothermia (35–37°C): shivering, cool cyanotic extremities, tachycardia.
- ▶ Mild hypothermia (32.2–35°C): confusion, disorientation, hyperventilation.
- ▶ Moderate hypothermia (28–32.2°C): amnesia, lethargy, J-wave on ECG, atrial fibrillation.
- ▶ Severe hypothermia (<28°C): coma, dilated pupils and absent tendon reflexes, absence of shivering, ventricular fibrillation, asystole, apnea.

General Considerations

Hypothermia is defined as an unintentional decline in the core body temperature. Below 35°C, the systems responsible for thermoregulation begin to fail because the compensatory physiologic responses to minimize heat loss are ineffective. Hypothermia may occur as a result of environmental exposure or during prolonged surgical procedures. Prompt diagnosis and treatment are necessary in severe cases to reverse organ dysfunction and to prevent death. Frostbite results from local cold injury and threatens mainly function. Cold injuries are being encountered with increasing frequency in the elderly, in the homeless, and in individuals participating in winter sports without proper protective clothing.

Hypothermia develops because of an imbalance between body heat generation and environmental losses. Body heat is generated as a by-product of metabolic processes and as a result of muscular contraction. Heat is lost from the body by radiation, convection, conduction, and evaporation. Immersion injuries result in rapid conductive heat loss to the cold water. Radiation and evaporation are the mechanisms by which heat is lost during prolonged open-cavity surgical procedures. Hypothermia may occur in individuals with normal thermoregulation following prolonged exposure to extreme cold. Neurologic disorders, drug intoxication, myxedema, and malnutrition may cause thermoregulatory malfunction, and hypothermia may occur after only mild to moderate cold exposure in individuals with these conditions. Hypothermia may be classified as acute if the patient has been hypothermic for less than 6 hours and chronic if for more than 6 hours. Dehydration and electrolyte imbalance are more likely to occur in patients with chronic hypothermia.

When the core body temperature falls below 36°C, increased sympathetic activity, shivering, and peripheral vasoconstriction develop. These mechanisms have the effect of increasing heat production and preventing further heat loss. Shivering may result in a profound increase in metabolic rate with a sixfold increase in oxygen consumption.

The principal defense against cold is peripheral vasoconstriction. Cold-induced vasoconstriction may lead to an initial rise in central venous pressure from redistribution of blood to the central circulation. Patients with severely compromised cardiac function may develop pulmonary edema as a result of this central circulatory overload. Limb ischemia may develop, and the resulting anaerobic metabolism may contribute to metabolic acidosis. As the core body temperature falls below 35°C, many patients no longer complain of being cold. When the core body temperature falls below 32°C, shivering ceases. The metabolic rate falls rapidly, and the muscles become rigid. With profound hypothermia, the metabolic rate is reduced to less than 50% of the basal level. Amnesia and lethargy develop, progressing to coma. Bradycardia is prominent, and cardiac output falls. The respiratory rate decreases, but a relative alkalosis is maintained. This alkalosis may be protective of protein and enzyme function, myocardial function, and cerebral autoregulation. The cerebral ischemic tolerance during hypothermia is considerably increased compared with the normothermic state. This may, in some cases, contribute to full neurologic recovery. For this reason, most patients with hypothermia should be rewarmed and reevaluated before a diagnosis of brain death is made. An additional consequence of the altered level of consciousness is that normal protective airway reflexes are abolished. This probably accounts for the high incidence of aspiration pneumonia in hypothermic patients. Atrial fibrillation, heart block, ventricular fibrillation, or asystole may develop when the core body temperature falls below 28°C. Ventricular fibrillation may occur spontaneously or may be induced by line placement or other therapeutic maneuvers. When ventricular fibrillation develops in this setting, it is difficult to convert by countershock or pharmacologic agents without further rewarming.

As the core body temperature falls below 26°C, hypotension and decreased systemic vascular resistance develop. An additional factor contributing to hypotension may be the hypovolemia that is commonly observed in accidental hypothermia victims. The hypovolemia is frequently related to a preexisting medical condition and may be exacerbated by hypothermia-induced diuresis. Although renal blood flow and the glomerular filtration rate decrease with hypothermia, cold diuresis usually results from the redistribution of blood to the central circulation and from a decreased response of the renal tubule to antidiuretic hormone. With profound hypothermia, severe oliguria develops as a result of generalized hypoperfusion and also may be related to acute tubular necrosis secondary to rhabdomyolysis.

Hypothermia has profound effects on the hematologic and coagulation systems. The hematocrit and the viscosity of the blood increase owing to hemoconcentration, and viscosity

is further increased by the fall in temperature. Coagulation is impaired as a result of platelet dysfunction and decreased enzymatic protein activity. These coagulation disorders are usually reversed on rewarming.

Hypothermia may result in severe GI complications, including ileus, pancreatitis, and gastric stress ulcers. Depressed hepatic function may result in alterations in the pharmacokinetics of many drugs and reduced clearance of toxins.

As core body temperature falls below 26°C, spontaneous respirations cease, asystole develops, and electrocerebral silence occurs.

Clinical Features

A. Symptoms and Signs—The history of the events prior to presentation is essential for the diagnosis of hypothermia. In cases such as cold water immersion or prolonged exposure to winter temperatures, the diagnosis will be obvious. The diagnosis may be less obvious in a patient with associated injuries or in the elderly patient with multiple medical problems. Suspicion of hypothermia is particularly relevant when the history suggests that an injury or disease has resulted in a prolonged period of immobility with or without the association of a cold environment.

Patients experiencing early hypothermia (35–37°C) usually present with shivering. The extremities are cool and cyanotic as a result of reflex vasoconstriction. Tachycardia results from increased sympathetic activity. In patients with mild hypothermia (33–35°C), confusion and disorientation are common. Hyperventilation may develop in response to increased metabolic activity. Patients with moderate hypothermia (30–33°C) are amnesic, obtunded, and often progress to coma. When the core temperature falls below 32°C, shivering ceases and bradycardia develops. Terminal additions to the QRS complex known as *Osborne waves* or *J waves* develop in the ECG, and the PR and QT intervals may be prolonged. Atrioventricular block or atrial fibrillation can develop. Patients with severe hypothermia (<30°C) present with coma, dilated pupils, and absent tendon reflexes. Life-threatening cardiac arrhythmias or asystole may be present.

B. Temperature Monitoring—Body temperatures should be accurately measured in all patients suspected of being hypothermic. Standard clinical thermometers have a low temperature limit of 32–33°C and should not be used. Electronic temperature-sensing systems accurate down to 25°C are desirable, and many of these systems provide for continuous temperature monitoring. If electronic equipment is not available, standard glass laboratory thermometers can be used to monitor temperature. In addition to sublingual, axillary, and rectal sites, specialized electronic systems allow for temperature monitoring in the esophagus, pulmonary artery, bladder, and tympanic membrane. Monitoring temperature at the tympanic membrane may offer some advantage because this area is warmed by cerebral blood flow, but temperature always should be recorded at several sites to ensure accuracy.

C. Laboratory Findings—A complete blood count, arterial blood gas measurements, and blood cultures should be obtained in all patients with hypothermia. The arterial blood gas should be interpreted with and without temperature correction to avoid misinterpretation. Coagulation studies are not usually of benefit because the blood sample is heated to physiologic temperature prior to testing, and the results thus do not correlate with the clinical situation.

D. Electrocardiography—Continuous electrocardiographic monitoring should be established immediately. In cases of moderate hypothermia, a complete ECG should be obtained to determine intervals and to check for the presence of J waves.

Differential Diagnosis

The signs and symptoms of early hypothermia are nonspecific. Accurate temperature determination is essential to establish or exclude the diagnosis. Hypothermia may complicate other disorders, including drug or alcohol intoxication and endocrinopathies—that is, hypoglycemia, hyperosmolar coma, diabetic ketoacidosis, and myxedema. Hypothermia also may occur as a complication of sepsis. Patients with severe trauma or burns are particularly at risk for the development of hypothermia.

Treatment

A. Airway—Orotracheal intubation is indicated for all hypothermic patients with altered mental status. Nasotracheal intubation should be avoided because nasal bleeding can be a significant problem in the patient with a coagulation disorder. Cricothyroid pressure should be maintained during intubation attempts to prevent aspiration. It should be recognized that even a cuffed endotracheal tube will not offer complete protection against aspiration, and an orogastric tube should be passed and placed on continuous suction to evacuate the stomach contents. During the rewarming process, endotracheal tube cuff pressures must be monitored frequently to avoid tracheal injury because the volume and pressure in the cuff will increase.

B. Breathing—Patients with moderate to severe hypothermia require mechanical ventilation. Warm humidified gases should be used to prevent further heat loss, but they will not play a major role in rewarming owing to the small amount of heat they convey. Adjustment of mechanical ventilation should be guided by non-temperature-corrected blood gas values for pH and PaCO₂. However, temperature correction is required for accurate determination of PaO₂ and hemoglobin saturation.

C. Circulation—Most patients with moderate to severe hypothermia also will be hypovolemic. These patients may require as many as 10 L of crystalloid during rewarming. Ideally, all intravenous fluids should be warmed to 39°C. This can be accomplished in a number of ways, including use of microwave ovens, but care must be taken to avoid overheating, which can lead to hemolysis. Heating units allow for rapid fluid administration with precise temperature control

and should be used if available. Central venous pressure or pulmonary artery pressure monitoring may be necessary in patients who do not respond to aggressive volume administration. Inotropic and vasoconstrictive agents such as dopamine should be avoided because they are usually ineffective and may result in cardiac arrhythmias.

D. Rewarming—The faster the patient is warmed, the better is the prognosis. Once the diagnosis of hypothermia is suspected, all efforts should be directed toward reducing further heat loss and rewarming the patient. In addition to the use of warm intravenous fluids and heated respiratory gases, warm blankets should be applied to prevent radiant heat loss during resuscitation and evaluation. There are three options for rewarming: (1) passive rewarming, (2) active external rewarming, and (3) active internal rewarming. The overall condition of the patient will determine the most appropriate method.

Most patients with mild to moderate hypothermia will be able to rewarm themselves, and passive external measures to prevent further heat loss will be all that are necessary. Active external rewarming, achieved by conductive surface warming with methods such as warm water immersion or heating blankets, is often ineffective in adults because of the low body-surface-to-body-volume ratio. The vasodilation resulting from these methods also may worsen hypotension. In addition, the reestablishment of flow in peripheral circulatory beds may lead to increased transport of colder peripheral blood to the central core, resulting in a paradoxical decrease in core temperature. To effect external rewarming, air circulating systems may prove to be more effective because they provide for additional heat exchange by convection. These devices are usually readily available in the operating room or recovery area. To minimize adverse circulatory effects, these systems can be applied initially only to the trunk. In most cases of moderate to severe hypothermia, active external rewarming will need to be combined with active internal rewarming.

Active internal rewarming is achieved by gastric, colonic, or bladder lavage with heated saline, pleural lavage, peritoneal lavage, and cardiopulmonary bypass. Gastric, colonic, and bladder lavage can be performed easily without specialized equipment or facilities. Although rewarming is relatively slow by these methods because of limited surface area, it may be enough to make the difference in cases of moderate hypothermia. Lavage fluid temperatures should not exceed 40.5°C to avoid mucosal injury. With gastric lavage, care should be taken to minimize the risk of aspiration. Gastric lavage should not be performed on a patient receiving chest compressions for cardiopulmonary resuscitation. Although more invasive, peritoneal lavage will result in more rapid warming. Lavage fluid up to 43°C can be used, and the placement of two catheters will provide for a continuous flow rate of up to 6 L/h. An intact cardiovascular status is necessary to provide adequate perfusion so that heat exchange can take place. If the patient has severe hypothermia and cardiac arrest, open cardiac massage and mediastinal and pleural lavage with warm saline is indicated.

The methods available for extracorporeal blood rewarming include hemodialysis, arteriovenous rewarming, venovenous

rewarming, and cardiopulmonary bypass. Hemodialysis offers the advantage of requiring only a single venous cannulation with a two-way flow catheter. The femoral approach is preferred to avoid cardiac irritation. Hemodialysis may offer additional advantages in patients with renal failure and drug or other toxicity.

In addition to providing circulatory support for the patient with cardiac arrest or arrhythmia, cardiopulmonary bypass will allow for rapid rewarming. A major drawback of cardiopulmonary bypass is that systemic heparinization is required. Therefore, the technique may be contraindicated in patients who have sustained severe trauma. The use of systems with heparin-bonded tubing may overcome some of these problems. Standard cannulation techniques may be used in the patient with a thoracotomy for open cardiac massage. Alternatively, femoral venoarterial bypass can be instituted by cutdown or by percutaneously placed catheters in the patient with intact cardiovascular function. Portable systems using percutaneous access may allow the institution of bypass warming in the ICU. The long-term outcome of patients with severe hypothermia treated with cardiopulmonary bypass has been favorable.

Prognosis

The outcome depends on a number of factors, including the severity and duration of hypothermia and the presence of coexisting medical conditions. Aggressive treatment is indicated because any hypothermic patient has the potential for full recovery despite severely depressed cardiac or respiratory function. Successful resuscitation with full recovery has been reported after documented ice water submersion for as long as 66 minutes in a small child. Success such as this probably depends on rapid symmetric cooling of the entire body, including the brain.

Current Controversies and Unresolved Issues

Techniques such as the use of very high temperature intravenous fluids are being explored for the treatment of moderate to severe hypothermia. Intravenous fluids heated to 65°C have been used in animal studies and have resulted in rewarming rates of 2.9–3.7°C per hour with minimal intimal injuries.

Diathermy involves the conversion of energy waves into heat. Ultrasound or low-frequency microwave radiation can deliver large amounts of heat to deep tissues. Although animal studies have yielded some promising results, further investigation is needed to determine the optimal clinical use of diathermy. There is controversy about when and when not to resuscitate the victim of hypothermia. The techniques necessary to reverse severe hypothermia require a major allocation of personnel and resources. Although it has been stated that no person is dead until “warm and dead,” in many cases additional information will establish a definitive diagnosis. Severe hyperkalemia (>10 meq/L) suggests that the patient died prior to the development of hypothermia because the potassium level is usually normal

or low in patients with hypothermia. Of course, other causes of hyperkalemia such as renal failure or crush injury must be ruled out.

Once instituted, resuscitation should proceed until a core temperature of 30°C is achieved. At this temperature, some signs of life should be evident, and successful cardioversion is usually possible.

► Frostbite

ESSENTIALS OF DIAGNOSIS

- **First degree:** hyperemia and edema after rewarming; no blister formation.
- **Second degree:** hyperemia, edema, and serous blister formation; severe pain during rewarming.
- **Third degree:** full-thickness skin injury resulting in skin necrosis, black eschars, and hemorrhagic blister formation.
- **Fourth degree:** complete necrosis of soft tissue, muscle, and bone; after rewarming, the tissue is cyanotic and ischemic; mummification with minimal edema.

General Considerations

Local injuries owing to cold include chilblains, immersion foot, and frostbite. Chilblains and immersion foot result from prolonged exposure of the extremities in wet conditions to temperatures above freezing. Severe neurovascular damage may result, and ulcerations with chronic infections may be incapacitating.

Frostbite occurs when the tissues are actually frozen. Edema and blister formation develop after thawing or partial thawing. These areas may progress to gangrene.

There are two phases of injury that occur with frostbite:

PHASE 1: DIRECT CELLULAR CRYOTOXICITY—As ice crystals form within the affected area, cell death occurs as a result of both dehydration and mechanical disruption owing to expanding ice crystals. The most severe injuries occur after partial thawing and refreezing of tissues.

PHASE 2: PROGRESSIVE VASCULAR THROMBOSIS—Cold exposure results in reflex arterial vasoconstriction and freezing of the tissues that result in capillary injuries. In addition, cold increases blood viscosity. When thawing occurs, the circulatory stasis and tissue swelling result in intravascular thrombosis. Tissue necrosis will occur when reperfusion cannot be sustained following rewarming.

Clinical Features

Freezing begins distally and progresses centrally. Therefore, the fingers and toes are most susceptible to severe injury. There is usually a line of demarcation between the frozen and unfrozen areas. However, the severity of injury and the extent of nonviable tissue will not become apparent until several days after thawing. In classifying frostbite, it is most important to differentiate between superficial frostbite with skin injury only and deep frostbite with injury to deeper structures of the extremities. Frostbite traditionally has been classified in somewhat the same way as burns.

Frostbitten extremities are painless, numb, and have a blanched, waxy appearance. Superficial frostbite involves only the skin and subcutaneous tissues. Deep frostbite extends deeper and produces a woody consistency. However, a wide range of frostbite injuries may appear similar at the time of the initial evaluation. Therefore, classification of frostbite should be applied after rewarming.

Treatment

The injury associated with freezing is progressive, and exposure should be limited as soon as possible. However, thawing should be avoided if refreezing is likely because this will increase the severity of injury.

A. Rapid Rewarming—Extremities can be rewarmed most effectively by immersion in a warm water bath with a mild antibacterial agent such as povidone-iodine at a temperature between 40 and 42°C. Lower temperatures may compromise

tissue survival. Higher temperatures should be avoided because of the risk of thermal injury. Thawing should continue until all the blanched tissues of the injured extremity are perfused with blood. A red to purple color and pliability of the tissues will indicate that warming is complete. Active motion during thawing may be beneficial, but it is important to avoid rubbing the affected area because this may worsen the injury. Severe pain is likely to develop during the warming process, and opioid analgesics are usually required. Unfortunately, the high opioid doses often required lead to side effects such as heavy sedation, respiratory depression, and nausea that may become a serious problem. In cases of frostbite injury of the lower extremities, epidural blockade has been demonstrated to provide good pain relief with fewer of these complications.

B. Postthaw Care—The affected area must be carefully protected after rewarming. White blisters should be debrided and hemorrhagic ones left intact. Aloe vera (available in generic preparations), a topical inhibitor of thromboxane, should be applied to the injured tissue every 6 hours. The extremity can be splinted in a position of function with elevation, for both protection and comfort. Tetanus prophylaxis should be administered if required. The use of ibuprofen as a systemic antithromboxane agent is preferable to aspirin because aspirin has been shown to inhibit prostaglandins beneficial to wound healing. Ibuprofen 400 mg should be given orally every 6 hours. Penicillin, with excellent coverage of *Streptococcus*, is the antibiotic of choice for prophylaxis and is usually continued for 48–72 hours. Daily hydrotherapy at 40°C for 30–45 minutes aids debridement of devitalized tissue. Range-of-motion exercises are essential for preservation of function. Adequate analgesia is necessary to permit effective physical therapy.

C. Avoid Early or Inappropriately High Amputation—Amputation should not be performed until the degree of tissue loss is clearly determined. This may not be possible until weeks or months after injury. In most cases, skin necrosis will not be associated with deep tissue loss. Occasionally, digital escharotomy or fasciotomy is necessary because a compartment syndrome develops or because the range of motion becomes severely limited. Imaging studies such as technetium scanning and MRI may allow for precise determination of viable tissue and earlier debridement and reconstruction with no loss in stump length. In some cases, the survival of deeper structures may be improved by coverage with vascularized tissue.

Prognosis

Patients who sustain superficial frostbite usually achieve complete recovery with minimal loss of tissue and no loss of function. Complete recovery is unlikely for patients with more severe degrees of frostbite injury. Amputation may result in loss of function and severe cosmetic defects. Patients may be incapacitated by the development of reflex sympathetic dystrophy. Numbness, hypertrophic skin changes, chronic

pain, hyperhidrosis, stiffness, and cold intolerance are all potential sequelae of frostbite. Regional sympathectomy may improve some of the symptoms of vasospasticity related to sympathetic hyperactivity.

Children exposed to extreme cold may develop early epiphyseal closure as a result of injury to the growth plate. This injury results in shortened phalanges. Hand function usually remains excellent, and reconstructive surgery is rarely required.

Current Controversies and Unresolved Issues

Current interest in frostbite management centers around heparin anticoagulation, low-molecular-weight dextran administration, and the role of early sympathectomy. Frostbite necrosis develops when reperfusion cannot be sustained following rewarming. This has led to the development of experimental treatments designed to maintain blood flow in the microcirculation during the period of reperfusion. However, none of these treatments has been proved to be effective in controlled trials. Low-molecular-weight dextran may improve circulation by decreasing blood viscosity and red blood cell clumping. Animal experiments have demonstrated a decrease in tissue loss, but this has yet to be established in a clinical trial. Clinical studies on the use of heparin anticoagulation have been inconclusive. Thrombolytic agents have resulted in significant improvement in tissue survival in animal models of frostbite. These studies have yet to be validated in human trials.

▶ Near-Drowning

ESSENTIALS OF DIAGNOSIS

- ▶ History.
- ▶ Hypoxemia.
- ▶ Metabolic or mixed acidosis.
- ▶ Hypovolemia.
- ▶ Profound electrolyte abnormalities.
- ▶ Hypothermia.
- ▶ Associated injuries.

General Considerations

Drowning is death from asphyxia while submerged. The near-drowning victim, having survived the acute episode, is

at major risk of developing severe organ dysfunction and of subsequent mortality.

Pathogenic mechanisms of near-drowning are related to hypoxemia and aspiration. The physiologic effects of aspiration differ depending on whether the drowning medium is fresh or salt water. Compared with plasma, these fluids are hypo- and hypertonic, respectively. Although it is possible for a drowning victim to die of hypoxemia without aspiration, this rarely occurs. When fresh water is aspirated, the fluid is rapidly absorbed from the alveoli, producing intravascular hypervolemia, hypotonicity, dilution of serum electrolytes, and intravascular hemolysis. Saltwater aspiration produces the opposite effects as water is drawn into the alveoli from the vascular space, producing hypovolemia, hemoconcentration, and hypertonicity. Hemolysis is not a major problem after saltwater drowning.

The initial contact of water with the upper respiratory tract usually stimulates severe laryngospasm. This occasionally results in hypoxia without significant aspiration of water. Aspiration of water into the trachea and bronchi can result in airway obstruction. Additional effects of water aspiration include bronchoconstriction, loss of surfactant, damage to alveolar and capillary endothelium, and direct alveolar flooding. Aspiration of gastric contents is common in near-drowning victims and dramatically increases the severity of the direct injury.

Hypoxemia occurs most often as a result of intrapulmonary shunting. Approximately 50% of near-drowning victims develop acute respiratory distress syndrome (ARDS), in most cases reversible.

The pathophysiology of brain injury is directly related to hypoxia and diffuse neuronal damage. The resulting brain edema may increase intracranial pressure, which may further compromise cerebral perfusion. In children, the diving reflex may play a protective role in cases of cold water submersion. Owing to a high surface-to-volume ratio, prompt hypothermia results in decreased cerebral metabolism, with shunting of the circulation to the cerebral and coronary systems.

Atrial and ventricular arrhythmias occur in the near-drowning victim owing to hypoxia, metabolic and respiratory acidosis, and catecholamine excess. Vagally mediated cardiac arrhythmias can develop as well. Electrolyte disturbances contribute to the generation of cardiac arrhythmias.

Acute tubular necrosis in the drowning victim develops as a result of hypotension and hypoxemia. Renal failure is exacerbated by rhabdomyolysis and hemolysis associated with disseminated intravascular coagulation.

Clinical Features

The diagnosis of near-drowning is necessarily based on the history. In the surviving victim, the severity of injury is determined by evaluation of the level of pulmonary and neurologic function, metabolic and respiratory acidosis, electrolyte abnormalities, and hypovolemia. Victims should be

examined carefully to exclude associated injuries that may require additional management decisions.

Differential Diagnosis

When a history of diving with compressed gas is obtained, several additional diagnoses must be considered. Pulmonary barotrauma occurs when expanding gases are unable to escape from the alveoli during ascent from a dive. Pneumothorax with arterial gas embolization then may occur. Arterial gas embolization may result in neurologic dysfunction and cardiovascular collapse. These diagnoses should be suspected in any case of near-drowning associated with compressed air diving.

The use of compressed air while diving may cause other problems owing to the release of excess gas from tissues on ascent. Severe pain is the usual clinical manifestation of decompression sickness and is due to the presence of gas bubbles in body tissues. Gas bubble formation also may result in spinal cord injury or CNS dysfunction. In some cases, this may have precipitated the drowning episode.

A blood alcohol level and a drug screen should be obtained in all adolescent and adult victims of near-drowning because intoxication is a factor in more than half the cases.

Treatment

A. Airway—Since a successful outcome in the near-drowning victim depends on early correction of hypoxia, endotracheal intubation should be performed early if there is any evidence of pulmonary dysfunction. Prior to intubation, it is important to clear the airway of vomitus or debris. Cervical spine precautions should be maintained in any victim who suffers a near-drowning episode after diving.

B. Breathing—The arterial oxygen saturation should be maintained at a level greater than 90%. If this level cannot be maintained with high concentrations of inspired oxygen or with continuous positive airway pressure, mechanical ventilation with positive end-expiratory pressure should be instituted. Alveolar flooding, with loss of surfactant and direct capillary injury, results in atelectasis and pulmonary edema. Aspiration injury may result from vomiting and aspiration of gastric contents. Aspiration of polluted water and foreign materials can result in additional lung injury. Early chest radiographs may be normal, with pulmonary infiltrates becoming evident 48–72 hours after injury. Delayed pulmonary complications include ARDS and aspiration pneumonia.

C. Circulation—The hypotensive near-drowning victim requires vigorous fluid resuscitation. Central venous pressure monitoring is instituted in patients who do not respond to volume resuscitation and in those with hypoperfusion despite fluid challenges.

D. Acid-Base Status—Metabolic acidosis is best managed by optimization of fluid status. In most cases, bicarbonate

should not be administered. Mechanical hyperventilation may be used to establish a compensatory respiratory alkalosis in victims with severe metabolic acidosis.

E. Correction of Electrolyte Abnormalities—Electrolyte abnormalities are usually not significant in victims of freshwater near-drowning. In the case of saltwater victims, critical elevations of sodium and chloride may occur. Treatment requires aggressive diuresis, adjustment of intravenous fluids, and in some cases hemodialysis. Hypermagnesemia and hypercalcemia also may develop in victims of saltwater drowning and require hemodialysis.

The kidney may be adversely affected if significant intravascular hemolysis has occurred. Hemoglobinuria is treated initially by establishing an osmotic diuresis and by alkalization of the urine. Despite these measures, acute tubular necrosis can develop and require dialysis.

Prognosis

The outcome depends on a number of factors, including the length of submersion, water temperature, time to first breath, initial pH, and the initial neurologic evaluation. A recent review reported 58% survival, with no neurologic deficit, in a group of pediatric victims of near-drowning. The major factors that improved outcome were the presence of a detectable heartbeat and hypothermia on admission to the hospital. Neurologic outcome in adults is also improved in cases of cold water near-drowning.

Current Controversies and Unresolved Issues

Emergency cardiopulmonary bypass may have a role in the resuscitation of the profoundly hypothermic near-drowning victim. Survival with subsequent normal neurologic function has been reported in victims with severe hypothermia and no vital signs on admission. An obvious limitation of this technique is the necessity for immediate availability of equipment and personnel to institute bypass and the need for systemic anticoagulation. However, it is unlikely that any other method of resuscitation would prove successful in this select group of patients.

Concern regarding the sequelae of cerebral edema in the near-drowning victim has prompted the consideration of various therapeutic interventions to prevent cerebral injury. Unfortunately, the use of steroids, intracerebral monitoring, hypothermia, and controlled hyperventilation have not resulted in improved outcomes in controlled clinical trials. The potential benefits of calcium channel blockers, prostaglandin inhibitors, free-radical inhibition, and hemodilution to decrease tissue injury remain unproved.

▶ Envenomation

1. Snakebite

ESSENTIALS OF DIAGNOSIS

Crotalidae:

- ▶ Swelling, erythema, ecchymosis.
- ▶ Coagulopathy.
- ▶ Metallic taste, perioral paresthesias.
- ▶ Hypotension.
- ▶ Tachypnea.
- ▶ Respiratory compromise.

Elapidae:

- ▶ Respiratory compromise, generalized paralysis.

General Considerations

It is estimated that 1500 snakebites are inflicted annually in the United States by 19 species of venomous snakes. Depending on the degree of envenomation, significant morbidity and potential mortality can result. Ninety-five percent of poisonous snakebites in the United States are caused by pit vipers (Crotalidae), which include rattlesnakes, cottonmouths and copperheads; only 4–5% of bites are inflicted by coral snakes (Elapidae).

The main functions of crotalid venom are immobilization, death, and digestion of prey. These venoms are complex mixtures of enzymes and toxic proteins. Other components include metalloproteins, glycoproteins, lipids, and biogenic amines. Crotalid venom causes local tissue injury, coagulopathy, and systemic manifestations. The local injury is due to a combination of direct toxic damage to tissue as well as to ischemic damage owing to elevated compartment pressure resulting from local tissue edema. The coagulopathy is caused by procoagulant esterases that act on fibrinogen and split off fibrinopeptides. This results in depletion of fibrinogen and elevation of the prothrombin and partial thromboplastin times. The platelet count usually remains normal. Bradykinin is released by the action of arginine ester hydroxylase on plasma kininogen and may cause vasodilation and pooling of blood in the pulmonary and splanchnic beds, resulting in decreased venous return, hypotension, and shock. Interstitial loss of intravascular fluid further worsens the hypotension. Myocardial ischemia and depression of contractility also have been associated with pit viper venom.

Renal failure probably results from hypotension, from the direct effects of the venom, and from myoglobinuria. Disseminated intravascular coagulation further contributes to the development of renal failure.

The Mojave rattlesnake has a different type of venom containing a toxin that immobilizes prey by neuromuscular blockade. This toxin is present to some extent in other crotalid species, but in Mojave rattlesnake venom the higher concentration significantly increases the risk of airway and breathing complications. For these reasons, Mojave rattlesnake venom has the lowest median lethal dose level of any North American crotalid venom.

Venom from the Elapidae causes symptoms that are primarily neurologic in nature, with little or no local tissue toxicity. The neurotoxic elements are polypeptides that bind postsynaptically and effect nondepolarizing blockade of the acetylcholine receptors. Generalized paralysis, bulbar paralysis, and respiratory arrest may occur. The neurotoxic effects of these venoms are severe and in some cases irreversible. The signs and symptoms of envenomation can be delayed for more than 12 hours and often occur precipitously.

Clinical Features

A. Signs and Symptoms—The symptoms in each individual case of snakebite vary depending on the degree of envenomation. It is estimated that approximately 3% of snakebites are “dry,” with no evidence of venom injection. In the case of crotalid bites, the degree of envenomation can be estimated by the presence and progression of signs and symptoms. The bites of elapid snakes usually cause minimal early symptoms—it is only after 1–12 hours that severe systemic symptoms suddenly appear.

Minimal envenomation is characterized by the presence of local findings with slow progression and the absence of systemic signs and symptoms. In the case of severe envenomation, local findings will progress rapidly, and systemic complications appear early and are particularly severe.

B. Laboratory Findings—Determination of coagulation parameters helps to evaluate the degree of envenomation in crotalid bites. Prothrombin time, partial thromboplastin time, platelet count, fibrinogen levels, and fibrin degradation products should be determined initially and repeated at regular intervals to estimate the severity and monitor the progression of coagulopathy. Serial red blood cell counts should be obtained to evaluate for the development of hemoconcentration caused by third spacing of fluid or to detect anemia owing to bleeding or hemolysis. Urinary myoglobin indicates myonecrosis. Laboratory data should be obtained on admission, again after the administration of antivenin, and then every 4 hours until the data have returned to near-normal levels.

Differential Diagnosis

Identification of the type of snake is necessary to secure the appropriate antivenin. In cases where the snake has not been identified, the diagnosis of venomous snakebite often can be

made by examination of the fang marks. Crotalid bites are characterized by two such marks. Remember that elapid bites may not result in local signs or symptoms despite envenomation.

Treatment

A. Resuscitation—The adequacy of the airway and ventilation should be verified. The primary survey and resuscitation should follow standard protocols available from the American College of Surgeons Advanced Trauma Life Support Course. The airway should be secured promptly in patients with envenomation to the head or neck. Subsequent swelling could make endotracheal intubation difficult or impossible. Hypotension is best treated with rapid crystalloid infusion. Fluid resuscitation should be aggressive to preserve organ function. Prophylactic antibiotics are not recommended.

B. Antivenin—In the patient with major systemic signs and symptoms owing to severe envenomation, antivenin should be administered as quickly as possible. Antivenin is recommended for moderate to severe envenomation and for any envenomation with symptoms of progression—particularly worsening local injury, progressive coagulopathy, and hemolysis. A skin test is performed with the antivenin prior to administration in an attempt to predict the likelihood of an allergic reaction. The test is performed by intradermal injection of 0.2 mL of antivenin diluted 1:10 with normal saline. Erythema and a wheal reaction within 30 minutes is a positive reaction indicating the need for treatment. Antivenin should be given only by slow intravenous infusion. The use of antivenin should be considered early because it may have to be obtained from a distance. The time required to prepare the antivenin will result in an additional delay. Patients may require additional doses of antivenin if their symptoms progress after the initial administration.

Moderate to severe antivenin reactions occur in 15–20% of patients who receive antivenin. Mild reactions can be treated with intravenous diphenhydramine and epinephrine; severe reactions require increased doses.

In cases of severe envenomation, further antivenin therapy should be strongly considered after treatment of a reaction. In less severe cases, antivenin should be withheld if possible after a reaction because there have been cases of death owing to anaphylaxis. Antivenin information can be obtained from local poison control centers or from a national service by calling 1-800-222-1222.

Exotic envenomations may occur occasionally in the United States from foreign snakes or lizards kept in zoos or private collections. The principles of management are the same: supportive care and administration of appropriate antivenin. Most exotic antivenins are available at the institutions that maintain the snakes. The availability of these antivenins also can be determined through the Antivenin Index.

C. Local Treatment—Local therapy consists of elevation and immobilization of the affected area until swelling recedes. Extremities should be observed for the development of

compartment syndrome. If muscle compartments become firm, or if pain increases, the compartment pressure should be measured. In some cases, fasciotomy may be required to prevent ischemic necrosis. Cruciate incisions should not be performed in an attempt to extract venom.

D. Tetanus Prophylaxis—Tetanus prophylaxis should be administered if the patient's immunization status is not current or is unknown.

Current Controversies and Unresolved Issues

Immediate excision of the bite down to fascia and including damaged fascia and muscle has been advocated to reduce the incidence of local necrosis and to reduce systemic symptoms. This therapy can be effective only in cases of recent envenomation and in the absence of local diffusion of venom or systemic symptoms. Surgical excision of the envenomation site cannot be recommended for a number of reasons: Most victims of snakebite do not reach medical care for several hours and are therefore beyond the point where local excision would be expected to have any benefit. In addition, wide local excision can increase morbidity in cases of minimal envenomation without offering any benefit.

A polyvalent antivenin, CroTAB, has been approved for clinical use. This antivenin is produced by immunizing sheep with venom from the eastern and western diamondback rattlesnakes, the Mojave rattlesnake, and the eastern cottonmouth. In a randomized trial in the United States, CroTAB was demonstrated to effectively terminate venom effects. In another study, CroTAB was successful in immediately and completely reversing neurotoxicity resulting from Mojave rattlesnake envenomation. Conventional polyvalent antivenin is often ineffective in the treatment of venom-induced neurotoxicity.

2. Spider & Scorpion Bites

ESSENTIALS OF DIAGNOSIS

Black widow spider:

- ▶ Numbing pain at the site of the bite.
- ▶ Muscle cramps and low back pain.
- ▶ Severe abdominal pain.
- ▶ Respiratory insufficiency.
- ▶ Cardiac conduction abnormalities.

Brown recluse spider:

- ▶ Pain beginning 1–4 hours after bite.
- ▶ Erythema, central pustule, bull's-eye lesion.
- ▶ Fever, malaise, arthralgias, rash, hemolysis.

Scorpions:

- ▶ Pain with little erythema or swelling.
- ▶ Generalized reactions within 1 hour.

General Considerations

Spider and scorpion bites are particularly common in the western United States. Only the female black widow spider (*Latrodectus mactans*) is dangerous. Its venom contains a potent neurotoxin that induces neurotransmitter release following interaction with a specific cell surface receptor. This action affects mainly the neuromuscular junction and results in unrestrained muscle contraction and severe cramping. The local reaction at the site of envenomation is usually mild.

Venom from the brown recluse spider (*Loxosceles reclusa*) contains sphingomyelinase D. It is primarily cytotoxic and causes local tissue destruction. Hemolysis is the principal systemic effect, and it is usually minor.

Most scorpion stings are harmless and produce only local reactions. However, venom from *Centruroides exilicauda* contains a neurotoxin that may cause severe systemic reactions.

Clinical Features

A. Symptoms and Signs—Initially, a black widow spider bite is painless. Symptoms begin within 10–60 minutes and include severe pain and muscle spasms of the abdomen and trunk. Headache, nausea, vomiting, and hyperactive deep tendon reflexes may be present. Spasms give way to agonizing pain. Rigidity of the abdominal wall may be confused with an intraabdominal catastrophe. Hypertension with or without seizures develops uncommonly. Symptoms are maximum at 2–3 hours after the bite and may persist for up to 24 hours.

Brown recluse spider bites produce pain after 1–4 hours. Initially, an erythematous area with a central pustule or hemorrhagic area appears. A bull's-eye appearance of the lesion may be noted because of an ischemic halo surrounded by extravasated blood. Over several days, an ulcer may form, which, if extensive, requires excision and skin grafting. Systemic reactions are infrequent but may occur 1–2 days after the bite and include massive hemolysis, hemoglobinuria, jaundice, renal failure, pulmonary edema, and disseminated intravascular coagulation.

Scorpion stings are extremely painful but often exhibit no erythema or swelling. Light palpation of the area causes extreme pain. Generalized reactions are not common but may develop within 60 minutes: restlessness, jerking, nystagmus, hypertension, diplopia, confusion, and rarely seizures. Death is uncommon.

Differential Diagnosis

The signs and symptoms of black widow spider envenomation can be easily confused with other common conditions, particularly those cases with minimal bite-related symptoms. In some cases, the abdominal pain may mimic an acute abdomen. Black widow spider envenomation should be considered in patients presenting with the acute onset of severe pain and muscle cramps, particularly if the history is consistent with spider bite.

Brown recluse spider bites are occasionally confused with those of other insects. It should be remembered that spiders usually bite only once, whereas other insects produce multiple bites.

Treatment

A. Black Widow Spider Bites—The most effective treatment options include specific antivenin alone or with a combination of intravenous opioids and muscle relaxants. Although calcium gluconate administration has been recommended, it has not been shown to be effective. Intravenous morphine and benzodiazepines are helpful in achieving relief of symptoms. Antivenin should be considered in moderate to severe cases but should be used with caution because it has been associated with fatal reactions. Advanced life support measures may be required for patients who develop cardiovascular collapse or respiratory failure.

B. Brown Recluse Spider Bites—Most patients can be treated with supportive measures. Ice may be beneficial. Exercise of the limb or application of heat will potentiate the actions of the venom. Patients requiring admission to the ICU are usually older, with systemic symptoms. Dapsone, 50–100 mg orally twice daily for 10 days, has been used in patients who do not have glucose-6-phosphate dehydrogenase deficiency. Some authorities use oral erythromycin, 250 mg four times daily for 10 days, to control skin infection.

C. Scorpion Stings—Children and older adults must be admitted to the ICU for observation. The affected part should be immobilized and ice applied. A tourniquet must not be used. Respiratory depression may result from the use of tranquilizers. Opioid analgesics are particularly dangerous because they seem to potentiate the toxicity of the venom. Seizures, when present, usually can be controlled with intravenous diazepam or phenobarbital. Hypertension may require the use of sympatholytic agents.

3. Marine Life Envenomations

ESSENTIALS OF DIAGNOSIS

- ▶ Pain at the site of envenomation.
- ▶ Systemic symptoms subsequently.
- ▶ Multiple wounds may be present.

General Considerations

Marine life envenomations are caused most commonly by stingrays, jellyfish (Portuguese man-of-wars), scorpion fish, and sea urchins. Although many victims can be treated in the emergency department and released, critical care may be required for hemodynamic and respiratory complications.

Clinical Features

A. Stingray—Multiple sites may be present, with pain and swelling occurring immediately. Local hemorrhage also may be present. Systemic symptoms, when present, include nausea, vomiting, weakness, vertigo, tachycardia, and muscle cramps. Syncope, paralysis, hypotension, and tachycardia may occur with extensive envenomations.

B. Scorpion Fish—Central radiation of pain from the wound may cause extreme discomfort requiring ICU admission for control. Systemic symptoms are manifest within the first few hours after envenomation and include vomiting, weakness, diarrhea, paresthesias, seizures, fever, hypertension, cardiac arrhythmias, and respiratory failure.

C. Sea Urchins—Sea urchin venoms contain several toxins, including cholinergic compounds and neurotoxins. Multiple spines usually are present in the skin and indicate the nature of the contact. Systemic reactions include nausea and vomiting, intense pain, paralysis, aphonia, and respiratory distress.

Treatment

A. Stingray—Wounds can be treated with local measures, including warm soaks and lidocaine. Ice should not be applied. Operative debridement may be required. Supportive therapy is usually all that is required. Infection prophylaxis should be instituted with trimethoprim-sulfamethoxazole or tetracycline.

B. Scorpion Fish—Care is similar to that outlined for stingray contact. Infection prophylaxis should be instituted in a similar fashion. Seizures can be treated with phenobarbital, phenytoin, or diazepam.

C. Sea Urchins—Although pain can subside within a few hours, paralysis may last for 6–8 hours and require intubation and mechanical ventilation until the patient has regained sufficient strength.

▶ Electric Shock & Lightning Injury

ESSENTIALS OF DIAGNOSIS

- ▶ Momentary or prolonged unconsciousness.
- ▶ Cardiac arrhythmias.
- ▶ Muscular pain, fatigue, headache.
- ▶ Rhabdomyolysis and renal failure.

General Considerations

Electrical injuries account for more than 500 fatalities each year in the United States. One-fifth of these deaths are due to lightning. The number of nonfatal injuries may be three or four times this number. Patients who have sustained electrical injury or a lightning strike exhibit a number of signs depending on the energy of the current conducted. Most household electrical injuries are produced by alternating current (50–60 Hz) in the 110–220-volt range. Direct current usually produces less severe injuries for the same amount of voltage. Electricity can cause partial- or full-thickness burns with injury to the deeper tissues of the body. In some cases, the burn injury at the entry and exit points may correlate directly with the extent of underlying muscle injury, but extensive deep injuries may be present with only minimal superficial findings. Myonecrosis and rhabdomyolysis are frequently present with higher-energy exposures. Rhabdomyolysis may lead to renal failure if not recognized and treated promptly. Compartment syndrome can occur in extremities with resulting circulatory compromise. Ventricular fibrillation may be present if the current pathway has included the heart.

A potential difference of more than 440 V is considered high voltage. At greater than 1000 V, severe tissue destruction occurs as a result of electrical energy being converted to heat. Electrocutation may be accompanied by arc and flash burns (see Chapter 35). Associated injuries are a result of falls owing to tetany of the major muscles.

Lightning strikes impart huge amounts of energy to their victims. Cardiac and respiratory failure are responsible for immediate deaths. Those surviving the immediate period are at risk for delayed neurologic, visual, and otologic as well as musculoskeletal complications. Although neurologic sequelae previously were thought to be transient, recent investigations have demonstrated permanent injury in one-half of the victims.

Clinical Features

A. Electric Shock—Shock from household current commonly produces transient loss of consciousness, although this may be prolonged. Patients frequently have regained normal function by the time they arrive in the emergency room, at which time they complain of headache, muscle cramps, and fatigue. Nervous irritability and a sensation of anxiety are other common findings. Patients with prolonged unconsciousness should undergo CT scanning to rule out an associated cerebral injury from a fall or direct injury. Cardiac arrhythmias typically are tachyarrhythmias, with atrial and ventricular fibrillation being the most common. Difficulty in breathing with varying degrees of respiratory paresis or complete paralysis requires immediate attention. Damage to skeletal muscles may produce a spurious rise in the CK-MB fraction, leading to the erroneous diagnosis of myocardial infarction.

Burn wounds often accompany electrocution victims. These injuries are of three types: (1) direct burn, (2) arc injury, or (3) flame burn from an associated ignition source. Burn wounds are more common with higher-voltage injuries. All patients with burn wounds should receive tetanus prophylaxis. Patients with more severe burns should be considered for transfer after stabilization to a specialized burn center. Additional management is discussed in Chapter 35.

B. Lightning Strike—Patients who require critical care after a lightning strike usually are admitted for complications or simply for cardiac monitoring. Lightning victims may present with paraplegia or quadriplegia that resolves over several hours. This may be accompanied by autonomic instability. In cases of prolonged paresis, imaging studies should be obtained to rule out a spinal injury. Electrocardiographic changes include nonspecific ST-T-segment changes that may be accompanied by elevation of cardiac enzymes. Initial hypertension usually resolves spontaneously and does not require treatment.

Lightning victims may have a number of associated findings related to blunt trauma sustained at the time of impact. Rib and long bone fractures in the extremities are particularly common. Burns may be present but are superficial in most patients and often require only superficial wound care. Unlike those who have sustained electrical injuries, patients with lightning injuries rarely develop myoglobinuria.

Table 37-1. Criteria for ICU admission following electrical injury.

High-voltage electrocution
Burns >20% of BSA
Evidence of entrance and exit burns
Cardiac arrhythmias
Unconsciousness
Respiratory or motor paralysis
Multiple associated injuries
Prior medical compromise

Treatment: Electric Shock

Patients suffering from electrical injuries should be admitted to the ICU when the conditions outlined in Table 37-1 are present.

A. General Measures—Most electrocution patients admitted to the ICU already will have had the airway secured (if necessary) and large-bore intravenous catheters inserted for resuscitation and fluid management. Adequate urine output must be ensured to prevent renal failure from myoglobinuria. The goal is to maintain a urine output of 75–100 mL/h. Mannitol may be given as a bolus (1 g/kg) and then as an infusion to maintain an osmotic diuresis as long as the urine contains myoglobin (positive hemoglobin nitrotoluidine test). Sodium bicarbonate may be added to alkalize the urine and prevent the precipitation of acid hematin. The calculated fluid requirement is approximately 1.7 times the standard fluid calculation based on the total body surface area burned. Electrolytes should be monitored frequently during the resuscitation period.

B. Arrhythmias—After initial stabilization, the most immediate risk is from cardiac arrhythmia, particularly when the electric current has passed through the thorax. Antiarrhythmics and inotropic support should be instituted when appropriate. However, most arrhythmias are self-limited and infrequently cause hemodynamic abnormalities. Atrial fibrillation occurs occasionally and usually will convert without treatment. Electrocardiographic changes are present in 10–30% of patients. The most common abnormality is nonspecific ST-T-wave changes. Myocardial infarction is unusual, but patients with high-voltage injuries may sustain direct myocardial damage. In these patients, close monitoring of fluid therapy may be necessary to prevent pulmonary edema.

C. Neurologic Sequelae—More than half of patients with severe electrical injury develop loss of consciousness, but full recovery usually ensues. Neurologic sequelae sometimes are delayed and may develop days to years after the injury. Deterioration of neurologic status may be of three types: (1) ascending paralysis, (2) amyotrophic lateral sclerosis, or

(3) transverse myelitis. Peripheral nerve injuries and motor neuropathies result from demyelination, vacuolization, gliosis, and perivascular hemorrhage. The prognosis for recovery of useful function is poor.

D. Burns—Most critical care required by victims of electrical injury relates to burns. This subject is discussed in Chapter 35.

Treatment: Lightning Strikes

The most severe complication of lightning injury is respiratory arrest caused by depression of the respiratory control center. This can result in secondary cardiac arrest in an otherwise salvageable patient. Surviving victims of lightning strikes tend to have fewer complications than patients with electrical injury. Early emergency resuscitation usually stabilizes these patients to the point that only observation is necessary. The need for cardiac monitoring for more than 24 hours is debatable. Most patients will be confused and have anterograde amnesia covering a period of several days after the incident. If neurologic deterioration is noted, CT scanning or MRI should be obtained to exclude the possibility of intracranial hemorrhage or other injury. In most cases, long-term sequelae from lightning injuries are rare.

▶ Radiation Injury

ESSENTIALS OF DIAGNOSIS

- ▶ Nausea and vomiting, diarrhea.
- ▶ Weakness, dehydration.
- ▶ Bone marrow depression.
- ▶ Sepsis.
- ▶ Severe neurologic changes.
- ▶ Cardiovascular collapse.

General Considerations

Acute radiation syndrome consists of characteristic clinical manifestations following accidental or therapeutic exposure to ionizing radiation. In cases of unknown level of exposure, knowledge of the manifestations enables the clinician to

estimate the exposure dose and determine appropriate treatment.

Ionizing radiation can be either electromagnetic (eg, x-rays and gamma rays) or particulate (eg, electrons, protons, and neutrons). The power of penetration of these particles is determined by the energy they carry. High-energy particles can travel deep into the body and cause severe damage to tissues.

The principal lethal effect of radiation appears to be the production of chemically active free radicals within cells that damage essential macromolecules such as DNA. Very high radiation doses will disrupt cell metabolism and result in rapid cell death. Moderate radiation doses produce breaks in double-stranded DNA. No visible effects occur until the cell attempts mitosis. At that time, cell division may be arrested, or the daughter cells may lack essential genetic material and become nonfunctional. Small doses of radiation can produce gene mutations. This may result in no observable effect or in subsequent malignant transformation.

Individual tissues vary greatly in their sensitivity to radiation damage. The most sensitive tissues are those that require continued cellular proliferation for proper function, such as the GI and hematopoietic systems. Acute radiation syndrome is most pronounced in these systems. With very high levels of exposure, dysfunction of the cardiovascular and central nervous systems is also observed, most likely resulting from direct organ injury.

Radiation Dosimetry

The rad is the unit of absorbed radiation dose. It is defined as that quantity of radiation that deposits 100 ergs of energy per gram of tissue. Clinically, a dose of radiation is often prescribed in grays (Gy) (1 Gy = 100 rads; 1 rad = 1 cGy).

Clinical Features

Radiation injury is characterized by an acute phase, referred to as the *prodromal phase*, and a subacute phase, characterized by bone marrow and GI dysfunction. The phases are separated by a latent period of 1–3 weeks, during which time the patient may be completely asymptomatic. The severity of acute radiation injury is determined by the dose and the time over which the exposure occurs. After exposure to less than 150 cGy, most patients have minimal or no prodromal symptoms. Slight depression of platelets and granulocytes may be observed after a latent period of 30 days. Lymphocytes are most sensitive to radiation and may be decreased.

Patients exposed to 150–400 cGy develop transient nausea and vomiting 1–4 hours following exposure. After a latent period of 1–3 weeks, GI symptoms occur: nausea, vomiting, and bloody diarrhea. Bone marrow depression is manifest by anemia, coagulopathy, and depressed immune function. Susceptibility to infection is increased significantly.

An acute whole body exposure of 600–1000 cGy results in an accelerated version of the acute radiation syndrome. GI complications predominate in the early phase of the illness

and may be life-threatening. Severe hematologic complications can be expected to develop in survivors.

A fulminating course is seen in patients sustaining acute whole body exposure to higher doses. Vomiting occurs shortly after exposure and is rapidly followed by diarrhea, tenesmus, dehydration, and circulatory collapse. CNS manifestations may include ataxia, incoordination, weakness, confusion, seizures, and coma. Death occurs within 48 hours.

Pericarditis with effusions and constriction are delayed manifestations that develop several months after exposure. Myocarditis can occur but is less common. If injury is mild, full recovery is the rule.

Treatment

In cases of moderate radiation exposure, initial treatment is supportive and uncomplicated. Immediate aggressive therapy is not indicated because the prodromal symptoms usually are not severe and are self-limited. It is after the latent period of 1–3 weeks that the more severe clinical manifestations of the syndrome develop. In cases in which severe symptoms develop without a latent period, death is inevitable, and only symptomatic care should be provided.

Patients with moderate to severe radiation exposure should be admitted to the hospital and isolated. Care should be exercised to limit patient and personnel movement through the hospital in order to contain the radiation. Many radioactive materials are in particulate form and will not pass through the skin and are removed by washing. To this end, clothes should be removed and stored in specially labeled plastic bags. Showering or washing skin surfaces removes most of the contamination. A Geiger counter should be used to assess the adequacy of decontamination. The process can be aided by hair removal. Undiluted household bleach (5% sodium hypochlorite) can be used after soap and water. A dilute solution (1 part bleach to 5 parts water) should be used around the face and wounds. Wounds should be thoroughly debrided and irrigated to remove radioactive material.

Fluid loss should be corrected with intensive intravenous replacement. The blood count should be monitored carefully. Reverse isolation is required when the white blood cell count falls below 1000/ μ L. Whole blood and platelet transfusions are nearly always required because of anemia and bleeding. When immunosuppression is apparent, blood products should be irradiated with 5000 cGy before transfusion to decrease the possibility of a graft-versus-host reaction. Intestinal microorganisms are a major source of infection, and prophylactic antibiotics directed against gram-negative organisms should be administered. The appearance of clinical signs of infection should prompt a thorough evaluation.

Broad-spectrum antibiotics should be administered until culture results are obtained.

The use of chlorpromazine or promethazine in an attempt to control radiation-induced vomiting should be avoided. These medications depress gastric emptying and may increase the risk of aspiration and subsequent pulmonary infection.

Current Controversies and Unresolved Issues

Antidopaminergic agents appear to prevent radiation-induced vomiting without causing gastroplegia. Clinical trials suggest that domperidone may be effective, but more controlled studies need to be completed.

In most cases of moderate to severe acute radiation injury, exposure of the bone marrow is not uniform, and a return of function can be anticipated. In cases of lethal exposures, the use of bone marrow transplantation as a form of therapy has been suggested. However, based on current experience, the likelihood of success cannot be adequately ensured. Numerous problems exist in the potential application of this type of therapy. It could not be used in a mass-casualty situation because of the extensive resources required for the treatment of individual patients. Additional problems can be anticipated in securing suitable HLA-compatible donors and in controlling graft-versus-host disease. This treatment was attempted in 13 victims of the Chernobyl accident. Eleven of these patients died. It is not clear whether the other two patients would have survived with conventional supportive therapy.

A newer mode of treatment of pancytopenia is the stimulation of hematopoietic tissue through the use of cytokines and colony-stimulating factors. This has been demonstrated to decrease the period of leukocyte count depression and to elevate the nadir. Additional studies are required to establish efficacy and optimal dosing regimens.

GI pathogen suppression may be accomplished by the deliberate inoculation of the gut with nonpathogenic bacteria such as lactobacilli. The theory is that this will result in normalization of the intestinal flora that had been altered by antibiotic therapy. Prolonged survival has been demonstrated in animal models, but studies in humans are lacking.

Critical Care Issues in Pregnancy

Marie H. Beall, MD
Andrea T. Jelks, MD

PHYSIOLOGIC ADAPTATION TO PREGNANCY

The average duration of gestation is 40 weeks from the first day of the last menses, with term defined as being between 37 and 42 weeks. The mother's basic physiology is altered in a number of ways during normal pregnancy. Some of these may alter her baseline state and response to critical illness, but others may predispose to injuries and conditions that require critical care.

► Cardiovascular System

Pregnancy causes changes in the appearance and function of the heart and great vessels. Elevation of the hemidiaphragms, which accompanies advancing pregnancy, causes the heart to assume a more horizontal position in the chest, and this results in lateral deviation of the cardiac apex, with a larger cardiac silhouette on chest x-ray and a shift in the electrical axis. The heart does increase in size in pregnancy, but only by about 12%. Cardiac output increases by 30–50%, with most of the increase occurring in the first trimester. Both stroke volume and heart rate increase. The heart rate increases by about 17%, with the maximum reached by the middle of the third trimester (32 weeks). Stroke volume increases by 32%, with the maximum reached by midgestation. After 20 weeks, cardiac output may decrease significantly (25–30%) when the patient lies in the supine position as compared with the left lateral position. This is apparently due to compression of the inferior vena cava by the pregnant uterus with resulting decreased venous return. The distribution of cardiac output is altered as well. At term, 17% of the cardiac output is directed to the uterus and its contents, and an additional 2% goes to the breasts. The skin and kidneys also receive additional blood flow compared with the nonpregnant state. Blood flow to the brain and liver may increase. Perfusion of other organs such as the skeletal muscle and gut is unchanged.

Peripheral vascular resistance decreases during pregnancy. A concomitant decrease in systemic blood pressure reaches its nadir at about 24 weeks of gestation. Blood pressure

then rises gradually until term but should not exceed non-pregnant levels at any time during pregnancy. Central hemodynamic studies of normal pregnant women demonstrate a significant decrease in both systemic and pulmonary vascular resistance. Mean arterial pressure, pulmonary capillary wedge pressure, central venous pressure, and left ventricular stroke work index are unchanged. Colloid osmotic pressure is decreased.

Labor and delivery are associated with cardiac stress beyond that of late pregnancy. Cardiac output may increase by as much as 40% in patients not receiving adequate pain relief, although those with adequate anesthesia experience much smaller rises. The rise in cardiac output is progressive over the different stages of labor, and there is a further rise of approximately 15% during each uterine contraction resulting from the expression of 300–500 mL of blood from the uterus back into the mother's circulation. Delivery of the fetus is associated with as much as a 59% increase in cardiac output, presumably as a result of autotransfusion of blood contained in the uterus. This increase may be blunted by the blood loss at delivery. In patients with clinically significant mitral stenosis, delivery may be associated with an increase in the pulmonary capillary wedge pressure of up to 16 mm Hg.

► Respiratory System

During pregnancy, the subcostal angle increases from about 68 degrees to about 103 degrees, with a concomitant increase in the transthoracic diameter. The resting level of the diaphragm is 4 cm higher at term than in the nongravid state. Many authors state that this elevation is a result of pressure from the expanding uterus. However, diaphragmatic excursions are increased by 1–2 cm over nonpregnant values, suggesting that uterine pressure is not the sole cause of the elevation.

Several aspects of pulmonary function change during pregnancy (Figure 38–1). Tidal volume increases by about 40%, and residual volume decreases by about 20%. These

▲ **Figure 38-1.** The components of lung volume in late pregnancy compared with those in nonpregnant women. (Reproduced, with permission, from Hytten FE, Leitch I: *The Physiology of Human Pregnancy*. Boston: Blackwell, 1964.)

changes may make the lung appear denser on x-ray because it is more collapsed during expiration. Data on vital capacity in pregnancy are contradictory, with older studies suggesting that there is no change and some newer ones suggesting that there is a marked increase. During pregnancy, expiratory reserve volume decreases by about 200 mL, and inspiratory reserve volume increases by about 300 mL. Forced expiratory volume appears to be unchanged.

Total body oxygen uptake at rest increases by about 30–40 mL/min in pregnancy, or about 12–20%. Most of the oxygen is needed to meet maternal metabolic alterations. The increased oxygen need is met by increased tidal volume alone because the pulmonary diffusing capacity appears to be decreased in pregnancy, and the respiratory rate does not significantly increase. There is a total increase in minute ventilation of 48% at term, which exceeds the need for increased oxygen delivery. This “hyperventilation of pregnancy” appears to be hormonally mediated and results in a decrease in P_{aCO_2} to below 30 mm Hg in normal women. Maternal pH does not change because there is a reciprocal decline in bicarbonate concentration. The net result of these acid-base alterations is facilitation of fetal-maternal CO_2 exchange.

► Hematologic System

Both the volume and the composition of the blood change during pregnancy. Plasma volume increases by 40–60%, the bulk of the increase occurring before the beginning of the third trimester. The red blood cell mass also expands, with a total increase of 25% at term. This percentage can be maximized (to about 30%) by iron supplementation. An increase in red blood cell mass occurs throughout pregnancy, but the early—and in some patients disproportionate—increase in plasma volume leads to a dilutional anemia. Normal pregnant women who are not iron-supplemented have hemoglobin concentrations of approximately 11 g/dL at 24 weeks of gestation, with little change until term. Those supplemented with iron have similar hemoglobin concentrations at 24 weeks but manifest an increase in hemoglobin to near-normal at term.

The white blood cell count increases to about 10,000/ μ L at term. The platelet count may decrease slightly to a mean value of 260,000/ μ L at 35 weeks of gestation. Platelet levels above 120,000/ μ L generally are regarded as normal in pregnancy.

Biochemical characteristics of the blood also change. Serum osmolality decreases by about 10 mOsm/L early in pregnancy and remains constant thereafter. Sodium, potassium, calcium, magnesium, and zinc all demonstrate minor decreases in their serum levels. Chloride does not change, although bicarbonate decreases markedly. Serum creatinine decreases early, with a mean creatinine of 0.66 mg/dL at 12 weeks, and this decrease is maintained at least until 32 weeks of gestation. The creatinine clearance in pregnancy is approximately 50% higher than in the nonpregnant state. The plasma concentrations of albumin and total protein decrease in proportion to the plasma volume expansion. Most of the commonly tested serum enzymes do not change in pregnancy, but alkaline phosphatase does increase as a result of the production of a placental form of this enzyme. Creatine kinase decreases in early pregnancy, although the serum levels return to normal by term. Serum lipids increase toward term, with the levels of cholesterol and triglycerides doubling during pregnancy.

The levels of many coagulation factors are altered. Fibrinogen increases to levels as high as 600 mg/dL at term, with levels below 400 mg/dL generally being regarded as unusual. The presence of fibrin degradation products in trace amounts is also not unusual at term and depends on the sensitivity of the test being used. Coagulation and bleeding times are not increased. The risk of thromboembolism increases, with a relative risk of 1.8 in gestation and 5.5 during the puerperium. The increased risk of thromboembolism also may be due to the increased incidence of venous stasis and vessel wall injury.

► Immune System

Pregnant women appear to be at increased risk of certain infections, probably owing to the same immune alterations that allow tolerance of the antigenically foreign placenta. For

this reason, reactivation of viral diseases and tuberculosis are more common during pregnancy. Severe complications of common disorders such as varicella and pyelonephritis are also more frequent. Measurable indices of immune function such as white blood cell counts and immunoglobulin levels do not explain the maternal immune dysfunction. Various theories have been offered to explain these observations, but none has achieved general acceptance.

GENERAL CONSIDERATIONS IN THE CARE OF THE PREGNANT PATIENT IN THE ICU

The care of the pregnant patient is necessarily the care of two patients. Although care of the mother is the primary concern in most circumstances, attention also must be paid to fetal health and well-being.

Position

As discussed earlier, a pregnant woman may experience a decrease in cardiac output with associated hypotension when lying in the supine position. For this reason, the pregnant woman who is beyond the twentieth week of gestation should avoid lying supine. In the ICU, this means that pregnant women who are bedridden and unable to move by themselves should be positioned with the right hip elevated, usually with an obstetric wedge, to about 4 in above the plane of the bed. Alternatively, the patient may be positioned in the right lateral decubitus position, taking care that she is tilted adequately to prevent caval compression. This is not necessary in a patient who is in Fowler's position, that is, with the head of the bed elevated. Because of the increased risk of thromboembolism in pregnancy or immediately postpartum, these patients also should receive measures to prevent deep venous thrombosis. Venous compression stockings may be of some benefit, but—especially in the recently delivered patient—heparin in doses adequate to achieve a partial thromboplastin time (PTT) of 65–85 s or low molecular weight heparin sufficient to achieve anti-factor Xa levels of 0.05–0.2 units/mL is considered necessary to avoid pelvic or lower extremity venous thrombosis.

Monitoring

When caring for a critically ill pregnant patient, the question of how to monitor the fetus arises frequently. Monitoring by auscultation of fetal heart tones is considered one of the vital signs in any hospitalized pregnant women. However, continuous fetal heart rate monitoring with an electronic monitor

may be indicated in the viable or near-viable fetus (23 weeks and beyond), especially if the maternal condition affects pulmonary or hemodynamic function. Use of the continuous fetal monitor requires personnel skilled in its interpretation.

Fetal monitoring may be especially helpful during special procedures or surgery when maternal position, hypotension, or anesthesia can lead to fetal compromise that could be reversed with changes in position or fluid resuscitation. Fetal heart rate monitoring according to a predetermined schedule (nonstress testing) also may be useful in gauging fetal response to the mother's illness and in determining when fetal compromise may necessitate early delivery. This strategy (as opposed to continuous fetal heart rate monitoring) should be reserved for the stable patient whose underlying condition might result in decreased uteroplacental perfusion or altered placental function. Additional biophysical testing might be deemed necessary by the consulting obstetrician, but that subject is beyond the scope of this chapter.

Teratogenesis and Drugs Used During Pregnancy

Critical care of a pregnant patient necessarily involves the use of drugs and physical agents that may have an effect on the developing fetus. The first concern of the physician is properly with the life and long-term health of the mother. In cases in which alternative therapies or diagnostic modalities are available, the physician must consider their possible fetal effects.

Information regarding the potential risk to the fetus of various agents is available from a number of published sources and from the manufacturers' package inserts. In addition, many areas are served by teratogen "hotline" services. The Food and Drug Administration (FDA) requires all drug manufacturers to rate their drugs for risk in pregnancy (Table 38–1). Most drugs are not studied in pregnancy during the FDA approval period, so most new drugs will be placed in category C. For this reason, many drugs used routinely during pregnancy are older ones, with an established record of safe use.

The overriding principle in choice of a therapeutic agent is that the anticipated benefit should outweigh any theoretic risks. Consequently, a potentially teratogenic—but life-sustaining—pharmacologic intervention for which there is no good alternative would be acceptable, whereas one with less proven risk but prescribed as a comfort measure only might not be.

Imaging Studies

Ionizing radiation is known to be a human teratogen, and the use of x-ray is appropriately limited in pregnant women. Persons exposed to high levels of ionizing radiation in utero may exhibit microcephaly, mental retardation, retarded growth, and various structural abnormalities. Some reports also have suggested an increased risk of childhood cancer following prenatal x-ray exposure. Data from atomic bomb survivors suggest that the most vulnerable period for the fetus is from 8–15 weeks of gestation. Fetuses in this gestational age

Table 38-1. Risk factors for drug use in pregnancy.

Category A	Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester (and there is no evidence of risk in later trimesters), and the possibility of fetal harm appears remote.
Category B	Either animal-reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women, or animal-reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).
Category C	Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal or other) and there are no controlled studies in women, or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.
Category D	There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (eg, if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).
Category X	Studies in animals or human beings have demonstrated fetal abnormalities, or there is evidence of fetal risk based on human experience, or both, and the risk of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

Federal Register 1980;44:31434-67.

range appear to have a linear increase in mental retardation with increasing x-ray exposure, with an incidence of 0.4% per rad of exposure, although a definite fetal effect may not be seen below 5 cGy. Fetuses older than 16 weeks were less sensitive to x-rays. In one study, the risk of childhood leukemia was estimated to be 1.7 times that of controls in patients exposed to radiation in utero. The risk for childhood cancers also appeared to be higher in fetuses exposed to x-rays in the second as compared with the third trimester. The fetal exposure for different radiologic studies has been calculated and is presented in Table 38-2. As will be apparent, many studies, such as chest films and head and neck studies, entail only slight exposure of the fetus, although the fetal exposure owing to abdominopelvic CT studies is appreciable. Nevertheless, the uterus and its contents should be shielded whenever possible.

Iodinated contrast media are not contraindicated in pregnancy and may be used as in nonpregnant patients. These media may be rated in category D owing to the risk of fetal goiter when these agents are injected into the amniotic fluid.

Radionuclide scans should be used with caution in pregnancy. Iodine is concentrated in the fetal thyroid after 10 weeks

Table 38-2. Estimated doses to the uterus from diagnostic procedures.

Examination	Absorbed Dose	
	Mrad	mGy
Upper GI series	100	1
Cholecystography	100	1
Lumbar spine radiography	400	4
Pelvic radiography	200	2
Hip and femur radiography	300	3
Retrograde pyelography	600	6
Barium enema study	1000	10
Abdominal (KUB) radiography	250	2.5
Hysterosalpingography	150	10
CT scan, head	~0	~0
CT scan, chest	16	0.16
CT scan, abdomen	3000	30

of gestation, and radioactive iodine may cause harm to the fetal thyroid. Other radionuclides may be associated with an increased risk of fetal mutagenesis or teratogenesis if they cross the placenta in large amounts. Agents bound to large protein aggregates do not cross the placenta and probably represent a negligible risk to the fetus. In particular, the performance of pulmonary ventilation-perfusion scanning for pulmonary emboli has been calculated to result in a fetal dose of only 50 mrem, and this is largely from fetal exposure to the agent in the maternal bladder during urinary excretion of the agent.

Ultrasonography is used extensively in obstetrics. Controlled studies are not available regarding its safety, but numerous observational studies have led to the conclusion that diagnostic ultrasound is safe for use in pregnancy. However, fetal damage has been demonstrated in animal models using ultrasound power levels sufficient to cause tissue heating. For this reason, the use of therapeutic ultrasound in pregnancy is contraindicated. Few studies are available concerning the safety of MRI in pregnancy. There is a theoretical concern that the strong magnetic field may affect fetal cell migration in the first trimester, and the use of MRI has been discouraged early in pregnancy, although there are no reports of adverse human fetal effects.

Total Parenteral Nutrition

As a consequence of depletion of maternal glucose by the fetoplacental unit, pregnant patients are more sensitive than

nonpregnant ones to starvation. Blood glucose is lower by 15–20 mg/dL in a pregnant woman after a 12-hour fast, and starvation ketosis is exaggerated. Undernutrition has been associated with increased infant mortality and decreased birth weight. These facts suggest that nutrition should be addressed early in the course of critical care. Total parenteral nutrition has been used in pregnancy with good fetal outcomes in patients with intractable nausea and vomiting of pregnancy as well as in patients with other chronic diseases. Total parenteral nutrition should be considered in any pregnant patient who is expected to be without oral intake for more than 7 days and in whom enteral (tube) feedings are contraindicated. In patients in whom shorter durations of starvation are expected, peripheral nutritional supplementation is essential. At a minimum, when the patient is denied oral intake, enough intravenous glucose should be administered to avoid ketonemia.

Patient Counseling

The fetal organs are essentially fully formed by the end of the first trimester. This is important when considering the teratogenic potential of medications given to the mother. Teratogenic effects are most likely to occur early, when pregnancy may not yet be diagnosed. CNS growth and development, body growth, and sexual organ development occur in the second trimester, with CNS development and body growth continuing during the third trimester. Drugs given during the last trimester may affect neurologic development but will not cause significant structural abnormalities other than impaired fetal growth. A woman in the ICU who is found to be pregnant should be given complete information on the timing and dosages of the drugs and diagnostic agents used in her care. It may be helpful to refer such a patient and her family to a medical geneticist or prenatal diagnostic center for counseling and possible diagnostic procedures. As a medicolegal issue, it also may be advisable to obtain an obstetric ultrasound examination as early as possible during the pregnant patient's stay in the ICU. Fetal abnormalities apparent at that time are probably preexisting conditions and not the result of medications given in the unit. Furthermore, this will document gestational age and establish a baseline from which to assess fetal growth.

Cardiopulmonary Resuscitation (CPR) in the Pregnant Woman

The American Heart Association has recommended that when cardiac arrest occurs in a pregnant woman, standard resuscitative measures and procedures can and should be taken without modification. In particular, they endorse the use of closed-chest compression, defibrillation, and vasopressors as indicated and emphasize the need to displace the uterus from the abdominal vessels by a right hip wedge or by manual pressure on the fundus. Finally, they endorse the performance of a perimortem cesarean section promptly if routine ACLS protocols are ineffective in restoring circulation (see below).

Labor and Delivery in the ICU

The presence of a pregnant woman in the ICU necessitates a plan for delivery of the pregnancy, if necessary. On occasion, spontaneous labor may occur in a patient too unstable to be transferred to the delivery room. In this case, labor and delivery must be undertaken in the ICU. Fetal heart rate monitoring may be useful in advising the pediatrician about the fetal condition even if cesarean section is not an option. Attention should be paid to achieving adequate maternal analgesia because of the significant maternal cardiac demands imposed by unmedicated labor. In the case of any fetus of 22 weeks or more of gestational age or expected to weigh more than 500 g, a neonatal resuscitation team should be in attendance at delivery. The delivery should be conducted by experienced personnel in an atraumatic manner.

Rarely, it may be necessary to perform perimortem cesarean section in the ICU if the mother has died and an attempt is being made to salvage the fetus. For this reason, in any critically ill hospitalized pregnant patient, a determination should be made as early as possible about the potential viability of the fetus. If perimortem cesarean section is a possibility, necessary instruments should be kept at or near the bedside. In a large series of such procedures, normal infant survival was associated with delivery within 5 minutes of maternal death (from cardiac arrest). Fewer than 15% of infants survived when delivery was performed more than 15 minutes after maternal demise, although fetal survival after a much longer delay has been reported. Given this information and data suggesting that the effectiveness of CPR in

the mother may improve with evacuation of the uterus, some authorities, including the American Heart Association, suggest that cesarean section should be started within 4–5 minutes of initiation of CPR.

Several reports have described mothers who met electroencephalographic criteria for death who were maintained for prolonged periods on life support in order to allow growth and maturation of the fetus. In a number of these cases, apparently healthy infants have been delivered, although the outcome of the infant in such cases cannot be guaranteed.

MANAGEMENT OF CRITICAL COMPLICATIONS OF PREGNANCY

► Preeclampsia-Eclampsia

ESSENTIALS OF DIAGNOSIS

- Hypertension.
- Proteinuria.
- Seizures (eclampsia).

General Considerations

Preeclampsia is a common disorder with an incidence of 14–20% in women undergoing their first pregnancy and about 6% in multigravidas. It is one of the leading causes of maternal death in the United States. Most preeclamptic patients will be managed in the delivery suite and will not require critical care. Patients with severe disease, however, may have significant complications warranting ICU care.

Preeclampsia appears to be associated with defects in placentalization; it therefore originates in events early in pregnancy. Although the mechanisms of preeclampsia are not completely understood, potential etiologies include abnormal trophoblast invasion, immunologic intolerance between mother and fetus, abnormalities of immune function, vitamin deficiencies, and genetic abnormalities. Preeclamptic women demonstrate an increased vascular smooth muscle response to pressor agents, particularly angiotensin II, that predates the development of overt hypertension. The resulting

vasospasm leads to hypertension and contraction of intravascular volume. In more severe cases, this is accompanied by endothelial cell injury with activation of the coagulation system and multi-organ-system damage.

Preeclampsia may occur in previously normotensive patients or in patients with preexisting chronic hypertension, who are then said to have superimposed preeclampsia. Indeed, preeclamptic patients with chronic hypertension or with underlying renal or collagen-vascular disease may have more severe disease and a more complicated course. Preeclampsia generally occurs only after the twentieth week of gestation but rarely may develop earlier in the woman with multiple fetuses or with hydatidiform mole.

Clinical Features

A. Symptoms and Signs—Preeclampsia is classically defined by the triad of hypertension, proteinuria, and edema. However, because of the frequent occurrence of edema in pregnancy without preeclampsia, edema has been omitted as a diagnostic criterion for preeclampsia. Nevertheless, a sudden and dramatic weight gain in late pregnancy often presages the development of overt preeclampsia. For this reason, all patients receiving prenatal care have regular determinations made of their weight, urine protein content, and blood pressure. According to the National High Blood Pressure Education Working Group Report on High Blood Pressure in Pregnancy, the minimum criteria for the diagnosis of preeclampsia are (1) sustained blood pressure elevation of 140 mm Hg systolic or 90 mm Hg diastolic in a previously normotensive woman after 20 weeks of gestation and (2) proteinuria—at least 300 mg of urinary protein in a 24-hour period or at least 30 mg/dL (1+) in a random urine sample.

Preeclampsia is classified as mild or severe. Severe preeclampsia is characterized by *at least one* of the following additional criteria: (1) blood pressure of 160 mm Hg or greater systolic or 110 mm Hg or greater diastolic, (2) proteinuria of 5 g or more in 24 hours, (3) elevated serum creatinine, (4) pulmonary edema, (5) oliguria (<500 mL/24 h), (6) microangiopathic hemolytic anemia, (7) thrombocytopenia, (8) hepatocellular dysfunction (abnormally elevated AST or ALT), (9) fetal growth restriction, (10) symptoms suggestive of end-organ involvement (eg, headache, visual disturbances, epigastric or right upper quadrant pain), or (11) eclampsia, defined by the presence of seizures in a pregnant patient without other known cause.

B. Laboratory Findings—Preeclampsia is diagnosed primarily by clinical criteria. The major role of the laboratory is identifying and following the course of complications. These include involvement of the renal, hepatic, or hematologic systems. In the care of a severely preeclamptic patient, serial determinations of platelet count, fibrinogen and fibrin degradation products, hemoglobin, liver function tests, and serum creatinine are essential.

Differential Diagnosis

In addition to preeclampsia, the differential diagnosis of hypertension in late gestation includes chronic hypertension, gestational hypertension (ie, pregnancy-induced hypertension without proteinuria), and acute fatty liver of pregnancy. Acute fatty liver, amniotic fluid embolism, and placental abruption also may be associated with coagulopathy. Proteinuria may result from urinary tract infection or from chronic renal disease. Edema is common in pregnancy and not necessarily a sign of preeclampsia, but nondependent edema is more commonly associated with preeclampsia.

Management

A. Delivery—The only definitive treatment for preeclampsia is delivery of the fetus. In the case of severe preeclampsia, this should be undertaken without delay, except in rare cases when the mother is stable and the fetus very immature. Such a delay in delivery in the patient with severe preeclampsia—while antihypertensive therapy is given—remains controversial and should be permitted only when the anticipated benefits to the fetus outweigh the potential risks to both mother and the fetus.

B. Seizure Prophylaxis—Seizure prophylaxis should be employed in all severely preeclamptic patients. This is usually begun as soon as the diagnosis is made and is continued until the patient is either delivered or the patient is deemed stable enough to be followed expectantly. Treatment greatly reduces the likelihood of eclamptic seizures that might occur during a patient's initial hospital evaluation. Once the decision is made to proceed with delivery of the patient with preeclampsia, seizure prophylaxis should be initiated and continued throughout labor and delivery and until 24 hours postpartum. The routine use of magnesium sulfate prophylaxis in patients with mild preeclampsia is controversial.

In the United States, magnesium sulfate is the most commonly employed seizure prophylaxis. It is usually administered intravenously, although the intramuscular route also can be employed. The usual regimen includes an intravenous loading dose of 4–6 g given over 20–30 minutes, followed by a continuous infusion of 2 g/h. The infusion rate should be adjusted to achieve serum magnesium levels in the therapeutic range of 4.8–8.4 mg/dL.

C. Control of Hypertension—In general, blood pressures over 180 mm Hg systolic or 110 mm Hg diastolic should be treated acutely with antihypertensives. Hydralazine, 5–20 mg intravenously, according to patient response, is used commonly. An acceptable alternative is labetalol 20 mg, also given by intravenous bolus. If an adequate response is not obtained, the dose should be doubled and repeated at 10-minute intervals up to a maximum single bolus dose of 80 mg and a total maximum dose of 220 mg. Oral or sublingual nifedipine also has been suggested for this situation, but concurrent use of

nifedipine and magnesium sulfate may result in profound hypotension. Nitroglycerin and sodium nitroprusside may be used if severe hypertension is unresponsive to the preceding agents, but intra-arterial pressure monitoring is recommended. Owing to the potential for fetal cyanide toxicity, the duration of nitroprusside treatment should be limited.

One should exercise caution in administering any vasodilators to patients with preeclampsia because intravascular volume contraction is often present, making them susceptible to dramatic falls in blood pressure. Excessive and rapid decreases in blood pressure—even to above-normal levels—may be associated with fetal distress secondary to decreased uteroplacental perfusion and therefore should be avoided.

D. Hemodynamic Monitoring—A pulmonary artery catheter may be indicated in the presence of oliguria unresponsive to initial fluid boluses, pulmonary edema that does not respond to furosemide diuresis and positioning, or severe hypertension unresponsive to hydralazine or labetalol. Untreated preeclamptic patients without pulmonary edema have been found to have greater systemic vascular resistance, increased cardiac index, and hyperdynamic left ventricular function when compared with normal controls. Treatment may modify these findings. The pulmonary artery catheter is essential in differentiating these mechanisms because central venous pressures have been found not to reliably reflect pulmonary artery pressures in preeclampsia.

E. Pulmonary Edema—Pulmonary edema may be due to left ventricular dysfunction secondary to high systemic vascular resistance, iatrogenic volume overload in the face of contracted intravascular space, decreased plasma colloid oncotic pressure (occurs in normal pregnancy and is exaggerated in preeclampsia), or pulmonary capillary membrane injury. Colloid oncotic pressure may decrease further following intravenous fluid replacement with crystalloids and as a result of rapid intravascular mobilization of edema fluid after delivery. Nevertheless, pulmonary edema remains an uncommon complication of preeclampsia, with an incidence of 2.9% in severe preeclampsia, usually occurring postpartum. Management consists of diuretics and oxygen, with digitalis glycosides reserved for the rare patient with evidence of left ventricular dysfunction.

F. Oliguria—Oliguria—defined as less than 30 mL of urine output per hour for 2 hours—in severe preeclampsia seldom progresses to frank renal failure. Oliguria associated with preeclampsia can be due to (1) intravascular volume depletion (most common), (2) oliguria accompanied by normal cardiac function and systemic vascular resistance, probably owing to isolated renal arteriolar spasm and perhaps responsive to low-dose dopamine, 1–5 µg/kg per minute, and (3) relative volume overload with depressed left ventricular function secondary to high systemic vascular resistance, managed with fluid restriction and afterload reduction. Echocardiographic assessment of cardiac function may assist in differentiating these scenarios.

G. HELLP Syndrome—Preeclampsia may be complicated by the hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome. There is controversy over whether the HELLP syndrome represents a separate clinical entity or is part of the spectrum of preeclampsia. Patients with the HELLP syndrome are older and more frequently multiparous than other preeclamptic women. The hemolysis observed in these patients is consistent with a microangiopathic hemolytic process and seldom requires specific treatment (other than fetal delivery). Severe thrombocytopenia (platelet count $<30,000/\mu\text{L}$) occurs in fewer than 10% of patients. Treatment with platelet transfusion is usually necessary only for cesarean section or other major surgery. The elevated liver enzymes result from hepatocellular injury secondary to vasospasm and may be associated with hepatic infarction, intrahepatic hemorrhage, and subcapsular hematomas. Rarely, a subcapsular hematoma may rupture, precipitating hemodynamic instability. In the absence of liver rupture, treatment of HELLP syndrome is usually supportive, although the laboratory derangements associated with the syndrome may be transiently reversed with steroid treatment. Dexamethasone, 10 mg intravenously every 12 hours, has been shown to result in clinical improvement and reversal of laboratory abnormalities in HELLP syndrome. Treatment may allow some delay in delivery in the extremely preterm pregnancy. This regimen has the added advantage of promoting fetal lung maturation. Abnormalities recur promptly if steroids are discontinued. In addition, a meta-analysis of steroid treatment confirmed an increase in platelet count but failed to demonstrate any improvement in maternal or fetal outcome. The maternal mortality rate associated with HELLP syndrome has been estimated to be 1–2%.

H. Eclampsia—Eclampsia is defined as the occurrence of grand mal seizures in a woman with preeclampsia in whom the seizures cannot be attributed to some other cause. Eclampsia carries a maternal mortality rate of 1–2% and a fetal mortality rate of approximately 10%. Onset of seizures is often preceded by a severe, unremitting headache. Management of eclampsia consists of control of seizures, pharmacologic control of severe hypertension, and delivery. Seizures can be controlled with a 4–6-g intravenous bolus of magnesium sulfate (8 g in 50 mL of 0.9% NaCl) given at a rate no more rapid than 1 g/min, followed by a continuous infusion of 2 g/h, with monitoring as described earlier. A 2-g bolus is employed if the patient is already receiving magnesium sulfate prophylaxis or if there is a recurrent seizure after the initial bolus. Magnesium sulfate is the treatment of choice because studies have demonstrated its superiority to either phenytoin or diazepam and because it has less sedating effect on the fetus. In addition, levels of magnesium are easy to monitor, and magnesium sulfate has a long record of safe use. Once seizures are controlled and the patient is considered stable, efforts should be directed toward accomplishing delivery. In many cases, labor can be induced safely and vaginal delivery achieved. Seizure prophylaxis with magnesium sulfate should be continued until 24 hours postpartum.

I. Other Complications—Disseminated intravascular coagulation, cerebral edema, cerebral bleeding, transient cortical blindness, retinal detachments, placental abruption, fetal growth restriction, and fetal distress rarely may complicate preeclampsia and eclampsia.

▶ Acute Fatty Liver of Pregnancy

ESSENTIALS OF DIAGNOSIS

- ▶ Hepatic dysfunction.
- ▶ Microvesicular fatty infiltration of hepatocytes.

General Considerations

Acute fatty liver of pregnancy is a rare but potentially catastrophic complication of pregnancy with an incidence of between 1:7,000 and 1:16,000 deliveries. It presents as hepatic dysfunction associated with microvesicular fatty infiltration of hepatocytes occurring during the last trimester of pregnancy or immediately postpartum. Hypertension is commonly present, and some consider the disorder to be a variant of preeclampsia. Indeed, there is an increased incidence of both conditions in first pregnancies and with twin gestations. Although in the past fetal and maternal mortality rates exceeding 70% were reported, data suggest that fetal and maternal mortality is closer to 20%. This discrepancy is most likely the result of earlier diagnosis and improved management as well as recognition that milder forms of this disorder exist.

The etiology of acute fatty liver of pregnancy remains unknown. In many, but not all, cases, mother or fetus has been found to have a genetic defect of fatty acid beta oxidation. This association is strong enough that infants of affected mothers should be screened.

Clinical Features

A. Symptoms and Signs—Typically, patients present with a history of nausea, vomiting, anorexia, and malaise for 1–2 weeks. Epigastric or right upper quadrant pain also may be present, as may jaundice of varying degrees. Hypertension with or without proteinuria and edema is frequently present, and transient diabetes insipidus is a common association. In severe acute fatty liver of pregnancy, ascites and progressive hepatic encephalopathy develop along with hypoglycemia, consumptive coagulopathy, metabolic acidosis, and renal failure. Pancreatitis and GI bleeding also may occur. Improvement usually follows delivery of the fetus. If delivery has not been performed, fetal death often results, presumably from uteroplacental insufficiency or hypoglycemia.

B. Laboratory Findings—The white blood cell count is usually elevated, often to greater than 20,000/ μ L. There may be normochromic, normocytic anemia with fragmented red blood cells consistent with disseminated intravascular coagulation (DIC) or microangiopathic hemolysis. Prothrombin time and partial thromboplastin time are usually prolonged, and there are decreased fibrinogen and platelets and elevated fibrin degradation products, all indicative of consumptive coagulopathy. Decreased coagulation factors also can result from decreased hepatic synthesis.

AST and ALT are elevated, but seldom more than 2000 IU/L. Alkaline phosphatase and bilirubin are also elevated, and serum albumin is decreased. Hypoglycemia is often present and may be severe. Uric acid is usually high, and blood urea nitrogen (BUN) and creatinine are elevated if renal impairment is present. Hyponatremia may be present if there is diabetes insipidus, and elevated serum lipase and amylase indicate the presence of pancreatitis.

Diagnosis of acute fatty liver of pregnancy can be made with reasonable certainty from the clinical presentation and the laboratory findings, but confirmation requires the demonstration of microvesicular fat within the hepatocytes on liver biopsy. This is done with either staining a frozen tissue section with oil red O stain or by electron microscopy. Percutaneous liver biopsy should not be attempted if there are significant coagulation abnormalities. Increased echogenicity of the liver on ultrasound examination and decreased attenuation over the liver on CT scan or MRI have been described in patients with this disorder, but these findings are not always present.

Treatment

Management of acute fatty liver of pregnancy can be divided into four categories: monitoring, stabilization, delivery, and support. Monitoring should apply to both the patient and her fetus. Because the fetal condition can deteriorate rapidly, continuous monitoring of the fetal heart rate should be performed until delivery can be accomplished. Fetal biophysical profiles sometimes can aid in the diagnosis of fetal compromise. In severe acute fatty liver of pregnancy, the patient

should be managed in the ICU and may require invasive hemodynamic monitoring. Laboratory parameters should be followed at frequent intervals.

Stabilization involves maintenance of a patent airway and adequate ventilation if mental obtundation exists, normalization of intravascular volume, correction of electrolyte disturbances, treatment of hypoglycemia with intravenous glucose, and correction of hematologic and coagulation abnormalities with transfusions of red blood cells, platelets, and fresh-frozen plasma. Intravenous magnesium sulfate and, less frequently, hydralazine may be required if there is concomitant preeclampsia. Maintenance magnesium sulfate dosage should be decreased if there is significant renal impairment.

Once the patient has been stabilized, delivery should be accomplished as soon as possible, for this is what will ultimately lead to improvement. Delivery is often by cesarean section because this is often the most expeditious method and permits correction of coagulation defects just prior to surgery. However, if the cervix is favorable for labor induction and there is no evidence of fetal compromise, vaginal delivery can be attempted. This avoids the risks of abdominal surgery in the face of coagulopathy and ascites and decreases the need for anesthesia. The choice of anesthetic for cesarean section is controversial. Conduction anesthesia can be used if coagulation abnormalities are corrected. General anesthesia is used otherwise, with care taken to avoid agents that are hepatotoxic or that require metabolism in the liver.

Following delivery, the patient will require supportive management until she recovers from her multiple-organ-system failure. Protein intake should be limited, and nutritional maintenance should be primarily in the form of glucose to decrease the load of nitrogenous waste until hepatic function improves. This can be administered intravenously or by nasogastric tube, and blood glucose should be monitored every 1–2 hours to prevent hypoglycemia. To decrease production of ammonia by intestinal bacteria, oral lactulose, 20–30 g (30–45 mL) every 1–2 hours to induce diarrhea and then enough to produce two to four soft stools per day, can be administered. Alternatively, oral neomycin, 0.5–1 g every 6 hours, can be used. Although poorly absorbed, small amounts of neomycin may reach the bloodstream, and care should be taken to avoid levels that might cause nephrotoxicity. Magnesium citrate administered orally will decrease intestinal transit time, further decreasing ammonia absorption.

Optimal fluid and electrolyte management is critical, particularly if there is significant renal impairment, diabetes insipidus, or ascites. Diabetes insipidus can be managed with desmopressin acetate until this phase of the disease resolves. Vitamin K should be administered to aid restoration of coagulation, and further transfusions of fresh-frozen plasma or platelets should be necessary only in the face of clinical bleeding or if a surgical procedure is anticipated. Care should be taken to avoid nosocomial infection in this already compromised patient. Some patients have been treated successfully with liver transplantation after delivery for acute fatty liver of pregnancy.

▶ Amniotic Fluid Embolism

ESSENTIALS OF DIAGNOSIS

- ▶ Hypotension, hypoxia, coagulopathy.
- ▶ Frequently seizures, pulmonary edema, cardiac arrest.

General Considerations

Amniotic fluid embolism is a rare but catastrophic complication of pregnancy. Its incidence is unknown but is thought to be between 1:80,000 and 1:8000 pregnancies. It is classically thought to be triggered by the release of amniotic fluid, containing fetal squamous cells, into the maternal pulmonary circulation, causing severe pulmonary vasoconstriction with subsequent hemodynamic and cardiorespiratory collapse and coagulopathy. Cardiac arrest is common, with 26–80% of cases ending in maternal demise. There is significant controversy about the pathophysiology of the condition, and treatment therefore is empirical and supportive.

Amniotic fluid embolism has been reported as a complication of first- and second-trimester pregnancy termination and during otherwise normal pregnancy and the puerperium. The time of greatest risk is during labor. Placental abruption and fetal death are common antecedents to amniotic fluid embolism. Although links with hypertonic uterine contractions, augmented labor, and meconium-stained amniotic fluid also have been reported, a national registry of amniotic fluid embolism did not confirm these associations.

Clinical Features

A. Symptoms and Signs—The patient with amniotic fluid embolism presents with dyspnea and hypotension, which may rapidly deteriorate to cardiac arrest. Half of all patients will die within an hour of developing symptoms. An alternative presentation is as a severe coagulopathy. Up to one-third of patients have seizures, and nearly 75% exhibit pulmonary edema.

Although animal studies demonstrate a rise in pulmonary artery pressure at the time of embolism, with resolution within 30 minutes, no patient has had an amniotic fluid

embolism with a pulmonary artery catheter in place. Reports of patients who have had a pulmonary artery catheter placed hours to days after the acute event show no clear pattern of pulmonary artery pressures. Patients surviving the initial phase of the disorder may exhibit left-sided heart failure with elevated pulmonary capillary wedge pressures and decreased systemic vascular resistance. Acute respiratory distress syndrome is common, and 40–50% may have DIC with hemorrhage. The bleeding picture may be further complicated by uterine atony, which appears also to be a result of the amniotic fluid embolism.

B. Laboratory Findings—The classic laboratory finding of amniotic fluid embolism has been fetal squamous cells in the maternal pulmonary circulation at autopsy. Some authors have reported finding such cells in blood from a pulmonary artery catheter in patients suspected of having the diagnosis, but these appear to come from the maternal skin as an artifact from insertion of the catheter. The presence of squamous cells in the pulmonary circulation is of uncertain significance.

Treatment

Amniotic fluid embolism is a rare and unpredictable disorder. Few practitioners have seen more than a handful of cases, and published data are subject to arguable interpretation. Treatment is supportive. The most common manifestation of the disorder in the ICU is acute respiratory distress syndrome (ARDS), which should be managed in the same way as for other patients. The severe uterine atony associated with amniotic fluid embolism may necessitate hysterectomy to control uterine bleeding.

▶ Pyelonephritis in Pregnancy

ESSENTIALS OF DIAGNOSIS

- ▶ Fever, flank pain.
- ▶ Dysuria, pyuria.

General Considerations

Pyelonephritis occurs in 1–2% of pregnancies. In pregnancy, progesterone mediates ureteral relaxation, predisposing to urinary stasis. In addition, compression of the ureters by the gravid uterus and engorged pelvic vessels is implicated. In this context, bacteria from lower urinary tract infections can

ascend more easily to the kidney. Obstetricians aggressively treat even asymptomatic lower tract infections because, untreated, 25% of such patients will progress to pyelonephritis. The most frequent etiologic organism in pregnant women is *Escherichia coli*. Pregnant women with pyelonephritis usually are treated as inpatients because of the greater incidence of severe complications of this disease in pregnancy. In one series, 17% of pregnant women with pyelonephritis developed septic shock, and 7% of these patients developed respiratory insufficiency, which can occur 24–48 hours after starting antibiotic therapy and is presumably due to release of bacterial endotoxin.

Clinical Features

A. Symptoms and Signs—The typical patient presents with flank pain and fever of recent origin, often with rigors or chills. There may be a history of lower urinary tract infection, and many patients complain of concurrent lower tract symptoms such as dysuria and frequency. Some patients also have nausea and vomiting and anorexia. On physical examination, flank tenderness is usually present, more frequently on the right. There is usually fever, occasionally higher than 40°C. Tachycardia of both mother and fetus may be present owing to fever and volume depletion. Uterine contractions also may be present. The presence of hypotension, tachypnea, extremely high fever, or marked tachycardia is ominous.

B. Laboratory Findings—The urine nearly always contains white blood cells and bacteria, and red blood cells and casts are also seen frequently. The urine should be sent for culture to confirm the diagnosis and to check for antibiotic resistance.

Differential Diagnosis

In any febrile pregnant patient it is critical to exclude the diagnosis of intraamniotic infection. If any doubt exists, consideration should be given to performing amniocentesis to exclude this possibility. Amniocentesis usually is performed after the administration of antibiotics in order to avoid injecting bacteria into a sterile uterus. Amniotic fluid should be sent for cell count, glucose, Gram stain, and cultures. A leukocyte count of more than 30/μL (especially polymorphonuclear cells [PMNs]) or a glucose concentration of less than 18 mg/dL should be considered suspicious for infection. Similarly, a Gram stain showing increased PMNs—even in the absence of organisms—suggests bacterial infection. Any organisms seen on Gram stain should be considered significant and probably are an indication for delivery.

The pregnant patient also may have a renal stone, and one should be sought, especially in patients in whom the febrile course does not respond to antibiotics. This diagnosis can be made by ultrasound in most cases, although an intravenous urogram (single film to minimize radiation exposure) is sometimes still necessary.

Also included in the differential are appendicitis, cholecystitis, and viral gastroenteritis. Appendicitis in the pregnant

patient often presents with tenderness higher in the abdomen than at McBurney's point, and in many cases there are less remarkable peritoneal signs.

Treatment

The mainstay of treatment is intravenous antibiotics, with an antimicrobial agent chosen empirically to cover the majority of community-acquired urinary pathogens. Since nausea and vomiting and anorexia frequently accompany pyelonephritis, volume depletion and dehydration are common and should be corrected promptly with intravenous crystalloid. The fever and dehydration of pyelonephritis frequently lead to premature uterine contractions. In addition, high maternal fevers have been shown to be associated with fetal neurologic harm. For this reason, fever should be brought down below 38.3°C with acetaminophen or a cooling blanket. Because of the high risk of pulmonary damage in these patients, fluid overload should be avoided, and tocolytic drugs should be reserved for patients who demonstrate clear cervical changes.

Even with adequate treatment, the patient with pyelonephritis may demonstrate a hectic fever course, although uncomplicated patients become afebrile after 48 hours. Effective treatment of pyelonephritis often results in the liberation of bacterial endotoxins that may be associated with hypotension, hypothermia, pulmonary infiltrates, and rarely, ARDS. Patients who develop pulmonary edema or respiratory distress syndrome typically do so 24–48 hours after hospital admission. Transient impairment of renal function is also common. One group found that essentially all patients with pyelonephritis demonstrated evidence of hemolysis, sometimes leading to anemia and associated with bacterial endotoxins. Finally, the number of uterine contractions increases after the initiation of antibiotic therapy in some patients; this effect also has been attributed to the release of bacterial endotoxins. Treatment for endotoxin-mediated complications is symptomatic and supportive while antibiotics are continued. Pyelonephritis-induced ARDS has been treated with the fetus in utero with subsequent good fetal outcome.

The possibility of endotoxin-mediated complications mandates close observation of pregnant patients with pyelonephritis even after antibiotics have been begun. This routinely should include continuous fetal heart rate monitoring in all pregnancies beyond 22 weeks of gestation. Even prior to this gestational age, maternal hypotension and hypoxemia should be detected and corrected before fetal injury results.

Pregnant patients with pyelonephritis typically are treated for 10–14 days with antibiotics. These antibiotics can be administered orally on an outpatient basis after the patient becomes afebrile. After an episode of pyelonephritis, the pregnant patient is at increased risk for a recurrence. Often these patients are given antibiotic prophylaxis for the duration of the pregnancy and for 6 weeks postpartum. Serial urine cultures are also an acceptable management scheme.

▶ Septic Abortion

ESSENTIALS OF DIAGNOSIS

- ▶ Fever.
- ▶ Uterine or pelvic tenderness.
- ▶ Recent history of uterine instrumentation with pregnancy.

General Considerations

Septic abortion is defined as sepsis in association with a recent pregnancy termination (spontaneous or induced). This complication was much more common when abortion was illegal. Abortion-induced sepsis can progress rapidly to septic shock with an incidence of 2–10%. Data from the 1960s suggests that 300 of 100,000 illegal abortion procedures resulted in death of the mother. The current maternal mortality related to legal abortion in the United States is 0.7 per 100,000 procedures, with infection and hemorrhage each accounting for about one-quarter of those deaths. The likelihood of complications increases in patients who have later abortions and in those having dilatation and evacuation procedures. Clostridial infection was a feared complication of illegal abortions and remains a factor in septic abortions today. Several recent cases of fatal maternal sepsis following medically induced abortion using mifepristone were due to *Clostridium sordellii*.

Clinical Features

A. Symptoms and Signs—Patients will present with pelvic pain and a serosanguineous to purulent discharge. Some patients will complain more of vaginal bleeding, whereas others will emphasize crampy pain. All describe a history of recent (within a week) pregnancy termination, spontaneous or induced, or other intrauterine instrumentation in pregnancy. Hematuria and shock may develop rapidly.

B. Laboratory Findings—Blood, urine, and cervical specimens should be obtained for culture. Gram stain of potentially infected material is useful for initial therapy. The diagnosis of clostridial infection (*C. perfringens*) is suggested by the presence of large gram-positive rods on Gram stain of the cervical secretions or tissue obtained by curetting. The white blood count is usually elevated but may be low in patients with severe disease. Studies of renal and coagulation function and blood gas analyses may be helpful to predict the more severe complications of the infection. Abdominal x-rays may be helpful in the diagnosis of uterine

or bowel perforation (which can be a complication of the original procedure) or in the diagnosis of clostridial infection. The presence of gas in the myometrium is consistent with clostridial infection and is a grave prognostic sign. Finally, ultrasound may be helpful in assessing the presence of retained products of conception and in detecting possible pelvic abscesses.

Treatment

Sepsis after spontaneous or induced abortion is treated with high-dose antibiotics followed promptly by uterine evacuation. In clostridial infections, which are more than superficial, prompt hysterectomy may be lifesaving. Pelvic surgery also may be required to drain hematomas or abscesses. These also may be approached by guided needle aspiration. Other aspects of septic shock, including hypotension, anemia, and ARDS, are treated supportively.

▶ Pulmonary Edema

ESSENTIALS OF DIAGNOSIS

- ▶ Dyspnea, hypoxemia, cough.
- ▶ Chest x-ray showing pulmonary edema with usually bilateral diffuse interstitial and alveolar infiltrates and perihilar congestion.

General Considerations

Women without known predisposing conditions may develop pulmonary edema during the course of pregnancy, especially at the time of delivery. Common obstetric conditions responsible for this complication are (1) hypertensive disorders of pregnancy, (2) undiagnosed underlying heart disease, especially mitral stenosis, (3) use of tocolytic drugs, especially β -adrenergic agonists, (4) iatrogenic fluid overload, (5) systemic infection, especially pyelonephritis or chorioamnionitis, and more rarely, (6) peripartum cardiomyopathy.

Hypertensive disorders of pregnancy were discussed earlier. These patients are particularly disposed to pulmonary edema because of increased systemic vascular resistance and decreased plasma oncotic pressure. Pulmonary edema also

may supervene in these patients if left ventricular function is compromised or in cases of pulmonary capillary or epithelial injury. In other patients, the rapid mobilization of edema fluid that follows delivery may result in transient pulmonary edema.

Patients with flow-restricting cardiac lesions (eg, mitral stenosis) may be intolerant of the increased vascular volume of pregnancy and especially of the autotransfusion that accompanies delivery. In some women, the first symptom of cardiac disease is pulmonary edema after delivery.

Pulmonary edema associated with the use of β -adrenergic agonists appears to be unique to pregnancy. There is no association of pulmonary edema with these drugs in nonpregnant patients despite considerable clinical experience. The incidence of pulmonary edema as a complication of tocolytic therapy with these drugs has been estimated to be between 0.15% and 4% in different studies. This risk may be increased to more than 20% in the face of intraamniotic infection. Intravenous β -adrenergic agonists are currently rarely used in pregnancy owing to the number and severity of complications experienced with these agents. Pulmonary edema also can complicate subcutaneous use of β -adrenergic agonists, but the risk appears to be much less. Pulmonary edema also has been described with other tocolytic agents, with an incidence of 1:300 in one study of magnesium sulfate.

Patients in labor typically receive large volumes of intravenous crystalloid fluids. It is common practice to give laboring women a 1000-mL bolus before administering epidural anesthesia, and most women receive a maintenance rate of crystalloid infusion at all other times. Most laboring patients tolerate this regimen well. In some patients with pyelonephritis or in those who are undergoing tocolysis, however, careful fluid management can make the difference in developing pulmonary edema.

Peripartum cardiomyopathy is a rare complication of pregnancy, occurring in about 1:2200 to 1:3200 pregnancies in the United States, with one study showing an increase in recent years. It is characterized by a dilated cardiomyopathy and frequently is associated with systemic and pulmonary emboli. About half of patients with peripartum cardiomyopathy have complete resolution after delivery, with return of normal heart size and cardiac function. The remainder have continued cardiac dilatation. These patients tolerate future pregnancies poorly, and some have required cardiac transplantation. The cause of this condition is unknown, but at least some of the affected patients have evidence of viral myocarditis.

The mechanism for the increased susceptibility to pulmonary edema in pregnancy is not clear. Fluid overload has been suggested as a cause because of the known increase in extracellular fluid volume during pregnancy, decreased excretion of sodium and water in pregnant patients when supine, and concomitant administration of large amounts of intravenous fluids in many cases. However, there is no convincing evidence of increased pulmonary artery wedge pressure to identify either fluid overload or left ventricular failure as the cause of pulmonary edema in many cases. The finding of a low pulmonary artery wedge pressure in

the face of pulmonary edema normally would be indicative of increased capillary permeability pulmonary edema, but evidence against this mechanism is the usually rapid resolution of edema with treatment in the case of tocolytic use or in many cases of preeclampsia. Hypoalbuminemia and decreased plasma oncotic pressure of pregnancy also may play a role in the etiology of pulmonary edema.

Clinical Features

A. Symptoms and Signs—Patients present with dyspnea, cough, chest discomfort, and frothy sputum. Findings include bilateral rales, but most patients lack other signs of heart failure, such as a third heart sound. Review of the hospital records frequently documents administration of large amounts of intravenous fluids, sometimes for treatment of tachycardia or mild hypotension. Patients may have fever or other symptoms of infection.

B. Laboratory Findings—The chest x-ray shows bilateral interstitial or alveolar infiltrates consistent with pulmonary edema. Occasionally, findings are unilateral. The cardiac size may not be greatly enlarged, but it has been pointed out that there is an apparent increase in heart size during normal pregnancy. Pleural effusions are rare. Arterial blood gases show hypoxemia with respiratory alkalosis in most patients. Fetal heart monitoring may reveal late decelerations and loss of variability of the fetal heart rate consistent with fetal hypoxia and acidemia.

Ventilation-perfusion lung scans may be useful in excluding pulmonary thromboembolism in selected patients. Echocardiography should be considered to exclude cardiomyopathy or valvular heart disease.

Differential Diagnosis

Acute onset of dyspnea during late pregnancy may be due to pulmonary embolism, amniotic fluid embolism, or asthma. Patients with known underlying heart or lung disease also should be suspected of having an exacerbation of these problems if symptoms occur.

Prevention

Patients who have severe underlying heart diseases should not receive β -adrenergic agonists as tocolytic therapy because of the risk of inducing pulmonary edema. Magnesium sulfate, if necessary, may be considered. There is no place for tocolytic therapy in preeclampsia. Any patient at increased risk of pulmonary edema requires careful attention to fluid status. The presence of an intraamniotic infection mandates delivery in the great majority of cases, and patients with other infections must be monitored closely while undergoing therapy.

Treatment

Discontinuation of tocolytic agents and administration of intravenous furosemide (20–40 mg as needed) and oxygen are

generally associated with rapid reversal of symptoms and resolution of pulmonary edema in the absence of structural heart disease or sepsis. Patients with associated infection should be treated with appropriate antibiotics. Continuous fetal heart rate monitoring is essential until normal maternal pulmonary function is restored and hypoxemia corrected.

In patients with slow resolution of pulmonary edema, structural abnormalities should be considered. A pulmonary artery catheter may be helpful in identifying the cause of pulmonary edema and guiding therapy. A normal echocardiogram often predicts rapid resolution, but in patients with abnormal findings, long-term treatment is usually needed.

► Status Asthmaticus in Pregnancy

Asthma is the most common respiratory disease occurring in conjunction with pregnancy. In general, the influence of pregnancy on lung volumes, tidal volume, minute ventilation, and arterial blood gases has little effect on asthma. About 30–40% of asthmatics who become pregnant have worsening of their asthma; 35–40% have no change in the frequency and duration of symptoms; and 20–30% show an improvement in symptoms. In most patients, the course of asthma during pregnancy is similar in subsequent pregnancies. This constancy of asthmatic outcome may be altered with newer methods of asthma control.

Asthma can have adverse effects on pregnancy, especially when maternal hypoxemia affects oxygenation of the fetus. Premature labor and low birth weight are well-known complications of maternal asthma, and patients with hypoxemia owing to asthma are also at increased risk of fetal death. Thus the central theme in managing the pregnant asthmatic is prevention of maternal asthma exacerbation and hypoxemia.

There is no known association of pregnancy with status asthmaticus (ie, asthma unresponsive to treatment and usually requiring hospitalization) or with severe asthma (ie, daily wheezing and need for medication). On the other hand, pregnant women with asthma may have worsening of asthma or may be reluctant to use prescribed asthma medications, thus increasing the risk of these complications. Patients with a history of asthma requiring hospitalization, mechanical ventilation, and prolonged use of systemic corticosteroids

or of asthma complicated by pneumothorax should be monitored carefully. These patients should be instructed to report any asthmatic exacerbations, upper respiratory infections, increased cough, or other respiratory symptoms. Anemia, because it can adversely affect maternal oxygen transport, should be assessed and treated.

Clinical Features

A. Symptoms and Signs—Pregnant asthmatics present no differently than other patients with asthma. Patients with status asthmaticus complain of dyspnea, wheezing, cough, and failure of response to inhaled bronchodilator drugs. They may note inability to sleep because of dyspnea or cough, and they may report a frank upper airway infection. The time from onset of the attack should be noted because a prolonged duration may be predictive of poor response to treatment. Physical findings include wheezing, use of accessory muscles of respiration, a prolonged expiratory phase, tachypnea, tachycardia, and cyanosis. Patients presenting with acute severe asthma usually have a history of asthma; rarely, asthma will present initially during pregnancy.

B. Laboratory Findings—Arterial blood gases should be interpreted in the light of changes seen in pregnancy. In normal pregnancy, serum bicarbonate is decreased, and PaCO₂ is approximately 30 mm Hg. Development of hypercapnia therefore may be subtle, and only a slight elevation of PaCO₂ above 40 mm Hg may be indicative of impending respiratory failure in the pregnant woman. Severe hypoxemia in status asthmaticus is due to ventilation-perfusion mismatching resulting from bronchospasm and plugging of airways with mucus. As in nonpregnant asthmatics, spirometry is useful for assessing severity of asthma and following the response to therapy, especially because the peak expiratory flow rate does not change in pregnancy. Strong consideration should be given to obtaining a chest x-ray in those with unexplained fever, persistent bronchospasm, heavy sputum production, asymmetry on chest examination, severe hypoxemia, or suspicion of heart disease, pleural effusion, or pneumothorax.

Differential Diagnosis

Dyspnea during pregnancy is common, with most patients complaining of some subjective shortness of breath during the last trimester. Patients with acute onset of shortness of breath may have congestive heart failure, pulmonary edema, pulmonary thromboembolism, amniotic fluid embolism, pneumothorax, or sepsis. Valvular heart disease should be considered—especially previously undiagnosed mitral stenosis, mitral valve prolapse, aortic regurgitation, and aortic stenosis. A rare but important problem that should be considered in young women is primary pulmonary hypertension; this disorder can present with new onset of dyspnea and other symptoms in response to the increased cardiac output that occurs with pregnancy.

Treatment

Treatment of status asthmaticus in the pregnant asthmatic should be aggressive and rapid. Fetal oxygenation is highly dependent on adequate maternal arterial blood oxygen content, and delay in treatment is hazardous to the fetus. As with all conditions adversely affecting maternal respiratory function, fetal heart rate should be monitored continuously in potentially viable fetuses. Bronchodilator and anti-inflammatory therapy are directed at reversing airway obstruction; oxygen is given to treat hypoxemia. Pharmacologic therapy of asthma in pregnancy is based on administering drugs with a long history of use with good outcome rather than drugs that have been tested specifically during pregnancy.

A. Bronchodilators— β -Adrenergic agonists have been used extensively in pregnancy, but there are no controlled experimental studies in pregnant women for any of these agents. Terbutaline, albuterol, and metaproterenol have been administered to pregnant asthmatics with good results. Inhaled terbutaline is an FDA category B drug, whereas metaproterenol and albuterol are category C drugs. Several clinical studies following pregnant asthmatics have not found any differences in complications of pregnancy or fetal outcome among asthmatics receiving bronchodilators and nonasthmatics who did not receive these drugs. In general, the newer more selective β_2 -adrenergic agonist drugs are used more commonly than other agents. Administration of β -agonists by metered-dose inhalers, as in nonpregnant asthmatics, is preferred to nebulizers. The dose and frequency of inhaled bronchodilators should be titrated to the clinical response (see Chapter 24).

B. Corticosteroids—These drugs play a major role in reversing airway obstruction. Systemic corticosteroids—for example, intravenous methylprednisolone and oral prednisone—are well tolerated in pregnant women and are essential in the management of status asthmaticus. The optimal dose of corticosteroids in status asthmaticus is not known in the nonpregnant patient, but 40–60 mg methylprednisolone every 6 hours is usually given, and the dose in pregnancy should be similar. Use of corticosteroids should be aimed at achieving control of asthma, followed by rapid tapering and discontinuation over approximately 2 weeks, if possible. In some patients, continued administration of oral prednisone, 15–30 mg/day, is necessary for prevention of asthma attacks. Inhaled corticosteroids also may be used in the treatment of chronic asthma in the pregnant patient.

C. Cromolyn Sodium—Cromolyn sodium in inhaled or nasal spray form has not been associated with any fetal effect in observational studies. In chronic asthma, inhaled cromolyn may be a valuable agent, but cromolyn has no role in status asthmaticus.

D. Oxygen and Other Therapy—Supplemental oxygen should be provided to maintain PaO_2 at 85–100 mm Hg at all times to ensure fetal oxygenation.

Antibiotics generally are not warranted in status asthmaticus because infection, when present as a triggering or exacerbating factor, is usually of viral origin. If there is evidence of bacterial infection, broad-spectrum antibiotics can be given. Ampicillin, cephalosporins, and erythromycin (but not erythromycin estolate) generally are considered safe for use during pregnancy. Sulfonamides should not be given—especially during the third trimester—owing to a theoretical risk of kernicterus in the newborn. Erythromycin estolate, tetracycline, chloramphenicol, and quinolones should be avoided.

E. Intubation and Mechanical Ventilation—If the patient fails to respond to the foregoing measures and exhibits a normal or increased PaCO_2 , she should be admitted to an ICU. If the fetus is potentially viable, fetal monitoring should be instituted. Intubation and mechanical ventilation are indicated for a PaO_2 of 70 mm Hg or less, significant mental status changes, respiratory acidosis, cardiac arrhythmias, or evidence of myocardial ischemia. If mechanical ventilation does not correct the hypoxemia and the fetus is potentially viable, delivery by cesarean section should be considered for fetal reasons.

▶ Postpartum Hemorrhage

ESSENTIALS OF DIAGNOSIS

- ▶ Rapid loss of 500–1000 mL or more of blood after delivery.

General Considerations

Postpartum hemorrhage has been defined classically as an estimated blood loss of more than 500 mL after delivery.

Investigations have shown, however, that the average blood loss after vaginal delivery is near 500 mL, whereas that following cesarean section is in excess of 1 L. The working definition of postpartum hemorrhage therefore is relative. Most would acknowledge the presence of postpartum hemorrhage when blood loss exceeds 1 L, when there is a 10% change in the hematocrit between admission and postpartum determinations, or when transfusion is necessary.

The most common causes of early postpartum hemorrhage (<24 hours after delivery) are uterine atony, lower genital tract lacerations, and retained products of conception. Less common causes include placenta accreta, uterine rupture, inversion of the uterus, and coagulopathies. Uterine atony is by far the most common and may be associated with the antepartum use of oxytocin or with uterine overdistention from multiple gestation or polyhydramnios. Other factors thought to be associated with uterine atony include high parity, prolonged labor, cesarean section, precipitous labor, chorioamnionitis, and the use of tocolytic agents (especially magnesium sulfate).

Lower genital tract lacerations occur frequently and usually present with vaginal bleeding immediately after delivery. Uterine lacerations can bleed into the peritoneal cavity or retroperitoneal space and therefore do not always present with vaginal hemorrhage. Factors associated with lower genital tract lacerations are forceps or vacuum delivery, fetal macrosomia or malpresentation, and precipitate delivery.

Failure of the placenta to completely separate is a risk factor for the development of both uterine atony and postpartum hemorrhage presumably owing to the placental fragments interfering with the normal contraction of the uterus that is necessary for hemostasis. Retention of a succenturiate lobe (accessory lobe of the placenta) may present with postpartum hemorrhage in the early postpartum period. Placenta accreta also may cause life-threatening hemorrhage owing to the inability of the placenta to completely separate from the uterine wall. Risk factors for placenta accreta include previous puerperal curettage or previous uterine surgery, including cesarean section, and placenta previa.

Uterine rupture is an uncommon but catastrophic cause of postpartum hemorrhage. Because uterine artery blood flow is between 500 and 600 mL/min, hemorrhage from this cause can result in rapid maternal exsanguination. Conditions thought to predispose to uterine rupture include previous uterine surgery, breech extraction, obstructed labor, abnormal fetal position, and high parity.

Uterine inversion is also a rare complication of delivery, although it may recur in a patient's subsequent pregnancies. Uterine inversion is most remarkable for the development of shock out of proportion to the amount of blood lost.

Coagulopathies frequently are associated with postpartum hemorrhage. They often occur in association with other complications of pregnancy such as abruptio placentae, retained dead fetus, and amniotic fluid embolism. In addition, preexisting chronic coagulation disorders are significant contributors to postpartum hemorrhage.

Delayed postpartum hemorrhage occurring between 24 hours and 6 weeks after delivery may require admission to the ICU for resuscitation, observation, and perioperative care. Common causes include infection, placental site subinvolution, and retained products of conception, as well as underlying coagulopathy.

Clinical Features

Although the initial management of postpartum hemorrhage will be accomplished in the delivery room, the ICU physician should be familiar with the basic principles of diagnosis and early management. The first priority is to establish the cause. The relationship between the onset of hemorrhage and the time of delivery is critical in establishing the diagnosis. Bleeding prior to delivery of the placenta often indicates a genital tract laceration, a coagulopathy, or a partial separation of the placenta. When bleeding begins after the placenta is delivered, uterine atony, uterine inversion, retained fragments of the placenta, or placenta accreta may be responsible. The placenta should be inspected to ensure that torn vessels are not present, which might indicate the presence of an accessory lobe; that appropriate contour is observed; and that portions are not missing (suggesting placenta accreta).

Uterine atony requires fundal massage and the administration of ecbolic drugs (see next). Lacerations should be sutured in a manner that allows closure of the wound and compression of the underlying vessels. Hematomas may form as the result of lacerations. Hematomas below the pelvic diaphragm usually are accompanied by severe pain and a palpable mass. Sudden onset of shock without significant apparent blood loss suggests that the bleeding point is above the pelvic diaphragm.

A coagulopathy is suggested by the presence of bleeding from remote locations such as intravenous insertion sites. The diagnosis of coagulopathy may be made rapidly by observing a tube of the patient's blood for clot formation. If a firm clot forms within 5 minutes, it is unlikely that clinically significant hypofibrinogenemia is present.

Treatment

A. General Measures—Postpartum hemorrhage represents a special cause of hemorrhagic (hypovolemic) shock. A stable airway and adequate intravenous access must be ensured. Initial resuscitation should be with balanced salt solutions, although blood replacement will be required early if hemorrhage cannot be arrested. Packed red blood cells are usually used. In the event of severe hemorrhage, replacement of clotting factors also may be needed via the use of fresh-frozen plasma. Fresh-frozen plasma should be given only if laboratory testing shows that the patient has developed a coagulopathy. Blood should be warmed to prevent hypothermia.

Arterial blood gas and hemoglobin determinations should be performed regularly during resuscitation and after control of bleeding. Measurements of blood pressure, pulse rate, and

urine output will help to assess volume status. Pulmonary artery catheters are seldom required, although a central venous catheter may be helpful in actively bleeding patients who require ongoing resuscitation and transfusion.

B. Ecbotic Agents—Hemorrhage from uterine atony should be managed with fundal massage plus an intravenous infusion of oxytocin (10–40 units/L of normal saline). If oxytocin does not arrest the hemorrhage, treatment with either methylergonovine (0.2 mg intramuscularly) or carboprost tromethamine (15-methylprostaglandin $F_{2\alpha}$), 0.25 mg intramuscularly, may be used. Misoprostol (800 mg per vagina or rectum) also may be effective. Methylergonovine may be associated with an increase in maternal blood pressure and should not be used in the patient with hypertension. Prostaglandin agents may provoke bronchospasm and should be not be used in patients with significant asthma.

C. Surgery—When postpartum hemorrhage cannot be controlled by massage and ecbotic agents, emergent surgery usually is required. In many cases, these procedures will have been performed before the patient is transferred to the ICU. Occasionally, however, a previously stable patient will require exploration for hemorrhage after it has been controlled. Common surgical procedures include evacuation of hematomas caused by lacerations (combined with suturing of the injury and control of the bleeding vessel), ligation of pelvic arterial vessels, packing, and hysterectomy. Recent reviews of cesarean hysterectomy reveal that the average blood loss for this procedure when done emergently was 3000 mL, and the most common antecedent complications were uterine rupture, placenta accreta and uterine atony.

D. Angiographic Embolization—When bleeding continues from an identifiable localized area, embolization via a radiographically placed catheter may be extremely helpful. Some authors have described the placement of embolization catheters prophylactically in patients at highest risk of postpartum hemorrhage.

E. Delayed Postpartum Hemorrhage—Fewer than 1% of patients with postpartum hemorrhage present more than 24 hours after delivery. Infection and retained products of conception are the most common causes, with subinvolution of the placental site also being a consideration. Uterine curettage should be performed only when retained products of conception are suspected because of the risk of intrauterine adhesions. Pelvic and uterine ultrasonography may be helpful in determining whether retained products are present, although all postpartum uteri contain some clot and debris. Even when there is not retained placental tissue, evacuation of intrauterine clots allows more efficient uterine contraction and often results in hemostasis. Estrogens may be used to improve endometrial regrowth after curettage and to avoid intrauterine adhesions. Ecbotic agents and antibiotics may be given if retained products of conception are not present. If hemorrhage persists more than 12–24 hours, the patient should undergo curettage for presumed retained products, even in the absence of a definite diagnosis.

► Trauma During Pregnancy

Accidental injury occurs in approximately 1 in 12 pregnancies. While many of these incidents are minor, one should bear in mind that two patients are at risk. Serious injuries during pregnancy do not result in a higher maternal mortality rate than do similar injuries in a nongravid patient. Fetal death, however, is common, with fetal loss rates of up to 61% reported in studies of severe trauma. Eighty-five percent of all maternal deaths from trauma are due to closed head injuries and hemorrhagic shock, whereas fetal deaths result from abruptio placentae as well as maternal death and fetal hypoxia. Because of this combined risk, and because of the risk of preterm labor, pregnant patients often require inpatient observation.

The physiologic changes of pregnancy make the patient both more and less susceptible to the effects of trauma. The increased plasma volume and decreased hematocrit further the potential for diminished oxygen delivery following blood loss. Fluid resuscitation requirements after hemorrhage are greater because of the 50% increase in maternal intravascular volume. Conversely, the increased blood volume makes the mother more tolerant of blood loss without change in her vital signs. The increase in maternal heart rate (15–20 beats/min) and the decrease in both systolic and diastolic blood pressures (10–15 mm Hg) may confound attempts to evaluate volume replacement. Furthermore, an elevation of coagulation factors during pregnancy increases the risk for thrombogenesis with surgery or prolonged immobilization.

As pregnancy progresses into the second trimester, fetal growth distends the uterus upward into the abdomen, where it becomes more susceptible to direct injury. The bladder also becomes more prone to injury, especially after the twelfth week of gestation. Because blood flow to the uterus is abundant (as much as 600 mL/min), direct injury to the uterus may cause rapid exsanguination. Uterine blood vessels lack autoregulation, so maternal shock causes a substantial decrease in fetal oxygen delivery. Uterine blood flow may fall before maternal shock becomes manifest and may result in fetal hypoxia in the face of normal maternal vital signs. Fetal responses to decreased perfusion and hypoxia include alterations in heart rate (bradycardia or tachycardia), loss of heart rate variability, and repetitive late decelerations.

Motor vehicle accidents are the principal cause of accidental injuries during pregnancy and account for about 50% of all cases of blunt abdominal trauma, but 82% of injuries

resulting in fetal death. Three-point-restraint seat belts are preferable for pregnant passengers because the incidence of body flexion and uterine compression is less than that induced by lap belts alone. Placental abruption is the most common cause of fetal demise after blunt abdominal trauma. Abruption is caused by deformation of the elastic uterus around the inelastic placenta. The shearing force thus produced tears the decidua basalis. Current evidence indicates that the position of the placenta does not influence the development of abruption. Uterine rupture is uncommon and probably occurs in less than 0.6% of all traumatic injuries during pregnancy. It carries a maternal death rate of less than 10%, but a fetal death rate of nearly 100%. Maternal pelvic fractures occur frequently but do not necessarily preclude subsequent vaginal delivery. Such fractures are of concern when they are comminuted and badly displaced because they carry the potential to injure the uterus and fetus. Placental abruption and pelvic fractures are highly correlated.

Gunshot wounds are the most common type of penetrating injury sustained by pregnant patients. Regrettably, incidents occur in which there was clear intent to harm the fetus. When compared with nonpregnant victims, pregnant patients actually have a lower mortality rate after abdominal gunshot wounds, perhaps because the enlarged uterus and its contents protect the patient by absorbing and dissipating the missile's kinetic energy. Upper abdominal gunshot and stab wounds, however, cause a higher incidence of intestinal injury because of cephalad displacement of the viscera by the uterus. Direct injury of the fetus by a bullet occurs in 70% of cases, with a 65% intrauterine fetal death rate. Maternal death is much less common.

Burns, electrocution, and suicide attempts are less common causes of injury. Unless a burn covers more than 30% of the patient's body surface area, it generally will not affect the pregnancy. Fetal outcome is probably related to gestational age at the time of the burn. The highest mortality rate is recorded during the first trimester. Topical iodine solutions should be avoided because large amounts may be absorbed through the burn wound. House current electrical injuries occur uncommonly but may be associated with a high fetal mortality rate because of the path of the current through the patient's body. Pregnant victims of electrocution may report a reduction in fetal movements immediately after the incident. Fetal demise or intrauterine growth retardation may follow. Oligohydramnios has been reported at the time of delivery.

Management

A. General Principles—Pregnant patients who require ICU admission following injury commonly will be resuscitated and stabilized in the emergency department. Initial treatment in the ICU may be advisable, however, because of the availability of invasive monitoring.

On arrival, initial concern must be directed toward the mother, with attention paid to establishment of an adequate airway, breathing, and circulation. The patient should lie in

the left lateral position, if possible, to prevent compression of the vena cava by the gravid uterus. Both maternal hypotension and fetal hypoxia may result from caval compression. If concern about the cervical spine precludes the decubitus position, an assistant should displace the uterus by hand to the left in an attempt to decompress the vena cava. Alternatively, the entire bed or support board can be tilted. Supplemental oxygen should be given to increase oxygen delivery to the fetus. Upper extremity intravenous catheters should be placed to ensure adequate intravenous access. A nasogastric tube should be inserted during the early stages of resuscitation to allow gastric decompression and prevent aspiration. In the presence of a viable fetus, continuous fetal heart rate monitoring should be instituted as soon as possible.

Blood is preferred as the initial fluid for resuscitation of hypotensive trauma patients. Particular attention must be paid to Rh compatibility. If Rh-incompatible blood is inadvertently given to an Rh-negative woman, anti-D antibody should be given in a dose of 300 mg for every 30 mL of whole blood or 15 mL of packed red blood cells transfused. Pregnant patients require more volume replacement than do nonpregnant patients because of their physiologically expanded intravascular space.

A bladder catheter should be placed as soon as possible both to measure the urine output and to help establish the integrity of the urethra and bladder. Urine so obtained should be inspected for gross blood and tested for microscopic hematuria.

Normal physical signs of abdominal injury such as pain and loss of bowel sounds may be masked by the pregnant uterus. Conversely, all these findings may be produced by the pregnancy itself. Vaginal bleeding generally is considered an ominous sign because it may signal placental abruption or severe pelvic injury.

B. Laboratory Studies—Studies should include hemoglobin serum electrolytes, coagulation profile, amylase, and blood crossmatch. Routine arterial blood gases are advisable. When placental separation is suspected because of a pelvic fracture, fetal distress, uterine tetany, or vaginal bleeding, measurements of blood fibrinogen concentration, fibrin degradation products, and platelet count are of particular importance. Additionally, a tube of blood should be obtained and observed for clot formation. Noncoagulable blood indicates probable placental abruption and mandates immediate replacement of fibrinogen with fresh-frozen plasma or cryoprecipitate, followed by evacuation of the uterus. The possibility of fetomaternal hemorrhage should be evaluated with a Kleihauer-Betke study. Fetomaternal hemorrhage is most common when the placenta is located anteriorly, when pelvic tenderness is present, and following motor vehicle accidents. If severe, it can result in fetal anemia or fetal death.

C. Imaging Studies—Critical radiographic studies should not be withheld in an attempt to avoid fetal x-ray exposure. The fetal risks from various doses of x-ray and the expected

doses from various procedures were discussed previously. The need for chest and abdominal x-rays should be guided by the nature and severity of the injury. Free air under the diaphragm on an upright chest x-ray is an indication for immediate laparotomy. Traumatic separation of the pubic symphysis in or after the second trimester is difficult to detect on x-ray because of the normal ligamentous laxity that accompanies pregnancy. Maternal and fetal complications are more common after pelvic fractures, and their presence must be identified.

Obstetric ultrasound should be performed in all cases of trauma during pregnancy. It is helpful in diagnosing a retroplacental clot, although absence of a visible clot on ultrasound cannot rule out placental abruption. Additionally, ultrasound can aid in estimating gestational age when a history cannot be obtained.

D. Peritoneal Lavage—Open peritoneal lavage through a supraumbilical incision is an excellent technique for diagnosing abdominal injuries. Approximately 1 L of lavage fluid is instilled through the small incision and allowed to return passively to the container. Criteria that constitute a positive lavage include (1) a red blood cell count of more than 100,000/ μ L, (2) a white blood cell count of more than 500/ μ L, (3) the presence of GI contents, bile, or bacteria, and (4) increased amylase.

E. Fetal Monitoring—Immediately on patient arrival in the ICU, fetal heart monitoring should be instituted. Such monitoring provides information about both the fetus and the mother. The fetus may be compromised by hypoxia before the mother becomes hypotensive. Bradycardia, tachycardia, and loss of beat-to-beat variability are ominous signs. Monitoring in gestations beyond 18–20 weeks may be able to predict abruptio placentae. Although intermittent auscultation is possible, it should not substitute for electronic surveillance. The gestational age at which monitoring is mandatory is controversial, but all authorities would monitor potentially viable fetuses (>22–23 weeks). Monitoring necessitates the presence in the ICU of personnel experienced in the interpretation of fetal heart rate patterns.

F. Tocodynamometry (Uterine Contraction Monitoring)—Tocodynamometry is of significant importance in predicting early placental abruption. The incidence of abruption increases with frequent uterine activity (more than eight uterine contractions per hour), and about 25% of trauma patients with at least three uterine contractions in a 20-minute period suffered either abruptio placentae or preterm labor. Another study found that these complications did not occur in patients who were without contractions for the first 4 hours. Monitoring during the first 4–6 hours after admission therefore has been proposed, with additional monitoring only in patients with contractions on initial monitoring or with a change in maternal condition.

G. Surgery

1. TRAUMA—Certain kinds of trauma must be managed operatively. Bowel injuries must be repaired, fractures reduced, and wounds closed. Pregnancy should not delay or contraindicate surgical exploration.

2. ABRUPTIO PLACENTAE—Evacuation of the uterus is indicated for placental abruption. If gestation has continued for more than 30 weeks, immediate cesarean section may save both the fetus and the mother. In cases of intrauterine fetal demise, labor and spontaneous vaginal delivery may occur. Caution must be exercised to detect DIC, which is more common after extensive abruption. If both the platelet count and the fibrinogen concentration decline, fresh-frozen plasma or cryoprecipitate should be given and a hysterotomy performed if delivery is not imminent. The coagulopathy usually ceases when the placenta is removed.

3. UTERINE RUPTURE—Shock, severe abdominal pain, and lack of fetal heart tones suggest uterine rupture. It may be difficult to localize the fundus of the uterus, and fetal parts may be easily palpable through the abdominal wall. An abdominal x-ray usually shows that the fetal skeleton is in an unusually high location in the abdomen. Peritoneal lavage is always positive for blood and returns more fluid than was instilled (amniotic fluid). At surgery, massive bleeding may have to be controlled with bilateral internal iliac artery ligation. Supracervical hysterectomy may be required.

4. CESAREAN SECTION—Adequate exposure of abdominal injuries usually can be achieved with careful mobilization of the uterus. Cesarean section may be required, however, when the gravid uterus prevents access to deep pelvic injuries. Patients with undisplaced pelvic fractures usually do not require cesarean section.

Premature separation of the placenta and fetal head injuries both may be consequences of maternal trauma during pregnancy. Placental separation coexisting with a living fetus often mandates an emergent cesarean section. In the case of a live fetus undergoing labor after maternal trauma, consideration should be given to fetal ultrasound for evidence of fetal head injury. If such evidence exists, this fetus also may benefit from cesarean delivery.

Antithrombotic Therapy

39

Elizabeth D. Simmons, MD

Pathologic blood clot formation within blood vessels (thrombosis) and embolization of clots to distant sites result from complex interactions among platelets and coagulation proteins, the fibrinolytic system, and the blood vessel itself. Thrombi are composed of red blood cells, platelets, and fibrin in varying proportions depending on the conditions present at the site of thrombus formation. Very diverse clinical conditions are associated with increased risks of such pathologic thrombosis and embolization (Table 39–1). Thromboembolic disease is a major cause of morbidity and mortality; 30–40% of all deaths in the United States are attributed to thrombotic events, and nonfatal events occur in hundreds of thousands of people each year.

Antithrombotic therapy consists of strategies (both pharmacologic and physical) to prevent pathologic blood clot formation or to treat established thromboses in order to limit the clinical consequences of such clots. The decision to use antithrombotic therapy in clinical practice is often complicated because of the diversity of the clinical conditions affecting patients, difficulties in establishing accurate diagnoses of thromboembolism, and our still incomplete understanding of the risks and benefits of antithrombotic therapy in the prevention and treatment of thromboembolic disease. Numerous new pharmacologic agents have been developed or are under development, and various combinations of antithrombotic agents are being used in diverse settings.

► Physical Measures

Venous stasis and damage to blood vessels are the two most important risk factors for the development of venous thromboembolism (VTE). Physical measures to decrease venous stasis are quite important in preventing venous clots, particularly in hospitalized patients. Limiting bed rest as much as possible for most medical patients and early mobilization after surgery can decrease the period of risk for venous thrombosis. Intermittent pneumatic compression devices (IPCs) and the venous foot pump (VFP) reduce venous stasis, increase

venous flow, and reduce the risk of deep vein thrombosis (DVT) in lower-risk patients but have not been demonstrated to reduce the risk of pulmonary embolism (PE). These devices are used primarily in patients with high bleeding risk or in combination with pharmacologic agents for prevention of VTE. IPCs should not be used in the presence of established thrombosis, severe peripheral vascular disease, skin ulcers, or after leg trauma if there is compromised tissue viability. Graduated compression stockings may help to control leg edema but are not highly effective for the prevention of VTE. They are not recommended as an isolated measure for prevention of VTE in patients at moderate to high risk.

Interruption of the inferior vena cava using a fluoroscopically placed filter is indicated for treatment of patients with lower extremity venous thrombosis who have a major contraindication to anticoagulant therapy or for patients with recurrent thromboembolism despite adequate anticoagulation. Inferior vena cava filter placement reduces the risk of PE but does not prevent recurrence or extension of lower extremity thromboses. Therefore, unless contraindicated, initiation of anticoagulation as soon as possible after filter placement is advised.

Surgical or transvenous embolectomy is performed occasionally in selected patients with life-threatening thromboembolic disease, particularly in patients with contraindications to anticoagulation or thrombolysis.

► Antiplatelet Agents

Antiplatelet therapy (alone or in combination with anticoagulants) is most beneficial in prevention or treatment of arterial thrombosis. Arterial thrombi usually develop in abnormal blood vessels and are associated with activation of both blood coagulation and platelets; however, arterial thrombi are composed primarily of platelets held together by fibrin strands. Antiplatelet agents inhibit platelet function through several biochemical pathways or by exerting effects on the platelet membrane.

Table 39–1. Conditions associated with pathologic thromboembolism.

Stasis	Immobilization Congestive heart failure Surgery Advanced age Obesity Atrial fibrillation
Blood vessel abnormalities	Trauma, coronary artery disease, peripheral vascular disease, varicosities, vasculitis, artificial surfaces (vascular grafts, heart valves, indwelling catheters), diabetes mellitus Homozygous homocystinuria Previous thrombosis
Abnormalities of physiologic antithrombotic mechanisms	Antithrombin deficiency Protein C or S deficiency Hereditary resistance to activated protein C (factor V Leiden and prothrombin gene mutation G20210A) Methylenetetrahydrofolate reductase (MTHFR) gene mutation C677T Defective or deficient plasminogen Plasminogen activator deficiency
Abnormalities of coagulation and fibrinolysis	Malignancy Pregnancy Oral contraceptives Hormone replacement therapy Tamoxifen Nephrotic syndrome Lupus anticoagulant/antiphospholipid antibody syndrome Prothrombin complex concentrate solution Dysfibrinogenemia Factor VIII >150%
Abnormalities of platelets	Myeloproliferative disorders Paroxysmal nocturnal hemoglobinuria Hyperlipidemia Diabetes mellitus Heparin-associated thrombocytopenia Thrombotic thrombocytopenic purpura
Hyperviscosity	Polycythemia Leukemia Sickle cell disease Leukoagglutinin Hypergammaglobulinemia

Antiplatelet agents are useful in the management of patients with unstable angina; suspected acute myocardial infarction; a history of myocardial infarction, nonfatal stroke, transient ischemic attacks, or peripheral vascular disease; and those undergoing vascular procedures. Antiplatelet agents are not as useful as other measures for prevention of VTE, such as

anticoagulation, particularly in high-risk surgical patients or for stroke prevention in patients with atrial fibrillation.

Inhibitors of Cyclooxygenase (Aspirin, Nonsteroidal Anti-inflammatory Agents)

Cyclooxygenase (COX) is a key enzyme in the prostaglandin pathway within platelets and endothelial cells. The final product of this pathway differs in platelets and endothelial cells. Thromboxane A₂ (TXA₂), a potent inducer of platelet aggregation, is produced in platelets, whereas prostacyclin, an inhibitor of platelet aggregation, is produced in endothelial cells. Aspirin irreversibly inhibits COX (COX-1 more so than COX-2), which cannot be resynthesized by platelets because they have no nucleus. Vascular prostacyclin production is affected to a much lesser extent by aspirin because endothelial cells can resynthesize cyclooxygenase, and because prostacyclin is also COX-2–derived, which is much less sensitive to inhibition by aspirin. Thus aspirin is an ideal pharmacologic agent for the treatment and prevention of thromboembolic disease. Several of the nonsteroidal anti-inflammatory drugs (NSAIDs) also inhibit platelet COX, but inhibition is reversible. NSAIDs may cause clinical bleeding in patients with underlying hemostatic defects or after invasive procedures, but they are generally not used therapeutically for treatment or prevention of thromboembolic disorders. COX-2 inhibitors do not inhibit production of platelet TXA₂ and do not have antithrombotic properties; these agents actually may increase the risk of thromboembolism.

Three reversible COX inhibitors (ie, indobufen, flurbiprofen, and triflusal) that may have beneficial effects similar to those of aspirin have been investigated as alternatives to aspirin; none are currently approved for use in the United States, and it is unclear whether they will prove to have any advantage over currently available treatments.

Aspirin is rapidly and completely absorbed from the GI tract, metabolized to salicylate, and circulates as salicylate bound primarily to albumin. Salicylate is metabolized in the liver and excreted in the urine. The serum half-life of salicylate is 15–20 minutes. The effect of aspirin on platelet function begins within 1 hour of ingestion (3–4 hours for enteric-coated preparations) and lasts the life of the platelet (8–10 days). Enteric-coated tablets should be chewed if rapid antiplatelet effect is necessary. Gastric irritation may be reduced with enteric-coated and timed-release forms of aspirin, but absorption may be reduced or delayed.

Ingestion of aspirin in doses commonly used in clinical practice prolongs the bleeding time in normal subjects somewhat variably, typically by 1–3 minutes, and out of the normal range only in about half of subjects. Aspirin inhibits platelet aggregation *in vitro*, but these laboratory effects do not correlate well with *in vivo* hemostasis. In patients with underlying hemostatic defects (eg, hemophilia, von Willebrand disease, uremia, mild preexisting disorders of platelet function, and thrombocytopenia), aspirin may markedly prolong the bleeding time and cause serious bleeding.

The clinical benefits of aspirin have been established by large trials of patients with various thromboembolic phenomena, with endpoints including development of thrombosis, death from thrombosis, and bleeding complications. Laboratory tests of platelet function are not useful for monitoring such patients in clinical practice. The measurable antiplatelet effects of aspirin are equivalent over a wide range of daily aspirin dosage (300–3600 mg/day), and the therapeutic benefits have been demonstrated with as little as 75 mg/day (or, in one study, 30 mg/day). The minimum effective dose varies for different disorders, but for most situations, a daily dose between 50 and 100 mg is effective and minimizes toxicity with long-term use. In acute myocardial infarction and acute ischemic stroke, a dose of 160 mg/day reduces early mortality and recurrent events. Higher-dose aspirin (eg, 650–1500 mg/day) does not improve outcome and actually may be detrimental.

Currently available data support the use of aspirin in cardiovascular disease prevention, stable and unstable angina, acute myocardial infarction, transient ischemic attacks and incomplete stroke, severe carotid stenosis, stroke following carotid artery surgery, and in patients with prosthetic heart valves (in combination with oral anticoagulation). The benefits of aspirin following vascular or valve surgery, arterial procedures, or creation of fistulas or shunts are less certain but appear to include a reduction in risk of arterial occlusion compared with no therapy. Aspirin, although more effective than placebo, is less effective than anticoagulation in preventing recurrent stroke associated with nonvalvular atrial fibrillation. Aspirin has not been shown to be effective for treatment of established VTE and is inferior to other measures for prevention of VTE, especially in high-risk patients. Although one large trial showed a benefit of aspirin—alone or in combination with anticoagulation—for patients undergoing hip surgery, it is less effective than anticoagulation.

The safety and efficacy of aspirin in combination with anticoagulants have not been clearly established.

Aspirin resistance resulting in treatment failure has been observed in some patients receiving aspirin for the treatment of ischemic vascular disease. The mechanisms underlying resistance are not known, and there is currently no reliable platelet function test to predict which patients are unlikely to benefit from aspirin. Concomitant therapy with other NSAIDs can reduce the antiplatelet effect of aspirin because of competition for binding sites in the platelet and may be one important mechanism of aspirin treatment failure because of widespread use of these over-the-counter medications. Patients who develop recurrent ischemic events despite aspirin are candidates for alternative antiplatelet therapy or anticoagulation.

Adverse effects of aspirin include dose-dependent GI irritation (eg, dyspepsia, nausea and vomiting, occult blood loss, and gastric ulceration), hypersensitivity reactions, abnormal liver function tests (rare), nephrotoxicity (rare), and at high doses, tinnitus and hearing loss. Enteric-coated aspirin does not reduce the risk of GI bleeding compared with regular aspirin. Concomitant use of NSAIDs may increase the risk of GI bleeding. Omeprazole is effective at treating and preventing GI ulceration

and bleeding associated with NSAIDs and may permit chronic use of aspirin in patients at high risk for cardiovascular events who have had this complication. Overdosage of aspirin (salicylate intoxication) may be life-threatening and is manifest by metabolic acidosis and respiratory alkalosis, dehydration, fevers, sweating, vomiting, and severe neurologic symptoms. Reye's syndrome in infants and children appears to be associated with aspirin usage. In patients at risk for major bleeding, the antithrombotic effects of aspirin may result in serious bleeding. High doses of aspirin may result in interference with prothrombin synthesis, prolongation of the prothrombin time, and significant hemorrhagic sequelae. Subarachnoid hemorrhage may occur with the use of more than 15 aspirin per week, particularly in older or hypertensive women.

Inhibitors of ADP-Mediated Platelet Aggregation (Ticlopidine, Clopidogrel)

Ticlopidine and clopidogrel are structurally related thienopyridines that inhibit platelet function. Repeated daily dosing results in cumulative inhibition of ADP-induced platelet aggregation and slow recovery of platelet function after stopping the drug. The major properties of ticlopidine and clopidogrel are compared in [Table 39–2](#).

Ticlopidine is well absorbed (80–90%) from the GI tract. It is rapidly metabolized with one active metabolite. Steady state levels are achieved with 250 mg twice daily after 14 days. The onset of antiplatelet effect is delayed (up to 2 weeks), so ticlopidine should not be used when a rapid antiplatelet effect is needed. Ticlopidine was introduced as a potential alternative to aspirin, but its high cost, toxicity, and only marginally better efficacy have limited its use in current practice. Ticlopidine is approved for stroke prevention when aspirin has failed or in patients who cannot tolerate aspirin.

Ticlopidine may cause neutropenia (2.4%), thrombocytopenia, or pancytopenia (0.04–0.08%), particularly in the first 3 months of therapy, so monitoring of blood counts must be done during that time. Thrombotic thrombocytopenic purpura (TTP) has been reported with ticlopidine therapy (0.02–0.04%), but ticlopidine also has been used successfully in management of TTP. Other adverse effects include diarrhea (20%), skin rash (2–15%), increase in total cholesterol levels (mean increase of 9%), and reversible liver function test abnormalities (rare).

Clopidogrel is rapidly absorbed and metabolized to active metabolites (the main one being SR 26334, a carboxylic acid derivative). The onset of inhibition of platelet aggregation is dose-dependent, occurring 2 hours after a single dose (400 mg) but after 2–7 days with lower daily dosing (50–100 mg daily). Platelet function returns to normal 7 days after stopping the drug, consistent with irreversible inhibition of platelet function. A loading dose of 300 mg followed by 75 mg daily will result in a rapid and sustained antiplatelet effect; a loading dose of 600 mg is used in patients undergoing percutaneous coronary intervention, but the optimal loading dose has not been determined. Clopidogrel appears to have

Table 39–2. Comparison of ticlopidine and clopidogrel.

	Ticlopidine	Clopidogrel
Absorption (oral)	90%	Rapid
Half-life	24–36 hours (single dose); 96 hours (after 14 days or therapy)	Active metabolite SR 26334: 8 hours
Active metabolites	Yes	Requires metabolism to active inhibitor: SR 26334
Onset of antithrombotic action	Delayed up to 2 weeks	2 hours (single 400 mg dose); 1 day (50–100 daily dose)
Recovery of platelet function after discontinuing drug	7 days	7 days
Recommended dose	250 mg orally twice daily	300 mg loading dose; 75 mg orally daily
Clinical use	Cerebral ischemia with aspirin failure or intolerance	Peripheral vascular disease, prevention of recurrent stroke, myocardial infarction. Combined with aspirin after coronary artery stent placement.
Side effects	Neutropenia (2.4%), thrombocytopenia, TTP (0.2%–0.04%), aplastic anemia, rash, diarrhea	Rash, diarrhea, TTP (1/1,000,000), neutropenia (0.8%), gastrointestinal bleeding (2%)
Expense	About \$2–3/pill	About \$3/pill

TTP = thrombotic thrombocytopenic purpura.

approximately the same antiplatelet effects as ticlopidine, but because of its better safety profile, it has replaced ticlopidine for most clinical situations. Its therapeutic efficacy appears to be equivalent to aspirin in most settings except for symptomatic peripheral artery disease, in which it may be superior. It is currently approved for use in patients with recent stroke or myocardial infarction and in those who have peripheral arterial vascular disease. Clopidogrel combined with aspirin decreases the rate of cardiovascular events following acute coronary syndromes compared with aspirin monotherapy and is the standard regimen following placement of coronary stents (for at least 1 month; longer duration may be better). Combination therapy is associated with more bleeding than with aspirin alone, but only with higher doses of aspirin (>100 mg/day). The most common side effects of clopidogrel are rash and diarrhea. GI bleeding occurs less often than with aspirin (2%); however, in one study in patients who had bleeding ulcers while taking aspirin, clopidogrel was associated with a higher rate of recurrent bleeding than aspirin when each was combined with a proton-pump inhibitor. Neutropenia has been reported less often than with ticlopidine (0.8%), as has TTP (reported occurrence 1:250,000 persons, about the same as the general population), usually occurs within the first 2 weeks of treatment.

Integrin α Ib β 3 (Platelet Glycoprotein IIb/IIIa) Receptor Inhibitors

Platelet glycoprotein IIb/IIIa (GP IIb/IIIa) inhibitors block the binding of fibrinogen to its receptor on the platelet

membrane, preventing platelet aggregation. There are three GP IIb/IIIa inhibitors currently approved for use in the United States: abciximab (recombinant humanized monoclonal antibody), eptifibatid (synthetic heptapeptide similar to that found in snake venom from *Sistrurus m barbouri*), and tirofiban (a nonpeptide mimetic), all of which are given intravenously. Prolongation of bleeding time and decreased platelet aggregation in vitro are seen with all these agents, but in contrast to aspirin, ticlopidine, and clopidogrel, these effects are rapidly reversible after discontinuation of the drug. Results of six large studies have shown that these agents, in combination with aspirin and heparin, are effective for preventing ischemic complications associated with percutaneous coronary artery interventions. The benefits of these agents are less certain for management of patients with acute coronary syndromes who are not undergoing percutaneous intervention; studies have yielded conflicting results in terms of benefits, whereas in all studies there is a higher risk of bleeding compared with standard therapy. Only diabetes have consistently benefited from addition of one of these agents to standard therapy. Although coronary flow and reinfarction rates are improved by adding GP IIb/IIIa blockade to thrombolytic therapy in acute myocardial infarction, there does not appear to be any mortality benefit for combined therapy, and bleeding is increased by the combination. Four orally active agents have been tested and are not more effective when combined with aspirin or when given in place of aspirin for patients with acute coronary syndromes and may increase mortality. The observed increase in mortality may be due to increased bleeding and a possible paradoxical prothrombotic

effect owing to activation of platelets. GP IIb/IIIa inhibitors can cause bleeding similar to that seen with fibrinolytic therapy. They are contraindicated in patients with platelet counts of less than 100,000/ μ L.

Abciximab binds rapidly to the platelet receptors, followed by dose-dependent inhibition of platelet aggregation, accompanied by prolongation of the bleeding time. Bleeding time returns gradually to normal by 12 hours after a bolus injection, and platelet aggregation normalizes within 48 hours. A bolus dose of 0.25 mg/kg followed by a 10 μ g/min continuous infusion results in sustaining of the antiplatelet effect. This regimen has been used to prevent ischemic events in patients undergoing percutaneous transthoracic coronary angioplasty (PTCA). Major bleeding, especially in combination with full-dose heparin, can occur with abciximab. Reversible thrombocytopenia may occur (1–2%) as soon as 2 hours after starting therapy. Antibodies develop in about 6%. The antiplatelet effects of abciximab may be responsible for its therapeutic benefits, but it also inhibits thrombin formation, which may contribute to its antithrombotic properties.

Eptifibatid may cause less bleeding time prolongation than other GP IIb/IIIa inhibitors while causing equivalent inhibition of platelet aggregation, although this effect may have been related to methods of measurement. Like abciximab, eptifibatid can inhibit thrombin generation. Several dosing regimens have been used for eptifibatid, ranging from a 90–180 μ g/kg bolus followed by continuous infusion rates between 0.5 and 2 μ g/kg per minute for 18–24 hours. Bleeding time returns to normal 1 hour after stopping the infusion, whereas inhibition of platelet aggregation may last 4 hours or more. Eptifibatid does not appear to increase the overall rate of thrombocytopenia, but it may cause severe thrombocytopenia in a small number of patients.

Tirofiban is a nonpeptide inhibitor of the GP IIb/IIIa receptor that increases bleeding time and inhibits platelet aggregation. Its effects are augmented by simultaneous administration of aspirin. Onset of platelet inhibition is rapid (5 minutes) and returns to normal within 1.5–4 hours after discontinuation. Reported studies use bolus doses of 5–15 μ g/kg followed by infusions of 0.05–0.15 μ g/kg per minute. Severe reversible thrombocytopenia may complicate treatment with tirofiban.

Dextran

Dextran (available in high- and low-molecular-weight formulations) interferes with platelet function and fibrin polymerization and enhances plasmin-mediated fibrinolysis. Although dextran is a volume expander, hemodilution induced by dextran does not appear to influence its antithrombotic effects. Dextran is less effective than other agents for prevention of VTE. Dextran has been used primarily during carotid endarterectomy and microvascular procedures, but because there are few data from controlled clinical trials, firm recommendations about its role cannot be made. Dextran is not effective in the treatment of active thromboembolic disease.

Because of its volume-expanding properties, dextran should be avoided in patients at risk for volume overload. Dextran occasionally may cause hypersensitivity reactions.

Phosphodiesterase Inhibitors

Dipyridamole is the only phosphodiesterase inhibitor currently in use in the United States. Dipyridamole does not affect platelet aggregation but prolongs platelet survival time in patients with arterial thrombosis or prosthetic heart valves. Dipyridamole does not appear to be a particularly effective antithrombotic agent on its own, in part, owing to limited bioavailability. A new preparation with improved bioavailability combined with aspirin is available (200 mg dipyridamole/25 mg aspirin) and has demonstrated a significant reduction in recurrent stroke or death in patients with prior strokes or transient ischemic attacks (TIAs). The most common side effect of dipyridamole is headache; it does not appear to increase the risk of bleeding compared with placebo.

▶ Anticoagulants

The commonly used anticoagulants interfere with blood clot formation and extension by inhibiting coagulation factors (eg, unfractionated and low-molecular-weight heparin) or blocking the synthesis of biologically active coagulation factors (eg, vitamin K antagonists). These anticoagulants have demonstrated efficacy in a wide range of thromboembolic conditions, both venous and arterial. Indications for use of anticoagulants are expanding. The development of several new anticoagulants, including several direct thrombin inhibitors (DTIs), with different mechanisms of action and more favorable therapeutic indices has expanded the use of anticoagulant therapy and increased the therapeutic options for patients with complicated medical conditions.

Unfractionated Heparin (UFH)

UFH is derived from porcine intestine or bovine lung and is a mixture of molecules of heterogeneous size (MW 3000–33,000). Heparin binds to antithrombin (AT; also known as antithrombin III) and accelerates antithrombin's inhibition of activated thrombin and other coagulation factors (particularly activated factor X). Only about a third of administered UFH contains the specific pentasaccharide sequence that is necessary for binding to AT, and only those molecules have anticoagulant activity. An additional sequence of 13 saccharides is required for the AT-heparin complex to bind with thrombin; however, only the pentasaccharide sequence is required for inactivation of activated factor X. This heparin-AT interaction is the major mechanism for heparin's anticoagulant effect. At high concentrations, heparin also can bind directly to heparin cofactor II and inactivate thrombin. Heparin, particularly the high-molecular-weight fractions, also inhibits platelet function. In addition to its anticoagulant properties, heparin can increase

vascular permeability, inhibit vascular smooth muscle cell proliferation, and interfere with normal bone homeostasis.

Heparin is not well absorbed from the GI tract, so it must be administered parenterally (subcutaneously or intravenously). Subcutaneous UFH has lower bioavailability and should be accompanied by an intravenous bolus injection if immediate anticoagulation is required and a higher initial dose (about 10% greater than for IV administration).

The pharmacology of heparin is complex. It circulates bound to plasma proteins, binds to endothelial cells, where it is neutralized by platelet factor 4, and is taken up by macrophages and desulfated. There is a nonlinear dose-response relation and a dose-dependent biologic half-life. The route of elimination of heparin is not certain; plasma clearance is accelerated by the presence of acute thromboembolism. The rate of clearance of heparin depends on the size of the molecules; larger molecules are cleared more rapidly than low-molecular-weight molecules.

Although there is a relationship between the dose of UFH and its efficacy (as well as safety), the variability of response to UFH requires monitoring and adjustment of dose. Monitoring of UFH activity is based on its biologic effect on *in vitro* coagulation. UFH prolongs three important *in vitro* coagulation parameters: the thrombin time (TT), the prothrombin time (PT), and the activated partial thromboplastin time (aPTT). The TT is the most sensitive

indicator of heparin's effect and may be used to detect even small amounts of heparin. The TT is useful to differentiate heparin's effect from that of circulating inhibitors of coagulation, which are phospholipid-dependent and therefore will result in a prolonged aPTT but normal TT. The PT is the least sensitive measure of heparin's effect and is usually normal unless the patient is also receiving oral anticoagulant treatment or is overanticoagulated. The aPTT is intermediate in sensitivity and is the most commonly used test for monitoring UFH. However, recent clinical studies have found that the aPTT does not always reliably predict response to therapy. In addition, commercial reagents used in the aPTT assay have variable sensitivity to heparin, which makes monitoring UFH therapy of uncertain accuracy. Nevertheless, the aPTT is still the most commonly used method for monitoring response to UFH. In most clinical situations, the desired aPTT while receiving UFH is one and one-half to two times the control time. Suggested adjustment of UFH dose based on aPTT results is outlined in Table 39-3 and ideally should be based on calibration of the aPTT reagent to correspond to therapeutic heparin levels (0.3–0.7 IU/mL). Dose modifications should be made when UFH is used in combination with thrombolytic therapy or platelet GP IIb/IIIa antagonists. When UFH is given subcutaneously, peak plasma levels are reached after 3 hours.

Table 39-3. Unfractionated heparin, dosing and adjustment.

A. Initial Dose			
Indication	Loading Dose by IV Bolus	Initial Maintenance Infusion*	
Venous thromboembolism	80 units/kg	18 units/kg/h	
Unstable angina or acute myocardial infarction	60–70 units/kg to maximum of 5000 units	12–15 units/kg/h (maximum 1000 units/h)	
Concomitant alteplase for acute STEMI	60 units/kg to maximum of 4000 units	12 units/kg/h (maximum 1000 units/h)	
B. Subsequent Dose Adjustments Based on aPTT (First aPTT Obtained 6 hours after Starting Unfractionated Heparin)			
aPTT (s)	Rate Change (units/kg/h)	Additional Action	Obtain Next aPTT
<35	+4	Rebolus 80 units/kg	6 h
35–45	+2	Rebolus 40 units/kg	6 h
46–70†	0	None	Following morning
71–90	–2	None	6 h
>90	–3	Hold infusion 60 min	6 h

*Unfractionated heparin, 25,000 units in 250 mL D₅W (100 units/mL).

†The therapeutic range for aPTT should be standardized to correspond to therapeutic anti-factor Xa levels (0.3–0.7 IU/mL).

Table 39-4. Indications and administration of anticoagulants in selected settings.*

Prevention of venous thromboembolism	Low risk (patients <40 with no risk factors undergoing minor surgery): early mobilization. Moderate risk (<40 with risk factors for VTE or patients age 40–60): UFH every 12 hours, LMWH (<3400 units/day), IPC. High risk (patient >60, 40–60 with risk factors): UFH every 8 hours, LMWH (>3400 units/day), or IPC. Highest risk (multiple risk factors, hip or knee arthroplasty, hip fracture surgery, major trauma, spinal cord injury): LMWH (>3400 units/day), fondaparinux, oral anticoagulant (INR 2–3), or IPC combined with UFH every 12 hours or LMWH daily.
Treatment of acute venous thromboembolism	Adjusted-dose UFH. Monitor and adjust according to Table 39-3; OR full-dose LMWH (dose varies by preparation). Begin oral anticoagulation on day 1. Continue UFH or LMWH until fully anticoagulated with oral agent (overlap with oral anticoagulant in therapeutic range at least 2 days, usually 4–5 days total heparin).
Coronary artery disease (if no contraindication to anticoagulation)	Non-ST-segment acute coronary syndrome (NSTEMI). Use UFH in combination with antiplatelet therapy. Dose as in Table 39-3, target aPTT between 50 and 75 seconds [†] or LMWH (dose varies with preparation). Acute MI with ST-segment elevation (STEMI) or new left bundle branch. Use UFH in combination with fibrinolytic. Dose as in Table 39-3, target aPTT between 50 and 75 seconds, administer for 48 hours (longer in patients at high risk for systemic or venous thromboembolism— anterior MI, pump failure, atrial fibrillation, left ventricular thrombus, previous thromboembolism) or LMWH (dose varies with preparation).
Chronic outpatient use (pregnancy, warfarin failure)*	UFH at 12,000 units SC twice daily. Monitor aPTT 6 hours after injection and adjust subsequent dose to maintain aPTT 50–85 seconds if LMWH is unavailable.

*Choice of specific regimen should take into account individual patient characteristics, including risk of thrombosis, risk of bleeding with anticoagulation and renal function.

[†]7th ACCP Conference Guidelines

UFH is effective for prevention and treatment of VTE (DVT and PE; Table 39-4), mural thrombus after myocardial infarction, unstable angina, and acute myocardial infarction. UFH is usually combined with antiplatelet agents (eg, aspirin, clopidogrel, and more recently, GP IIb/IIIa receptor inhibitors) in the treatment of acute ischemic heart disease. UFH has been used in conjunction with thrombolysis for coronary artery occlusion; however, recent studies have suggested that UFH may increase the risk of bleeding with little added benefit over thrombolysis, particularly in patients receiving aspirin. UFH is used alone or in combination with GP IIb/IIIa inhibitors during percutaneous coronary intervention (PCI). UFH is not effective for prevention of restenosis after coronary angioplasty, and prolonged infusion of UFH after completion of PCI increases bleeding without reducing ischemic events. Guidelines for use of UFH in coronary artery disease have been proposed (see Table 39-4); however, ongoing trials probably will result in modification of these guidelines as results of studies using newer agents and combinations of agents are reported. UFH is also used during extracorporeal circulation of blood (in cardiovascular surgery and hemodialysis), prior to cardioversion in atrial fibrillation (if no mural thrombus is detected by transesophageal echocardiography), in some cases of disseminated intravascular coagulation, and to treat fetal growth retardation in pregnant women. Heparin (UFH or low-molecular-weight heparin) is generally the anticoagulant of

choice during pregnancy because it does not cross the placenta and is not teratogenic. Heparin is also used when chronic oral anticoagulation (eg, in patients with heart valves, atrial fibrillation, and recurrent thromboembolic disease) is interrupted for invasive procedures or when recurrent thromboembolism occurs despite adequate oral anticoagulation.

Multiple factors modify the anticoagulant effects of UFH (Table 39-5), so the precise dose of UFH in a given patient cannot be predicted in advance. When immediate anticoagulation is required, an intravenous bolus is given followed by continuous intravenous infusion or intermittent subcutaneous UFH (see Table 39-3). Continuous infusion is used more often because of its lower risk of hemorrhage, but intermittent subcutaneous UFH may be used in selected situations (eg, thromboprophylaxis). Long-term use of subcutaneous UFH during pregnancy or other conditions requiring long-term outpatient heparin therapy has been replaced with subcutaneous low-molecular-weight heparin. Careful monitoring of the aPTT is essential for patients maintained on UFH to ensure adequate anticoagulant effect without undue risk of hemorrhage (see Table 39-3). Larger doses of UFH are required to treat established thromboembolic disease than for prevention of VTE possibly because thrombin bound to fibrin is much less sensitive to inhibition by UFH than circulating thrombin and because of increased plasma reactive proteins, which bind and neutralize UFH. Heparin resistance (requirement of

Table 39-5. Endogenous factors modifying the anticoagulant effect of heparin.

Factor	Mechanism
Platelets	Bind and protect factor Xa from heparin. Produce platelet factor 4 and neutralizes heparin.
Fibrin	Binds thrombin and protects it from heparin.
Endothelial surfaces	Bind thrombin and protects it from heparin. Bind and neutralize heparin via displaced platelet factor 4.
Plasma proteins	Bind and neutralize heparin.
Antithrombin (antithrombin III)	Hereditary or acquired deficiency state results in heparin resistance.

very large doses of heparin to prolong the aPTT) may occur owing to the presence of elevated factor VIII or fibrinogen levels, increased heparin-binding proteins, increased heparin clearance, or AT deficiency. Measuring anti-factor Xa levels may be a better alternative for monitoring heparin therapy in these patients. It is not necessary to cause prolongation of the aPTT for prevention of VTE in moderate-risk patients, although in very high-risk patients—for example, those undergoing orthopedic surgery—prolongation of the aPTT to the upper end of normal is required to prevent thrombosis.

Hemorrhage is the most common complication of heparin therapy. Hemorrhage occurs more frequently with high-dose heparin therapy and when the aPTT is prolonged beyond the therapeutic range. Intermittent bolus UFH results in a higher rate of hemorrhage than continuous-infusion UFH, which may be due to the higher total daily dose required to maintain a therapeutic aPTT with intermittent administration. Concomitant use of aspirin or other antiplatelet drugs increases the risk of hemorrhage, but in patients with coronary thrombosis, the risk is felt to be acceptable. The presence of other hemostatic defects, chronic alcoholism, and the overall general condition of the patient also influence the risk of hemorrhage with heparin therapy.

Management of hemorrhage associated with UFH varies depending on the severity of the bleeding and the degree of the anticoagulant effect, as measured by the aPTT. If the indication for anticoagulation is strong, continuation of UFH with close monitoring of the aPTT and blood counts may be acceptable for patients with trivial bleeding. If minor bleeding is associated with an aPTT that is markedly prolonged above the therapeutic range, withholding UFH until the aPTT falls into the desired range (usually within a few hours) is recommended if the patient is stable, with clinical evaluation of the patient before resuming UFH for evidence of continued hemorrhage. Serious bleeding requires cessation of

UFH therapy, whereas truly life-threatening bleeding (eg, intracranial hemorrhage or hemorrhage associated with hemodynamic instability) may require immediate reversal of UFH with protamine sulfate. One milligram of protamine sulfate per 100 units of UFH (50 mg protamine sulfate for a 5000-unit dose of UFH), given intravenously over 10 minutes (to avoid hypotension), will neutralize UFH given 30 minutes earlier. The dose of protamine sulfate should be reduced depending on the time interval from UFH administration (eg, give 50% of the dose if 60 minutes have elapsed and 25% if 2 hours have elapsed), and for reversal of continuous-infusion UFH, the dose of protamine sulfate should be estimated based on the UFH infused in the preceding 2–3 hours. Since protamine sulfate has a shorter half-life than UFH, the dose may need to be repeated. Side effects of protamine sulfate include hypotension with rapid administration and prolongation of the aPTT (with possible bleeding) if excess protamine is given. Recombinant platelet factor 4 (2.5–5 mg/kg) has been reported to be effective for reversal of UFH as well but is not available everywhere.

Heparin-induced thrombocytopenia (HIT) occurs commonly (5–15%) with therapeutic UFH administration, less commonly with prophylactic UFH, and appears to be more common with UFH derived from bovine lung than that from porcine intestine. The onset of thrombocytopenia is usually between 3 and 15 days after initiation of treatment with UFH (median 10 days) but may be as short as a few hours in a previously sensitized individual, particularly if the prior treatment with UFH was within 3 months of reexposure. Resolution of thrombocytopenia occurs within 4–5 days of discontinuation of UFH.

Thrombocytopenia in this disorder is immunologically mediated. Heparin molecules greater than MW 4000 bind to platelet factor 4 and form complexes to which heparin-induced antibodies bind. Platelets are activated, resulting in increased thrombin generation. Thrombosis, usually associated with very severe thrombocytopenia, occurs in about 0.4% of patients.

Diagnosis is usually made on clinical grounds, but serologic tests are available to confirm the presence of HIT antibodies. Although these tests are sensitive for the presence of HIT antibodies, they are less specific and therefore must be interpreted with caution. Prevention of this disorder by shortening the duration of UFH administration is important. Initiation of oral anticoagulants simultaneously with UFH in patients who will require long-term anticoagulation will permit a shorter course of UFH and is highly recommended for patients requiring long-term anticoagulation. Frequent (every 1–2 days) monitoring of the platelet count is important for identification of patients before thrombosis occurs. The use of low-molecular-weight heparin (or heparinoids) appears to be associated with a lower risk of heparin-induced thrombocytopenia as well.

Management of HIT is outlined in [Table 39-6](#). Stopping UFH is the most common intervention, but there appears to be a marked risk in clinically significant thrombosis in the

Table 39-6. Management of heparin-induced thrombocytopenia.

1. Monitor platelet counts during heparin therapy every 1–2 days.
2. Exclude other causes of acute thrombocytopenia (other drugs, sepsis, DIC, pseudothrombocytopenia).
3. Evaluate for thrombotic complications (iliofemoral artery occlusion, cerebral infarction, and myocardial infarctions are the most common; other arterial thromboses and venous thromboses occur less commonly).
4. Do not administer platelet transfusions (increased risk of thrombosis).
5. Discontinue heparin (including heparin flushes) for platelet count below 100,000/ μ L.
6. Administered alternative anticoagulant until the platelet count has recovered and oral anticoagulation has taken effect, if long-term anticoagulation is required. Overlap alternative anticoagulant with warfarin for a minimum of 5 days.*
7. Consider lower extremity ultrasound to assess for subclinical thrombosis.

Anticoagulant	Dose/Monitoring
Lepirudin (a recombinant hirudin derivative)	0.4 mg/kg (up to 44 mg) IV bolus followed by 0.15 mg/kg/h. Adjust dose to maintain aPTT 1.5–2.5 times normal range. May omit bolus in patients with renal failure.
Danaparoid (a heparinoid, available outside the United States)	2250 units IV bolus followed by 400 units/h for 4 hours, then 300 units/h for 4 hours, then 150–250 units/h. Monitor anti-factor Xa activity (if available), maintain at 0.5–0.8 anti-factor Xa units/mL
Argatroban (a selective direct thrombin inhibitor)	2 μ g/kg/min. Adjust dose to maintain aPTT 1.5–3 times control (but <100 seconds)
Bivalirudin [†] (an analog of hirudin)	0.2 mg/kg/h. Adjust dose to maintain aPTT 1.5–2.5 times baseline.
Fondaparinux (a synthetic pentasaccharide)	Not approved for HIT but may be useful as an alternative to heparin in patients with preexisting thrombocytopenia to avoid the development of HIT.

*Do not administer warfarin in patients with heparin-induced thrombocytopenia and deep venous thrombosis until platelet count is >100,000 (potential risk for venous-limb gangrene). If anticoagulant therapy is necessary in a patient with a suspected history of heparin-induced thrombocytopenia without complicating thrombosis, laboratory assessment for heparin-dependent antibodies (platelet activation assay or antigen assay) may help determine risk of reexposure. If negative, short-term treatment with heparin along with careful monitoring may be acceptable. Patients with a history of heparin-induced thrombocytopenia-associated thrombosis should be considered for alternative anticoagulants.

[†]FDA-approved for other indications (angioplasty).

week after cessation of UFH. Warfarin may aggravate thrombosis and should be delayed until the platelet count is over 100,000/ μ L. There are two anticoagulants currently approved in the United States for use in HIT—lepirudin (a recombinant hirudin) and argatroban (a selective direct thrombin inhibitor)—that should be considered even without overt thrombosis. Bivalirudin (another hirudin analogue), which is approved in the United States as an alternative to heparin in patients undergoing percutaneous coronary interventions, appears to be promising, and because it has only minor renal excretion, it may be preferable to lepirudin in patients with significant renal impairment. Anticoagulation with the alternative agent should be continued until the platelet count has returned to normal. Ancrod also has been used for treatment of HIT but is not available in the United States.

If anticoagulant therapy is necessary in a patient with a suspected history of HIT (without complicating thrombosis), heparin-dependent antibodies (platelet activation assay or antigen assay) may help to determine the risk of reexposure to heparin. If negative, short-term treatment with UFH with careful monitoring may be acceptable. Patients with a

history of HIT-associated thrombosis should be considered for treatment with anticoagulants other than heparin.

Other adverse effects of UFH include transient elevation of liver function tests (particularly ALT and AST), hyperkalemia, osteoporosis (owing to heparin binding to osteoblasts that release factors that stimulate osteoclasts; clinically significant with long-term UFH administration), skin necrosis, alopecia, hypersensitivity reactions, and hypoadosteronism.

Low-Molecular-Weight Heparins (LMWHs)

LMWHs are prepared by depolymerization of UFH by chemical or enzymatic means. Like UFH, LMWH accelerates antithrombin-mediated inactivation of factor Xa, but unlike UFH, LMWH does not inactivate thrombin because it lacks the additional 13 saccharides required for heparin to form a complex with AT. Because it binds less strongly to plasma proteins, cells, and thrombin, LMWH has greater bioavailability at low doses, a longer half-life, and a more predictable anticoagulant response than UFH. LMWH can be administered subcutaneously at a fixed dose (adjusted for weight)

once or twice daily (dosing depends on specific preparation) and does not require laboratory monitoring using the aPTT. These two factors make outpatient use of LMWH possible in selected situations. LMWH preparations are excreted renally, and the biologic half-life is prolonged in patients with renal failure. The incidence of HIT appears to be less with LMWH than with UFH. LMWH has been used in some patients with HIT, but thrombocytopenia may persist.

Several LMWH preparations are now approved for use in the United States: enoxaparin, dalteparin, and tinzaparin. Selection of one preparation over another is difficult at present because few studies comparing different preparations and dosing regimens have been performed. Cost ultimately may be as important as any other factor for choosing which LMWH to use. The major advantage of LMWHs compared with UFH relates to their convenience of administration, predictable anticoagulant response at a weight-adjusted fixed dose, and lack of need for laboratory monitoring. Exceptions include renal failure and obesity, in which cases monitoring may be useful. In patients with creatinine clearances of less

than 30 mL/min, anti-factor Xa activity accumulates with repeated dosing, although this varies among the different LMWHs. Use of UFH may be preferable in these patients, but when LMWH is needed, decreasing the dose and monitoring anti-factor Xa activity should be performed to prevent over-anticoagulation. Few studies have addressed dosing in very obese patients. There does not appear to be an increased risk of bleeding during therapeutic anticoagulation with LMWH in obese patients, but most studies have included very few markedly obese patients. Measuring anti-factor Xa activity 4 hours after subcutaneous administration may provide useful information for dose reduction. Conversely, since obesity is an independent risk factor for thromboembolism, weight-based dosing or a 25% increase in fixed-dose LMWH may be preferable for thromboprophylaxis in very obese patients. A comparison of UFH and LMWH is presented in [Table 39-7](#).

LMWH is effective for prevention of VTE in patients undergoing major orthopedic procedures (eg, hip fracture or replacement or knee replacement) or neurosurgery, after major trauma (in patients eligible for anticoagulation), and

Table 39-7. Comparison of unfractionated heparin and low-molecular-weight heparin.

	Unfractionated Heparin (UFH)	Low-Molecular-Weight Heparin (LMWH)
Plasma half-life	Dose-dependent; range 1-2.5 hours	Increased; range 2-6 hours; prolonged in renal failure
Bioavailability	Lower	Better
Molecular weight: range (Mean)	3000-30,000 (15,000)	100-10,000 (4500-5000)
Binding properties: proteins, cells (macrophages, endothelium, osteoblasts)	High	Low
Relative inactivation: Xa/IIa	Lower	Higher (five to six times compared with unfractionated heparin)
aPTT	Prolonged	Not prolonged
Efficacy	Equivalent	Equivalent (most situations)
Major bleeding	Approximately equivalent: 0-7% higher (fatal, 0-2%), higher in acute stroke	Approximately equivalent: 0-3% (fatal, 0-0.8%), higher in acute stroke
Heparin-induced thrombocytopenia	2.5-6%	Decreased
Osteoporosis	30%: decreased bone density; 15%: vertebral fractures 2-3%: vertebral fractures in pregnancy	Decreased 2.5%: vertebral fractures
Cost	\$15/d, full dose	>\$100/d, full dose
Reversibility with protamine sulfate (PS)	Good: 1 mg PS/100 units UFH (bolus dose); estimate for infusion based on total amount in preceding 2-3 hours.	Fair, not reliable: <8 hours since LMWH at 1 mg/100 anti-factor Xa units (1 mg enoxaparin = 100 units) >8 hours: smaller dose. Repeat with 50% of original dose if persistent bleeding.

in high-risk medical patients (see Table 39-4). LMWH is as effective as UFH in the treatment of DVT and PE. It can be administered to outpatients with acute DVT, but treatment of PE may require hospitalization. LMWH is equivalent in efficacy to warfarin for prevention of recurrent DVT following acute DVT, with a lower incidence of minor bleeding, but it is much more expensive. There also may be a higher rate of rebound thromboembolism after discontinuation of the drug than with warfarin.

The role of LMWH in coronary artery disease continues to evolve as studies in various clinical syndromes are completed. LMWH is more effective than UFH in combination with aspirin in the acute treatment of unstable angina and non-ST-segment-elevation myocardial infarction. LMWH in combination with thrombolytic therapy for acute myocardial infarction has not been studied as extensively as UFH and cannot be recommended until adequate studies demonstrate efficacy and safety. LMWH may be used as an alternative to UFH in patients undergoing PCI but is more difficult to monitor and adjust than UFH. LMWH is not effective for prevention of restenosis after coronary angioplasty and does not reduce post-PCI ischemic events when administered following PCI. The use of LMWH is not recommended for thromboprophylaxis in patients with prosthetic heart valves but may be used as bridging therapy for these patients when oral anticoagulation is temporarily interrupted.

Complications of therapy with LMWH are similar to those seen with UFH heparin, with the exceptions of thrombocytopenia and osteoporosis, which occur less often with LMWH. There may be less major bleeding in patients treated for DVT with LMWH, but in most other situations the risk is approximately equivalent to that seen with UFH. The use of LMWH and heparinoids in the setting of spinal or epidural anesthesia—or with spinal puncture—may cause bleeding in the spinal column with subsequent prolonged or permanent paralysis. If excessive bleeding does occur, laboratory assessment with a anti-factor Xa heparin assay can be performed. The usual therapeutic range is between 0.5 and 1.0 unit/mL. When heparin anti-factor Xa is greater than 1.0 unit/mL, the aPTT also may be prolonged. Protamine sulfate is much less effective for reversing the effect of LMWH than UFH, but if serious bleeding occurs, protamine sulfate, 1 mg per 100 anti-factor Xa units of LMWH (1 mg of enoxaparin = 100 anti-factor Xa units), may be given, and a smaller (50% of the original dose) dose may be given if bleeding continues. Activated factor VII therapy recently has been reported to reverse bleeding owing to LMWH, but has not been adequately evaluated.

► New Anticoagulants

Direct Thrombin Inhibitors

Lepirudin (a recombinant hirudin derivative), bivalirudin (an analogue of hirudin), and argatroban are direct thrombin inhibitors that do not depend on antithrombin to exert

their anticoagulant effects. Unlike heparin, these agents bind to free and clot-bound thrombin, do not bind to plasma proteins, and are not neutralized by platelet factor 4. Hirudin and argatroban are approved for use in HIT; bivalirudin is approved for use as an alternative to heparin in patients undergoing PCI (see Table 39-6). Studies of these agents in other clinical settings have not shown clear advantages over heparin, and there are no antidotes available to reverse the anticoagulant effects of these drugs should bleeding occur. Therefore, use of these agents has been restricted to the specific indications listed earlier. Lepirudin is cleared extensively by the kidneys, requiring significant dose reduction and careful monitoring in patients with renal impairment. Bivalirudin has minor renal excretion and may be useful for patients with impaired renal function as an alternative to lepirudin. Argatroban is a carboxylic acid derivative that interferes with thrombin by binding to its active site. Several other agents in this class are under investigation, some of them well absorbed from the GI tract (eg, ximelagatran) with a predictable anticoagulant response, making laboratory monitoring unnecessary.

Indirect Thrombin Inhibitors

A. Pentasaccharide Analogues—These are synthetic analogues of the pentasaccharide sequence responsible for binding heparin to antithrombin. They form a complex with antithrombin that binds to and inhibits factor Xa; the pentasaccharide is then released and can be reused. Fondaparinux is the only agent in this class approved for use in the United States for thromboprophylaxis following major orthopedic surgery. It is administered subcutaneously once a day, is excreted renally, and cannot be given to patients with creatinine clearances of less than 30 mL/min. Because it does not bind to platelet factor 4, it should not cause thrombocytopenia. Fondaparinux is more effective than enoxaparin for prevention of thromboembolism following major orthopedic surgery. The rate of major bleeding may be higher than with enoxaparin but appears to be similar if the first dose is given 6–8 hours after surgery. Fondaparinux is as effective as UFH or LMWH in the initial treatment of VTE and is under investigation for patients with acute coronary syndromes. There is no antidote for fondaparinux, but severe, uncontrolled bleeding is potentially treatable with recombinant factor VIIa. However, this extremely expensive agent is not available everywhere.

B. Heparinoids—Heparinoids are low-molecular-weight glycosaminoglycuronans derived from porcine intestinal mucosa. Danaparoid is available only outside the United States for treatment of HIT and is a mixture of heparan sulfate, dermatan sulfate, and chondroitin sulfate. The small heparan sulfate portion of this drug (4% of the total) has a high affinity for antithrombin and is responsible for the major anticoagulant effect of danaparoid. Dermatan sulfate also mediates development of heparin cofactor II–thrombin complexes and contributes to the anticoagulant effect. Danaparoid has a higher ratio of anti-factor Xa activity compared with

anti-factor IIa activity (20:1) than UFH (1:1) and LMWH (2–4:1) and has fewer effects on platelet function than UFH. It is similar to LMWH in its anticoagulant effects and has minimal effect on coagulation parameters (ie, aPTT, PT, and thrombin time), but it has certain structural differences (eg, contains galactosamine, absent in LMWH) that distinguish it from LMWH. A functional anti-factor Xa assay using danaparoid as the standard can be used to monitor the anticoagulant effect of danaparoid when the agent is given for more than 3 days. Danaparoid is as effective as lepirudin in the treatment of HIT with less major bleeding. Danaparoid does not cross the placenta, so it should be safe for treatment of HIT during pregnancy.

▶ Defibrinating Agents

Ancrod, an enzyme derived from the Malayan pit viper, is an anticoagulant that cleaves fibrinogen and causes hypofibrinogenemia. Ancrod is licensed for use in Canada. Ancrod is an effective anticoagulant that apparently causes minimal excess bleeding. It is not associated with the development of thrombocytopenia, is an excellent alternative anticoagulant for patients with HIT, and has shown some promise in the treatment of acute ischemic stroke. An initial dose of 1 unit/kg is infused intravenously over 8–12 hours, followed by daily maintenance doses adjusted for the level of fibrinogen (see Table 39–7). Neutralizing antibodies develop with long-term use, thus limiting its usefulness to situations in which only short-term anticoagulation is required. An antivenom is available to reverse its effect, and cryoprecipitate also may be required for fibrinogen replacement if excessive bleeding occurs.

▶ Oral Anticoagulants

Warfarin

Warfarin (a 4-hydroxycoumarin compound) is the most commonly used oral anticoagulant in North America. Warfarin interferes with the metabolism of vitamin K, inhibiting reduction of vitamin K to its active form, vitamin KH_2 , in a two-step process in the liver. Vitamin KH_2 is essential for posttranslational modification (γ -carboxylation) of the vitamin K–dependent coagulation factors and natural anticoagulants (eg, factors II, VII, IX, and X and proteins C and S). Decreased carboxylation of these important proteins impairs their biologic function by impeding calcium-binding capability and induces an anticoagulant effect. Reduced protein C and S levels have the potential for causing thrombosis, but in most situations, the anticoagulant effect predominates.

Warfarin is absorbed rapidly from the GI tract, reaching peak plasma levels in 90 minutes, circulates bound to plasma proteins (97% albumin-bound), is metabolized in the liver, and is excreted in urine and bile. The anticoagulant effect of warfarin is not immediate. Until carboxylated coagulation

factors are adequately depleted, blood coagulation is normal. The vitamin K–dependent proteins have plasma half-lives ranging from 6 hours (factor VII) to 72 hours (prothrombin and factor II). Proteins C and S have relatively short half-lives (~8 hours). Because levels of factor VII, protein C, and protein S fall at about the same time—and 1–3 days before depletion of the other coagulation factors—a relative hypercoagulable state may exist in the first 1–2 days after initiation of warfarin. Although an observable anticoagulant effect usually occurs after 2 days, the full antithrombotic effect is delayed for 4–5 days. The delayed effect may be of importance for patients with HIT and those with inherited or acquired deficiency of protein C or protein S, who may be particularly susceptible to warfarin-induced skin necrosis.

Whenever rapid anticoagulation is needed or in patients with known thrombophilic states (eg, protein C or S deficiency), heparin (UFH or LMWH) should be given for at least 4 days at the start of warfarin therapy until the international normalization ration (INR) is in the therapeutic range. A loading dose of warfarin should not be given. The initial dose should be between 5 and 10 mg for most patients (lower for patients at high risk of bleeding or elderly patients), with subsequent dosing based on results of the INR. The average dose required to achieve a therapeutic level by 4–5 days is 5 mg daily.

The anticoagulant effect of warfarin is assessed by *in vitro* coagulation tests, the PT and aPTT. The therapeutic range for warfarin depends on the indication for which it is used, but at usual doses, the aPTT is normal or minimally prolonged, whereas the PT is maintained at 1.3 (low intensity) to 2.5 (high intensity) times control (PT ratio). Because of marked interlaboratory variability in the sensitivity of the thromboplastin reagents used in the PT assay, a standardized approach has been adopted. This approach requires calibration of the thromboplastin to a reference preparation using the international sensitivity index (ISI). Results then are reported as the INR based on a formula comparing the PT ratio obtained with the laboratory thromboplastin with that with the reference thromboplastin. The therapeutic range of warfarin for most indications ranges from an INR of 2–3 (low intensity) to an INR of 2.5–3.5 (high intensity). If the thromboplastin reagent used by a clinical laboratory remains constant, the PT and INR will be predictably related to each other. Substitution of a reagent with either more or less sensitivity, however, may dramatically alter the relationship of the PT and INR. The INR is more reliable than the PT and is the preferred method of reporting for warfarin monitoring. It is important to fill the collection tube adequately when measuring the INR because the concentration of the citrate anticoagulant in the test sample affects the INR. Underfilling the tube may lead to erroneously high INR results.

Although there is a direct dose-response relation, there is marked variation in anticoagulant response to warfarin among patients. There is also significant variability of anticoagulant response during long-term therapy in individual patients. This variability results from many factors, including

endogenous stores of vitamin K, changes in dietary intake or recent therapeutic administration of vitamin K, genetically determined differences in warfarin sensitivity, use of antibiotics (which may impair synthesis of vitamin K by intestinal flora) or other drugs (which may increase or decrease warfarin effect), the presence of liver disease, fat malabsorption (including obstructive jaundice), hypermetabolic states, pregnancy, poor patient compliance, and laboratory inaccuracy. In addition, elderly patients appear to be more sensitive to warfarin, possibly owing to decreased clearance of warfarin with age. Because of this marked variability, continued monitoring is required, and most patients require dosage adjustments periodically. Initial monitoring should be performed daily until therapeutic and then two or three times weekly until the INR is stable. When the PT or INR is stable, monitoring every 4 weeks is usually adequate, although more frequent monitoring may increase the amount of time the PT or INR is in the therapeutic range (time in therapeutic range [TTR]). Intensity of therapy and TTR are important determinants of therapeutic efficacy of warfarin. More frequent monitoring is advisable for elderly patients, those who take multiple medications, or those who are at higher risk for bleeding.

Although patients taking warfarin are commonly instructed to limit their intake of vitamin K–rich vegetables, it is preferable to suggest that the intake of these vegetables remain relatively constant in the diet because the nutritional benefits of these foods unrelated to vitamin K may be important. Numerous drugs influence the anticoagulant effect of warfarin through multiple mechanisms, and bleeding unrelated to the anticoagulant effect of warfarin may result from effects on other hemostatic pathways (eg, aspirin and other antiplatelet drugs and heparin), as well as effects on intestinal mucosa (eg, aspirin). Before beginning warfarin therapy—or before adding new medications when a patient is taking warfarin—a review of potential interactions should be undertaken (readily available in pharmaceutical handbooks such as the *Physicians' Desk Reference* or other drug compendiums). The frequency of monitoring should be increased in patients taking warfarin whenever new medications are started to allow proper dose adjustments.

The decision to use long-term oral anticoagulation is based on an assessment of the risk to the patient of bleeding compared with the potential benefits related to its anticoagulant effect. Warfarin is effective for management of multiple thromboembolic conditions and is used when long-term anticoagulation is required. Candidates for long-term anticoagulation include those with artificial heart valves, chronic atrial fibrillation, left ventricular mural thrombus, recurrent cerebrovascular ischemia, and antiphospholipid antibody syndrome.

The role of warfarin is well established and accepted in the prevention and treatment of VTE. Long-term use is effective for prevention of recurrent VTE. Treatment for 3–6 months reduces the risk of recurrent VTE compared with shorter durations of treatment. Patients with temporary or

reversible risk factors for VTE, such as surgery or trauma, have a lower risk of recurrence and can be managed with 3 months of warfarin. For patients with idiopathic VTE, extended treatment duration beyond 6 months reduces the risk of recurrence but carries an increased risk of serious bleeding, and when discontinued, the risk of recurrence increases. Therefore, treatment duration for patients with idiopathic VTE must take into consideration individual patient characteristics and preferences. Two years of warfarin therapy has been shown to reduce the risk of recurrent VTE significantly (from 8.6–2.2%) in the subset of patients with factor V Leiden or prothrombin 20210A mutation compared with 6 months. Patients with antiphospholipid antibodies have an increased risk of recurrent VTE and mortality (29% and 15%, respectively) and should be considered for extended duration of treatment with warfarin. Patients with cancer have a higher risk of recurrent VTE and also should be considered for longer term treatment with warfarin. Following a second VTE, indefinite anticoagulation with warfarin reduces the risk of recurrence compared with 6 months of therapy from 20.7–2.6% but is associated with a threefold increase in the risk of major bleeding. Careful patient selection and monitoring are needed to balance the benefits of longer-duration anticoagulation with its risks.

Warfarin is effective for prevention of systemic or cerebral emboli in patients with atrial fibrillation, artificial heart valves, left ventricular mural thrombus, or very low left ventricular ejection fractions. It is also effective for long-term treatment of patients with peripheral arterial embolism and may prevent thrombosis of peripheral arterial bypass grafts in high-risk patients. Antiplatelet agents are preferred over warfarin for the prevention of acute myocardial infarction in patients with peripheral arterial disease; for prevention of stroke, recurrent infarction, or death in patients with acute myocardial infarction; and for prevention of myocardial infarction in men at high risk, but cardiac mortality is reduced in the highest-risk patients by combining low-intensity warfarin with aspirin. This combination carries a risk of cerebral hemorrhage if blood pressure is not monitored and controlled. Warfarin is not better than aspirin for prevention of recurrent stroke, even in patients taking aspirin at the time of the stroke, but is still recommended by some neurologists for patients with recent noncardiac embolic strokes or TIAs. Low-dose warfarin (0.5–1 mg/day) is often used to prevent thrombosis of vascular access catheters in cancer patients and to prevent thrombosis associated with thalidomide therapy, but efficacy has not been established for these situations.

The target INR for most indications is 2–3. A higher INR (2.5–3.5) is recommended for patients with certain prosthetic heart valves (eg, tilting-disk and bileaflet mitral valves and caged-ball or disk valves). Higher-intensity warfarin may be considered for patients with recurrent VTE occurring on therapeutic doses of warfarin or thrombosis associated with antiphospholipid antibodies (although this remains controversial). Lower-intensity warfarin treatment

(INR 1.5) is recommended when it is combined with aspirin for prevention of fatal coronary events in patients at very high risk.

Bleeding is the most common complication of warfarin and is related to the intensity of the anticoagulation (especially in patients over 75 years of age), concomitant use of aspirin, coexisting hemostatic defects (including renal failure), age over 75 years, history of GI bleeding, cancer, presence of anemia, and history of stroke or atrial fibrillation. If GI bleeding or hematuria occurs when the INR is less than 3.0, an underlying GI or renal lesion should be suspected, although spontaneous bleeding may occur when the INR is in the high-intensity range or above. Prolonged use (lifelong) also may increase the cumulative risk of bleeding. Patients who consume excess alcohol or those who suffer from frequent falls have a much higher risk of serious bleeding. There are rare patients who have been identified to have mutations in factor IX that cause an unusual susceptibility to bleeding without prolongation of the INR.

Overdosage of warfarin (accidental or intentional) may lead to serious bleeding. Management of hemorrhage associated with warfarin is similar to that encountered with heparin in terms of using clinical criteria to determine the urgency of the situation. Mild excess prolongation of the INR (<5.0) without hemorrhage should be managed expectantly by withholding warfarin until the INR returns to the desired range and then resuming at a lower dose. Serious bleeding may require immediate reversal with fresh-frozen plasma (2–3 units) to provide functional vitamin K–dependent factors. Because vitamin K is a fat-soluble vitamin that is stored in the liver, reversal of warfarin effects with vitamin K may

result in resistance to subsequent warfarin therapy. Low-dose oral vitamin K₁ (phytonadione, 1–2.5 mg) will lower the INR to less than 5 in patients with INR values between 5 and 9, and 5 mg will correct INR values of greater than 9 in the majority of patients within 24 hours without inducing warfarin resistance. Intravenous vitamin K₁ should be reserved for patients with an urgent need to reverse anticoagulation—particularly patients with life-threatening hemorrhage not controlled by fresh frozen plasma who will not require subsequent warfarin therapy.

Patients receiving chronic warfarin therapy undergoing invasive procedures likely to cause bleeding may require interruption of warfarin. Depending on the patient's risk for perioperative thromboembolism, coverage with UFH or LMWH may be necessary until the patient resumes warfarin. Dental procedures may not require interruption of warfarin; local hemostasis can be achieved with the use of topical agents, such as tranexamic acid or aminocaproic acid mouthwashes. Tables 39–8 and 39–9 summarize guidelines proposed by the American College of Chest Physicians for warfarin therapy (ie, dose, monitoring, adjustment, and perioperative management). Included in Table 39-9 are suggested strategies for reversal of warfarin when time does not permit withholding warfarin for several days (eg, for urgent or emergent surgery).

Warfarin skin necrosis is a rare but serious complication of warfarin, usually occurring 2–7 days after initiation of warfarin therapy. Extensive thrombosis of venules and capillaries of subcutaneous fat, particularly in the lower extremities, buttocks, or breast, appears to be most common in patients who have an inherited or acquired deficiency of

Table 39–8. Administration and monitoring of warfarin.

Initial dose: 5 mg/d (lower in patients who are elderly, on multiple medications, malnourished, or have liver disease).
Check INR daily until therapeutic, then two or three times per week until stable, then every 4 weeks.

INR	Intervention
Subtherapeutic	Increase dose. Continue frequent monitoring until therapeutic.
Therapeutic (range based on underlying condition requiring anticoagulation)	Continue current dose.
Between therapeutic range and 5	Omit dose. Resume at a lower dose when INR is therapeutic.
5.0–9.0, no bleeding	Omit 1 or 2 doses. Resume at a lower dose when INR is therapeutic OR give vitamin K ₁ , 1–2.5 mg orally. Resume warfarin at reduced dose when therapeutic.
>9.0, no bleeding	Hold warfarin, give vitamin K ₁ , 3–5 mg orally. Resume warfarin at reduced dose when therapeutic.
>20.0 or serious bleeding	Hold warfarin. Give vitamin K ₁ , 10 mg by slow intravenous infusion. Supplement with fresh frozen plasma or prothrombin complex concentrate if needed.

Table 39–9. Management of warfarin during invasive procedures.

Low risk for thromboembolism (VTE >3 months ago or atrial fibrillation without stroke risk factors)	Stop warfarin 4 days before surgery. Give heparin (UFH or LMWH) briefly at prophylactic doses and resume warfarin simultaneously in the postoperative period.
Intermediate risk for thromboembolism	Stop warfarin 4 days before surgery. Use low-dose UFH or prophylactic dose of LMWH starting 2 days before surgery. After surgery, resume warfarin and continue heparin until INR therapeutic.
High risk for thromboembolism (VTE <3 months ago; multiple VTE; mechanical mitral valve; ball-and-cage prosthetic heart valve)	Stop warfarin 4 days before surgery. Start full-dose intravenous or subcutaneous heparin or LMWH when INR falls (usually about 2 days before surgery). Stop heparin before surgery (5 hours for intravenous or 12 hours for subcutaneous UFH or LMWH). Resume warfarin and continue heparin postoperatively until INR therapeutic.
Low risk of bleeding	Continue warfarin at lowered dose (INR 1.3–1.5) for 4–5 days before surgery. Resume full dose postoperatively. Use prophylactic dose of heparin until INR therapeutic.
Dental procedures with low risk of bleeding	Continue warfarin at usual dose and INR.
Dental procedures with higher risk of bleeding	Continue warfarin at usual dose and INR. Use tranexamic acid or aminocaproic acid mouthwash to control bleeding.
Urgent/emergent surgery (1–8 hours)	Vitamin K 10 mg IV over 30 minutes and fresh frozen plasma (2–4 units depending on INR < or >2.5).
Urgent/emergent surgery (8–12 hours)	Vitamin K 10 mg IV over 30 minutes and fresh frozen plasma (2 units if INR >2).
Urgent/emergent surgery (12–24 hours)	Vitamin K 10 mg IV or SC; UFH if high risk for thromboembolism until 6 hours before surgery.
Urgent/emergent surgery (24+ hours)	Vitamin K 10 mg SC if INR >2; UFH if high risk for thromboembolism until 6 hours before surgery.

VTE = venous thromboembolism.

protein C or protein S. Patients who are known to be deficient in protein C or protein S should receive warfarin only with simultaneous administration of heparin for at least 5 days to allow for depletion of all the vitamin K–dependent coagulation proteins to prevent skin necrosis.

Warfarin is teratogenic, resulting in a fetal embryopathy associated with multiple anomalies when is administered during the first trimester of pregnancy (estimated incidence 7–28%). Warfarin crosses the placenta and may result in fetal bleeding. Because of these negative fetal effects, warfarin is contraindicated between weeks 6 and 12 of pregnancy, and because it may cause fetal bleeding, it should be avoided near term. Women of reproductive age who are taking warfarin should be advised of the teratogenic effects of the drug, and if pregnancy is contemplated, UFH or LMWH should be substituted prior to pregnancy (except for women with mechanical heart valves; see “Antithrombotic Therapy in Pregnancy”). Warfarin does not cause anticoagulation in infants who are breastfed by mothers taking warfarin.

Other infrequent side effects of warfarin include alopecia, GI discomfort, rash, and liver dysfunction. In patients with underlying arterial vascular disease, warfarin therapy has been associated rarely with the development of atheroembolic complications, including ischemic toes, livedo reticularis,

gangrene, abdominal pain, and renal and other visceral infarctions owing to cholesterol emboli. Early reports suggested that chronic warfarin therapy may increase the risk of bone fractures and osteoporosis, but a meta-analysis of available studies failed to show a definite association.

Anisindione

Patients who cannot tolerate warfarin may be treated with anisindione, an oral anticoagulant that is structurally unrelated to warfarin but works by a similar mechanism, namely, inhibition of γ -carboxylation of the vitamin K–dependent coagulation factors. The drug is well absorbed from the GI tract, is highly protein-bound, and is metabolized to inactive metabolites that are excreted in the urine. These metabolites may cause a red-orange discoloration of the urine. The anticoagulant response of anisindione occurs within 20–72 hours, and it is cleared slowly from circulation with a half-life of 3–5 days. Like warfarin, its anticoagulant effect can be reversed by vitamin K and fresh-frozen plasma. Anisindione crosses the placenta and causes fetal malformations and fetal bleeding, so it should be avoided during pregnancy.

Anisindione is FDA approved for use in myocardial infarction and venous thrombosis, but there is a lack of good

clinical studies to support its use as a substitute for warfarin except for patients who are truly intolerant of warfarin. In those patients, a loading dose of 300 mg on day one, 200 mg on day two, and 100 mg on day three is followed by daily maintenance of 50–250 mg, adjusted according to the INR. Anisindione may cause myelosuppression, dermatitis, jaundice, and renal insufficiency, which have limited its use.

▶ Thrombolytic Therapy

Thrombolytic (fibrinolytic) agents differ from other antithrombotic agents in that they actually dissolve established clots rather than interfering with initiation and propagation of thrombosis. The mechanism of action of these agents is complex and involves many components of the naturally occurring fibrinolytic system. Activation of plasminogen to plasmin (the major fibrinolytic enzyme) is enhanced by these drugs, accompanied by increased consumption of its inhibitor (α_2 -antiplasmin). The net effect is an increase in free plasmin, which results in degradation of fibrin and other coagulation factors.

All the available agents cause varying degrees of systemic activation of the fibrinolytic mechanism and therefore induce generalized fibrinolysis and fibrinogenolysis and some degree of platelet dysfunction owing to proteolysis of key membrane receptors by plasmin, although some are more specific for plasmin bound to clot (fibrin-specific). These drugs work best when given soon after onset of symptoms (eg, within 3–4 hours in acute arterial thrombosis, 48 hours for pulmonary thromboembolism, and 7 days for DVT), before thrombi are highly cross linked and more resistant to thrombolysis.

Five thrombolytic agents are approved for use in the United States. Selected features of these agents are outlined in Table 39–10. Thrombolytic therapy may be used in the treatment of acute arterial thrombosis, including myocardial infarction and peripheral arterial occlusion, and in the treatment of severe VTE (eg, massive pulmonary thromboembolism with hemodynamic compromise, massive DVT, or phlegmasia cerulea dolens). Thrombolysis can improve neurologic function in patients with acute nonhemorrhagic stroke if patients at high risk for bleeding are excluded and if

Table 39–10. Comparison of selected fibrinolytic agents.

Drug	$t_{1/2}$ (min)	Fibrin-Specific	Indications (FDA-Approved)	Neutralizing Antibodies*	Typical Dose†	Estimated Cost
Alteplase	5	Yes (2+)	Myocardial infarction, acute cardiovascular accident, pulmonary thromboembolism	No	Myocardial infarction: 100 mg infusion over 90 minutes to 3 hours; cerebrovascular accident: 0.9 mg/kg (maximum 90 mg) infused over 60 minutes with 10% of total dose given as an initial bolus	\$2200
Tenecteplase	18–20	Yes (3+)	Myocardial infarction.	No	Single bolus, 30–50 mg depending on weight in kg	\$2200
Retepase	13–16	Yes (1+)	Myocardial infarction	No	Two bolus injections, 10 units each given 30 minutes apart	\$2200
Streptokinase	20	No	Myocardial infarction (intravenous or intracoronary), deep vein thrombosis, pulmonary thromboembolism, catheter thrombosis, peripheral arterial occlusion	Yes	1.5 million units infused over 30–60 minutes intravenously OR 20,000 units by intracoronary bolus followed by 2000 to 4000 units/min for 30 to 90 minutes	\$300
Urokinase	20	No	Myocardial infarction (intracoronary), pulmonary thromboembolism, catheter thrombosis	No	6000 units/min infused intracoronary for up to 2 hours OR 4400 units/kg infused over 10 minutes followed by 4400 units/kg/hr for 12 hours OR 5000 units for catheter thrombosis	\$4000–\$6000 (myocardial infarction, pulmonary embolus) \$60 (catheter thrombosis)

*Presence of neutralizing antibodies precludes repeat use within 6–24 months, possibly longer, because of allergic reactions and decreased effectiveness of the agent.

†Doses may vary depending upon clinical situation.

administered within 3 hours of onset of symptoms. Thrombolytic agents are also used to reestablish patency of clotted indwelling venous catheters and vascular grafts. Indications, timing of administration, use of adjunctive antithrombotic agents, and choice of specific agent for thrombolytic therapy are evolving. Thrombolysis reduces mortality from acute myocardial infarction by about 20–50%. In patients not undergoing percutaneous transthoracic coronary angioplasty for acute myocardial infarction, alteplase may be more effective than streptokinase. Bolus fibrinolytic agents, reteplase and tenecteplase, are potentially advantageous because they can be given quickly and could be available in the prehospital setting. Reteplase appears to be equivalent in safety and efficacy to alteplase, whereas tenecteplase has a somewhat lower rate of major bleeding. Any available fibrinolytic agent may be used with acute myocardial infarction. Although the newer agents are much more expensive than streptokinase, the contribution of drug costs to the overall cost of care—particularly for acute myocardial infarction—has not been shown to be significant. When cost-effective analyses have been done, streptokinase appears to be marginally more cost-effective than the other agents but should not be given to patients previously treated with streptokinase owing to its antigenicity. Urokinase is used primarily for dissolution of catheter thromboses.

The principal goal of fibrinolytic therapy is to reestablish patency of an occluded blood vessel (or indwelling catheter). Fibrinolytic therapy for myocardial infarction results in angiographically confirmed patency about 50% of the time. Additional antithrombotic therapy may be required to improve reperfusion. The role of heparin combined with fibrinolytics for patients with acute myocardial infarction is controversial, and the combination appears to be associated with a high rate of major bleeding. Ongoing studies are required to define the optimal use of heparin (UFH or LMWH) or other anticoagulants such as the hirudin derivatives and heparinoids in combination with fibrinolytic therapy. Antiplatelet agents have been shown to be very important as an adjunct to fibrinolytic therapy. Platelets play a key role in the development of coronary thrombosis. Aspirin and platelet GP IIb/IIIa inhibitors potentiate fibrinolysis and improve coronary artery patency rates, although bleeding complications also may be increased when streptokinase is combined with GP IIb/IIIa inhibitors. Large trials recently completed will provide additional information about the safety and efficacy of various combinations of antiplatelet agents and fibrinolytics in the treatment of acute myocardial infarction. In addition, the combination of reduced-dose fibrinolytic therapy with invasive coronary interventions (eg, angioplasty) may improve outcomes. Further study in this area is needed to define optimal dosing to enhance coronary artery patency while maintaining an acceptable rate of hemorrhage.

Alteplase is approved for use in acute nonhemorrhagic stroke and is effective when administered intravenously within 3 hours of the onset of symptoms. The risk of intracerebral hemorrhage is 3%, but because it can lead to improved

neurologic function, this may be an acceptable risk. Only an estimated 2% of all stroke patients are able to receive alteplase within the 3-hour time frame, limiting its potential impact on outcomes from stroke. Streptokinase increases early mortality and intracerebral hemorrhage when used in the treatment of acute stroke and is not recommended. Recently, MRI to locate arterial occlusions, followed by superselective intraarterial thrombolysis, has been suggested as a potentially beneficial approach for patients with acute stroke who are more than 3 hours from the onset of symptoms. This approach has an even higher risk of hemorrhage (10% overall), but in centers equipped with a stroke unit and all necessary personnel and technologic support quickly available, it may prove to increase the number of patients who could benefit from thrombolysis for acute stroke.

Fibrinolytic therapy is of limited value in the treatment of massive PE. Hemodynamic instability and radiographic changes improve more rapidly than with anticoagulation only, but there does not appear to be any significant improvement in overall outcome compared with anticoagulation alone. Fibrinolytic therapy of PE should be considered for patients with hemodynamic instability, severe gas-exchange abnormalities, or significant impairment in right ventricular function. Echocardiography to assess right ventricular function plays a key role in determining the potential benefit of fibrinolytic therapy or other means of reducing clot burden (eg, thromboembolectomy). Fibrinolytic therapy for DVT has not improved outcome over anticoagulation in most patients, with the possible exception of patients with severe venous occlusion and threatened gangrene of the limb. Despite a high rate of clot lysis, there is no good evidence that thrombolytic therapy reduces the rate of post-phlebotic syndrome following DVT. Furthermore, hemorrhagic complications are much higher than with standard anticoagulation in the treatment of VTE.

Fibrinolytic therapy is effective in the treatment of acute arterial thrombus in medium and large peripheral arteries. A fibrinolytic agent administered through a catheter proximal to the clot dissolves it completely about 75% of the time. Catheter-directed intraarterial administration appears to be superior to intravenous administration. Thrombolysis should be considered prior to revascularization surgery as long as the affected limb is still salvageable. Surgery can be avoided in 35% of these patients, and overall mortality appears to be somewhat better than with immediate surgery.

Urokinase, 5000 units, may be instilled into an occluded venous catheter without excessive pressure, which could dislodge the clot or rupture the catheter. Because venous catheters may be occluded by substances other than clots (eg, drug precipitate), urokinase is not always effective.

The most common complication of thrombolytic therapy is hemorrhage (3–40%). Hemorrhagic complications can be minimized if patients are selected properly and monitored carefully. The use of other antithrombotic agents—particularly heparin—increases the risk of bleeding. Contraindications to thrombolytic therapy include major ischemic changes or

signs of intracranial hypertension on CT scan, seizure at the onset of a stroke, previous stroke or serious head injury within the preceding 3 months, active or recent visceral bleeding, aortic dissection, major surgery, trauma, arterial or lumbar puncture in the preceding 2 weeks, severe uncontrolled hypertension (>180/110 mm Hg), significant thrombocytopenia (platelet count <100,000/ μ L), signs of pericarditis, pregnancy, recent retinal laser surgery, cardiogenic shock (except when owing to massive PE), and the use of heparin with a prolonged aPTT or oral anticoagulants resulting in an INR greater than 1.5. Thrombolytic therapy results in decreased plasma fibrinogen concentration and increased fibrin degradation products, but these tests are not predictive of efficacy or clinical bleeding. The bleeding time, if prolonged, may correlate with minor bleeding but is not usually monitored.

The thrombin time is the best laboratory test for monitoring the status of the fibrinolytic system. When the thrombin time is prolonged more than five to seven times normal, the incidence of bleeding complications increases significantly. Intracerebral hemorrhage is more common in patients who are elderly or underweight, who have prior neurologic disease, or who are receiving antithrombotic drugs. Women appear to have a higher risk of intracerebral hemorrhage. If major bleeding occurs with thrombolytic therapy, the drug should be stopped immediately. Hypofibrinogenemia can be reversed with cryoprecipitate, and aminocaproic acid can be given to inhibit plasmin activity. If the patient is receiving heparin, protamine sulfate can be used to reverse its effect.

Other potential adverse reactions to certain thrombolytic agents (eg, streptokinase and anistreplase) include allergic reactions and the development of neutralizing antibodies that preclude repeated usage for 6–24 months and perhaps longer. Cholesterol emboli rarely may complicate thrombolytic therapy, resulting in the “purple toe syndrome” and multiorgan failure. Arrhythmias may accompany reperfusion of an ischemic myocardium.

► Antithrombotic Therapy in Pregnancy

Pregnancy and the postpartum period pose special challenges in the management of thromboembolic disorders. In addition to the apparent increased risk of venous thromboembolic events, certain pregnancy complications (eg, fetal loss, preeclampsia, abruption, fetal growth retardation, and intrauterine death) are associated with maternal thrombophilias (eg, antiphospholipid antibodies, factor V Leiden, prothrombin gene mutation, antithrombin deficiency, and hyperhomocysteinemia). In addition, women who are taking warfarin for preexisting conditions (eg, venous thromboembolism or mechanical heart valves) require continued antithrombotic therapy during this higher-risk period. Warfarin is contraindicated between 6 and 12 weeks of pregnancy because of its teratogenicity and because it may increase the risk of fetal bleeding. UFH does not cross the

placenta and appears to be safe and effective during pregnancy. LMWH and danaparoid have a lower risk of osteoporosis and thrombocytopenia than UFH. Dosing may be adjusted for increasing weight, or anti-factor Xa levels (drawn 4 hours after morning dose) can be monitored (target range 0.5–1.2 units/mL). Because these agents do not cross the placenta, fetal bleeding is not a complication; however, there have been recent reports of congenital anomalies with some of the LMWH preparations (eg, enoxaparin and tinzaparin), and there has been insufficient clinical experience with danaparoid during pregnancy to determine its teratogenicity. Maternal bleeding occurs with the same frequency as in other situations requiring anticoagulation (major bleeding, about 2%). Bleeding can complicate delivery. The aPTT may not adequately reflect the anticoagulation effect of UFH because of increased factor VIII and fibrinogen that occurs during pregnancy. When possible, UFH or LMWH should be discontinued 24 hours before labor (eg, when electively induced). UFH and LMWH are not secreted in breast milk, and warfarin does not appear to cause an anticoagulant effect in babies who are breastfed by mothers taking warfarin. Guidelines for the management of antithrombotic agents during pregnancy are outlined in [Table 39-11](#).

The use of heparin (UFH and LMWH) during pregnancy appears to be effective for prophylaxis and treatment of VTE. In women with mechanical heart valves, heparin is not as effective as warfarin for prevention of thromboembolic complications, particularly if the aPTT is only moderately elevated. Choices for anticoagulation in these women include using warfarin (target INR 3.0), except for weeks 6–12 and near delivery, when UFH can be substituted, to prevent fetal embryopathy or bleeding, or to use UFH throughout pregnancy. If UFH is used, it is imperative that high doses be used and that the aPTT (6 hours after subcutaneous injection) is monitored closely. The addition of low-dose aspirin (81–162 mg/day) may reduce the risk of thrombosis but also increases the risk of bleeding. Maternal and fetal deaths from thrombotic complications have been reported when enoxaparin was used for thromboprophylaxis in pregnant women with prosthetic heart valves; however, the incidence of this complication is not known. The optimal approach for management of anticoagulation for women with mechanical valves during pregnancy is not clear owing to a lack of sufficient clinical trials.

Low-dose aspirin appears to be safe when administered in the second and third trimesters to modestly reduce the risk of preeclampsia and intrauterine growth retardation in high-risk women and appears to be safe for both mother and fetus. Additional studies are required to determine the optimal selection of patients, timing, and dose of aspirin therapy. Low-dose aspirin combined with heparin reduces the risk of miscarriage in women with the antiphospholipid antibody syndrome and recurrent miscarriage, but it is uncertain whether this strategy is effective in women with other thrombophilic conditions.

Table 39–11. Antithrombotic therapy during pregnancy.

Clinical Situation	Recommendation
Women on long-term anticoagulation who wish to become pregnant	Frequent pregnancy tests; convert to LMWH or adjusted-dose UFH once pregnant
VTE during pregnancy	LMWH or adjusted-dose UFH throughout pregnancy and for at least 6 weeks postpartum
Prior VTE with transient risk factors*	Close surveillance during pregnancy; postpartum anticoagulation [†]
Prior VTE with thrombophilia or family history*	Low- to moderate-dose UFH or LMWH throughout pregnancy; postpartum anticoagulation
Multiple prior VTE*	LMWH or adjusted-dose UFH throughout pregnancy; resume long-term anticoagulation postpartum
Thrombophilia without history of VTE	No clinical data to support specific recommendation; consider prophylaxis for patients with AT deficiency, factor V Leiden or prothrombin G20210A heterozygotes, homozygous factor V Leiden or prothrombin G20210A mutation
Mechanical heart valve	Options: 1. LMWH, monitor anti-Xa activity 2. Adjusted-dose UFH 3. LMWH or adjusted-dose UFH until week 13; warfarin until mid-third trimester, resume LMWH or UFH until term 4. Consider adding aspirin, 75–162 mg/day for high-risk women

*Recommendations should be individualized; very low recurrence of VTE in small study of these patients.

[†]All pregnant women with history of VTE should consider use of graduated compression stockings throughout pregnancy and postpartum.

Women at high risk for thromboses during pregnancy, such as those with prior VTE, inherited thrombophilic disorders, and antiphospholipid antibody syndrome (without prior thrombosis or miscarriage), should be considered for prophylactic anticoagulation with UFH or LMWH during pregnancy and the postpartum period. Determining the optimal management strategy for these patients is difficult because there are inadequate data available to support specific recommendations. A discussion of the potential risks and benefits, known and uncertain, with each patient must be undertaken at the onset of pregnancy.

▶ Antiphospholipid Antibody Syndrome

Significant thrombotic events in the presence of the antiphospholipid antibody syndrome (APLA) pose special therapeutic challenges. Acute management with heparin may be complicated by baseline elevation in the aPTT. If baseline aPTT is prolonged, monitoring should be performed using a specific heparin assay that depends on factor Xa inhibition (therapeutic range 0.3–0.7). LMWH can be used without the need for laboratory monitoring. The optimal intensity and duration of warfarin therapy (following initial therapy with

UFH or LMWH) for these patients is unclear, but higher-intensity warfarin (INR at least 3) is probably superior to lower-intensity warfarin, and longer-duration therapy (2–4 years) offers a lower rate of recurrence than 6 months of anticoagulation. Low-dose aspirin (81 mg daily) should be added to oral anticoagulation for arterial thrombosis or for recurrent VTE despite adequate oral anticoagulation. Heparin therapy (UFH or LMWH) has been advocated by some for patients with APLA syndrome, but there is no direct evidence that it is superior if INR is monitored and adjusted carefully. Some patients also have hypoprothrombinemia, with baseline prolongation of the PT, which makes monitoring with INR unreliable. Coagulation tests that are insensitive to the lupus anticoagulant may be required in these patients (eg, prothrombin-proconvertin test or chromogenic factor X level). Corticosteroids and immunosuppressive agents may improve coagulation abnormalities, but the benefits are usually short-lived. If patients have multisystem involvement, corticosteroids, immunosuppressives, and plasmapheresis may be beneficial; however, ongoing treatment of the thrombotic diathesis with anticoagulation is advisable. Management of APLA syndrome during pregnancy was discussed earlier.

Immunologically mediated thrombocytopenia is common in APLA syndrome but generally is mild and does not require treatment. When severe thrombocytopenia ($<20,000/\mu\text{L}$) is present, increased bleeding during anticoagulation may occur. Treatment as for other immune thrombocytopenias should be given to achieve a reasonable platelet count (ie, $>50,000/\mu\text{L}$) to decrease the risk of serious hemorrhage with concomitant anticoagulation. Catastrophic APLA syndrome (eg, multiorgan and bowel thrombosis, gangrene, livedo reticularis, and stroke) requires aggressive therapy with anticoagulation, plasmapheresis, and immunosuppressive agents but is associated with a high rate of mortality despite these measures.

► Thrombosis in Cancer Patients

The risk of thrombosis in patients with cancer is significant and is due to several factors, many of which may be present simultaneously: activation of coagulation by tumors, thrombocytosis, tumor angiogenesis, trapping of cancer cells in the microcirculation of organs, treatment (ie, chemotherapy and hormonal therapy), indwelling vascular catheters, obstruction of venous and lymphatic channels, surgical procedures, and limited mobility. Postoperative VTE is much higher in patients undergoing cancer surgery, and recurrence of VTE after completion of anticoagulation is more common in patients with cancer. Patients undergoing major cancer surgery, especially when associated with prolonged immobility, should be considered for thromboprophylaxis with LMWH postoperatively. Extending the duration of prophylaxis from 8–10 days to 4 weeks reduces the risk of VTE from 12–4.8%. LMWH may be superior to warfarin for the treatment of established VTE in cancer patients, reducing the rate of treatment failure and improving survival. Studies have shown conflicting results with LMWH therapy for patients with advanced malignancy without established VTE. There may be a small survival advantage for selected patients with better initial prognosis, but the risks of bleeding, cost, and inconvenience to the patient must be considered before initiating therapy. Prevention of catheter-associated thrombosis has not been studied adequately, but low-dose warfarin therapy may be considered for patients at high risk of clotting. Patients receiving therapy associated with an increased rate of thrombosis should be educated about symptoms of VTE and monitored closely. Prophylactic dose LMWH may be useful for the prevention of thrombosis associated with thalidomide therapy for multiple myeloma, whereas low-dose warfarin, although used frequently, has not yet been shown to be effective.

► Future Directions

There are several exciting active areas of research in the field of antithrombotic therapy. Many new agents are in various stages of development. Modifications of existing

antithrombotic agents may serve to increase the predictability of anticoagulant effect, improve bioavailability and convenience, and decrease complications. Combinations of various antithrombotic agents are under investigation in an attempt to improve efficacy while maintaining an acceptable risk for hemorrhage.

Several classes of anticoagulants are under active investigation: inhibitors of the factor VIIa–tissue factor pathway, factor Xa inhibitors, and direct thrombin inhibitors. One of the most promising agents had been an orally active thrombin inhibitor, ximelegatran. The development of an orally active agent with a more predictable anticoagulant response would be a major advance over warfarin for the outpatient management of thromboembolic disease. Ximelegatran is metabolized to melagatran (the active agent), has a predictable anticoagulant response at a fixed dose, and does not require monitoring. It had been shown to be effective and safe for postoperative thromboprophylaxis and treatment of VTE, atrial fibrillation, and acute coronary syndromes (combined with aspirin). Unfortunately, liver toxicity led to this drug being withdrawn from the market worldwide in 2006.

In addition to new anticoagulants, attempts to augment the naturally occurring anticoagulant pathway of protein C and the fibrinolytic system may prove useful. Recombinant activated protein C has been tested in patients with sepsis and has been shown to decrease mortality; however, it may increase the risk of bleeding. New antiplatelet agents, including additional platelet GP IIb/IIIa receptor inhibitors, are also being studied.

While endeavoring to improve the benefit-risk ratio of antithrombotic therapy, cost-effectiveness holds major importance in the future of antithrombotic therapy. The indications for antithrombotic therapy are continuously expanding, and the cost of many new agents is very high. It is important that any new antithrombotic drug be compared with older, established therapies, with demonstration of definite advantage, before changing the standard of care for patients with or at risk for thromboembolic disease.
