Contents

Authors	vii		
Preface	xi		
1. Philosophy & Principles of Critical Care	1		
<i>Darryl Y. Sue, MD, & Frederic S. Bongard, MD</i>			
General Principles of Critical Care	1		
Role of the Medical Director of the Intensive Care Unit	8		
Critical Care Scoring	10		
Current Controversies & Unresolved Issues	12		
2. Fluids, Electrolytes, & Acid-Base	14		
<i>Darryl Y. Sue, MD, & Frederic S. Bongard, MD</i>			
Disorders of Fluid Volume	14		
Disorders of Water Balance	22		
Disorders of Potassium Balance	34		
Disorders of Phosphorus Balance	42		
Disorders of Magnesium Balance	47		
Disorders of Calcium Balance	51		
Acid-Base Homeostasis & Disorders	56		
3. Transfusion Therapy	71		
<i>Elizabeth D. Simmons, MD</i>			
Blood Components	71		
Blood Component Administration	79		
Complications of Transfusion	79		
Current Controversies & Unresolved Issues	82		
4. Pharmacotherapy	88		
<i>Darryl Y. Sue, MD</i>			
Pharmacokinetic Parameters	88		
Pharmacokinetic Considerations	88		
Medication Errors & Prevention in the ICU	95		
5. Intensive Care Anesthesia & Analgesia	97		
<i>Tai-Shion Lee, MD, & Biing-Jaw Chen, MD</i>			
Physiologic Effects of Anesthesia in the Critically Ill	97		
Airway Management	101		
Pain Management in the ICU	103		
Muscle Relaxants in Intensive Care	106		
Sedative-Hypnotics for the Critically Ill	110		
Malignant Hyperthermia	115		
6. Nutrition	117		
<i>John A. Tayek, MD</i>			
Nutrition & Malnutrition in the Critically Ill Patient	117		
Nutritional Therapy	126		
Nutritional Support in Specific Diseases	130		
New Treatment Strategies for the Malnourished Critically Ill Patient	134		
7. Imaging Procedures	137		
<i>Kathleen Brown, MD, Steven S. Raman, MD, & Nam C. Yu, MD</i>			
Imaging Techniques	137		
Iodinated Contrast Agents	138		
Use of Central Venous Catheters for Contrast Injection	139		
Imaging of Support & Monitoring Devices in the ICU	139		
Imaging in Pulmonary Diseases	144		
Imaging in Pleural Disorders	161		
Imaging of the Abdomen & Pelvis	167		
Imaging of Acute Gallbladder & Biliary Tract Disorders	181		
Imaging in Emergent & Urgent Genitourinary Conditions	184		
8. Intensive Care Monitoring	187		
<i>Kenneth Waxman, MD, Frederic S. Bongard, MD, & Darryl Y. Sue, MD</i>			
Electrocardiography	187		
Blood Pressure Monitoring	188		
Central Venous Catheters	193		
Pulmonary Artery Catheterization	196		
Cardiac Output	199		
Pulse Oximetry	201		
Airway CO ₂ Monitoring	203		
Transcutaneous Blood Gases	204		
Respiratory Mechanics	204		
Respired Gas Analysis	206		
Clinical Applications	206		
9. Transport	208		
<i>Samuel J. Stratton, MD, MPH</i>			
Interhospital Transport	208		
Equipment & Monitoring	211		
Education & Training	212		
Reimbursement Standards & Costs	213		
Current Controversies & Unresolved Issues	214		

10. Ethical, Legal, & Palliative/End-of-Life Care Considerations	215		
<i>Paul A. Selecky, MD</i>			
Ethical Principles	215		
Conflicts Between Ethical Principles	216		
Ethical Decision Making	216		
Advance Care Planning	217		
Medicolegal Aspects of Decision Making	217		
Withholding & Withdrawing Life Support	218		
Organ Donation	219		
Role of the Health Care Professional	219		
Web Sites for Health Care Ethics Information & Policies	221		
11. Shock & Resuscitation	222		
<i>Frederic S. Bongard, MD</i>			
Hypovolemic Shock	222		
Distributive Shock	230		
Cardiac Shock	242		
12. Respiratory Failure	247		
<i>Darryl Y. Sue, MD, & Janine R. E. Vintch, MD</i>			
Pathophysiology of Respiratory Failure	247		
Treatment of Acute Respiratory Failure	253		
Acute Respiratory Failure from Specific Disorders	280		
13. Renal Failure	314		
<i>Andre A. Kaplan, MD</i>			
Nondialytic Therapy for Acute Renal Failure	330		
Dialytic Therapy for the Critically Ill Patient	334		
Critical Illness in Patients with Chronic Renal Failure	342		
14. Gastrointestinal Failure in the ICU	345		
<i>Gideon P. Naudé, MD</i>			
Pancreatitis	345		
Bowel Obstruction	351		
Obstruction of the Large Bowel	354		
Adynamic (Paralytic) Ileus	355		
Diarrhea & Malabsorption	356		
Pancreatic Insufficiency	357		
Lactase Deficiency	357		
Diarrhea	357		
15. Infections in the Critically Ill	359		
<i>Laurie Anne Chu, MD, & Mallory D. Witt, MD</i>			
Sepsis	359		
Community-Acquired Pneumonia	362		
Urosepsis	365		
Infective Endocarditis	367		
Necrotizing Soft Tissue Infections	370		
Intraabdominal Infections	372		
Infections in Special Hosts	373		
Principles of Antibiotic Use in the ICU	376		
Evaluation of the ICU Patient with New Fever	379		
Nosocomial Pneumonia	379		
Urinary Catheter–Associated Infections	382		
Intravenous Catheter–Associated Infections	384		
<i>Clostridium Difficile</i> –Associated Diarrhea	386		
Hematogenously Disseminated Candidiasis	388		
Antimicrobial Resistance in the ICU	389		
Botulism	392		
Tetanus	394		
16. Surgical Infections	397		
<i>Timothy L. Van Natta, MD</i>			
Evaluation and Management of Infection by Body Site	400		
17. Bleeding & Hemostasis	409		
<i>Elizabeth D. Simmons, MD</i>			
Approach to the Bleeding Patient	427		
Current Controversies & Unresolved Issues	427		
18. Psychiatric Problems	431		
<i>Stuart J. Eisendrath, MD, & John R. Chamberlain, MD</i>			
Delirium	431		
Depression	436		
Anxiety & Fear	438		
Staff Issues	440		
19. Care of the Elderly Patient	443		
<i>Shawkat Dhanani, MD, MPH, & Dean C. Norman, MD</i>			
Physiologic Changes with Age	443		
Management of the Elderly Patient in the ICU	445		
Special Considerations	447		
20. Critical Care of the Oncology Patient	451		
<i>Darrell W. Harrington, MD, & Darryl Y. Sue, MD</i>			
Central Nervous System Disorders	451		
Metabolic Disorders	457		
Superior Vena Cava Syndrome	465		
21. Cardiac Problems in Critical Care	467		
<i>Shelley Shapiro, MD, PhD, & Malcolm M. Bersohn, MD, PhD</i>			
Atrial Arrhythmias	486		
Ventricular Arrhythmias	488		

Heart Block	491	Hyperglycemia	594
Cardiac Problems During Pregnancy	493	Hypoglycemia	595
Toxic Effects of Cardiac Drugs	494	Other Complications of Diabetes Mellitus	597
22. Coronary Heart Disease	498	27. HIV Infection in the Critically Ill Patient	598
<i>Kenneth A. Narahara, MD</i>		<i>Mallory D. Witt, MD, & Darryl Y. Sue, MD</i>	
Physiologic Considerations	498	Complications of HIV Disease: An Overview	598
Myocardial Ischemia (Angina Pectoris)	499	Other Infectious Causes of Pneumonia and Respiratory Failure	604
Acute Coronary Syndromes: Unstable Angina and Non-ST-Segment-Elevation Myocardial Infarction	502		
Acute Myocardial Infarction with ST-Segment Elevation	505		
23. Cardiothoracic Surgery	514	28. Dermatologic Problems in the Intensive Care Unit	609
<i>Edward D. Verrier, MD, & Craig R. Hampton, MD</i>		<i>Kory J. Zipperstein, MD</i>	
Aneurysms, Dissections, & Transections of the Great Vessels	514	Common Skin Disorders	609
Postoperative Arrhythmias	518	Drug Reactions	612
Bleeding, Coagulopathy, & Blood Product Utilization	520	Purpura	619
Cardiopulmonary Bypass, Hypothermia, Circulatory Arrest, & Ventricular Assistance	525	Life-Threatening Dermatoses	623
Postoperative Low-Output States	529	Cutaneous Manifestations of Infection	626
24. Pulmonary Disease	534	29. Critical Care of Vascular Disease & Emergencies	632
<i>Darryl Y. Sue, MD, & Janine R. E. Vintch, MD</i>		<i>James T. Lee, MD, & Frederic S. Bongard, MD</i>	
Status Asthmaticus	534	Vascular Emergencies in the ICU	632
Life-Threatening Hemoptysis	540	Critical Care of the Vascular Surgery Patient	651
Deep Venous Thrombosis & Pulmonary Thromboembolism	545	30. Critical Care of Neurologic Disease	658
Anaphylaxis	562	<i>Hugh B. McIntyre, MD, PhD, Linda Chang, MD, & Bruce L. Miller, MD</i>	
Angioedema	563	Encephalopathy & Coma	658
25. Endocrine Problems in the Critically Ill Patient	566	Seizures	662
<i>Shalender Bhasin, MD, Piya Ballani, MD, & Ricky Phong Mac, MD</i>		Neuromuscular Disorders	666
Thyroid Storm	566	Cerebrovascular Diseases	673
Myxedema Coma	570	31. Neurosurgical Critical Care	680
Acute Adrenal Insufficiency	572	<i>Duncan Q. McBride, MD</i>	
Sick Euthyroid Syndrome	576	Head Injuries	680
26. Diabetes Mellitus, Hyperglycemia, & the Critically Ill Patient	581	Aneurysmal Subarachnoid Hemorrhage	686
<i>Eli Ipp, MD, & Chuck Huang, MD</i>		Tumors of the Central Nervous System	688
Diabetic Ketoacidosis	581	Cervical Spinal Cord Injuries	690
Hyperglycemic Hyperosmolar Nonketotic Coma	593	32. Acute Abdomen	696
Management of the Acutely Ill Patient with Hyperglycemia or Diabetes Mellitus	594	<i>Allen P. Kong, MD, & Michael J. Stamos, MD</i>	
		Specific Pathologic Entities	700
		Current Controversies & Unresolved Issues	701

33. Gastrointestinal Bleeding	703		
<i>Sofiya Reicher, MD, & Viktor Eysselein, MD</i>			
Upper Gastrointestinal Bleeding	703		
Lower Gastrointestinal Bleeding	710		
34. Hepatobiliary Disease	714

Dermatologic Problems in the Intensive Care Unit

Preface

The third edition of *Current Diagnosis & Treatment: Critical Care* is designed to serve as a single-source reference for the adult critical care practitioner. The diversity of illnesses encountered in the critical care population necessitates a well-rounded and thorough knowledge of the manifestations and mechanisms of disease. In addition, unique to the discipline of critical care is the integration of an extensive body of medical knowledge that crosses traditional specialty boundaries. This approach is readily apparent to intensivists, whose primary background may be in internal medicine or one of its subspecialties, surgery, or anesthesiology. Thus a central feature of this book is a unified and integrated approach to the problems encountered in critical care practice. Like other books with the Lange imprint, this book emphasizes recall of major diagnostic features, concise descriptions of disease processes, and practical management strategies based on often recently acquired evidence.

INTENDED AUDIENCE

Planned by two internists and a surgeon to meet the need for a concise but thorough source of information, *Current Diagnosis & Treatment: Critical Care* is intended to facilitate both teaching and practice of critical care. Students will find its consideration of basic science and clinical application useful during clerkships on medicine, surgery, and intensive care unit electives. House officers will appreciate its descriptions of disease processes and organized approach to diagnosis and treatment. Fellows and those preparing for critical care specialty examinations will find those sections outside their primary disciplines particularly useful. Clinicians will recognize this succinct reference on critical care as a valuable asset in their daily practice.

Because this book is intended as a reference on various aspects of adult critical care, it does not contain chapters on pediatric or neonatal critical care. These areas are highly specialized and require entire monographs of their own. Further, we have not included detailed information on performing bedside procedures such as central venous catheterization or arterial line insertion. Well-illustrated pocket manuals are available for readers who require basic technical information. Finally, we have chosen not to include a chapter on nursing or administrative topics, details of which can be found in other works.

ORGANIZATION

Current Diagnosis & Treatment: Critical Care is conceptually organized into three major sections: (1) fundamentals of critical care applicable to all patients, (2) topics related primarily to critical care of patients with medical diseases, and (3) essentials of care for patients requiring care for surgical problems. Early chapters provide information about the general physiology and pathophysiology of critical illness. The later chapters discuss pathophysiology using an organ system- or disease-specific approach. Where appropriate, we have placed the medical and surgical chapters in succession to facilitate access to information.

OUTSTANDING FEATURES

- ▶ Concise, readable format, providing efficient use in a variety of clinical and academic settings
- ▶ Edited by both surgical and medical intensivists, with contributors from multiple subspecialties
- ▶ Illustrations chosen to clarify basic and clinical concepts
- ▶ Careful evaluation of new diagnostic procedures and their usefulness in specific diagnostic problems
- ▶ Updated information on the management of severe sepsis and septic shock, including hydrocortisone therapy
- ▶ New information on the serotonin syndrome
- ▶ Carefully selected key references in Index Medicus format, providing all information necessary to allow electronic retrieval

ACKNOWLEDGMENTS

The editors wish to thank Robert Pancotti and Ruth W. Weinberg at McGraw-Hill for unceasing efforts to motivate us and keep us on track. We are also very grateful to our families for their support.

Philosophy & Principles of Critical Care

Darryl Y. Sue, MD
Frederic S. Bongard, MD

1

Critical care is unique among the specialties of medicine. While other specialties narrow the focus of interest to a single body system or a particular therapy, critical care is directed toward patients with a wide spectrum of illnesses. These have the common denominators of marked exacerbation of an existing disease, severe acute new problems, or severe complications from disease or treatment. The range of illnesses seen in a critically ill population necessitates well-rounded and thorough knowledge of the manifestations and mechanisms of disease. Assessing the severity of the patient's problem demands a simultaneously global and focused approach, depends on accumulation of accurate data, and requires integration of these data. Although practitioners of critical care medicine—sometimes called *intensivists*—are often specialists in pulmonary medicine, cardiology, nephrology, anesthesiology, surgery, or critical care, the ability to provide critical care depends on the basic principles of internal medicine and surgery. Critical care might be considered not so much a specialty as a “philosophy” of patient care.

The most important development in recent years has been an explosion of evidence-based critical care medicine studies. For the first time, we have evidence for many of the things that we do for patients in the ICU. Examples include low tidal volume strategies for acute respiratory distress syndrome, tight glycemic control, prevention of ventilator-associated pneumonia, and use of corticosteroids in septic shock (Table 1–1). The resulting improvement in outcome is gratifying, but even more surprising is how often evidence contradicts long-held beliefs and assumptions. Probably the best example is recent studies that conclude that the routine use of pulmonary artery catheters in ICU patients adds little or nothing to management. Much more needs to be studied, of course, to address other unresolved issues and controversies.

Do intensivists make a difference in patient outcome? Several studies have shown that management of patients by full-time intensivists does improve patient survival. In fact,

several national organizations recommend strongly that full-time intensivists provide patient care in all ICUs. It can be argued, however, that local physician staffing practices; interactions among primary care clinicians, subspecialists, and intensivists; patient factors; and nursing and ancillary support play large roles in determining outcomes. In addition, recent studies show that patients do better if an ICU uses protocols and guidelines for routine care, controls nosocomial infections, and provides feedback to practitioners.

The general principles of critical care are presented in this chapter, as well as some guidelines for those who are responsible for leadership of ICUs.

GENERAL PRINCIPLES OF CRITICAL CARE

► Early Identification of Problems

Because critically ill patients are at high risk for developing complications, the ICU practitioner must remain alert to early manifestations of organ system dysfunction, complications of therapy, potential drug interactions, and other premonitory data (Table 1–2). Patients with life-threatening illness in the ICU commonly develop failure of other organs because of hemodynamic compromise, side effects of therapy, and decreased organ function reserve, especially those who are elderly or chronically debilitated. For example, positive-pressure mechanical ventilation is associated with decreased perfusion of organs. Many valuable drugs are nephro- or hepatotoxic, especially in the face of preexisting renal or hepatic insufficiency. Older patients are more prone to drug toxicity, and polypharmacy presents a higher likelihood of adverse drug interactions. Just as patients with acute coronary syndrome and stroke benefit from early intervention, an exciting finding is the evidence that the first 6 hours of management of septic shock are very important.

Table 1-1. Recent developments in evidence-based critical care medicine.

- Corticosteroids improve outcome in exacerbations of chronic obstructive respiratory disease (COPD).
- A low tidal volume strategy decreases mortality in acute respiratory distress syndrome (ARDS).
- A lower hemoglobin decision point for transfusion of red blood cells in many ICU patients results in similar outcome and greatly reduced use of blood products.
- Tight glycemic control in postoperative surgical patients, most of whom did not have diabetes, resulted in less mortality and fewer complications.
- Elevating the head of the bed to 30-45 degrees in ICU patients reduces the incidence of nosocomial pneumonia.
- Daily withholding of sedation in the ICU decreases the number of ICU days and results in fewer evaluations for altered level of consciousness.
- Daily spontaneous breathing trials lead to faster weaning from mechanical ventilation and shorter duration of ICU stay.
- Low-dose (physiologic) vasopressin may reduce the need for pressors in septic shock.
- Fluid resuscitation using colloid-containing solutions is not more beneficial than crystalloid fluids.
- Low-dose dopamine does not improve renal function or diuresis and does not protect against renal dysfunction.
- Acetylcysteine or sodium bicarbonate protect against radiocontrast material-induced acute renal failure.
- Patients with bleeding esophageal varices have a higher rebleeding risk if they have infection, especially spontaneous bacterial peritonitis.
- Noninvasive positive-pressure ventilation decreases the need for intubation in patients with COPD exacerbation.
- Noninvasive positive-pressure ventilation is associated with fewer respiratory infections than conventional ventilation.
- Early goal-directed therapy for sepsis (specific targets for central venous pressure, hemoglobin, and central venous oxygen content during the first 6 hours of care) decreases mortality.

Identifying and acting on new problems and complications in the ICU demands *frequent and regular review* of all information available, including changes in symptoms, physical findings, and laboratory data and information from monitors. In some facilities, early identification and treatment are provided by *rapid-response teams*. Once notified that a patient outside the ICU may be deteriorating, the team is mobilized

Table 1-2. Recommendations for routine patient care in the ICU.

- Assess current status, interval history, and examination.
- Review vital signs for interval period (since last review).
- Review medication record, including continuous infusions:
 - Duration and dose
 - Changes in dose or frequency based on changes in renal, hepatic, or other pharmacokinetic function
 - Changes in route of administration
 - Potential drug interactions
- Correlate changes in vital signs with medication administration and other changes by use of chronologic charting.
- Integrate nursing, respiratory therapists, patient, family, and other observations.
- Review, if indicated:
 - Respiratory therapy flow chart
 - Hemodynamics records
 - Laboratory flowsheets
 - Other continuous monitoring
- Review all problems, including adding, updating, consolidating, or removing problems as indicated.
- Periodically, review supportive care:
 - Intravenous fluids
 - Nutritional status and support
 - Prophylactic treatment and support
 - Duration of catheters and other invasive devices
- Review and contrast risks and benefits of intensive care.

to provide a mini-ICU environment in which critical care can be delivered early, even before the patient is actually transferred.

► Effective Use of the Problem-Oriented Medical Record

The special importance of finding, tracking, and being aware of ICU issues demands an effective problem-oriented medical record. In order to define and follow problems effectively, each problem should be reviewed regularly and characterized at its current state of understanding. For example, if the general problem of “renal failure” subsequently has been determined to be due to aminoglycoside toxicity, it should be described in that way in an updated problem list. However, even the satisfaction of identifying a cause of the renal failure may be short-lived. The same patient subsequently may develop other related or unrelated renal problems, thereby forcing reassessment.

In our opinion, ICU problems must not be restricted to “diagnoses.” We list intravascular catheters and the date they

were inserted on the problem list. This helps us to remember to consider the catheter as a site of infection if the patient has a fever. Other “nondiagnoses” on our problem list include nutritional support, prevention of deep vein thrombosis and decubitus ulcers, drug allergies, patient positioning, and prevention of stress ulcers. It may be useful to include nonmedical issues as well so that they can be discussed routinely. Examples are psychosocial difficulties, unresolved end-of-life decisions, and other questions about patient comfort. Finally, we share the patient’s problem-oriented record with nonphysicians caring for the patient, a process that enhances communication, simplifies interactions between staff members, and furthers the goals of patient care.

► Monitoring & Data Display

A tremendous amount of patient data is acquired in the ICU. Although ICU monitoring is often thought of as electrocardiography, blood pressure measurements, and pulse oximetry, ICU data include serial plasma glucose and electrolyte determinations, arterial blood gas determinations, documentation of ventilator settings and parameters, and body temperature determinations. Taking a daily weight is invaluable in determining the net fluid balance of a patient.

Flowcharts of laboratory data and mechanical ventilator activity, 24-hour vital signs, graphs of hemodynamic data, and lists of medications are indispensable tools for good patient care, and efforts should be made to find the most effective and efficient ways of displaying such information in the ICU. Methods that integrate the records of physicians, nurses, respiratory therapists, and others are particularly useful.

Computer-assisted data collection and display systems are found increasingly in ICUs. Some of these systems import data directly from bedside monitors, mechanical ventilators, intravenous infusion pumps, fluid collection devices, clinical laboratory instruments, and other devices. ICU practitioners may enter progress notes, medications administered, and patient observations. Advantages of these systems include decreased time for data collection and the ability to display data in a variety of formats, including flowcharts, graphs, and problem-oriented records. Such data can be sent to remote sites for consultation, if necessary. Computerized access to data facilitates research and quality assurance studies, including the use of a variety of prognostic indicators, severity scores, and ICU decision-making tools. Computerized information systems have the potential for improving patient care in the ICU, and their benefit to patient outcome continues to be studied.

The next step is to integrate ICU data with treatment, directly and indirectly. One excellent example is glycemic control so that up-to-date blood glucose measurements will be linked closely to insulin protocols—at first with the nurse and physician “in the loop” but potentially with

real-time feedback and automated adjustment of insulin infusions.

► Supportive & Preventive Care

Many studies have pointed out the high prevalence of gastrointestinal hemorrhage, deep venous thrombosis, decubitus ulcers, inadequate nutritional support, nosocomial and ventilator-associated pneumonias, urinary tract infections, psychological problems, sleep disorders, and other untoward effects of critical care. Efforts have been made to prevent, treat, or otherwise identify the risks for these complications. As outlined in subsequent chapters, effective prevention is available for some of these risks (Table 1–3); for other complications, early identification and aggressive intervention may be of value. For example, aggressive nutritional support for critically ill patients is often indicated both because of the presence of chronic illness and malnutrition and because of the rapid depletion of nutritional reserves in the presence of severe illness. Nutritional support, prevention of upper gastrointestinal bleeding and deep venous thrombosis, skin care, and other supportive therapy should be included on the ICU patient’s problem list. To these, we have added glycemic control because of recent data indicating reduced morbidity and mortality in medical and surgical patients whose plasma glucose concentration is maintained in a relatively narrow range.

Because of expense and questions of effectiveness and safety, studies of preventive treatment of ICU patients continue. For example, a multicenter study reported that clinically important gastrointestinal bleeding in critically ill patients was seen most often only in those with respiratory failure or coagulopathy (3.7% for one or both factors). Otherwise, the risk for significant bleeding was only 0.1%. The authors suggested that prophylaxis against stress ulcer could be withheld safely from critically ill patients unless they had one of these two risk factors. On the other hand, about half the patients in this study were post-cardiac surgery patients, and the majority of patients in many ICUs have one of the identified risk factors. Thus there may not be sufficient compelling evidence to discontinue the practice of providing routine prophylaxis for gastrointestinal bleeding in all ICU patients.

Other routine practices have been challenged. For example, several studies show that routine transfusion of red blood cells in ICU patients who reached an arbitrary hemoglobin level did not change outcome when compared with allowing hemoglobin to fall to a lower value. Further studies are needed to define the role of other preventive strategies. Important questions include differences in the need for glycemic control, critical differences in the intensity and type of therapy needed to prevent thrombosis, the optimal hemoglobin for patients with myocardial infarction, and the benefit of tailored nutritional support.

Table 1-3. Things to think about and reminders for ICU patient care.

Things To Think About	Reminders
General ICU Care	
<ol style="list-style-type: none"> 1. Nosocomial infections, especially line- and catheter-related. 2. Stress gastritis. 3. Deep venous thrombosis and pulmonary embolism. 4. Exacerbation of malnourished state. 5. Decubitus ulcers. 6. Psychosocial needs and adjustments. 7. Toxicity of drugs (renal, pulmonary, hepatic, CNS). 8. Development of antibiotic-resistant organisms. 9. Complications of diagnostic tests. 10. Correct placement of catheters and tubes. 11. Need for vitamins (thiamine, C, K). 12. Tuberculosis, pericardial disease, adrenal insufficiency, fungal sepsis, rule out myocardial infarction, pneumothorax, volume overload or volume depletion, decreased renal function with normal serum creatinine, errors in drug administration or charting, pulmonary vascular disease, HIV-related disease. 	<ol style="list-style-type: none"> 1. Discontinue infected or possibly infected lines. 2. Need for H₂ blockers, antacids, or sucralfate. 3. Provide enteral or parenteral nutrition. 4. Change antibiotics? 5. Chest x-ray for line placement. 6. Review known drug allergies (including contrast agents). 7. Check for drug dosage adjustments (new liver failure or renal failure). 8. Need for deep venous thrombosis prophylaxis? 9. Pain medication and sedation. 10. Weigh patient. 11. Give medications orally, if possible. 12. Does patient really need an arterial catheter? 13. Give thiamine early.
Nutrition	
<ol style="list-style-type: none"> 1. Set goals for appropriate nutrition support. 2. Avoid or minimize catabolic state. 3. Acquired vitamin K deficiency while in ICU. 4. Avoidance of excessive fluid intake. 5. Diarrhea (lactose intolerance, low serum protein, hyperosmolarity, drug-induced, infectious). 6. Minimize and anticipate hyperglycemia during parenteral nutritional support. 7. Adjustment of rate or formula in patients with renal failure or liver failure. 8. Early complications of refeeding. 9. Acute vitamin insufficiency. 	<ol style="list-style-type: none"> 1. Calculate estimated basic caloric and protein needs. Use 30 kcal/kg and 1.5 g protein/kg for starting amount. 2. Regular food preferred over enteral feeding; enteral feeding preferred over parenteral in most patients. 3. Increased caloric and protein requirements if febrile, infected, agitated, any inflammatory process ongoing, some drugs. 4. Adjust protein if renal or liver failure is present. Adjust again if dialysis is used. 5. Measure serum albumin as primary marker of nutritional status. 6. Give vitamin K, especially if malnourished and receiving antibiotics. 7. Consider volume restriction formulas (both enteral and parenteral). 8. Give phosphate early during refeeding. 9. Control hyperglycemia (glucose <110–120 mg/dL).
Acute Renal Failure	
<ol style="list-style-type: none"> 1. Volume depletion, hypoperfusion, low cardiac output, shock. 2. Nephrotoxic drugs. 3. Obstruction of urine outflow. 4. Interstitial nephritis. 5. Manifestation of systemic disease, multiorgan system failure. 6. Degree of preexisting chronic renal failure. 	<ol style="list-style-type: none"> 1. Measure urine Na⁺, Cl⁻, creatinine, and osmolality. 2. Volume challenge, if indicated. 3. Discontinue nephrotoxic drugs if possible. 4. Adjust all renally excreted drugs. 5. Renal medicine consultation for dialysis, other management. 6. Renal ultrasound if indicated for obstruction. 7. Check catheter and replace if indicated. 8. Stop potassium supplementation if necessary. 9. Adjust diet (Na⁺, protein, etc.). 10. If dialytic therapy is begun, adjust drugs if necessary. 11. Weigh patient daily.

(continued)

Table 1-3. Things to think about and reminders for ICU patient care. (continued)

Things To Think About	Reminders
Acute Respiratory Failure, COPD	
<ol style="list-style-type: none"> 1. Adequacy of oxygenation. 2. Exacerbation due to infection, malnutrition, congestive heart failure. 3. Airway secretions. 4. Other medical problems (coexisting heart failure). 5. Hypotension and low cardiac output response to positive-pressure ventilation. 6. Hyponatremia, SIADH. 7. Severe pulmonary hypertension. 8. Sleep deprivation. 9. Coexisting metabolic alkalosis. 	<ol style="list-style-type: none"> 1. Should patient be intubated or mechanically ventilated? Noninvasive mechanical ventilation? 2. Bronchodilators. 3. Consider corticosteroids, ipratropium. 4. Sufficient supplemental oxygen. 5. Antibiotic coverage for common bacterial causes of exacerbations. Evaluate for pneumonia as well as acute bronchitis. 6. Early nutrition support. 7. Check theophylline level, if indicated. 8. Ventilator management: low tidal volume, long expiratory time, high inspiratory flow, watch for auto-PEEP. 9. Think about weaning early.
Acute Respiratory Failure, ARDS	
<ol style="list-style-type: none"> 1. Sepsis as cause, from pulmonary or nonpulmonary site (abdominal, urinary). 2. Possible aspiration of gastric contents. 3. Fluid overload or contribution from congestive heart failure. 4. Anticipate potential multiorgan system failure. 5. Assess the risks of oxygen toxicity versus complications of PEEP. 6. Consider the complications of high airway pressure or large tidal volume in selection of type of mechanical ventilatory support. 7. Low serum albumin (contribution from hypo-oncotic pulmonary edema). 	<ol style="list-style-type: none"> 1. Early therapeutic goal of FiO_2 <0.50 and lowest PEEP (<5–10 cm H_2O), resulting in acceptable O_2 delivery. 2. Directed (if possible) or broad-spectrum antibiotics. 3. Evaluate for soft tissue or intra-abdominal infection source. 4. Diuretics, if necessary. Assess need for fluid intake to support O_2 delivery. 5. Evaluate intake and output daily; weigh patient daily. 6. Use low tidal volume, ≤ 6 ml/kg to keep plateau pressure <30 cm H_2O. 7. Follow renal function, electrolytes, liver function, mental status to assess organ system function.
Asthma	
<ol style="list-style-type: none"> 1. Airway inflammation is the primary cause of status asthmaticus. 2. Auto-PEEP or hyperinflation dominates gas exchange when using mechanical ventilation. 3. Potentially increased complication rate of mechanical ventilation. 	<ol style="list-style-type: none"> 1. High-dose corticosteroids are primary treatment. 2. Aggressive inhaled aerosolized β_2 agonists (hourly, if needed). 3. Early intubation if necessary. 4. Adequate oxygen to inhibit respiratory drive. 5. Use low tidal volume, high inspiratory flow, low respiratory frequency with mechanical ventilation to avoid barotrauma and auto-PEEP. 6. May need to sedate or paralyze to reduce hyperinflation. 7. Measure peak flow or FEV₁ as a guide to therapeutic response.
Diabetic Ketoacidosis	
<ol style="list-style-type: none"> 1. Evaluate degree of volume depletion and relationship of water to solute balance (hyperosmolar component). 2. Avoid excessive volume replacement. 3. Look for a trigger for diabetic ketoacidosis (infection, poor compliance, mucormycosis, other). 4. Avoid hypoglycemia during correction phase. 5. Identify features of hyperosmolar complications. 6. Calculate water and volume deficits. 7. Evaluate presence of coexisting acid-base disturbances (lactic acidosis, metabolic alkalosis). 8. Avoid hypokalemia and hypophosphatemia during correction phase. 	<ol style="list-style-type: none"> 1. Give adequate insulin to lower glucose at appropriate rate (increase aggressively if no response). Use continuous insulin infusion. 2. Give adequate volume replacement (normal saline) and water replacement, if needed (half normal saline, glucose in water). 3. Follow glucose and electrolytes frequently. 4. Consider stopping insulin infusion when glucose is about 250 mg/dL and HCO_3^- is >18 meq/L. 5. Avoid hypoglycemia; if you continue insulin drip with glucose <250mg/dL, then give D₅W. If glucose continues to fall, lower insulin drip rate. 6. Monitor serum potassium, phosphorus. 7. Calculate water deficit, if any. 8. Urine osmolality, glucose, etc. 9. Check sinuses, nose, mouth, soft tissue, urine, chest x-ray, abdomen for infection.

(continued)

Table 1-3. Things to think about and reminders for ICU patient care. (continued)

Things To Think About	Reminders
Hyponatremia	
<ol style="list-style-type: none"> 1. Consider volume depletion (nonosmolar stimulus for ADH secretion). 2. Consider edematous state with hyponatremia (cirrhosis, nephrotic syndrome, congestive heart failure). 3. SIADH with nonsuppressed ADH. 4. Drugs (thiazide diuretics). 5. Adrenal insufficiency, hypothyroidism. 	<ol style="list-style-type: none"> 1. Measure urine Na⁺, Cl⁻, creatinine, and osmolality. 2. Calculate or measure serum osmolality. 3. Volume depletion? Give volume challenge? 4. Ask if patient is thirsty (may be volume-depleted). 5. Review medication list. 6. Primary treatment may be water restriction. 7. Consider need for hypertonic saline (carefully calculate amount) and furosemide. 8. Other treatment (demeclocycline).
Hypernatremia	
<ol style="list-style-type: none"> 1. Diabetes insipidus (CNS or renal disease, lithium?) 2. Diabetes mellitus. 3. Has patient been water-depleted for a long-time? 4. Concomitant volume depletion? 5. Is the urine continuing to be poorly concentrated? 	<ol style="list-style-type: none"> 1. Calculate water deficit and ongoing water loss. 2. Replace with hypotonic fluids (0.45% NaCl, D₅W) at calculated rate. 3. Replace volume deficit, if any, with normal saline. 4. Measure urine osmolality, Na⁺, Cl⁻, creatinine. 5. Does patient need desmopressin acetate (central diabetes insipidus)?
Hypotension	
<ol style="list-style-type: none"> 1. Volume depletion. 2. Sepsis. (Consider potential sources; may need to treat empirically.) 3. Cardiogenic. (Any reason to suspect?) 4. Drugs or medications (prescribed or not). 5. Adrenal insufficiency. 6. Pneumothorax, pericardial effusion or tamponade, fungal sepsis, tricyclic overdose, amyloidosis. 	<ol style="list-style-type: none"> 1. Volume challenge; decide how and what to give and how to monitor. 2. If volume-depleted, correct cause. 3. Gram-positive or gram-negative sepsis (or candidemia) may also cause hypotension and shock. 4. Give naloxone if clinically indicated. 5. Echocardiogram (left ventricular and right ventricular function, pericardial disease, acute valvular disease) may be helpful. 6. Does the patient need a Swan-Ganz catheter? 7. Cosyntropin stimulation test or empiric corticosteroids.
Swan-Ganz Catheters	
<ol style="list-style-type: none"> 1. Site of placement (safety, risk, experience of operator). 2. Coagulation times, platelet count, bleeding time, other bleeding risks. 3. Document in medical record. 4. Estimate need for monitoring therapy. 5. Predict whether interpretation of data may be difficult (mechanical ventilation, valvular insufficiency, pulmonary hypertension). 	<ol style="list-style-type: none"> 1. Check for contraindications. 2. Write a procedure note. 3. Make measurements and document immediately after placement. 4. Obtain chest x-ray afterward. 5. Level transducer with patient before making measurement; eliminate bubbles in lines or transducer. 6. Discontinue as soon as possible. 7. Use Fick calculated cardiac output to confirm thermodilution measurements. 8. Send mixed venous blood for O₂ saturation.
Upper Gastrointestinal Bleeding	
<ol style="list-style-type: none"> 1. Rapid stabilization of patient (hemoglobin and hemodynamics). 2. Identification of bleeding site. 3. Does patient have a nonupper GI bleeding site? 4. Consider need for early operation. 5. Review for bleeding, coagulation problems. 6. Determine when “excessive” amounts of blood products given. 7. Do antacids, H₂ blockers, PPIs play a role? 8. Reversible causes or contributing causes. 	<ol style="list-style-type: none"> 1. Monitor vital signs at frequent intervals. 2. Monitor hematocrit at frequent intervals. 3. Choose hematocrit to maintain. 4. Consider need and timing of endoscopy. 5. Consult surgery. 6. Patients with abnormally long coagulation time may benefit from fresh-frozen plasma (calculate volume of replacement needed). 7. Platelet transfusions needed? 8. Desmopressin acetate (renal failure).

(continued)

Table 1–3. Things to think about and reminders for ICU patient care. (continued)

Things To Think About	Reminders
Fever, Recurrent or Persistent	
<ol style="list-style-type: none"> 1. New, unidentified source of infection. 2. Lack of response of identified or presumed source of infection. 3. Opportunistic organism (drug-resistant, fungus, virus, parasite, acid-fast bacillus). 4. Drug fever. 5. Systemic noninfectious disease. 6. Incorrect empiric antibiotics. 7. Slow resolution of fever (deep-seated infection: endocarditis, osteomyelitis). 8. Infected catheter site or foreign body (medical appliance). 9. Consider infections of sinuses, CNS, decubitus ulcers; septic arthritis. 	<ol style="list-style-type: none"> 1. Examine catheter sites (old and new), surgical wounds, sinuses, back and buttocks, large joints, pelvic organs, catheters and tubes, skin rashes, hands and feet. 2. Consider pleural, pericardial, subphrenic spaces; perinephric infection; spleen, prostate, intra-abdominal abscess; bowel infarction or necrosis. 3. Abscess in area of previous known infection. 4. Review prior culture results and antibiotic use. 5. Consider change in empiric antibiotics. 6. Culture usual locations plus any specific areas. 7. Discontinue or change catheters. 8. Consider candidemia or disseminated candidiasis. 9. Discontinue antibiotics? 10. Abdominal ultrasound, CT scan, gallium, leukocyte scans.
Pancytopenia (After Chemotherapy)	
<ol style="list-style-type: none"> 1. Fever, presumed infection, response to antimicrobials. 2. Thrombocytopenia and spontaneous bleeding. 3. Drug fever. 4. Transfusion reactions. 5. Staphylococcus, candida, other opportunistic infections. 6. Infection sites in patient without granulocytes may have induration, erythema, without fluctuance. 7. Pulmonary infiltrates and opportunistic infection. 	<ol style="list-style-type: none"> 1. Fever workup; see above. 2. Special sites: soft tissues, perirectal abscess, urine fungal cultures, lungs. 3. Bronchoscopy with bronchoalveolar lavage. 4. Empiric antibiotics, continue until afebrile, doing well, granulocytes >1000/μL. 5. Empiric or directed vancomycin, antifungal drugs, antiviral drugs, antituberculous drugs. 6. Check intravascular catheters, bladder, catheter. 7. Platelet transfusions, prophylaxis for spontaneous bleeding (or if already bleeding).

▶ Attention to Psychosocial & Other Needs of the Patient

Psychosocial needs of the patient must be a major consideration in the ICU. The psychological consequences of critical illness and its treatment have a profound impact on patient outcome. Leading factors include the patient's lack of control over the local environment, severe disruption of the sleep-wake cycle, inability to communicate easily and quickly with critical care providers, and pain and other types of physical discomfort. Inability to communicate with family members, as well as concern about employment status, activities of daily living, finances, and other matters, further inflates the emotional costs of being seriously ill. The intensivist and other staff members must pay close attention to these problems and issues and consider psychological problems in the differential diagnosis of any patient's altered mental status. Adequate yet appropriate sedation and analgesia are mandatory to preserve the balance of comfort with patient assessment and interaction needs.

There is increased awareness of the potential harm to patients and caregivers from the ICU environment. The

noise level is high (reported to exceed 60–84 dB, where a busy office might have 70 dB and a pneumatic drill at 50 feet might be as loud as 80 dB), notably from mechanical ventilators, conversations, and telephones but especially from audio alarms on ICU equipment. One study found that caregivers were unable to discern and identify alarms accurately, including alarms that indicated critical patient or equipment conditions.

Sleep disruption deserves much more attention. Very disruptive sleep architecture has been identified in patients in the ICU. Frequent checking of vital signs and phlebotomy were most disruptive to patients, and environmental factors were less of a problem to patients surveyed. Most recently, in addition, the impact of duty hours, sleep, and time off on the cognitive and patient care ability of house officers is being studied and reported.

▶ Understand the Limits of Critical Care

All physicians involved with critical care must be familiar with the limitations of such care. Interestingly, physicians and other care providers may have to be reminded that

critical illness is and always will be associated with high morbidity and mortality rates. The outcome of some disease processes simply cannot be altered despite the availability of modern comprehensive treatment. On the basis of medical evidence and after consultation with the patient and family, some patients will continue to receive aggressive treatment; for others, withdrawal or withholding of ICU care may be the most appropriate and correct decision.

It is not surprising that critical care physicians, together with medical ethicists, have played a major role in developing a body of ethical constructs concerned with such issues as forgoing of care, determination of brain death, and withholding feeding and hydration. The critical care physician must be familiar with ethical and legal concepts of patient autonomy, informed consent and refusal, application of advanced directives for health care, surrogate decision makers, and the legal consequences of decisions made in this context. The cost of care in the ICU will be scrutinized increasingly because of economic constraints on health care.

There is evidence that care in the ICU improves outcome in only a small subgroup of patients admitted. Some patients may be so critically ill with a combination of chronic and acute disorders that no intervention will reverse or even ameliorate the course of disease. Others may be admitted with very mild illness, and admission to the ICU rather than a non-ICU area does not improve the outcome. On the other hand, two other subgroups emerge from this analysis of ICU patients. First, a small subgroup with a predictably poor outcome may have an unexpectedly successful result from ICU care. A patient with cardiogenic shock with a predicted mortality rate of over 90% who survives because of aggressive management and reversal of myocardial dysfunction would fall into this group. The other small group consists of patients admitted for monitoring purposes only or for minor therapeutic interventions who develop severe complications of treatment. In these patients with predicted favorable outcomes, unanticipated adverse effects of care may result in severe morbidity or death.

Areas of critical care outcome research have, for example, focused on the elderly, those with hematologic and other malignancies, patients with complications of AIDS, and those with very poor lung function from chronic obstructive pulmonary disease, interstitial lung disease, acute respiratory distress syndrome, multiorgan failure, or pancreatitis. Much more needs to be learned about prognosis and factors that determine outcome, but it is essential that data be used appropriately and not applied indiscriminately for individual patient decisions.

Alternatives to current care should be reviewed periodically and considered in every patient in the ICU. Some patients may no longer require the type of care available in the ICU; transfer to a lower level of care may benefit the patient medically and emotionally and may decrease the

risk of complications and the costs of treatment. Admission criteria should be reviewed regularly by the medical staff. Similarly, ongoing resource utilization efforts should be directed at determining which types of patients are best served by continued ICU care.

ROLE OF THE MEDICAL DIRECTOR OF THE INTENSIVE CARE UNIT

The medical director of the ICU has administrative and regulatory responsibilities for this patient care area. As medical director, leadership is vital in establishing policies and procedures for patient care, maintaining communication across health care disciplines, developing and ensuring quality care, and helping to provide education in a rapidly and constantly changing medical field. The medical director and the ICU staff may choose to coordinate care in a number of areas.

▶ Protocols, Practice Guidelines, & Order Sets

A survey of outcomes from ICUs concluded that established protocols for management of specific critical illnesses contribute to improved results. The medical director and medical staff, nursing staff, and other health care practitioners may choose to develop protocols that define uniformity of care or ensure that complete orders are written. Some protocols may be highly detailed, complete, and focused on a single clinical condition. An example might be a protocol for treatment of patients with suspected acute myocardial infarction—the protocol could specify the frequency, timing, and types of cardiac enzyme or troponin determination and the timing for ECGs and other diagnostic tests. Certain standardized medications, such as aspirin, heparin, angiotensin-converting enzyme inhibitors, and beta-adrenergic blockers, might be included in such a protocol, and the physician could choose to give these or not depending on the particular clinical situation. Protocols are used by many ICUs for community-acquired pneumonia, ventilator-associated pneumonia, sepsis, ventilator weaning, and other clinical situations.

Another type of protocol can be “driven” by critical care nurses or respiratory therapists. In these protocols, nurses or therapists are given orders to assess the effectiveness and side effects of therapy and are given freedom to adjust therapy based on these results. A protocol for aerosolized bronchodilator treatment might specify administration of albuterol by metered-dose inhaler, but the respiratory therapist would determine the optimal frequency and dose on the basis of how much improvement in peak flow or FEV₁ was obtained and how much excessive tachycardia was encountered.

The ICU medical director may consider limiting the use of certain medications based on established protocols. For example, some antibiotics may be restricted because of cost, toxicity, or potential for development of microbial resistance.

Neuromuscular blocking agents may be restricted to use only by certain qualified personnel because of need for special expertise in dosing or patient support. Protocols can take several different forms, and patient care in the ICU may benefit from their development.

Physician practice guidelines are being developed for many aspects of medical practice. Although some critics of guidelines argue that these are unnecessarily restrictive and that elements of medical practice cannot be rigidly defined, practice guidelines may be useful for diagnosing and treating patients in the ICU. Guidelines may vary from recommendations for dose and adjustment of heparin infusion for anticoagulation to specific minimum standards of care for status asthmaticus, unstable angina, heart failure, or malignant hypertension. Practice guidelines will be found commonly in the ICU of the near future, and ICU directors will be called on to develop, review, accept, or modify guidelines for individual ICUs.

The next step beyond practice guidelines is ICU order sets. Order sets, either paper or paperless, can streamline practice guidelines accepted by the ICU staff. Highly recommended orders can be preselected, whereas guidance may be given for other choices. A major feature of order sets will be reduction of errors because the order sets include preprinted medication names, recommended dosages, and potential drug interactions. Computerized order entry goes beyond the ICU order set, permitting immediate dosage calculations, for example, or other real-time recommendations. Although some have questioned the “one size fits all” nature of order sets, evidence suggests that there is an increase in the correct application of evidence-based treatment with implementation of ICU order sets.

► Quality Assurance

The ICU medical director participates in quality-of-care evaluation. Quality of care may be assessed by measurement of patient satisfaction, analyzing frequency of delivery of care, monitoring of complications, duration of hospitalization, analysis of mortality data, and other ways. Patient outcome eventually may emerge as the most effective global determination of the quality of care, but such measures suffer from the difficulty in stratifying severity in very complex patients with multiple medical problems. The development of protocols and programs to measure and enhance the quality of care is beyond the scope of this presentation. However, the medical and nursing leadership of the ICU must play key roles in any such projects.

The medical director also plays an important role in granting privileges to practice in the ICU. Competence in and experience with medical procedures must be investigated, documented, and maintained for all physicians who use the service. While this is especially important for invasive procedures such as placement of pulmonary artery catheters and endotracheal intubation, consideration also should be

given to developing and granting privileges for mechanical ventilator management, management of shock, and other nonprocedural care. Similarly, the skills and knowledge of nurses, respiratory therapists, and other professionals in the ICU should be determined, documented, and matched to their duties. The ICU medical director has the responsibility to develop standards for those who care for the patients in that unit.

Effective quality improvement activities go far beyond simple data collection and reporting. A dedicated group of health care providers should meet regularly to review the data, establish trends, and suggest methods for improvement. The importance of “closing the loop” in the quality improvement process cannot be overstated. Monitoring of outcomes after instituting change is an important part of this activity and is mandatory if patient care is to be effectively and expeditiously improved.

► Infection Control

Nosocomial infections are important problems in the ICU, and their prevention and management can provide insight into the effectiveness of protocols and quality assurance functions. Infection control is particularly important because of increased antimicrobial resistance of organisms such as methicillin-resistance *Staphylococcus aureus* (MRSA), multidrug-resistant *Acinetobacter*, vancomycin-resistant enterococci (VRE), and *Clostridium difficile*. As described elsewhere, nosocomial infections are often preventable by adherence to procedures and policies designed to limit spread of infection between patients and between ICU staff and patients. The ICU medical director must take the lead in establishing infection control protocols, including procedures for aseptic technique for invasive procedures, standards for universal precautions, duration of invasive catheter placement, suctioning of endotracheal tubes, appropriate use of antibiotics, procedures in the event of finding antibiotic-resistant microorganisms, and the need for isolation of patients with communicable diseases. Consequently, an important measure of the quality of care being provided is the nosocomial infection rate in the ICU, especially intravascular infections secondary to indwelling catheters. The ICU medical director should work closely with the nursing staff and hospital epidemiologist in the event of excessive nosocomial infections. Often a breach in procedures can be identified and corrected. Importantly, it has been demonstrated that simple measures to prevent infection at the time of placement of intravenous catheters is highly effective.

► Education & Errors

The ICU medical director is required to provide educational resources for the staff of the ICU, including critical care nurses, respiratory therapists, occupational therapists, and other physicians. This may be in the form of lectures, small

group discussions, audiovisual presentations, or prepared handouts or directed readings. An effective strategy is to focus presentations on problems recently or commonly encountered; recent experience may help to clarify and amplify the more didactic portion. Very often in critical care areas there is a need for personnel to develop skills for using new equipment such as monitors, catheters, and ventilators. Appropriate time and feedback should be planned with the introduction of such equipment before it can be assumed that it can be used for patient care.

In the teaching hospital, the faculty and attending staff not only must convey the principles of critical care practice but also must foster an attitude of rigorous critical review of data, cooperation between medical and other personnel, and attention to detail. The new focus on reduction of medical errors has greatly changed the way critical care medicine is practiced. The potential for errors is enormous in the ICU. Data show that changing error reporting from a potentially punitive system to one in which future errors are prevented is key.

► Communication

The ICU medical director serves as a communication link between physician staff, including primary care and consulting physicians, and the nursing and other health care professional staff in the ICU. Most of this communication will occur naturally as a result of interaction during patient care, quality assurance activities, and other administrative meetings. On occasion, further communication is needed to address specific complaints, procedures, or policies. Depending on the organization of the hospital, the ICU also may be served by a multidisciplinary committee that can participate in development of protocols and policies. This committee may function with respect to a single ICU in a hospital or may have responsibility for standardization of activities in several ICUs in the area.

► Burnout

A different topic is burnout among ICU physicians, nurses, and other health care workers. Valuable data are now available about the risks of burnout and its effects on patient care, productivity, and career planning. Burnout is one effect of psychosocial stress and is related to duration of work hours, the impact of taking care of patients with critical illness, the effects of poor patient outcome despite maximal effort, and organizational issues. Intensivists, ICU nurses, and respiratory therapists may experience occupational burnout.

► Outcomes & Alternatives

In many facilities, ICU beds are limited in number, and incoming patients with varying degrees of morbidity often must be evaluated and compared to determine who might best be treated in the ICU. A number of published

studies have confirmed that a good proportion of patients admitted to ICUs receive diagnostic studies and monitoring of physiologic variables *only*—ie, no therapy that could not be given outside the ICU. On the other hand, other patients admitted to the ICU do receive such “intensive” therapy, and some of these have better outcomes. Because ICU beds are a limited resource in all hospitals, ICU medical directors must develop familiarity with the overall outcomes and results of patients admitted to their ICU beds. They will be called on not infrequently to make decisions about admissions, discharge, and transfer from the ICU, and these decisions at times may be arrived at painfully. As with all decisions affecting patient care, the medical director must weigh the body of medical knowledge available; the wishes of patients, families, and physicians; and the likelihood or not that intensive care will benefit the patient. At times, these decisions will involve only “medical judgment”; at other times, the choice will reflect an ethical, legal, or philosophical perspective.

Specific practice guidelines for individual diseases have been developed for the purpose of identifying particular patients. Recognition that many patients previously admitted to ICUs did not require or receive major diagnostic or therapeutic interventions led to the design of progressive care, “step-down,” or noninvasive monitoring units in some hospitals. Equipped and staffed generally for electrocardiography, pulse oximetry, and sometimes for noninvasive respiratory impedance plethysmography—but not for intravascular instrumentation—these units have potential as highly effective, less costly alternatives to ICUs. A number of studies have provided justification for intermediate care units either as an area for patients leaving the ICU or as an area devoted to care of certain kinds of medical problems—primarily mild respiratory failure, cardiac arrhythmias, or moderately severe electrolyte disorders.

CRITICAL CARE SCORING

The combination of an increasing patient population and diminished funding for hospital services is creating a need for optimized distribution of medical resources. This challenge is being met in a number of ways, including regionalization of care, specialization of critical care facilities (both between and within hospitals), and better allocation of available personnel and equipment. To this end, the intensivists must be prepared to make both administrative and medical decisions about which patients will benefit most from admission to a critical care unit. Data in 1987 indicated that up to 40% of patients in ICUs were inappropriately admitted either because they probably would have died regardless of the care provided or because their illnesses were not life-threatening enough to require ICU care. Indeed, a substantial number of patients treated in critical care units at teaching hospitals are admitted for “observation and monitoring” only.

Illness scoring has become a popular method for triage within and between hospitals. Many such scores have been introduced over the past two decades in an attempt to prioritize illness and injury for ICU admission purposes. Such scores must be used with full appreciation of their limitations. While they are useful for comparing institutional performances and outcomes in studies of certain groups of patients, great caution must be exercised when applying these protocols to individual patients.

The most commonly used trauma and critical care scores are discussed below and are illustrated in the accompanying tables.

Glasgow Coma Scale

The Glasgow Coma Scale assesses the extent of coma in patients with head injuries (Table 1–4). The scale is based on eye opening, verbal response, and motor response. The total is the sum of each of the individual responses and varies between 3 points and 15 points. Mortality risk is correlated with the total score and with a similar Glasgow Outcome Scale. Examination of the patient and calculation of the score can be accomplished in less than 1 minute. The scale is easy to use and highly reproducible between observers. It has been incorporated into several other scoring systems. The Glasgow Coma Scale is useful for prehospital trauma triage as well as for assessment of patient progress after arrival and during critical care admission.

Trauma Score and Revised Trauma Score

Because of the increasing number of trauma patients admitted to critical care facilities, familiarity with trauma scales is important. The Trauma Score is based on the Glasgow Coma Scale and on the status of the cardiovascular and respiratory systems.

Table 1–4. The Glasgow Coma Scale.

Eye	Motor	Verbal
4 = Spontaneous	6 = Obedient	5 = Oriented
3 = To Voice	5 = Purposeful	4 = Confused
2 = To pain	4 = Withdrawal	3 = Inappropriate
1 = None	3 = Flexion	2 = Incomprehensible
	2 = Extension	1 = None
	1 = None	

Weighted values are assigned to each parameter and summed to obtain the total Trauma Score, which ranges from 1 to 16 (Table 1–5). Mortality risk varies inversely with this score.

After extensive use and evaluation of the Trauma Score, it was found to underestimate the importance of head injuries. In response to this, the Revised Trauma Score (RTS) was introduced and is now the most widely used physiologic trauma scoring tool. It is based on the Glasgow Coma Scale, systolic blood pressure, and respiratory rate. For evaluation of in-hospital outcome, coded values of the Glasgow Coma Scale, blood pressure, and respiratory rate are weighted and summed (Table 1–6). Better prognosis is associated with higher values.

CRAMS Scale

The Circulation, Respiration, Abdomen, Motor, Speech (CRAMS) Scale is another trauma triage scale that has found

Table 1–5. Trauma Score.

A. Systolic blood pressure		B. Respiratory rate		C. Respiratory effort		D. Capillary refill	
>90	4	10–24	4	Normal	1	Normal	2

Glasgow Coma Scale (GCS)	Systolic Blood Pressure (SPB) (mm Hg)	Respiratory Rate (RR) (Breaths/min)	Coded Value
13-15	>89	10-29	4
9-12	76-89	>29	3
6-8	50-75	6-9	2
4-5	1-49	6-9	1
3	0	1-5	0

¹RTS = 0.9368 GCS_c + 0.7326 SBP_c + 0.2908 RR_c, where the subscript c refers to coded value.

regional acceptance (Table 1-7). It is frequently used to decide which patients require triage to a trauma center. Patients with lower CRAMS Scale scores would be expected to require critical care unit admission.

Injury Severity Score (ISS)

The ISS attempts to quantitate the extent of multiple injuries by assignment of numerical scores to different body regions (head and neck, face, thorax, abdomen, pelvic contents, extremities, and external). A book of codes is available that provides information on the scoring of each injury. The worst injury in each region is assigned a numerical value, which is then squared and added to those from each of the other areas. The total score ranges from 1 to 75 and correlates with mortality risk. The major limitation of the ISS is that it considers only the highest score from any body region and considers injuries with equal scores to be of equal importance irrespective of body region. Similarly, since the ISS is an anatomic score, a small injury with a significant potential for deleterious outcome (closed head injury) may lead to the false impression of a minimally injured patient. ISS is the most commonly used measure of the severity of anatomic injury and provides a rough survival estimate for the severely injured patient.

Acute Physiology, Age, Chronic Health Evaluation (APACHE)

The APACHE scoring system (APACHE III) is probably the most widely used critical care scale. It permits comparisons between groups of patients and between facilities. It was not designed to evaluate individual patient outcomes. To this end, APACHE III was introduced to objectively estimate patient risk for mortality and other important outcomes related to patient stratification. While some centers have adopted the APACHE III score, it is not used widely except for study of trends in patient groups.

Table 1-7. The CRAMS Scale.¹

Circulation	
Normal capillary refill and BP >100 mm Hg	2
Delayed capillary refill or 85 <BP <100	1
No capillary refill or BP <85 mm Hg	0
Respiration	
Normal	2
Abnormal	1
Absent	0
Abdomen	
Abdomen and thorax nontender	2
Abdomen or thorax tender	1
Abdomen rigid or flail chest	0
Motor	
Normal	2
Responds only to pain (other than decerebrate)	1
No response (or decerebrate)	0
Speech	
Normal	2
Confused	1
No intelligible words	0

¹Score ≤ 8 indicates major trauma; score ≥ 9 indicates minor trauma.

CURRENT CONTROVERSIES & UNRESOLVED ISSUES

The usefulness of scales such as the APACHE III scoring system remains to be determined long after their introduction. Furthermore, the ability of experienced physicians to make such management decisions may be as good as such scales and perhaps often better. Some authors have concluded that ICU scoring systems can be used to compare outcomes within and between ICUs and can provide adequate adjustment of mortality rates based on preadmission severity for the purpose of assessing quality of care.

DISORDERS OF FLUID VOLUME

In normal persons, water, distributed between the intracellular and extracellular spaces, makes up 50–60% of total body weight. Critical illness not only can result from abnormalities in the amount and distribution of water but also can cause strikingly abnormal disorders of water and solutes.

Distribution of Body Water

Total body water is distributed freely throughout the body except for a very few areas in which movement of water is limited (eg, parts of the renal tubules and collecting ducts). Water diffuses freely between the intracellular space and the extracellular space in response to solute concentration gradients. Therefore, the amount of water in different compartments depends entirely on the quantity of solute present in that compartment.

The two major fluid compartments of the body are the intracellular space, in which the major solutes are potassium and various anions, and the extracellular space, for which sodium and other anions are the major solutes. Sodium moves into and potassium out of cells passively along concentration gradients. Thus active transport of sodium and potassium by Na^+, K^+ -ATP-dependent pumps on the cell membrane determines the relative quantities of these cations on the inside and outside of each cell. The distribution of Na^+ and K^+ determines the relative volumes. In normal individuals, about two-thirds of total body water is intracellular and one-third is extracellular.

Addition of solute to either compartment will increase the volume of that compartment by redistribution of water from the compartment of lower solute (higher water) concentration into the compartment to which the solute was added. Thus the solute concentration in both compartments will increase (see “Water Balance”). To restore normal volumes, the body will seek to eliminate or redistribute the added solute and correct the increased solute concentration (eg, stimulation of thirst or conservation of water). Similarly, the loss of solute from a

compartment results in a shrinkage of that compartment. The body then tries to restore the lost solute to reestablish the original volume and distribution of solute and water.

Distribution of Extracellular Volume

Extracellular volume is divided into the interstitial and the intravascular space. The distribution of water between these two compartments is complex in normal subjects and more so during disease states in which edema (increase in interstitial volume) or accumulation of fluid in normally nearly dry spaces (eg, peritoneal cavity or pleural space) is present. Normally, intravascular volume is maintained by the oncotic pressure of large molecules that are confined to the intravascular space, by movement of lymph from the interstitial to the intravascular space, and by forces that maintain extracellular volume. Countering these are the hydrostatic pressure developed by the heart and circulation and interstitial fluid oncotic pressure, which tend to push fluid out of the intravascular space. The volume of the intravascular compartment determines the adequacy of the circulation; this, in turn, determines the adequacy of delivery of oxygen, nutrients, and other substances needed for organ function.

Hypovolemia and Hypervolemia

Because sodium is the predominant extracellular solute, extracellular volume is determined primarily by the sodium content of the body and the mechanisms responsible for maintaining sodium content (Table 2–1). However, the term *hypovolemia* generally refers only to decreased intravascular volume and not decreased extracellular volume, and this disorder results from inadequate intravascular volume maintenance. On the other hand, the term *hypervolemia* generally denotes increased extracellular volume with or without increased intravascular volume. Thus patients with edema or ascites have hypervolemia (frequently with decreased intravascular volume), but so do

Table 2-1. Factors affecting body sodium balance.

<p>Increased body sodium content (increased extracellular volume)</p> <ul style="list-style-type: none"> • Increased sodium intake (in absence of increased sodium excretion) • Decreased sodium excretion by kidneys <ul style="list-style-type: none"> Decreased glomerular filtration Increased renal tubular sodium reabsorption Increased renin, angiotensin, aldosterone Excessive mineralocorticoid activity <p>Decreased body sodium content (decreased extracellular volume)</p> <ul style="list-style-type: none"> • Decreased sodium intake (in presence of normal sodium excretion) • Increased sodium excretion <ul style="list-style-type: none"> Renal: <ul style="list-style-type: none"> Renal failure Salt-losing nephropathy Osmotic diuresis Diuretic drugs Atrial natriuretic peptide Decreased renin, angiotensin, aldosterone, or cortisol Extrarenal: <ul style="list-style-type: none"> Diarrhea Vomiting Sweating Surgical drainage

patients with congestive heart failure (who have increase in both intravascular and extracellular volumes).

Normally, daily sodium excretion equals intake, so sodium excretion varies with dietary or other intake. The average diet contains 4–8 g of sodium daily, and this quantity must be excreted. With severe limitation of dietary sodium, normal kidneys can vigorously reabsorb sodium, so as little as 1–5 meq Na⁺/L of urine appears, and only 1–2 meq of Na⁺ is excreted daily. A daily sodium intake and excretion of approximately 40–65 meq (about 1–1.5 g) is sufficient in normal individuals.

▶ Hypovolemia

ESSENTIALS OF DIAGNOSIS

- ▶ Evidence of decreased intravascular volume: hypotension, low central venous or pulmonary artery wedge pressures
- ▶ Indirect evidence of decreased effective intravascular volume: tachycardia, oliguria, avid renal sodium reabsorption
- ▶ Circumstantial evidence of depleted effective intravascular volume: end-organ dysfunction, peripheral vasoconstriction
- ▶ Potential source of loss of extracellular volume or evidence of inadequate repletion

General Considerations

A. Definition—Hypovolemia is decreased volume of the intravascular space. Although extracellular volume, of which the intravascular space is a part, is often diminished, hypovolemia can occur even in the presence of normal or increased extracellular volume (Table 2-2). The assessment of adequacy of intravascular volume in the presence of normal or increased extracellular volume is often difficult, especially in critically ill patients. It is central to the concept of hypovolemia that *total* intravascular volume need not be diminished but that *effective* intravascular volume is low, such that there is insufficient volume in the circulation to provide circulatory adequacy. The term *effective arterial volume* is sometimes used to characterize the physiologically effective part of the intravascular volume.

Some clinicians use the term *dehydration* as a substitute for hypovolemia. This is incorrect, and this term should be reserved to mean insufficient water relative to total body solute (see below).

B. Pathophysiology—Decreased effective intravascular volume can occur with decreased, normal, or increased extracellular volume. Decreased extracellular volume leading to depletion of intravascular volume is most common and can arise from increased loss of extracellular fluid, failure to replete normal losses, or a combination of both. Bleeding, diarrhea, vomiting, and excessive skin loss of fluid (sweating, burns) can quickly deplete extracellular volume. Abnormally large urinary losses of sodium and water from renal disease, adrenal insufficiency, diuretics, or hyperglycemia (osmotic diuresis) also should be considered as sources of volume depletion. Decreased extracellular volume also can arise

Table 2-2. Hypovolemia (decreased effective intravascular volume).

<p>With decreased extracellular volume</p> <ul style="list-style-type: none"> • Increased fluid losses <ul style="list-style-type: none"> Gastrointestinal tract (diarrhea, vomiting, fistulas, nasogastric suction) Renal (polyuria with renal sodium wasting, osmotic diuresis) Skin or wound losses (sweating, burns) Hemorrhage (trauma, other bleeding site) • Decreased intake of sodium and water • Impaired normal capacity to retain sodium and water <ul style="list-style-type: none"> Renal sodium wasting (polycystic kidneys, diuretics) Adrenal insufficiency Osmotic diuresis (hyperglycemia) <p>With increased or normal extracellular volume</p> <ul style="list-style-type: none"> • Cirrhosis with ascites • Protein-losing enteropathy • Congestive heart failure • Increased vascular permeability (sepsis, shock, trauma, burns)

from inadequate replacement; this is particularly likely to occur in ill patients who do not eat or drink appropriately or who do not have access to adequate amounts of water and solutes.

Hypovolemia with normal extracellular volume results from any disorder that alters the balance between intravascular and extravascular fluid compartments. Intravascular oncotic pressure and intact vascular integrity largely maintain intravascular volume, whereas hydrostatic pressure tends to push fluid out of the circulation. Sepsis, acute respiratory distress syndrome (ARDS), shock, and other critical illnesses alter this balance by increasing the permeability of the vasculature, thereby raising nonintravascular fluid volume (ie, interstitial compartment, pleural effusions, or ascites) at the expense of the intravascular volume. Although decreased vascular oncotic pressure and increased hydrostatic pressure also should shift fluid balance in this direction, these rarely develop rapidly enough to be seen with unchanged total extracellular fluid volume.

Disorders that increase hydrostatic pressure in certain vascular beds or reduce intravascular oncotic pressure also can deplete intravascular volume. Reduced intravascular volume stimulates increased renal sodium reabsorption, which causes an increase in total extracellular volume. Thus cirrhosis with hypoalbuminemia results in ascites from a combination of portal hypertension and decreased oncotic pressure, heart failure leads to edema as a result of increased hydrostatic pressure, and edema in nephrotic syndrome results from severely reduced oncotic pressure. The paradox in these clinical situations is that effective intravascular volume may be severely reduced even though the extracellular volume is greatly increased.

Clinical Features

The diagnosis of volume depletion in the critically ill patient is often difficult largely because of the confounding effects of organ system dysfunction and the frequency with which drugs, edematous states, altered cardiovascular and renal function, and other factors interfere with assessment of volume status.

A. Symptoms and Signs—Symptoms and signs suggesting hypovolemia in the critically ill patient may or may not be helpful. Volume depletion causing inadequate systemic perfusion leads to altered mental status, confusion, lethargy, and coma; cold skin and extremities from vasoconstriction; cardiac ischemia and dysfunction; and liver and kidney failure. None of these are specific for hypovolemia, but all are common to hypotension and shock from any cause. A potentially important symptom is thirst in a patient with hyponatremia; lack of an osmotic stimulus leaves volume depletion as the only physiologic reason for thirst. In the patient with hypovolemia with increased extracellular fluid volume, edema, and ascites make determination of effective intravascular volume even more difficult.

Symptoms and signs do not have sufficiently high sensitivity and high specificity to be of strong clinical value. Postural lightheadedness increases the likelihood of volume depletion, but an increase in heart rate from supine to standing must be greater than 30 beats/min to be specific for hypovolemia. Orthostatic blood pressure changes lack sensitivity and specificity, but these should be part of the evaluation of potential hypovolemia. Dry axillae, longitudinal furrows on the tongue, and sunken eyes have some slight predictive value for hypovolemia.

A source of volume loss or an explanation for inadequate volume repletion strongly supports the diagnosis of hypovolemia. In the ICU patient, blood loss, diarrhea, and polyuria are usually obvious; less easily identified are heavy sweating during fever, fluid losses from extensive burns, volume changes during hemodialysis or ultrafiltration, and drainage from surgical incisions or wounds. Review of intravenous and enteral fluid intake is often helpful, along with comparison of patient weights on a daily basis or more often.

Indirect evidence of hypovolemia can come from the response of the cardiovascular and renal systems. Depleted intravascular volume leads to decreased venous return to the heart; the normal response is a lower stroke volume and sinus tachycardia to maintain cardiac output.

B. Laboratory Findings—Intravascular volume depletion may lead to avid retention of water because of increased antidiuretic hormone (ADH) release and, if there is sufficient water intake, hyponatremia. Decreased intravascular volume causes prerenal azotemia with elevation of plasma creatinine and urea nitrogen concentrations.

Except in the case of a primary renal cause of hypovolemia, decreased renal blood flow, even if glomerular filtration is maintained, increases renal tubular sodium reabsorption. Urine volume diminishes, and urine becomes highly concentrated under the influence of ADH and other factors. Urine sodium and chloride concentrations may become very low (<5–10 meq/L) with correspondingly low fractional excretion of sodium ($FE_{Na} < 1\%$), chloride, and urea (<35%). Because of decreased renal tubular flow, urea is reabsorbed more readily, and the plasma urea nitrogen:plasma creatinine ratio increases, often greater than 30:1. In some patients, avid sodium reabsorption comes at the expense of increased potassium losses in the urine and hypokalemia. Potassium depletion and increased sodium reabsorption in the distal tubule enhance hydrogen ion excretion, leading to metabolic alkalosis (contraction alkalosis); this is especially common in volume depletion owing to vomiting.

On the other hand, if there is a primary renal-mediated mechanism of hypovolemia, urine sodium concentration and FE_{Na} may not decrease in the face of decreased intravascular volume. Urinary indices of volume depletion may be misleading, and paradoxical polyuria and high urine sodium may be found. For patients taking diuretics, the fractional excretion of urea may be low (<35%) in the face of hypovolemia even though the fractional excretion of sodium is

misleadingly high. Some patients will have mild to severe renal insufficiency. Excessive and inappropriate renal sodium loss is also seen in adrenal insufficiency; these patients also may have hyponatremia, hyperkalemia, hyperchloremic metabolic acidosis, and other features of inadequate adrenocortical hormone production. Osmotic diuresis (eg, from hyperglycemia or administration of mannitol) and diuretic drugs also cause hypovolemia with paradoxically increased urine sodium and water.

C. ICU Monitoring—Pressure measurements provide evidence of volume depletion but must be interpreted with caution. The volume of the intravascular space determines “pressure” as a function of the physical properties, size, and character of the vessels—whether arteries or veins—along with the amount of propulsive force imparted to the blood by the heart. In a patient with “normal” vessels and a normal heart, hypotension indicates that the volume of fluid is insufficient to fill the arterial vessels. Hypotension of the venous system can be assessed in the same way, using central venous pressure (CVP) or pulmonary capillary wedge pressure (PCWP).

Differential Diagnosis

Hypotension from cardiogenic shock results from decreased systolic function of the heart, and septic shock arises largely from extreme dilation of the vascular space, causing relative hypovolemia. Orthostatic changes in blood pressure in the absence of hypovolemia may be seen with autonomic dysfunction, peripheral neuropathy, diabetes mellitus, or hypokalemia and in response to antihypertensive medications.

Treatment

A. Estimate Magnitude of Hypovolemia—The amount of volume depletion in the hypovolemic patient in the ICU cannot be easily estimated. In a normal-sized adult, extracellular volume depletion of 15–25%, or 2–4 L, is needed before orthostatic blood pressure and pulse changes occur. During acute blood loss, changes in blood pressure and heart rate are seen only when more than 2 units of blood (about 1 L, or 20%, of normal blood volume) are lost.

CVP and PCWP measurements are most useful for identifying volume depletion, but their magnitudes provide only a rough guide to the degree of hypovolemia. The response to a trial of fluid administration is often the best evidence for hypovolemia and gives a useful (albeit retrospective) measure of the amount of volume depletion originally present. Acutely, such as during hemodialysis or ultrafiltration, the change in weight is an accurate measure of extracellular fluid change, but this may not be true in other circumstances. Further confounding the assessment of hypovolemia is the highly variable speed of mobilization of interstitial fluid (edema) or pleural or peritoneal fluid as intravascular volume decreases. In general, an adult ICU patient in whom hypovolemia is strongly suspected is likely to be depleted by about

1–4 L of extracellular volume, but correction of severe volume depletion may require considerably more.

B. Determine Rate of Correction of Hypovolemia—Hypovolemic shock with severe organ dysfunction, hypotension, and oliguria requires immediate and rapid correction of hypovolemia. Under less severe circumstances, repletion of extracellular and intravascular volume can be undertaken more slowly and carefully to avoid overcorrection with subsequent pulmonary or peripheral edema. In all cases, the volume of replacement should be estimated and some proportion of this quantity given over a defined period of time. Evidence of continued volume depletion should be reviewed regularly, and volume repletion should be halted as soon as there is no longer evidence of hypovolemia or when complications of therapy (pulmonary edema) are discovered.

About 50–80% of the estimated fluid replacement volume should be given over 12–24 hours if the patient is not acutely hypotensive. This generally puts the rate of fluid intake in the range of 50–150 mL/h above maintenance fluid administration, depending on the estimated degree of volume depletion. In other patients—especially those in whom the diagnosis of hypovolemia is less certain or those who have known or suspected heart disease—a “fluid challenge” may be more appropriate, that is, giving 100–300 mL (less in smaller persons) of intravenous fluid over 1–2 hours and then making a careful reassessment and checking urine output, CVP or PCWP, blood pressure, and other signs. At this point, a decision can be made about whether to repeat the challenge, start a continuous infusion, or consider other issues. Patients with severe volume depletion and organ dysfunction should be given fluid rapidly (200–300 mL/h) for short periods and reassessed frequently.

C. Type of Fluid Replacement—Because hypovolemia is depletion of the volume of the intravascular space, replacement fluid should predominantly fill and remain in the intravascular space. In practice, replacement fluids given intravenously consist of crystalloid solutions, made of water and small solutes, and colloid solutions, consisting of water, electrolytes, and higher-molecular-weight proteins or polymers (Table 2–3).

At first glance, crystalloid solutions would appear to be inefficient for intravascular fluid repletion because the small solutes and water distribute quickly into both the interstitial and the intravascular spaces. Nevertheless, repletion of the total extracellular volume is essential in patients with hypovolemia and extracellular fluid depletion (eg, blood loss, gastrointestinal tract losses, polyuria, and sweating), and intravascular volume will be corrected along with correction of extracellular volume. In theory, large volumes of crystalloid would be undesirable in patients with hypovolemia and increased extracellular volume (ie, ascites and/or edema), but this does not present serious problems in most patients. Solutions containing only dextrose and water (eg, 5% dextrose in water) are poor volume replacement solutions because the glucose is rapidly taken up by cells (with water subsequently distributed freely into both the intracellular and extracellular

Table 2-3. Fluids for intravenous replacement of extracellular volume or water deficit.

compartments). Although sometimes used to replace extracellular volume deficits, Ringer's lactate (containing Na⁺, K⁺, Cl⁻, Ca²⁺, and lactate) is no more effective than 0.9% NaCl in most clinical situations. However, evidence suggests that large volumes of NaCl-containing fluids are likely to cause mild hyperchloremic acidosis, the consequences of which are unclear. Therefore, some practitioners advocate crystalloid replacement with Ringer's lactate, especially in hemorrhagic shock before blood replacement is available.

For years, colloid solutions have been advocated for more efficient repletion of intravascular volume, especially in states of normal or elevated extracellular volume and in hypovolemic shock. In theory, colloids are restricted at least transiently to the intravascular space and thereby exert an intravascular oncotic pressure that draws fluid out of the interstitial space and expands the intravascular space by an amount out of proportion to the volume of colloid solution administered. A theoretical disadvantage is that the interstitial space would be depleted of water, leading to an increase in interstitial oncotic pressure that would draw water back out. Nevertheless, studies have failed to identify clear-cut advantages of colloid-containing solutions over crystalloid solutions in critically ill patients. This is probably because increased capillary permeability in patients with sepsis, shock, and other problems negates the potential benefit of retaining colloid within the vascular space. Furthermore, some investigators have suspected that leakage of colloid into the interstitial space of the lungs and other organs can contribute to persistent organ system dysfunction and edematous states. In hypovolemia associated with ascites, rapid movement of colloid into the ascitic fluid may occur, resulting in only a transient increase in intravascular volume. In patients with nephrotic syndrome or protein-losing enteropathies, albumin and other colloids may be lost fairly rapidly.

Colloid solutions for intravenous replacement include human serum albumin (5% and 25% albumin, heat-treated to reduce infectious risk) and hetastarch (6% hydroxyethyl starch). Albumin is considered nonimmunogenic, but it is expensive, offers few advantages over other solutions, and has not been shown to improve outcome. Hetastarch is a synthetic colloid solution used for volume expansion. Clinical benefit of the use of this solution is unclear. Fresh frozen plasma is an expensive and inefficient volume expander and should be reserved for correction of coagulation factor deficiencies. There is little rationale for the use of whole blood; red blood cells and other blood components should be given for specific indications, along with crystalloid or colloid supplements as needed.

Meta-analyses have found either no difference or a trend toward increased mortality in critically ill patients given albumin. In a large prospective trial comparing albumin or isotonic crystalloid, however, there was no difference in mortality. A few clinical conditions have been shown to benefit from albumin infusions. Antibiotics and intravenous albumin, 1.5 g/kg on day 1 and 1 g/kg on day 3, significantly reduced mortality and renal failure in patients with cirrhosis and spontaneous bacterial peritonitis. Albumin may be helpful after large-volume paracentesis and to correct dialysis-related hypotension.

D. Complications—Complications of fluid replacement include excessive fluid repletion owing to overestimation of the hypovolemia or inadvertent excessive fluid administration. Patients with renal and cardiac dysfunction are especially prone to fluid overload, and pulmonary edema may be the first manifestation. Pulmonary edema is also likely—and may occur without excessive fluid repletion—in patients who have increased lung permeability or ARDS. During fluid repletion, worsening of peripheral edema or ascites may occur. Large

Table 2-4. Guidelines for replacement of fluid losses from the gastrointestinal tract.

	Replace mL per mL with	Add
Gastric (vomiting or nasogastric aspiration)	5% dextrose in 0.45% NaCl	KCl, 20 meq/L
Small bowel	5% dextrose in 0.45% NaCl	KCl, 5 meq/L NaHCO ₃ , 22 meq/L
Biliary	5% dextrose in 0.90% NaCl	NaHCO ₃ , 45 meq/L
Large bowel (diarrhea)	5% dextrose in 0.45 NaCl	KCl, 40 meq/L NaHCO ₃ , 45 meq/L

amounts of isotonic saline may contribute to expansion acidosis—a hyperchloremic metabolic acidosis owing largely to dilution of plasma bicarbonate—but this is uncommon.

E. Maintenance Fluid Requirements—Normal maintenance fluids to prevent hypovolemia should provide 1.5–2.5 L of water per day for normal-sized adults, adjusted to account for other sources of water intake (eg, medications and/or food intake) and the ability of the kidneys to concentrate and dilute the urine. Sodium intake in the ICU generally should be limited to a total of 50–70 meq/day, but many critically ill patients avidly retain sodium, and they may have a net positive sodium balance with even a smaller sodium intake. Patients are frequently given much more sodium than needed. For example, 0.9% NaCl has 154 meq/L of sodium and chloride, and some patients are inadvertently given as much as 3–4 L/day. Although it is sometimes necessary, it is difficult to rationalize giving diuretics to a patient simply to enhance removal of sodium given as part of replacement fluids. On the other hand, diuretics are useful when needed to facilitate excretion of the sodium ingested from an appropriate diet. In states of ongoing losses of extracellular volume, appropriate fluid replacement in addition to maintenance water and electrolytes should be given as needed (Table 2-4).

▶ Hypervolemia

ESSENTIALS OF DIAGNOSIS

- ▶ Edema, ascites, or other evidence of increased extracellular volume
- ▶ Intravascular volume may be normal, low (hypovolemia), or high
- ▶ Potential causes of increased extracellular volume: renal insufficiency, congestive heart failure, liver disease, or other mechanism of sodium retention or excessive sodium administration

General Considerations

In contrast to hypovolemia, in which there is always decreased volume of the intravascular space, in hypervolemia the intravascular volume may be high, normal, or paradoxically low. Peripheral or pulmonary edema, ascites, or pleural effusions are the evidence for increased extracellular volume. Increased extracellular volume may not be an emergency in ICU patients, but this depends on how much and where the excess fluid accumulates. If associated with decreased intravascular volume (eg, hypovolemia), increased intravascular volume (eg, pulmonary edema), or severe ascites (with respiratory compromise), rapid intervention may be indicated.

A. Hypervolemia with Decreased Intravascular Volume

—Because sodium—along with anions—is the predominant solute in the extracellular space, increased extracellular volume is an abnormally increased quantity of sodium and water. The body normally determines whether sodium and water should be retained by sensing the adequacy of intravascular volume, and the nonvascular component does not play a role in stimulating or inhibiting sodium and water retention. Thus excessive sodium retention resulting in hypervolemia may occur in states of inadequate effective circulation, such as heart failure, or suboptimal filling of the vascular space resulting from loss of fluid into other compartments, such as occurs with hypoalbuminemia, portal hypertension, or increased vascular permeability to solute and water.

Ascites owing to liver disease arises from a combination of portal hypertension and hypoalbuminemia, as seen in severe hepatic disease, but occasionally it occurs as a result of pre- or posthepatic portal obstruction. Decreased plasma albumin by itself, though a cause of edema, is an unusual cause of severe ascites or pleural effusions. Ascites also may be a marker of local inflammatory or infectious disorders. Pleural effusions may indicate hypervolemia if associated with heart failure or hypoalbuminemia, but they also may be associated with pneumonia or other local causes.

B. Hypervolemia with Primary Increased Sodium Retention

The other major mechanism of hypervolemia is excessive function of the normal mechanisms that ensure sodium and water balance. Normal extracellular volume is maintained by an interactive system that includes renin, angiotensin, aldosterone, glomerular filtration, renal tubular handling of sodium and water, atrial natriuretic factor, and ADH, along with the intake of sodium and water in the diet. Hyperfunction of some of these mechanisms, such as hyperaldosteronism or excessive intake of sodium, or renal dysfunction causes net positive sodium balance with inevitable expansion of the extracellular volume. Although due in some degree to hypoalbuminemia with decreased effective intravascular volume, nephrotic syndrome with renal dysfunction is considered a state in which there is also impaired renal sodium excretion. While not a dysfunction of normal sodium balance, excessive administration of sodium, especially from hypertonic fluid or dietary sources, may expand the extracellular volume. Administration of drugs that impair sodium excretion also may contribute, including corticosteroids, mineralocorticoids, and some antihypertensive agents.

Clinical Features

A. Symptoms and Signs—Increased extracellular volume may be localized to certain compartments (eg, ascites) or generalized. Edema is often a major feature of increased extracellular volume, collecting in dependent areas of the body, and the lower back and sacral areas may demonstrate edema in the absence of edema of the lower extremities in ICU patients. Edema always indicates increased extracellular volume except when there is a localized mechanism of fluid transudation or exudation, for example, local venous insufficiency, cellulitis, lymphatic obstruction, or trauma. The presence of edema may or may not signify that the intravascular volume is increased.

Abdominal distention and other findings consistent with ascites may be present. Pleural effusions indicate hypervolemia when associated with congestive heart failure.

Other clinical features depend on the mechanism of hypervolemia. Intravascular volume may be low, high, or normal in the face of increased extracellular volume. If low, evidence of inadequate circulation may be found, including tachycardia,

Table 2-5. Hypervolemia (increased extracellular volume).

With decreased effective intravascular volume

- Cirrhosis with ascites
- Pre- and posthepatic portal hypertension with ascites
- Hypoalbuminemia from protein-losing enteropathy, malnutrition, nephrotic syndrome
- Congestive heart failure
- Excess sodium intake

With increased intravascular volume

- Increased sodium retention
 - Renal insufficiency (especially glomerular disease)
 - Hyperaldosteronism, hypercortisolism
 - Increased renin and angiotensin
 - Drugs (corticosteroids, some antihypertensives)

peripheral cyanosis, and altered mental status. If extracellular volume is high, signs of pulmonary edema may be present. Patients with hypervolemia owing to endocrine disorders or renal failure may have findings specific to the underlying cause. As shown in Table 2-5, the associated conditions leading to hypervolemia can be divided according to the presumed pathogenesis into those associated with decreased effective intravascular volume (eg, heart failure, liver disease, or increased vascular permeability) and those associated with increased or normal intravascular volume (eg, primary disorder of sodium excretion or excessive administration of sodium).

B. Laboratory Findings—Except in a few instances, laboratory findings in hypervolemia are nonspecific. Hypoalbuminemia is seen in patients with nephrotic syndrome, protein-losing enteropathy, malnutrition, and liver disease. Urine sodium is usually very low in the face of avid sodium retention in the untreated patient. Nephrotic syndrome patients have moderate to severe proteinuria. Decreased glomerular filtration (increased plasma creatinine and urea nitrogen) is seen in patients with severely decreased intravascular volume.

Despite the increased extracellular quantity of sodium, plasma sodium concentrations are often low (120–135 meq/L) in patients with decreased effective intravascular volume because of strong stimulation of ADH release. Plasma potassium is often low as well. Patients with excess endogenous or administered corticosteroids (Cushing's syndrome) or mineralocorticoids may have hypokalemic metabolic alkalosis; those with cirrhosis often have respiratory alkalosis.

Treatment

The need for treatment and the treatment approach depend on the mechanism of hypervolemia. Hypervolemia associated with severely decreased or markedly increased intravascular volume requires rapid and aggressive treatment.

A. Hypervolemia with Decreased Intravascular Volume—

The critically ill patient with decreased intravascular volume and increased extracellular volume may have an acute increase in permeability of the vascular system with leakage of fluid into the interstitial space (eg, sepsis). More commonly, the patient may have a chronic condition leading to edema or ascites accompanied by a subtle and gradual decrease in intravascular volume. Diuretic treatment should be delayed until the intravascular fluid deficit is corrected to avoid further deterioration. Treatment of decreased intravascular volume was described earlier (in the section “Hypovolemia”), but with preexisting hypervolemia, necessary fluid replacement may worsen edema, ascites, or other fluid accumulations. In some patients, some worsening of hypervolemia (edema) may be accepted for a time until intravascular volume is repleted. Then, by improving renal perfusion, there may be appropriate natriuresis with mobilization of edema fluid. A special situation is the patient with cor pulmonale who develops edema secondary to impaired right ventricular function and who may have low effective intravascular volume. These patients may benefit from reduction of pulmonary hypertension following administration of oxygen.

B. Hypervolemia with Increased Intravascular Volume—

In these patients, severely increased intravascular volume may be manifested by pulmonary edema, hypoxemia, and respiratory distress. If intravenous fluids are being administered, these should be discontinued unless blood transfusions are necessary for severe anemia. Intravenous furosemide (10–80 mg) is given, with repeated doses every 30–60 minutes depending on the diuretic response. Supportive care includes oxygen, changes in the patient’s position, and mechanical ventilation if necessary. Cardiogenic pulmonary edema also may benefit from morphine, vasodilators (eg, nitroprusside or angiotensin-converting enzyme [ACE] inhibitors), venodilators (nitrates), or nesiritide. Mechanical ventilatory support, either intubation or noninvasive positive-pressure ventilation, may be necessary.

In some critically ill patients, sodium excretion is impaired, and diuretics must be given in larger than usual doses. Patients with previous diuretic use, those with severe cardiac failure, and those with renal insufficiency may require furosemide in doses up to 400 mg given slowly. Metolazone, which acts in the distal renal tubule, may facilitate the response to furosemide. There is no role for osmotic diuretics such as mannitol because these will further expand the intravascular volume, especially if they are ineffective in producing diuresis. Potassium-sparing collecting tubule diuretics, such as triamterene, amiloride, and spironolactone, usually have little acute effect in these patients. Failure to induce appropriate diuresis in the situation of expanded intravascular volume may require acute hemodialysis or ultrafiltration.

For critically ill patients, rapid decreases in intravascular volume may be particularly hazardous in those with chronic hypertension (associated with hypertrophic, poorly compliant

ventricles), pulmonary hypertension, pericardial effusion, sepsis, diabetes mellitus, autonomic instability, electrolyte disturbances, or recent blood loss. Patients receiving alpha- or beta-adrenergic blockers, arterial or venous dilators (including hydralazine, nitroprusside, and nitroglycerin), and mechanical ventilation may be very sensitive to rapid depletion of intravascular volume. Severe hypotension and hypovolemic shock may be induced by diuretics or other fluid removal.

C. Increased Extracellular Volume without Change in Intravascular Volume—

Conditions such as this are usually chronic. Edema and ascites do not by themselves cause immediate problems, but edema may impair skin care and lead to immobility, whereas ascites may become uncomfortable, may cause respiratory distress and hypoxemia, and may become infected (spontaneous bacterial peritonitis).

1. SODIUM RESTRICTION—Treatment centers around net negative sodium balance. Urine sodium concentration can provide a guide to the degree of sodium intake restriction and diuretics needed. In severe states, urine sodium concentration may be as low as 1–2 meq/L, but more often it is 5–20 meq/L. With daily urine volumes of 1–2 L, only a total of 1–40 meq of Na⁺ may be excreted daily. In contrast, moderate dietary sodium restriction is often considered to be 2 g (87 meq) of sodium per day and therefore unlikely to be successful alone. Nevertheless, most patients should be restricted to 1–2 g of sodium daily, although only 10–15% of patients with severe fluid retention will respond.

2. DIURETICS—Ascites and edema often will respond best to a combination of furosemide and spironolactone. Furosemide is usually started at 40 mg daily; spironolactone’s starting dose is 100 mg daily. If needed, furosemide can be increased to 160 mg/day and spironolactone up to 400 mg/day.

Diuretics should be used cautiously if there is concomitant marginal or decreased effective intravascular volume (eg, ascites, heart failure, or nephrotic syndrome). Too-rapid depletion of extracellular volume not only may worsen circulatory dysfunction but also will sometimes further enhance sodium retention, perhaps inducing a state of “escape” from diuretic responsiveness. Concern has been expressed about the possibility of an increased incidence of hepatorenal syndrome in patients with severe liver disease who are given large doses of diuretics.

Complications of diuretics depend somewhat on their effectiveness in inducing natriuresis and volume depletion. Furosemide may cause severe hypokalemia and contributes to metabolic alkalosis, and hypomagnesemia and hypernatremia are occasionally significant problems. Spironolactone and triamterene should not be used in patients with hyperkalemia, and patients receiving potassium supplementation should be monitored carefully when these agents are given. Patients may have allergic or other unpredictable reactions to any of these drugs.

3. INCREASED ELIMINATION OF EXTRACELLULAR FLUID—

Removal of ascites by paracentesis in patients with chronic liver disease has some advocates. Although earlier studies found an association of excessive depletion of intravascular volume following removal of more than 800–1500 mL of ascitic fluid, recent investigations have suggested that large-volume paracentesis (>1500 mL) may be safe—usually if intravenous albumin is given to maintain intravascular volume immediately after fluid removal. Paracentesis is indicated in patients with severe respiratory distress or discomfort from their ascites, but the exact amount of fluid that can be removed safely remains unclear.

Patients with congestive heart failure with hypervolemia are often treated with a combination of diuretics, inotropic agents such as digitalis, and systemic vasodilators. Vasodilators that reduce left ventricular afterload and improve cardiac output are very effective in decreasing hypervolemia without compromising organ system perfusion. These agents, primarily ACE inhibitors and angiotensin-receptor blockers, have been particularly useful in reversing the consequences of decreased effective intravascular volume.

Extracellular volume can be readily removed in most ICU patients by ultrafiltration, especially using continuous venovenous hemofiltration. This can be accomplished rapidly or slowly depending on the method chosen. Hypotension may accompany too-rapid intravascular fluid removal.

DISORDERS OF WATER BALANCE

The term water balance refers to the normally closely regulated relationship between total body water and total body solute that determines solute concentration throughout the body. With the exception of a few special areas such as the renal medulla and collecting ducts, water moves freely between all body compartments—intracellular and extracellular—by way of osmotic gradients. Therefore, solute concentration is equal everywhere, but the amount of water in a given body space is determined by the quantity of solute contained within that space.

Clinical disorders of water balance are estimated from plasma sodium $[\text{Na}^+]$ because the concentration of that predominantly extracellular cation is inversely proportional to the

quantity of total body water relative to total solute. There is one caveat, however. Hyponatremia always denotes hypertonicity (increased solute relative to total body water), but hyponatremia may be seen with hypotonicity, normotonicity, or hypertonicity. This is so because solutes other than sodium may be present in high enough quantity to exert an osmotic effect.

Solute concentration can be expressed as osmolarity (mOsm/L) or osmolality (mOsm/kg). For clinical purposes, these are generally interchangeable, and osmolality will be used. The term *tonicity* is often considered synonymous with *osmolality* but should be used to express “effective osmolality.” This is so because some solutes, notably urea, move freely into and out of cells. Thus urea contributes to the osmolality of plasma but does not add to plasma tonicity.

Total Body Water and Plasma Sodium Concentration

If total body exchangeable solute is dissolved hypothetically in a volume equal to total body water (TBW), the osmolality of the solution will be as shown in the following equation:

$$\text{Body osmolality (mOsm/kg)} = \frac{\text{total solute (mOsm)}}{\text{TBW (kg)}}$$

If water moves freely between body compartments, then water will move from compartments with low osmolality to those with high osmolality, equalizing solute concentrations. Therefore, for the plasma compartment,

$$\text{Plasma osmolality (mOsm/kg)} = \frac{\text{total solute (mOsm)}}{\text{TBW (kg)}}$$

Plasma osmolality is approximately the sum of cation plus anion concentrations, often expressed as milliequivalents per liter (meq/L) rather than milliosmols per kilogram (mosm/kg) for monovalent solutes. Since sodium is the most abundant extracellular cation, the sum of cation and anion concentrations is approximately $2 \times [\text{Na}^+]$. Therefore,

$$2 \times [\text{Na}^+] = \frac{\text{total solute (mOsm)}}{\text{TBW (L)}} \quad \text{or} \quad [\text{Na}^+] \propto \frac{1}{\text{TBW (L)}}$$

A useful form of this equation relates TBW and $[\text{Na}^+]$ under abnormal conditions to normal TBW and $[\text{Na}^+]$, assuming that total body solute does not change:

$$\text{TBW (L)} = \text{normal TBW (L)} \times \frac{\text{normal } [\text{Na}^+]}{[\text{Na}^+]}$$

This equation estimates TBW from plasma $[\text{Na}^+]$, and the difference between TBW and normal TBW is the water

deficit or water excess. Normal TBW is approximately 60% of body weight in men and 50% of body weight in women who are near ideal body weight. The TBW as a proportion of body weight decreases with obesity and in the elderly to as low as 45–50% of body weight.

It should be understood that this analysis is an oversimplified model that does not account entirely for changes in exchangeable solute, all shifts in water between different compartments, and solute and water gains and losses.

Regulation of Water Balance

Water balance is maintained primarily by water intake (water consumption mediated by thirst plus water produced from metabolism) and water excretion by the kidneys. Other sources of water loss such as intestinal secretions and sweating are unregulated. Normally, enough excess water is taken in to allow the kidneys to control body osmolality by increasing or decreasing water excretion as necessary. Although normal persons filter as much as 150 L/day through the glomeruli, about 99% of the water is reabsorbed in the renal tubules. The amount of water that can be excreted in 24 hours depends on renal concentrating and diluting ability (depending on renal function) and the quantity of solute excreted per day. Solute consists of electrolytes and urea (Table 2–6), and the latter depends on the dietary protein intake and catabolic rate. Healthy normal subjects are theoretically able to maintain water balance with as little as 670 mL or as much as 12,000 mL water intake per day. This wide range depends on normal glomerular filtration rate, normal urinary concentrating and diluting ability, and normal solute excretion rate. Patients with abnormal renal function are consequently much more limited in their ability to tolerate and correct water imbalances.

A. Urine Concentration—The urine concentration depends on the amount of ADH present and renal tubular function. ADH, also known as *arginine vasopressin* (AVP), is secreted by the posterior pituitary in response to changes in

plasma osmolality sensed by the hypothalamic supraoptic and paraventricular nuclei. Increased plasma osmolality increases ADH secretion; decreased osmolality inhibits ADH secretion. ADH also is released in response to decreased extracellular volume, sensed by receptors in the atria. Extracellular volume status and osmolality interact to determine plasma ADH levels. For example, with hypovolemia plus hyponatremia, ADH release may continue despite inhibition by low plasma osmolality.

Maximum urine concentrating capacity requires sufficient solute delivery to the distal nephrons, maintenance of a high solute concentration in the renal medulla, and high levels of ADH. Active transport of sodium out of the thick ascending limb of the loop of Henle generates high solute concentration in the renal medullary interstitium, whereas tubular fluid becomes progressively more dilute because water is kept in the tubules. In the distal tubules and collecting ducts, the tubular fluid is exposed to the medullary concentration gradient, and—in the presence of ADH—water moves freely out of the lumen, thereby concentrating the urine. Maximum urine concentration, when needed to conserve water excretion, may be limited if there is insufficient sodium presented to the loop of Henle (renal insufficiency), inhibition of active transport in the thick ascending limb (loop diuretics), inadequate response to ADH (nephrogenic diabetes insipidus), or absence of ADH (central diabetes insipidus).

Maximum urine diluting capacity also depends on function of the ascending loop of Henle and the distal convoluted tubule, as well as maintenance of an impermeable collecting duct and suppression of ADH release. Excess water in the body should be countered by increased volume of maximally diluted urine. Failure to dilute urine maximally may result from renal insufficiency, especially with tubulointerstitial diseases, inappropriate secretion of ADH, and abnormally increased permeability of the collecting ducts to water (adrenal insufficiency). In addition, sedative-hypnotic drugs, analgesics, opioids, and antipsychotic drugs may interfere with renal diluting ability.

Table 2–6. Range of urinary water excretion with normal solute load.

• Minimum urine concentration: 50 mosm/L
• Maximum urine concentration: 1200 mosm/L
• Normal urine solute excretion: 800 mosm/d
• Minimum urine volume (water excretion) per day = $\frac{800 \text{ mosm/d}}{1200 \text{ mosm/L}} = 0.67 \text{ L/d}$
• Maximum urine volume (water excretion) per day = $\frac{800 \text{ mosm/d}}{50 \text{ mosm/L}} = 16 \text{ L/d}$

B. Solute Excretion and Water Excretion Rate—The quantity of solute excreted also determines the maximum and minimum water excretion rates. In normal subjects, there is an obligate solute loss of about 800 mOsm/day, including sodium, potassium, anions, ammonium, and urea. Urea, from breakdown of amino acids, makes up about 50% of the solute excreted. In the presence of severely limited protein intake, 24-hour urine urea excretion is reduced. This decrease in urine solute excretion limits maximum water excretion even if urine is maximally diluted. A fall in the total 24-hour urine solute excretion to 300 mOsm/day, for example, means that even if urine concentration is 50 mOsm/kg, only 6 L of water can be excreted per day. In contrast, if there is 800 mOsm/day of solute to excrete, 16 L of water per day could have been excreted with maximum urinary dilution.

► Hyponatremia

ESSENTIALS OF DIAGNOSIS

- ▶ Plasma sodium <135 meq/L
- ▶ Altered mental status (confusion, lethargy) or new onset of seizures
- ▶ Most cases discovered by review of routinely obtained plasma electrolytes

General Considerations

Hyponatremia is encountered commonly in the ICU. It has been estimated that 2.5% of hospitalized patients have hyponatremia. Low plasma sodium is associated with a variety of endocrine, renal, neurologic, and respiratory disorders; medications and other treatment; and other medical conditions. Severe hyponatremia is manifested by altered mental status (hyponatremic encephalopathy), seizures, and high mortality. Hyponatremia is particularly dangerous in patients with acute neurologic disorders, especially head injury, stroke, and hemorrhage. Severe hyponatremia must be corrected rapidly, carefully, and in a controlled fashion to avoid further complications.

In the absence of hyponatremia associated with normal or increased tonicity (see below), low plasma sodium indicates excess total body water for the amount of solute (dilutional hyponatremia). In normal subjects, this condition would initiate compensatory mechanisms that facilitate rapid excretion of water, correcting the imbalance. Therefore, in states of persistent hyponatremia, there is physiologic or pathologic inability to excrete water normally.

Hyponatremia (dilutional hyponatremia) is seen in three distinct clinical situations in which extracellular volume is low, high, or normal (Table 2–7).

A. Hyponatremia with Decreased Extracellular Volume—Decreased extracellular volume leads to vigorous water conservation, primarily mediated by increased ADH release

Table 2–7. Disorders of water balance: Hyponatremia.

Normal plasma osmolality

Pseudo hyponatremia (hyperlipidemia); rare if measured with ion-specific Na⁺ electrode

Elevated plasma osmolality

Hyperglycemia

Mannitol, glycerol, radiocontrast agents

Decreased plasma osmolality

Urine maximally diluted:

1. Decreased solute excretion (low protein intake)
2. Excessive water ingestion or intake

Urine not maximally diluted:

1. Normal extracellular volume
 - a. SIADH
 - Lung disease
 - CNS disease
 - Drugs
 - Anxiety
 - b. Adrenal insufficiency (may also have volume depletion)
 - c. Hypothyroidism
2. Low extracellular volume
 - a. Extrarenal loss
 - b. Renal loss: diuretics, sodium-losing nephropathy
3. Increased extracellular volume
 - a. Congestive heart failure
 - b. Cirrhosis
 - c. Nephrotic syndrome

stimulated by atrial receptors and increased thirst leading to increased water intake. Generally, urinary sodium excretion is very low, and water intake and retention lead to increased TBW relative to the reduced amount of solute. However, in conditions in which the hypovolemic state is due to sodium and water loss in the urine, such as adrenal insufficiency, diuretic use, and salt-losing nephropathies, urine sodium excretion may be normal or high. In adrenal insufficiency, hyponatremia is facilitated because lack of cortisol causes collecting ducts to be excessively permeable to water reabsorption, and ADH fails to be suppressed normally by low plasma osmolality. A frequently seen form of hypovolemic hyponatremia occurs with thiazide diuretics. Chronic volume depletion leading to stimulation of ADH release is an important factor. In addition, thiazides impair urinary dilution by blocking sodium and chloride transport in the diluting segment of the distal nephron and potentiate the effect of ADH. Finally, thiazide-induced renal potassium excretion further reduces total body solute content, also contributing to hyponatremia.

B. Hyponatremia with Increased Extracellular Volume—Hyponatremia in the presence of increased extracellular volume is seen in congestive heart failure, nephrotic syndrome,

cirrhosis, protein-losing enteropathy, and pregnancy. These disorders have in common edema, ascites, pulmonary edema, or other evidence of increased extracellular volume. However, these patients appear to have an inability to maintain normal intravascular volume because of forces generating excessive venous and extravascular volume. Hyponatremia is a consequence of ADH release in response to decreased intravascular volume, even though extracellular volume and TBW are high. Some patients with hypothyroidism have hyponatremia owing primarily to heart failure, but hypothyroidism also interferes directly with the ability to dilute urine maximally.

C. Hyponatremia with Normal Extracellular Volume—

Hyponatremia in association with normal extracellular volume is seen with psychogenic water ingestion, decreased solute intake, and, most commonly, the syndrome of inappropriate secretion of ADH (SIADH). Massive intake of water rarely results in severe hyponatremia if the ability to excrete water is unimpaired. However, decreased solute intake as described earlier limits the maximum volume of water that can be excreted even when urine is maximally diluted. The syndrome of “beer-drinker’s potomania” results from heavy consumption of beer and other low-solute fluids that limit the quantity of solute available for excretion. A very low protein diet also generates very little urea for excretion.

The majority of patients with normovolemic hyponatremia have SIADH, resulting from release of ADH in response to a variety of disorders but primarily from lung and CNS problems. Lung diseases include lung cancer, tuberculosis, pneumonia, chronic obstructive pulmonary disease (COPD), asthma, respiratory failure from any cause, and use of mechanical ventilation. SIADH is also associated with encephalitis, status epilepticus, brain tumors, meningitis, head trauma, and strokes. The mechanism of ADH release in these disorders is unclear. Some cancer chemotherapeutic drugs, chlorpropamide, nicotine, tricyclics, serotonin reuptake inhibitors, and some opioids are associated with SIADH.

Some patients with septic shock are thought to have physiologic vasopressin deficiency, which contributes to refractory hypotension. Thus these patients are treated with physiologic replacement doses of vasopressin (ADH). While these physiologic doses should not be associated with hyponatremia, hyponatremia is reported to be a side effect.

D. Hyponatremia without Hypotonicity—Hyponatremia without hypotonicity was seen in patients with severe hypertriglyceridemia or hyperproteinemia (>10 g/dL) when plasma sodium was measured by flame photometry. This should no longer be a problem with the use of ion-specific sodium electrodes.

E. Hyponatremia with Hypertonicity—In this seemingly paradoxical situation, hyponatremia is not associated with increased TBW but with decreased TBW. It is seen commonly with hyperglycemia and occasionally with administration of mannitol. Enhanced gluconeogenesis or glycogenolysis

in diabetics—or exogenous glucose administration—adds a large quantity of osmotically active molecules to the extracellular compartment. Water moves from the intracellular space to the extracellular space to equalize osmotic gradients. Osmolality increases throughout the body, but plasma sodium falls because of the additional water moving out of the cells into the extracellular space. The hyponatremia may be mistakenly thought to be evidence for excessive TBW when instead there is a TBW deficit.

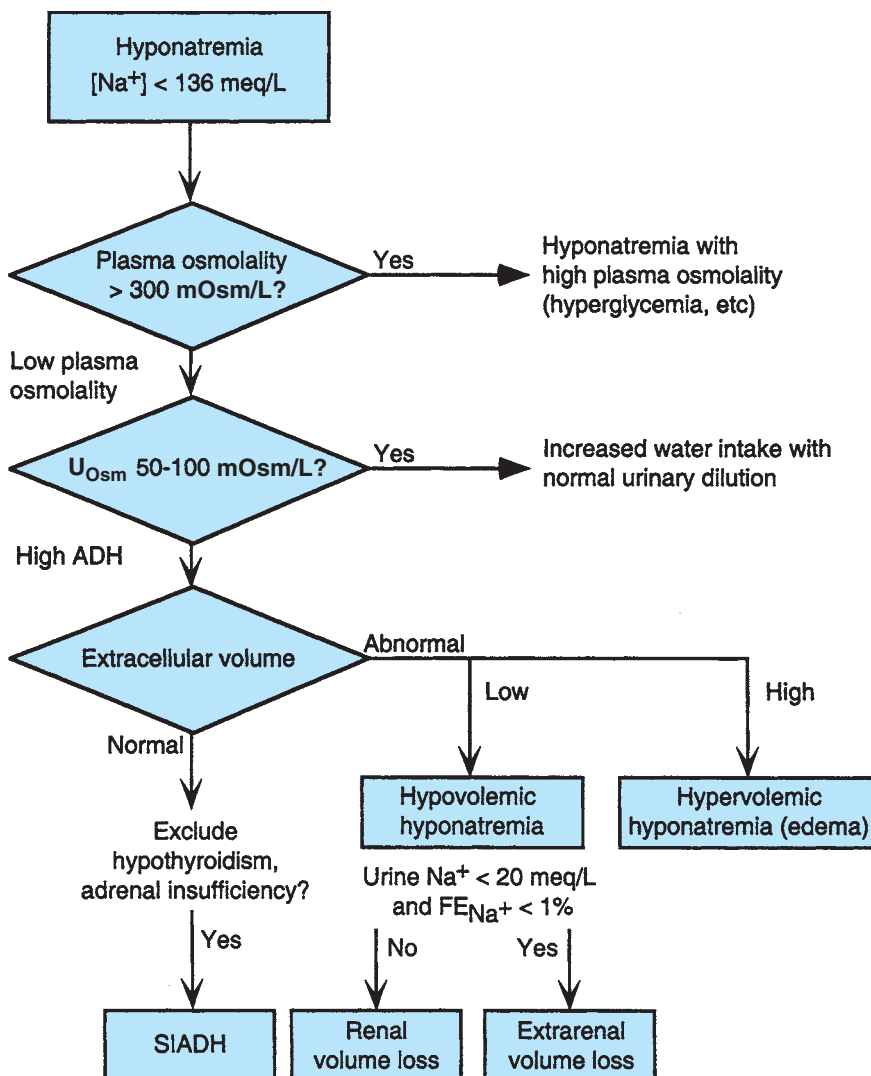

Hyponatremia in the presence of hyperglycemia can be addressed in several ways. First, laboratory measurement of plasma osmolality will give a correct assessment of water balance; plasma osmolality will be higher than estimated from plasma sodium. Another way is to “correct” the plasma sodium for the degree of hyperglycemia. One empirical correction is to add to the measured plasma sodium 1 meq/L for every 60 mg/dL the plasma glucose is increased above 100 mg/dL. For example, if plasma sodium is 130 meq/L and plasma glucose is 1300 mg/dL (1200 mg/dL above 100 mg/dL), the “corrected” plasma sodium will be $130 + 20 = 150$ meq/L. The corrected plasma sodium is a valid estimate of the increase or decrease of TBW relative to solute. Although glucose is the most commonly encountered solute that causes this phenomenon, other extracellular solutes such as mannitol and radiopaque contrast agents can cause hyponatremia with decreased TBW.

Clinical Features

Figure 2–1 shows a clinical and laboratory approach to the diagnosis of hyponatremia and identification of the cause of low plasma sodium.

A. Symptoms and Signs—Hyponatremia associated with decreased osmolality is often asymptomatic until plasma sodium falls below 125 meq/L, but the rate of change is clearly important. Rapid development is associated with more severe acute changes. Subtle neurologic findings sometimes can be identified, such as decreased ability to concentrate or perform mental arithmetic. Severe symptoms—including altered mental status, seizures, nausea, vomiting, stupor, and coma—occur when plasma sodium is less than 115 meq/L, when hyponatremia develops acutely, or when plasma sodium is less than 105–110 meq/L during chronic hyponatremia. A syndrome of opisthotonos, respiratory depression, impaired responsiveness, incontinence, hallucinations, decorticate posturing, and seizures has been termed *hyponatremic encephalopathy*. Occasionally, patients with chronic hyponatremia may be awake, alert, and oriented even with the plasma sodium as low as 100 meq/L; these patients are almost always found to have slowly developed hyponatremia.

Symptoms and signs of any underlying disorder should be sought. Medications that can affect urinary water excretion should be identified and discontinued. These include thiazide diuretics and drugs that impair renal function. Thiazide-induced hyponatremia has been reported to be more common in women, but advanced age was not a risk

▲ **Figure 2-1.** Clinical and laboratory approach to the diagnosis of hyponatremia.

factor. Enalapril given to elderly patients is reported to cause hyponatremia. Excessive water drinking can be identified from the history and the presence of polyuria, but large volumes of water may be given inadvertently in the ICU. Adrenal insufficiency and hypothyroidism should be considered in critically ill patients. Hyponatremia has been associated with hospitalized AIDS patients; volume depletion from gastrointestinal fluid losses and SIADH were the most common causes, and there was an increase in morbidity and mortality in those with hyponatremia. For unclear reasons, young women recovering from surgery can have particularly severe symptoms and a poor prognosis from hyponatremia.

Although previously thought to be caused by excessive hypotonic fluid replacement, hyponatremia results from generation of inappropriately concentrated urine, high ADH levels, and possibly estrogen-induced sensitivity to ADH.

Patients with hypovolemic hyponatremia may have evidence of volume depletion such as hypotension, tachycardia, decreased skin turgor, or documented weight loss, but these findings may be subtle or absent; those with hypervolemia have edema and weight gain. SIADH is confirmed by lack of evidence of abnormal extracellular volume and is sometimes accompanied by clinical findings suggesting pulmonary or CNS disease.

Hyponatremic encephalopathy is thought to be due to cerebral edema from water shifts into the brain and increased intracranial pressure. Decreased cerebral blood flow plays a role. Movement of solute out of brain cells—given sufficient time—minimizes the effects, probably explaining the lack of symptoms of slowly evolving hyponatremia. On the other hand, evidence has linked a specific neurologic syndrome, osmotic demyelination syndrome (central pontine and extrapontine myelinolysis), with both severe hyponatremia and rapid correction of hyponatremia. It is speculated that adaptation to hyponatremia may be the cause of demyelination in susceptible regions of the brain. A firm conclusion cannot be made about whether osmotic demyelination syndrome is due to the severity of hyponatremia or to excessively fast correction. Osmotic demyelination syndrome is reported to occur about 3 days after the start of correction of hyponatremia, but findings may be seen before, during, or after plasma sodium has been corrected. Corticospinal and corticobulbar signs are reported most often, including weakness, spastic quadriparesis, dysphonia, and dysphagia, but impaired level of consciousness is common. Radiolucent areas on CT scan or decreased T₁-weighted MRI intensity provides evidence of myelinolysis in the central pons and elsewhere.

B. Laboratory Findings—Plasma electrolytes; glucose, creatinine, and urea nitrogen; plasma osmolality; urine osmolality; urine Na⁺; and urine creatinine (to calculate fractional excretion of Na⁺) should be measured. Low plasma osmolality (<280 mOsm/kg) confirms hyponatremia owing to increased water relative to solute. The corrected plasma sodium should be used if there is hyperglycemia. An association has been found between hyponatremia with hypokalemia and severe body potassium depletion. Hypokalemia also may predispose patients with hyponatremia to osmotic demyelination syndromes and encephalopathy. Particularly high mortality has been found when hyponatremia is associated with hypoxemia.

In patients with excessive water intake as the cause of hyponatremia, urine osmolality will be low (<300 mOsm/kg). Patients with hypovolemia will have low urine sodium (<20 meq/L), fractional excretion of sodium (<1%), and fractional excretion of urea (<35%), and these also may be seen in patients with increased extracellular volume but low intravascular volume. If, however, hypovolemia is caused by a renal mechanism, urine sodium may not be appropriately conserved.

The diagnosis of SIADH is made by finding inappropriately high urine osmolality (usually 300–500 mOsm/kg) in the presence of low plasma osmolality and the absence of low urinary sodium concentration. It should be noted that in SIADH, urine osmolality may be less than plasma osmolality but not as low as it should be because urine should be maximally diluted in the presence of severe hyponatremia. For example, in SIADH, plasma osmolality may be 240 mOsm/kg, indicating severe water excess, whereas urine

osmolality is 200 mOsm/kg. Because maximally dilute urine can be as low as 50 mOsm/kg in young healthy persons, these findings are consistent with SIADH. Patients with renal disease may be limited in their maximum urinary diluting ability to 100–200 mOsm/kg.

Treatment

Severity of hyponatremia ([Na⁺] <120 meq/L), acuteness of onset, and the presence of neurologic symptoms (ie, confusion, stupor, coma, or seizures) determine how quickly treatment should be instituted and how aggressively it should be pursued. If the patient is asymptomatic and hyponatremia is mild and chronic, the need to treat is less emergent, and aggressive treatment is not needed.

A. Estimation of Water Excess—Water excess can be estimated by relating current measured [Na⁺] to TBW and substituting 140 meq/L for normal [Na⁺]:

$$\text{TBW (L)} = \text{normal TBW (L)} \times \frac{140}{[\text{Na}^+]}$$

For a 70-kg man with a normal TBW of 0.6 L/kg, normal TBW would be 42 L. If [Na⁺] is 110 meq/L, TBW would be estimated as $42 \times 140 \div 110 = 53.5$ L. The water excess would be $53.5 \text{ L} - 42 \text{ L} = 11.5 \text{ L}$. If it is desired to correct [Na⁺] to 125 meq/L because of concern about too-rapid correction to normal in a patient with chronic hyponatremia, the estimated water excess to be corrected would be $53.5 \text{ L} - (42 \times 125 \div 110) = 5.8 \text{ L}$.

B. Determine Need for Rapid or Aggressive Correction—Patients with hyponatremia who have altered mental status or seizures attributed to hyponatremia require rapid treatment. Most patients with severely reduced [Na⁺] (<105 meq/L) are also a concern even if asymptomatic. Symptomatic hyponatremia is usually associated with severely reduced [Na⁺], and only rarely do these patients have water intoxication from psychogenic water ingestion, thiazide diuretics, decreased solute excretion, or conditions of hypo- or hypervolemia. SIADH is the most commonly encountered problem requiring aggressive and rapid correction of hyponatremia. Patients with neurologic disorders, including stroke, hemorrhage, and head injury, are at particularly high risk for complications of hyponatremia.

C. Correct the Underlying Problem—Of the underlying problems leading to hyponatremia, the most straightforward and easily corrected is hypovolemia. Administration of normal saline repletes the intravascular volume and inhibits ADH release by reducing the hypovolemic stimulus. Water excretion is enhanced by the increased glomerular filtration rate, and urine should become quickly and near maximally dilute, facilitating water excretion. Patients with psychogenic water intoxication and those being given large volumes of intravenous fluid already should be maximally excreting water; removing

the intake of water leads to rapid restoration of normal $[\text{Na}^+]$ if there are no other medical problems. Discontinuation of thiazide diuretics results in rapid restoration of maximum urinary dilution in most patients. Hypokalemia should be corrected because this has been associated with complications of hyponatremia and its treatment.

Hypervolemia (edematous states) with hyponatremia represents a more difficult problem of management, but severe hyponatremia is unusual. It is especially important to avoid “correcting” a low plasma $[\text{Na}^+]$ in congestive heart failure by giving more sodium and chloride. Although effective arterial volume is diminished, additional volume expansion will have only a transient effect on ADH release and can worsen peripheral edema, ascites, or pulmonary edema. In patients with congestive heart failure, improvement of hyponatremia has followed successful treatment with afterload reduction. Patients with nephrotic syndrome and cirrhosis have a temporary response to albumin infusions, but longer-term therapy depends on improving the underlying disease.

Adrenal insufficiency, hypothyroidism, and other specific causes of hyponatremia will respond to correction of the underlying problem. SIADH occasionally responds to treatment of the condition leading to this syndrome, but therapy is usually directed toward correction of the hyponatremia itself.

If vasopressin is being administered for refractory septic shock, it should be discontinued unless absolutely necessary to help maintain blood pressure.

D. Specific Treatment of Normovolemic Hyponatremia (SIADH)—There is not yet agreement on the rate of correction of hyponatremia that minimizes the risk from low plasma tonicity and the risk of excessively rapid correction with osmotic demyelination syndrome. Because symptomatic hyponatremia almost always will respond to a small increase in $[\text{Na}^+]$ (~5 meq/L) and the risk of osmotic demyelination appears to be minimal when $[\text{Na}^+]$ increases at less than 12 meq/L per day, a compromise target of about 8 meq/L per day is often recommended. In general, rapid correction of hyponatremia is not indicated after the patient's $[\text{Na}^+]$ is greater than 125 meq/L or symptoms have abated.

The specific treatment of hypotonic hyponatremia is a combination of water restriction and efforts to enhance water excretion. Water restriction is usually sufficient for asymptomatic or mild hyponatremia; hypertonic saline and furosemide are indicated for symptomatic hyponatremia and asymptomatic hyponatremia in which $[\text{Na}^+]$ is less than 105 meq/L.

1. RESTRICTION OF WATER INTAKE—Restriction of water intake, both oral and parenteral, will improve hyponatremia from any cause and should be considered in all patients except those with hypovolemia. Most patients with hyponatremia have decreased ability to excrete water, but water restriction to a volume the kidneys can eliminate adequately will lead to net water loss and correction of hyponatremia.

Water restriction to less than 1000–1500 mL/day is usually successful in reversing hyponatremia when $[\text{Na}^+]$ is between 125 and 135 meq/L and patients are asymptomatic. More severe water restriction may be useful in some patients. It is a mistaken belief that only electrolyte-free water must be restricted and that solute-containing fluids (eg, normal saline) can be given safely. Normal saline (osmolality 308 mOsm/kg) may be hyperosmolar relative to the plasma but is frequently hypoosmolar relative to the more concentrated urine of patients with SIADH. Thus administration of normal saline may result in a net gain of water and worsening of hyponatremia.

2. HYPERTONIC SALINE AND FUROSEMIDE—The most potent combination therapy for treating symptomatic hyponatremia is hypertonic saline (usually 3% NaCl) and furosemide. Furosemide alone (40–80 mg given frequently enough to maintain a brisk diuresis) will increase sodium and chloride excretion and, by inhibiting solute transport from the ascending loop of Henle, produce urinary dilution. Although this will promote water loss, sodium and chloride will be lost. Therefore, the goal is to replace urinary solute losses but with a more concentrated solution than the urine so that there is a net loss of water from the body.

Ideally, the amount of sodium in the urine can be measured hourly, and the exact amount of sodium and chloride can be replaced using hypertonic saline. However, a more practical approach assumes that urine osmolality will be about 280–300 mOsm/kg in the presence of furosemide. Furosemide should be given to achieve a urine output of 200–300 mL/h. If the urine contains approximately 280 mOsm/kg, then about 70 mOsm/h is lost if urine output is 250 mL/h. Replacing 70 mOsm/h using 3% NaCl (1026 mOsm/L) requires only 68 mL/h. This causes a net water excretion rate of 182 mL/h (250 mL/h – 68 mL/h) with a rise in plasma $[\text{Na}^+]$ of about 1 meq/L per hour. In practice, replacing about 25–30% of urine volume each hour with 3% NaCl will approximate the solute replacement required. As recommended earlier, furosemide and 3% NaCl solution should be discontinued when $[\text{Na}^+]$ is above 120–125 meq/L. Furthermore, $[\text{Na}^+]$ must not exceed 130 meq/L in the first 48 hours. Excessive volume or rate of hypertonic saline should not be given because acute volume overload and pulmonary edema may occur. Calculation of the amount of hypertonic saline needed should be double-checked, and it is unlikely that the total amount of hypertonic saline will exceed 1000 mL or a rate greater than 60–75 mL/h. Plasma sodium should be followed closely and appropriate adjustments made in the rate of correction.

A very useful formula can be derived from the preceding relationship between plasma $[\text{Na}^+]$ and TBW. This formula estimates the amount of change in plasma $[\text{Na}^+]$ when 1 L of any fluid is administered:

$$\Delta \text{Plasma } [\text{Na}^+] = \frac{\text{fluid } [\text{Na}^+] - \text{plasma } [\text{Na}^+]}{\text{TBW} + 1}$$

where TBW is the calculated estimate of total body water (see earlier). This formula is useful for determining how much the plasma $[Na^+]$ will change in response to administration of 1 L of hypertonic or normal saline. It does not take into account fluid losses, however. To calculate the change for more than 1 L of fluid administration, you must calculate for each liter incrementally—that is, calculate the change in plasma $[Na^+]$ for the first liter and then enter the new value for $[Na^+]$ into the formula to calculate the change for the next liter.

3. VASOPRESSIN ANTAGONISM—Conivaptan, an arginine vasopressin receptor antagonist, is approved for treatment of euvolemic hyponatremia, such as SIADH, in which inappropriate levels of vasopressin are present. It should not be used for hypovolemic hyponatremia. It works by antagonizing the action of endogenous vasopressin at both V_{1A} and V_2 receptors. Conivaptan is given as an intravenous loading dose of 20 mg followed by a continuous infusion of 20 mg/day for 1–3 days. Since the effect will vary among patients, careful monitoring of urine output and plasma sodium is indicated.

E. Other Treatment for Chronic Hyponatremia—Patients with reversible CNS or lung disease generally will respond after correction or resolution of the underlying problem. Mild to moderate water restriction may be necessary. A few patients will need additional help to facilitate water excretion; demeclocycline induces a mild nephrogenic diabetes insipidus–like condition and may be useful in the management of chronic hypotonic hyponatremia.

▶ Hyponatremia

ESSENTIALS OF DIAGNOSIS

- ▶ Plasma sodium >145 meq/L
- ▶ Serum osmolality >300 mOsm/kg
- ▶ Evidence of increased solute administration, polyuria with dilute urine (diabetes insipidus), or inadequate water intake
- ▶ Altered mental status

General Considerations

In contrast to hyponatremia, for which hypotonicity is often but not always present, hypernatremia, defined as $[Na^+]$ greater than 145 meq/L, is always associated with hypertonicity, defined as plasma osmolality greater than 300 mOsm/kg. Severe hypernatremia must be treated vigorously but carefully to avoid excessively rapid correction and further complications.

Hypernatremia indicates a deficit of TBW relative to total body solute (Table 2–8). This condition occasionally develops when a large amount of solute is given in concentrated form, but hypernatremia is much more commonly associated with either insufficient water intake or excessive water loss.

A. Addition of Solute—Addition of solute to the body without a corresponding addition of water results in an increase in plasma osmolality. The source of solute may be exogenous, such as administration of hypertonic saline or sodium bicarbonate, glucose, mannitol, or other solutes. The only common endogenous mechanism is gluconeogenesis and glycogenolysis causing hyperglycemia. As discussed earlier, hyperglycemia increases plasma osmolality without causing hypernatremia. Increased plasma urea increases plasma osmolality but does not increase tonicity because urea concentration also increases within cells. When solute is added, increased plasma osmolality stimulates maximum ADH release to minimize water excretion (urine osmolality increases). Correction of the hyperosmolar state results when the excess solute is disposed of or, in the case of glucose, excreted or taken into the cells as glycogen. However, the obligate loss of water needed to excrete solute requires that water be given to the patient to achieve appropriate correction.

B. Inadequate Water Intake—Insufficient water intake results in hypernatremia because of obligatory renal and non-renal water losses. Daily insensible loss of water amounts to about 500 mL, increasing somewhat with body temperature and sweating. Because most insensible loss is through the airways, intubation and mechanical ventilation with humidified air decrease insensible losses to minimal amounts.

Minimum urine volume is determined by maximum urine concentration and obligate solute excretion. As calculated in Table 2–6, the normal urinary solute excretion of

Table 2–8. Disorders of water balance: Hypernatremia.

2. Decreased ADH effectiveness (nephrogenic diabetes insipidus)
a. Tubulointerstitial disease
b. Lithium
c. Demeclocycline
d. Hypokalemia
e. Hypercalcemia

800 mOsm/day necessitates a mandatory loss of 670 mL of water per day if urine is maximally concentrated (to 1200 mOsm/L). Thus minimal water loss in adults of normal size is approximately 1170 mL/day (670 mL urine plus 500 mL insensible loss). Because metabolism generates about 500–600 mL water per day, there is a mandatory intake of 600–700 mL water per day. Failure to take in at least this much water predictably results in hypernatremia.

C. Excessive Water Loss—The final major mechanism of hypernatremia is excessive water loss with inadequate replacement. Some patients are unable to concentrate urine maximally, thereby making mandatory an increased intake of water to avoid development of hyperosmolality. Maximum urine concentration in normal subjects is 1200 mOsm/L but depends on having normal renal tubular function, normal solute load, and normal ADH release and response. Renal tubulointerstitial disease such as seen in sickle cell anemia, urate nephropathy, and renal cystic disease; use of loop diuretics such as furosemide; and use of drugs such as demeclocycline and lithium interfere with urine concentrating ability. An increase in renal tubular solute load forces the tubules to

produce a urine that is isosmotic with plasma (isosthenuria). Glucose, mannitol, and urea are the most likely encountered poorly reabsorbable solutes that contribute to such an “osmotic diuresis,” limiting maximum urine concentration.

Patients who lack appropriate ADH release from the posterior pituitary or whose kidneys do not respond properly to ADH have impaired urine concentrating ability and polyuria and will develop hypernatremia in the absence of increased water intake. Lack of ADH production (central diabetes insipidus) results from head trauma, pituitary tumors, tumors adjacent to the pituitary, granulomatous diseases such as tuberculosis and sarcoidosis, meningitis, and vascular anomalies near the hypothalamus. Occasionally, diabetes insipidus is idiopathic. If ADH is present but the kidneys do not respond by increasing urine concentration, a diagnosis of nephrogenic diabetes insipidus is made. This relative or absolute resistance to ADH is seen in a familial form, may be due to drugs such as demeclocycline or lithium, or may be found in conjunction with tubulointerstitial diseases of the kidneys.

Sweating increases water loss greatly, especially during hot weather and with high fever, and gastrointestinal tract losses may be marked in patients with diarrhea or vomiting.

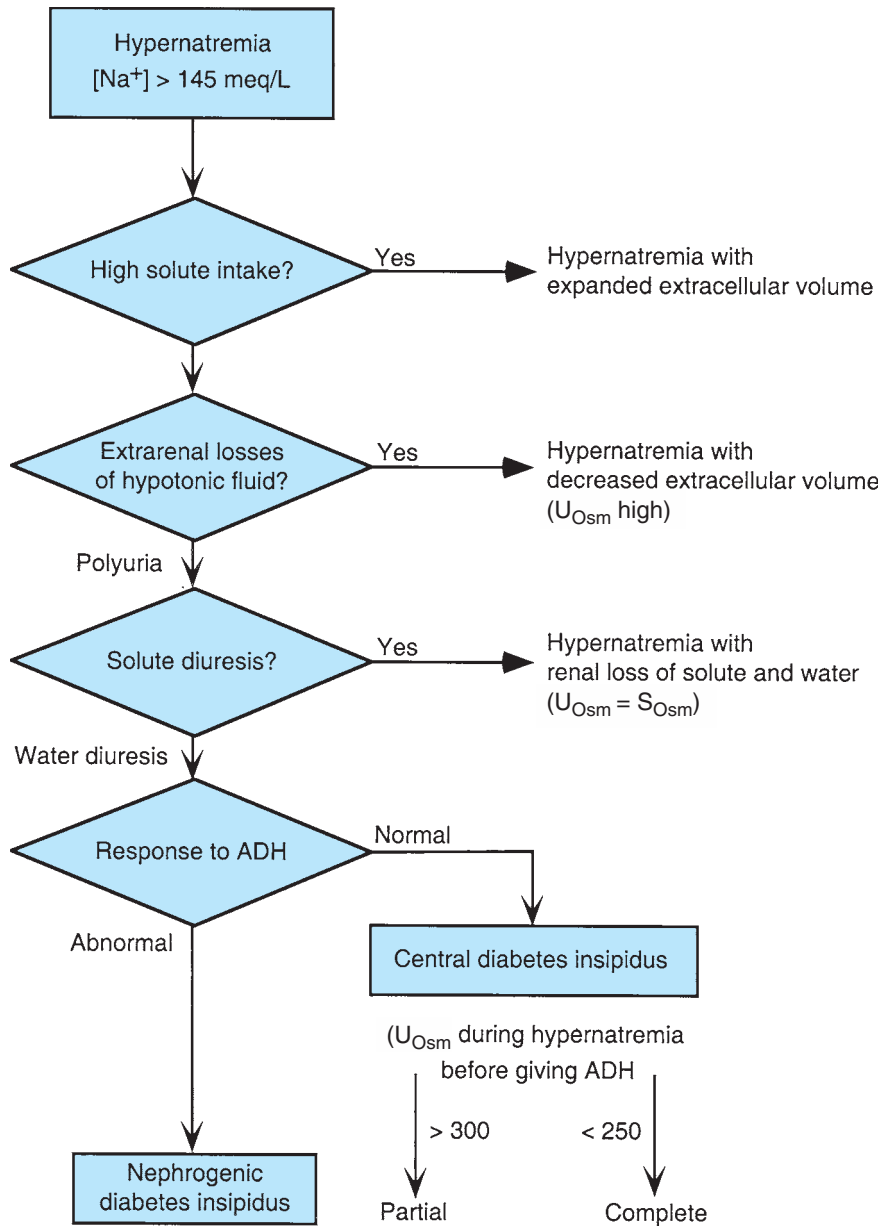

Clinical Features

Hypernatremia and hyperosmolality should be suspected in patients with decreased access to water, especially with altered mental status, or those with a history of polyuria. The elderly patient living in a chronic care facility is especially susceptible. However, many patients are identified through routine electrolyte determinations. The severity of water deficit is estimated from the plasma electrolytes and body weight. [Figure 2–2](#) shows a clinical and laboratory approach to patients with hypernatremia.

A. Symptoms and Signs—As with hyponatremia, hypernatremia and hypertonicity affect primarily the brain. Both the addition of solute to the extracellular compartment (causing water to move out of cells) and the net loss of water from the body acutely decrease the size of brain cells. Shrinkage of brain cells can lead to altered mental status, impaired thinking, and loss of consciousness. Cerebral hemorrhage, thought to be due to tearing of blood vessels owing to brain shrinkage, is a rare complication. In patients who can respond, thirst is an important clue to both hypovolemia and hypertonicity. A history of polyuria and nocturia is important in establishing the cause of hypernatremia as diabetes insipidus.

The clinical situation, symptoms, and signs may provide clues to the cause of hypernatremia. Addition of large quantities of solute is a rare cause. Saltwater near-drowning is said to cause hypernatremia by absorption of Na^+ and Cl^- through the lungs, but this is rare in those who survive asphyxiation. Others will have a history of receiving hypertonic saline, mannitol, glucose, or sodium bicarbonate. Volume overload may cause pulmonary and peripheral edema in these patients.

A history of decreased water intake may be obtained in patients who have not had access to water at home or in the

▲ **Figure 2-2.** Clinical and laboratory approach to the diagnosis of hypernatremia.

hospital (eg, acute illness, altered mental status, or trauma) or who have had increased normal losses of water from extrarenal mechanisms (eg, exertion in hot weather or diarrhea). Features suggestive of decreased extracellular volume status include hypotension, tachycardia, and oliguria.

If the patient has hypernatremia, polyuria with dilute urine suggests that the excessive water loss is due to inability to concentrate the urine appropriately (central or nephrogenic

diabetes insipidus). Hypernatremia with polyuria and isosthenuric urine suggests solute diuresis.

B. Laboratory Findings—Laboratory studies are needed to make the diagnosis of hypernatremia, confirm plasma hyperosmolality, and determine the cause. In general, plasma electrolytes and osmolality; glucose, creatinine, and urea nitrogen; urine osmolality; urine Na⁺ and creatinine; and urine volume

should be measured. Plasma sodium greater than 145 meq/L makes the diagnosis of hypernatremia, and this will be accompanied by plasma osmolality greater than 300 mOsm/kg.

1. HYPERNATREMIA WITHOUT POLYURIA—In the absence of renal disease and with normal ADH response, patients in whom addition of solute is the cause of hypernatremia will excrete small amounts of concentrated urine. Urine osmolality is greater than 300 mOsm/kg and usually much higher (up to 1200 mOsm/kg in normal young adults). Patients with decreased water intake relative to nonrenal water losses with normal renal function also will have maximum conservation of urine volume with oliguria, plasma urea nitrogen:plasma creatinine ratio greater than 30, low urine Na^+ , and low fractional excretion of Na^+ .

2. HYPERNATREMIA WITH POLYURIA—In the presence of hypernatremia, polyuria with dilute urine suggests that the mechanism of water loss is inability to concentrate the urine appropriately, but the driving force for polyuria may be either solute (osmotic) diuresis or water diuresis. Water diuresis and solute diuresis can be distinguished by the ratio of urine to plasma osmolality ($U_{\text{Osm}}/P_{\text{Osm}}$). $U_{\text{Osm}}/P_{\text{Osm}}$ in solute diuresis (osmotic diuresis) is greater than 0.9; $U_{\text{Osm}}/P_{\text{Osm}}$ in water diuresis is less than 0.9. Thus solute diuresis generally is associated with isosthenuria, whereas water diuresis is associated with excretion of dilute urine. Solute diuresis can be further subdivided into electrolyte diuresis or nonelectrolyte diuresis. If $2 \times (U_{[\text{Na}^+]} + U_{[\text{K}^+]}) > 0.6 \times U_{\text{Osm}}$, then the majority of solute in the urine consists of electrolytes such as sodium and potassium; if it is less than $0.6 \times U_{\text{Osm}}$, then urea, glucose, mannitol, or other nonelectrolyte solute is the cause of the diuresis. Electrolyte diuresis is seen with administration of diuretics and is the normal response to correction of increased extracellular volume. Patients in the ICU who are receiving excessive amounts of normal saline have increased urine output and NaCl diuresis. Urea-induced diuresis occurs after relief of obstructive nephropathy and in the diuretic phase of acute tubular necrosis.

The polyuria with water diuresis may be normal (eg, if the patient has hyponatremia) but is abnormal during hypernatremia, suggesting diabetes insipidus.

3. DIABETES INSIPIDUS—Diabetes insipidus is usually characterized by hypernatremia, polyuria, and decreased ability to concentrate urine maximally, but some mild cases may be difficult to identify, and in other cases, earlier treatment may confuse the diagnosis. A water deprivation test may be necessary. In this test, a patient with normal or near-normal plasma osmolality is deprived of water for a scheduled interval while weight, plasma sodium and osmolality, and urine volume and osmolality are measured. If polyuria continues and urine concentration fails to increase into an appropriately high range (>800 mOsm/kg) despite a plasma osmolality greater than 290–300 mOsm/kg, a diagnosis of diabetes insipidus is made.

Water deprivation is allowed to continue until the patient loses 3–5% of body weight. For safety when designing the water deprivation test, patients should be anticipated to continue to maintain

urine output at the starting rate. Thus, for example, if urine volume is initially 600 mL/h, a 60-kg patient could be expected to lose 3% of body weight in just 3 hours; if this urine is maximally dilute (eg, severe central diabetes insipidus), the expected increase in plasma osmolality also can be calculated. Actual weight loss and urine volume should be used to make the decision to stop the test. Five units of aqueous vasopressin is administered at the end of the test if urine concentration fails to rise. Lack of response to vasopressin indicates that the cause is nephrogenic rather than failure of release of ADH. Lack of ADH or of response to ADH can be complete or partial. Identification of intermediate response may be important in deciding treatment, and this usually can be concluded from the degree of urine concentration achieved during the water deprivation test.

Treatment

A. Calculation of Water Deficit—All patients with hypernatremia have increased plasma osmolality, and the amount of water needed to correct this state can be calculated from the following equation:

$$\text{TBW (L)} = \text{normal TBW (L)} \times \frac{140}{[\text{Na}^+]}$$

If $[\text{Na}^+]$ is 170 meq/L and normal TBW is 0.6 L/kg, the TBW for a man whose customary weight is 70 kg is approximately $42 \text{ L} \times 140 \div 170 = 35 \text{ kg (L)}$, and the water deficit is $42 - 35 = 7 \text{ L}$. Note that this is the amount of water needed to correct $[\text{Na}^+]$ to 140 meq/L. In practice, the patient's normal body weight may not be known, but only the current body weight. Using current weight is acceptable as an estimate, but it is potentially misleading because the water deficit may contribute to the weight difference.

B. Rate of Correction of Hypernatremia—Just as with hyponatremia, too-rapid correction of hypernatremia may be harmful. Cerebral edema with neurologic complications has occurred during correction as a result of a compensatory mechanism intended to maintain normal brain cell volume. In response to development of hypertonicity, brain cells fairly rapidly increase the amount of inorganic ions; this restores cell volume to near normal, but at the expense of disrupted cellular function. With persistence of hypertonicity, brain cells generate and take up idiogenic osmoles, sometimes called *organic osmolytes*. Since cell volume is determined from the amount of solute contained within the cell, organic osmolytes resist the movement of water out of the cells and maintain brain volume close to normal. Many of the organic osmolytes are taken up from the extracellular space by the formation of specific membrane channels. These channels do not disappear quickly or reverse function when hypernatremia is corrected. Therefore, rapid restoration of water to the body theoretically may cause overexpansion of these cells, resulting in cerebral edema. Although mild controversy exists,

conservative recommendations are to correct hypernatremia by no more than 10 meq/L per day to allow elimination of organic osmolytes and avoid cerebral edema. This slow rate of correction may not be necessary in patients who develop hypernatremia over the course of a few hours, however.

The following formula is very helpful in calculating the anticipated changes in plasma $[\text{Na}^+]$ in the hypernatremic patient given intravenous fluids. The rate of correction of plasma $[\text{Na}^+]$ can be estimated. This formula estimates the amount of change in plasma $[\text{Na}^+]$ when 1 L of any fluid is administered:

$$\Delta\text{Plasma } [\text{Na}^+] = \frac{\text{fluid } [\text{Na}^+] - \text{plasma } [\text{Na}^+]}{\text{TBW} + 1}$$

where TBW is the calculated estimate of total body water (see above). This formula demonstrates how little the plasma $[\text{Na}^+]$ changes when normal saline ($[\text{Na}^+] = 154$ meq/L) is given to a hypernatremic patient. In order to determine how much hypotonic fluid is needed to achieve a 10 meq/L decrease in plasma $[\text{Na}^+]$ in 24 hours, begin by calculating the change for 1 L of fluid administered, and then calculate for the next liter, etc., until the desired change is reached. The total number of liters of fluid divided by 24 hours will be the hourly infusion rate. Serial measurements of plasma $[\text{Na}^+]$ are essential because the formula does not account for other fluid sources, urinary losses, or insensible water loss.

C. Hypernatremia Associated with Increased Solute—

These patients should have facilitation of solute excretion— if possible, with diuretics and administration of water or 5% dextrose in water. Diuretics will speed removal of sodium and chloride, but the obligate loss of water with the solute will increase the amount of water that must be given. If patients have renal insufficiency, removal of solute may require hemodialysis or ultrafiltration with replacement of water. A few patients have been treated by hemodialysis with dialysate containing hypotonic solution, facilitating water replacement. Peritoneal dialysis using hypotonic solutions should be efficacious in removing extracellular solute and increasing water replenishment.

Patients with hyperosmolality owing to severe hyperglycemia are treated with intravenous insulin to lower blood glucose, but normal saline (0.9% NaCl) is the preferred initial fluid replacement. Movement of glucose into cells is accompanied by movement of water out of the intravascular space, resulting in severe volume depletion. After adequate normal saline is given, hypotonic fluid (5% dextrose in water) is used to correct net water deficits.

D. Hypernatremia with Diminished Extracellular Volume—These patients have either an extrarenal or renal loss of hypotonic fluid. Therefore, both solute and water have to be replaced. Extracellular volume should be replaced with normal saline first, but it should be remembered that even

large volumes of normal saline, despite being hypotonic to plasma in most hypernatremic patients, correct the water deficit only very slightly. For example, if $[\text{Na}^+] = 170$ meq/L for a normally 70-kg patient, 1 L of 0.9% NaCl will add 308 mOsm of solute and 1 L of water, predictably decreasing $[\text{Na}^+]$ to only about 169.5 meq/L. Therefore, if more rapid correction of hypernatremia is desired, hypotonic fluid (5% dextrose in water or 0.45% NaCl) should be given as well. In practice, volume repletion is generally a higher priority, but after some correction of the volume deficit, the water deficit should be addressed directly.

E. Hypernatremia Associated with Diabetes Insipidus—

Hypernatremia in diabetes insipidus will respond to administration of water orally or 5% dextrose in water intravenously, but correction of hypernatremia depends on giving enough water both to overcome the water deficit and to compensate for continued urine water losses. In severe diabetes insipidus, urine volume can exceed 500 mL/h, and with a severe water deficit, water may have to be given at rates exceeding 600–700 mL/h.

Central diabetes insipidus should respond to synthetic ADH compounds. Aqueous vasopressin (5–10 units two or three times daily) can be given subcutaneously, or desmopressin acetate, which lacks vasopressor effects but retains ADH activity, can be given intravenously or subcutaneously (2–4 $\mu\text{g}/\text{day}$) or by nasal spray. The dose should be adjusted on the basis of plasma $[\text{Na}^+]$, urine output, and urine osmolality. Ideally, urine output should be reduced to 3–4 L/day, an amount that can be replaced readily by oral or intravenous administration.

Nephrogenic diabetes insipidus is rarely as severe as complete central diabetes insipidus, and during water deprivation, urine osmolality is sometimes as high as 300–400 mOsm/kg. Administration of enough water to maintain normal plasma $[\text{Na}^+]$ usually can be achieved. If a reversible cause such as lithium toxicity is found, the offending agent can be discontinued, although the effect on renal concentrating ability may persist for days. Thiazide diuretics induce mild volume depletion, leading to increased proximal tubular sodium reabsorption and decreased delivery of sodium and water to the distal diluting segment, so that less water is lost.

DISORDERS OF POTASSIUM BALANCE

Potassium is the most abundant intracellular cation and the second most common cation in the body. The ratio of intracellular to extracellular potassium concentration is normally about 35:1, whereas sodium is much higher in the extracellular space. The importance of these distributions is reflected in the ubiquitous Na^+, K^+ -ATPase pumps on the cell membranes that continuously move K^+ into and Na^+ out of the cells to maintain these gradients. The intracellular:extracellular ratios for Na^+ and K^+ determine the electrical potential across the cell membrane and are responsible for initiating and transmitting electrical signals in nerves, skeletal muscle, and myocardium. The two major mechanisms that determine plasma $[\text{K}^+]$ are renal potassium handling and the distribution of potassium between the intracellular and extracellular compartments.

Plasma Potassium and Total Body Potassium

Laboratory determinations of potassium are made on either serum or plasma. There is no appreciable difference between the two in the absence of thrombocytosis (which can cause elevated serum potassium but has minimal effect on plasma potassium), and plasma potassium will be used in this discussion. Plasma potassium $[\text{K}^+]$ is closely regulated, but hyper- and hypokalemia do not necessarily indicate increased and decreased total body potassium because of the high proportion of intracellular potassium. For example, movement of K^+ out of the cells and into the extracellular space can mask severe depletion of total body K^+ ; similarly, hypokalemia may be seen despite increase in total body K^+ . The use of plasma $[\text{K}^+]$ to estimate the need to administer or remove potassium from a patient always must take into account factors that alter the intracellular:extracellular distribution of potassium.

Renal Potassium Handling

In the normal steady state, dietary potassium intake is excreted almost entirely by the kidneys, although small amounts of potassium are lost in sweat and gastrointestinal fluids. Large amounts of potassium can be excreted by the kidneys as long as sufficient time to adapt is given, and potassium can be conserved with moderate efficiency in normal individuals, although not to the same extent as sodium.

Almost all potassium in the glomerular filtrate is reabsorbed. Therefore, urinary potassium comes from secretion of potassium into the tubular fluid through potassium channels on distal renal tubular cells, especially those of the cortical collecting tubules. Increased concentration of tubular cell potassium and a greater degree of electronegativity of adjacent tubular fluid increase the rate of potassium secretion. The strongest impetus to potassium secretion, though, is sodium reabsorption. The aldosterone-regulated Na^+, K^+ -ATPase pump on the blood side of the tubular cell transports

potassium into the cell against its concentration gradient and moves Na^+ out of the cell into the blood. This creates a sodium gradient from the tubular lumen into the cell causing passive movement of sodium through epithelial sodium channels (enhanced by aldosterone) and generating an electronegative luminal fluid as anions such as chloride and bicarbonate remain in the lumen. In turn, potassium moves passively from a high concentration inside the cell into the tubule both because of the lower tubular potassium concentration and because of the more electronegative fluid. Potassium excretion is facilitated by increased aldosterone (increased Na^+, K^+ -ATPase pump activity and opening of luminal Na channels), increased distal tubular Na^+ delivery (larger quantity of Na^+ to draw out of tubule), the presence of poorly reabsorbable tubular anions, and increased intracellular potassium concentration. Clinical correlates of each of these factors can be shown in Table 2–9, by which normal and abnormally excessive potassium excretion can be explained. Failure of these mechanisms for potassium excretion potentially leads to increased total body potassium in the face of continued potassium intake.

Distribution of Total Body Potassium

The other major mechanism determining potassium balance and plasma $[\text{K}^+]$ is the intracellular-extracellular distribution of potassium. Only a small quantity of potassium is found in the extracellular space. If plasma $[\text{K}^+]$ is 4 meq/L and potassium is freely distributed throughout the estimated 12 L of extracellular water in a normal 60-kg subject, then only 48 meq of K^+ is present in this space. The intracellular compartment has a concentration of 130 meq $\text{K}^+/\text{L} \times 24 \text{ L}$ intracellular volume, or 3120 meq K^+ within cells. The main mechanisms for maintaining this distribution are the Na^+, K^+ -ATPase membrane pumps that draw K^+ into the cells and move Na^+ out of cells. These pumps are subject to control by insulin and epinephrine, each stimulating increased Na^+ and K^+ exchange by different mechanisms. Insulin has in fact been considered by some to have plasma potassium regulation as its major role. Clinically, exogenous insulin administration is associated with potential for hypokalemia despite no change in total body potassium. In addition, insulin-dependent diabetics with renal insufficiency (inability to excrete potassium readily) are prone to severe hyperkalemia unless adequate insulin therapy is given. Beta-adrenergic agonists also can cause hypokalemia by an epinephrine-like effect, and beta-adrenergic antagonists prolong and amplify the rise in plasma potassium after administration of potassium.

Blood pH also has an effect on the intracellular-extracellular potassium distribution but does not act through the Na^+, K^+ -ATPase pump. However, acid-base disturbances have less effect on plasma $[\text{K}^+]$ than is generally assumed. Of the acid-base disturbances, metabolic acidosis in which the acid is predominantly extracellular and inorganic—that is, hyperchloremic acidosis—causes the largest increase in plasma potassium, potentially with severe life-threatening

Table 2-9. Plasma and total body potassium regulation by renal excretion and extracellular-intracellular distribution.

Mechanism of Regulation	Examples
Renal potassium excretion	
Facilitated by: Increased Na ⁺ reabsorption in distal nephron Increased Na ⁺ delivery to distal nephron Increase in poorly reabsorbable tubular anions Increased intracellular K ⁺ concentration Magnesium depletion	Volume depletion, aldosterone Loop diuretics, thiazides Carbenicillin, bicarbonate, keto acids, inorganic anions Increased intracellular K ⁺ distribution Amphotericin B, cisplatin, aminoglycosides
Impaired by: Decreased K ⁺ filtration Decreased Na ⁺ delivery to distal nephron Inhibition of K ⁺ secretion	Renal insufficiency Volume depletion with proximal Na ⁺ reabsorption Amiloride, spironolactone, triamterene, trimethoprim, decreased aldosterone
Decreased extracellular:intracellular K ⁺ ratio (hypokalemia) Increased plasma insulin level Catecholamines (beta-adrenergic agonists) Metabolic alkalosis	Exogenous insulin, hyperalimentation Bronchodilators, decongestants, theophylline Vomiting, volume depletion
Increased extracellular:intracellular K ⁺ ratio (hyperkalemia) Decreased plasma insulin level Beta-adrenergic blockade Metabolic acidosis (hyperchloremic) Depolarizing neuromuscular blockade	Diabetes mellitus Propranolol Ammonium chloride, lysine hydrochloride, arginine hydrochloride, parenteral nutrition Succinylcholine

hyperkalemia. The mechanism is thought to be exchange of extracellular hydrogen ion for intracellular potassium in the absence of simultaneous movement of chloride into the cell. Metabolic acidosis in which an organic anion is largely intracellular—for example, lactic acidosis or ketoacidosis—results in little or no change in plasma [K⁺]. Metabolic alkalosis often causes hypokalemia, but its major effect is to increase the quantity of bicarbonate in the distal tubule, resulting in severe renal potassium losses.

▶ **Hypokalemia**

- ▶ Plasma [K⁺] <3.5 meq/L.
- ▶ Usually asymptomatic, but there may be muscular weakness.
- ▶ Severe hypokalemia affects neuromuscular function and electrical activity of the heart: arrhythmias, ventricular tachycardia, increased likelihood of digitalis toxicity.

General Considerations

Hypokalemia is a potentially hazardous electrolyte disturbance in many critically ill patients. Because the intracellular potassium concentration is so much larger, and because it is the ratio of intracellular to extracellular potassium that determines cell membrane potential, small changes in extracellular potassium can have serious effects on cardiac rhythm, nerve conduction, skeletal muscles, and metabolic function. Patients in the ICU may have a number of disorders that are associated with hypokalemia, including diarrhea, solute diuresis, vomiting, metabolic alkalosis, and malnutrition. Treatment with insulin, beta-adrenergic agonists, diuretics, some antibiotics, and other drugs increases the likelihood of potassium depletion and hypokalemia.

Hypokalemia may or may not be associated with depletion of total body potassium. Thus mechanisms of hypokalemia can be divided into those in which total body potassium is low (eg, decreased intake or increased loss) or those in which total body potassium is normal or high (eg, redistribution of extracellular potassium into cells).

A. Depletion of Body Potassium—Normal subjects require at least 30–40 meq/day to replace obligate losses of potassium,

but decreased intake of potassium alone is very rarely a cause of hypokalemia except in critically ill patients who are not being fed or given potassium. More commonly, potassium depletion results from increased potassium loss without adequate replacement. One classification is to divide potassium loss into nonrenal and renal sources (see Table 2–9).

Nonrenal potassium losses can result from severe diarrhea and excessive sweating (although vomiting and nasogastric suction stimulate renal potassium excretion), but increased renal potassium loss that results from increased secretion of potassium is found more commonly in ICU patients. Almost all filtered potassium is reabsorbed, and renal tubular dysfunction rarely leads to impaired reabsorption.

Several factors facilitate renal potassium secretion. First, any cause of increased mineralocorticoids contributes to renal loss of potassium—including volume depletion, in which aldosterone increase is compensatory, and primary hyperaldosteronism. Cushing's syndrome and pharmacologic administration of hydrocortisone, prednisone, or methylprednisolone often lead to decreased $[K^+]$ owing to the mineralocorticoid activity of these corticosteroids. Unusual causes of increased mineralocorticoid activity include licorice ingestion (inhibits 11β -hydroxysteroid dehydrogenase) and administration of potent synthetic mineralocorticoids such as fludrocortisone. Second, increased delivery of sodium to the distal nephron enhances potassium secretion. Solute diuresis from glucose, mannitol, or urea increases distal sodium delivery by interfering with proximal sodium reabsorption. Furosemide and other loop diuretics, which also increase potassium loss because of volume depletion, increase distal tubular sodium delivery by inhibiting sodium reabsorption in the ascending loop of Henle. Thiazide diuretics increase potassium exchange for sodium in the distal tubules. Rarely, Bartter's syndrome (a congenital defect of one of several mechanisms of Na-Cl reabsorption in the ascending limb of the loop of Henle) and Gitelman's syndrome (a defect of the thiazide-sensitive Na-Cl cotransporter in the distal nephron) cause hypokalemia by renal salt wasting.

Any increased quantity of poorly reabsorbed anions in the tubular lumen increases the electronegative gradient, drawing potassium out of the distal tubular cells. Bicarbonate is less easily absorbed than chloride, and increased distal tubular bicarbonate is found in proximal renal tubular acidosis, during compensation for respiratory alkalosis, and in metabolic alkalosis. Other anions include those of organic acids such as keto acids and antibiotics such as sodium penicillin. Hypomagnesemia reduces Na^+,K^+ -ATPase pump activity, impairing intracellular potassium movement and impairing repletion of total body potassium. Hypokalemia is seen in about 40% of patients with magnesium deficiency; renal potassium loss paradoxically increases during repletion of potassium in this condition because of failure of cellular uptake. Amphotericin B can cause renal potassium wasting by acting as a potassium channel in the distal tubular cell. Aminoglycosides are associated with hypokalemia by a similar

mechanism, but clinically significant hypokalemia attributed to aminoglycosides is uncommon.

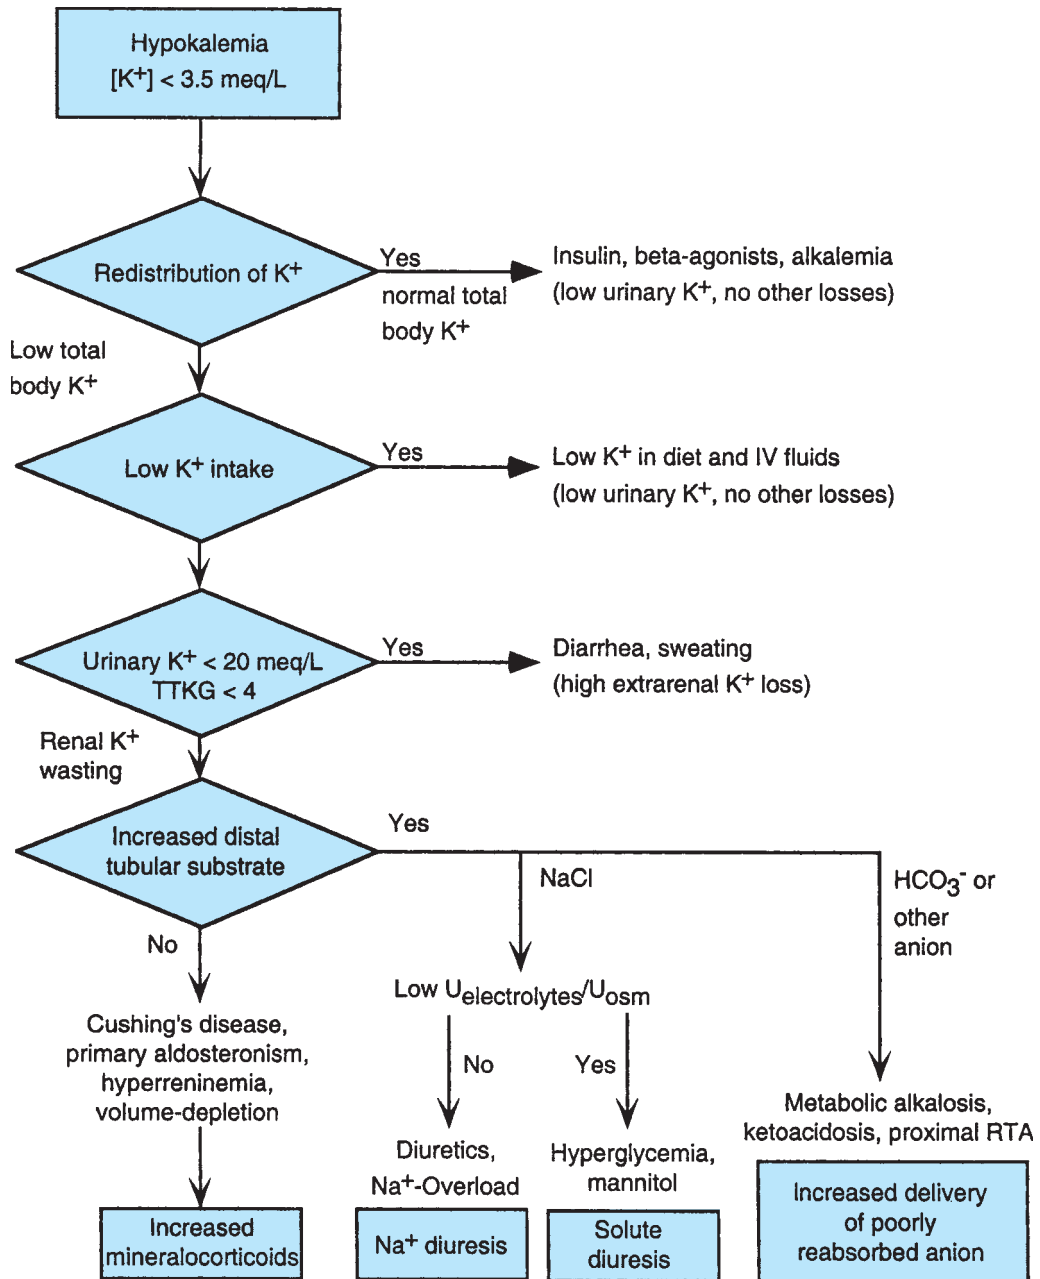

B. Abnormal Distribution of Potassium—Hypokalemia in the face of normal or increased total body potassium must be due to abnormal distribution of potassium between the extracellular and intracellular spaces. Common causes of decreased $[K^+]$ from potassium redistribution in ICU patients include drugs and acid-base disturbances. Insulin has a major role in transmembrane potassium transport. Either endogenous insulin, increased after glucose administration, or the combination of exogenous insulin and glucose can lead to hypokalemia by this mechanism. Beta-agonists increase the activity of the Na^+,K^+ -ATPase pump, so beta-adrenergic bronchodilators, sympathomimetic vasopressors, and theophylline are causes of decreased $[K^+]$. Metabolic and respiratory alkaloses do result in some shift of potassium into cells in exchange for hydrogen ion; the major effect of metabolic alkalosis, however, is to increase renal potassium secretion.

Clinical Features

Figure 2–3 shows a clinical and laboratory approach to the diagnosis of hypokalemia.

A. Symptoms and Signs—Most hypokalemic patients are asymptomatic, but mild muscle weakness may be missed in critically ill patients. More severe degrees of hypokalemia may result in skeletal muscle paralysis, and respiratory failure has been reported owing to weakness of respiratory muscles. Cardiovascular complications include electrocardiographic changes, arrhythmias, and postural hypotension. Cardiac arrhythmias include premature ventricular beats, ventricular tachycardia, and ventricular fibrillation. Rhythm disturbances are seen more commonly in association with myocardial ischemia, hypomagnesemia, or when drugs such as digitalis and theophylline have been given. Hypokalemia may exacerbate hepatic encephalopathy by stimulating ammonia generation. The combination of severe hypokalemia, metabolic alkalosis, and hyponatremia is often seen in patients with evidence of volume depletion such as tachycardia, hypotension, and mild renal insufficiency.

Although hypokalemia is most often a laboratory diagnosis, it should be suspected in patients at risk. In the ICU, hypokalemia is found commonly because many critical illnesses and their treatments contribute to renal and nonrenal potassium wasting. Patients being given diuretics (eg, thiazides, loop diuretics, acetazolamide, or osmotic diuretics), beta-adrenergic bronchodilators, theophylline, corticosteroids, insulin, large amounts of glucose, total parenteral nutrition, aminoglycosides, high-dose sodium penicillin, and amphotericin B are among those who should have particular attention paid to monitoring plasma $[K^+]$. Toxic levels of theophylline in particular can cause profoundly reduced plasma $[K^+]$. Patients with volume depletion, especially from diarrhea, vomiting, or nasogastric suctioning (which induces both volume depletion and metabolic alkalosis), and osmotic diuresis

▲ **Figure 2-3.** Clinical and laboratory approach to the diagnosis of hypokalemia.

should be watched carefully for development of hypokalemia. In patients with renal failure undergoing dialysis, excessive potassium losses are unusual, although they may occur.

B. Laboratory Findings—A plasma potassium concentration of less than 3.5 meq/L makes the diagnosis of hypokalemia. However, there is some evidence that complications of

hypokalemia may occur even when plasma potassium is in the low end of the normal range. The electrocardiogram may show nonspecific ST- and T-wave changes, although flattening of the T wave with development of a U wave is considered characteristic with more severe hypokalemia. Plasma [Na⁺] may be low as a consequence of total body potassium depletion.

Other laboratory findings are helpful for identifying the cause of hypokalemia. Finding the mechanism of hypokalemia is important because inappropriate replacement with large amounts of potassium may lead to hyperkalemia if redistribution rather than depletion of potassium is the cause of hypokalemia. Confirmation of renal potassium wasting can be useful. In the presence of hypokalemia, a urinary potassium concentration of less than 20 meq/L suggests nonrenal potassium wasting, whereas a urinary potassium concentration of greater than 20 meq/L increases the likelihood of renal potassium wasting.

The transtubular potassium gradient (or ratio) can be helpful in diagnosing renal potassium wasting:

$$\text{TTKG} = \frac{\text{urine } [K^+]}{\text{plasma } [K^+]} \times \frac{P_{\text{osm}}}{U_{\text{osm}}}$$

where $[U_{\text{osm}}]$ is urine osmolality and $[P_{\text{osm}}]$ is plasma osmolality. This formula estimates the potassium concentration in the distal nephron by multiplying the urine $[K^+]$ by the ratio of urine osmolality to plasma osmolality to account for the change in water concentration through the collecting ducts. A ratio of distal tubular $[K^+]$ (numerator) to plasma $[K^+]$ (denominator) of less than 2 indicates appropriate renal conservation of potassium in the face of hypokalemia. A ratio greater than 4 suggests renal tubular potassium wasting. Even if it is known that the mechanism of hypokalemia is excessive urinary loss, urinary potassium determination can be a useful guide to the amount of potassium replacement needed to maintain normal levels or to correct hypokalemia.

Identification of a poorly absorbable anion in the urine is usually not feasible, but an increased quantity of unmeasured anions can be inferred if the sum of urine sodium and potassium exceeds urine chloride concentration by greater than 40 meq/L. Redistribution of potassium leading to hypokalemia cannot be definitely diagnosed by laboratory studies, although metabolic or respiratory alkalosis can be identified by arterial blood gases. Measurement of drug level may confirm theophylline toxicity as a factor contributing to hypokalemia.

Treatment

A. Estimating Total Body Potassium Deficit—Plasma $[K^+]$ reflects only extracellular potassium. Although normal intracellular potassium concentration is 35 times extracellular and normal intracellular volume is twice extracellular, there is no simple relationship between plasma $[K^+]$ and total body potassium. Nomograms and formulas for estimating total body potassium deficit based on plasma $[K^+]$, pH, and plasma osmolality are available, but these should not be relied on heavily. However, in general, patients with severe hypokalemia ($[K^+] < 2.5$ meq/L) and severe metabolic alkalosis have the largest potassium deficits—up to 400 or 500 meq—whereas those with hyperchloremic acidosis and mild hypokalemia have milder deficits.

The magnitude of the potassium deficit has implications for the amount of potassium needed to correct the deficit but not necessarily for the urgency or amount immediately needed. Because the clinical manifestations of hypokalemia are determined by the ratio of extracellular and intracellular $[K^+]$, any degree of moderate to severe hypokalemia, regardless of the size of the potassium deficit, may impose the same risk to the patient.

B. Severe Hypokalemia—The oral route is preferred for potassium replacement, except in those patients whose oral intake is restricted or whose hypokalemia is life-threatening. The rate of administration and the amount of potassium that can be given are limited by local complications (irritation at the intravenous site) and because potassium is distributed initially only into the extracellular space. Too-rapid administration can result in large and dangerous increases in extracellular and plasma $[K^+]$ before potassium can be taken into cells. Special care should be taken in patients receiving beta-adrenergic blockers, in type 1 diabetics, and in patients with oliguric acute or chronic renal failure.

Potassium chloride and potassium phosphate are available for intravenous use. Potassium chloride should be given unless there is hypophosphatemia (see “Hypophosphatemia” below). Intravenous potassium chloride can be given in concentrations as high as 60 meq/L. The total amount of potassium in a single intravenous bag should be restricted, however, to 20–40 meq to avoid the risk of inadvertent rapid administration of excessive amounts, and these amounts should be administered over at least 1 hour into a peripheral vein. Because of the size of the extracellular space into which potassium is initially distributed, 20–40 meq of potassium can cause the potassium to rise as much as of 2–4 meq/L if it is not distributed quickly to the intracellular compartment.

Intravenous potassium into central venous catheters must be given cautiously and only when absolutely necessary. Very high plasma $[K^+]$ levels can be achieved within the heart, resulting in conduction system disturbances. However, the large volume of blood into which the potassium mixes generally dilutes $[K^+]$ rapidly. Large quantities of potassium may be needed in special circumstances to counteract hypokalemia, such as after open heart surgery. It is recommended that each ICU develop a protocol to ensure safety in giving potassium into central venous sites. In any patient receiving intravenous potassium, frequent (every 1–2 hours) serial monitoring of plasma $[K^+]$ is mandatory.

C. Potassium Replacement—Potassium needs should be anticipated in ICU patients to avoid hypo- and hyperkalemia. Patients receiving potent diuretics, those on continuous nasogastric suction, those starting intravenous glucose for parenteral nutrition, and those receiving digitalis should be considered for increased potassium supplementation.

Patients with acute myocardial ischemia and infarction may be more prone to arrhythmias, which can be prevented by careful attention to plasma potassium levels. Other patients with a

potential for hypokalemia include those prescribed beta-adrenergic agonists (bronchodilators) or theophylline and patients with hypomagnesemia. A special case is the treatment of diabetic ketoacidosis. Insulin is expected to drive potassium into cells along with glucose. Although potassium should be withheld in those presenting with hyperkalemia, patients with normal plasma $[K^+]$ generally can be expected to require potassium supplementation during insulin treatment because most patients have moderate to severe potassium deficits from earlier solute diuresis. In many patients with diabetic ketoacidosis, moderate to severe hypophosphatemia develops, and potassium phosphate is indicated.

D. Correct Underlying Disorder—The underlying disorder contributing to hypokalemia may or may not be correctable. Correction of magnesium deficiency may correct a state of refractory potassium deficiency. Efforts should be made to control extrarenal losses of potassium and fluid. Diuretics causing hypokalemia generally must be continued for treatment of volume overload states, but benefit sometimes can be obtained from potassium-sparing diuretics such as spironolactone, triamterene, or amiloride, although these are less potent natriuretic agents than furosemide. In critically ill patients, potassium replacement plus furosemide is generally preferred over potassium-sparing diuretics, especially if there is renal insufficiency, hypokalemia requiring simultaneous potassium supplementation, and a severe edematous state. Similarly, amphotericin B, aminoglycosides, corticosteroids, and other drugs associated with hyperkalemia used in critically ill patients may not be avoidable and must be continued.

▶ Hyperkalemia

ESSENTIALS OF DIAGNOSIS

- ▶ Plasma $[K^+] >5$ meq/L.
- ▶ Severe hyperkalemia affects neuromuscular function and electrical activity of the heart, with abnormal ECG. May develop heart block, ventricular fibrillation, or asystole.

General Considerations

While hypokalemia is more common in ICU patients, renal failure, metabolic acidosis, potassium-sparing diuretics, adrenal insufficiency, drugs, and iatrogenic administration of potassium may lead to hyperkalemia. Hyperkalemia has serious effects on myocardial conduction, and most life-threatening emergencies from hyperkalemia involve the heart.

The mechanisms of hyperkalemia can be divided into those in which increased addition of potassium to the extracellular space overwhelms the normal mechanisms of potassium disposal and those in which the capacity for potassium disposal is impaired. Because hyperkalemia reflects plasma $[K^+]$ and not total body potassium, impaired disposal may be due to impaired redistribution of potassium into the cell or impaired excretion of potassium.

A. Addition of Potassium to Extracellular Space

Exogenous potassium can lead to hyperkalemia if enough potassium is given rapidly enough to raise potassium concentration in the extracellular space. Both exogenous and endogenous sources cause hyperkalemia. Impaired insulin release or beta-adrenergic blockade facilitate hyperkalemia, and because the normal extracellular potassium store is only as little as 40–60 meq, rapid potassium administration can easily overwhelm normal redistribution mechanisms. If potassium is given more slowly, however, normal renal excretion makes development of hyperkalemia much less likely. Endogenous sources of large potassium loads are not infrequent in the ICU from rhabdomyolysis owing to infection, trauma, or drugs; tumor lysis of lymphoma or leukemia; and severe hemolysis or other tissue breakdown.

A special case of endogenous potassium leading to a false diagnosis of hyperkalemia results from hemolysis of red blood cells after blood has been drawn. Pseudohyperkalemia also can be seen in patients with extreme thrombocytosis or leukocytosis.

B. Impaired Disposal of Potassium

Redistribution of potassium from the intracellular to the extracellular space or impaired potassium disposal can cause hyperkalemia. Metabolic acidosis, insulin deficiency, and beta-adrenergic blockade may redistribute potassium out of cells and cause hyperkalemia. Administration of acids with chloride anion (eg, hydrochloric acid, lysine hydrochloride, or arginine hydrochloride) is associated with hyperkalemia because of exchange of hydrogen ion for potassium inside the cell. Organic acidoses affect plasma potassium much less. Muscle paralysis with succinylcholine, a depolarizing muscle relaxant, releases potassium from muscle cells and prevents reuptake. Type 1 diabetic patients are prone to hyperkalemia because they lack the ability to increase insulin secretion in the face of increased plasma potassium.

1. RENAL INSUFFICIENCY—The kidneys are largely responsible for excretion of potassium and can greatly increase potassium excretion in response to hyperkalemia. Potassium is

filtered and then almost completely reabsorbed; this is true even in the face of hyperkalemia. However, in contrast to hypokalemia, in which increased filtration does not cause potassium depletion, decreased filtration does contribute to hyperkalemia. As with hypokalemia, aldosterone plays an important role in renal potassium handling.

Acute renal insufficiency more commonly causes hyperkalemia than chronic renal insufficiency, in the absence of increased intake of potassium. Chronically, aldosterone is released in direct response to hyperkalemia and facilitates secretion of potassium in the distal nephron. Decreased glomerular filtrate affects potassium secretion primarily by decreasing the amount of sodium available for lumen–tubular cell exchange, thereby limiting generation of the electronegative gradient that drives potassium secretion.

2. ALDOSTERONE DEFICIENCY—Deficiency of aldosterone predictably causes hyperkalemia. Diseases that destroy the adrenal glands result in loss of endogenous glucocorticoids and aldosterone (Addison's disease), but isolated cases of hypoaldosteronism are also seen. In long-standing diabetes, hyporeninemic hypoaldosteronism causes hyperkalemia and hyperchloremic metabolic acidosis (type 4 renal tubular acidosis). Spironolactone, an aldosterone antagonist, causes hyperkalemia in susceptible patients.

C. Drugs Associated with Hyperkalemia—Drugs associated with hyperkalemia are classified according to their mechanism of hyperkalemia. Those that impair intracellular potassium distribution include beta-adrenergic blockers, succinylcholine, hydrochloric acid, and other acidifying agents. Some earlier formulations of total parenteral nutrition solutions contained excess chloride salts of amino acids that contributed to hyperkalemia. Drugs that interfere with renal potassium secretion include aldosterone antagonists (eg, spironolactone), potassium-sparing diuretics (eg, triamterene and amiloride), ACE inhibitors, and drugs that decrease renal function (nonsteroidal anti-inflammatory drugs [NSAIDs]). Patients with heart failure are at risk for both hypokalemia and hyperkalemia because they may be prescribed potent loop diuretics, aldosterone, beta-adrenergic blockers, and ACE inhibitors simultaneously. Heparin and, to a lesser extent, low-molecular-weight heparin suppress aldosterone synthesis and can result in hyperkalemia in patients with diabetes mellitus and renal failure.

A number of patients receiving high doses of trimethoprim-sulfamethoxazole may have hyperkalemia. Trimethoprim has an amiloride-like effect, blocking distal tubular sodium channels and inhibiting potassium secretion because of decreased tubular electronegativity. Small amounts of potassium in potassium penicillin G (1.7 meq per million units) and transfused blood can cause hyperkalemia but usually only in patients with impaired potassium handling.

Clinical Features

A clinical and laboratory approach to the diagnosis of hyperkalemia is shown in [Figure 2-4](#).

A. Symptoms and Signs—Hyperkalemia is usually identified by routine measurement of electrolytes in the ICU. In critically ill patients, hyperkalemia may present acutely without warning. The most serious concern is cardiac rhythm disturbances, but weakness also may be present.

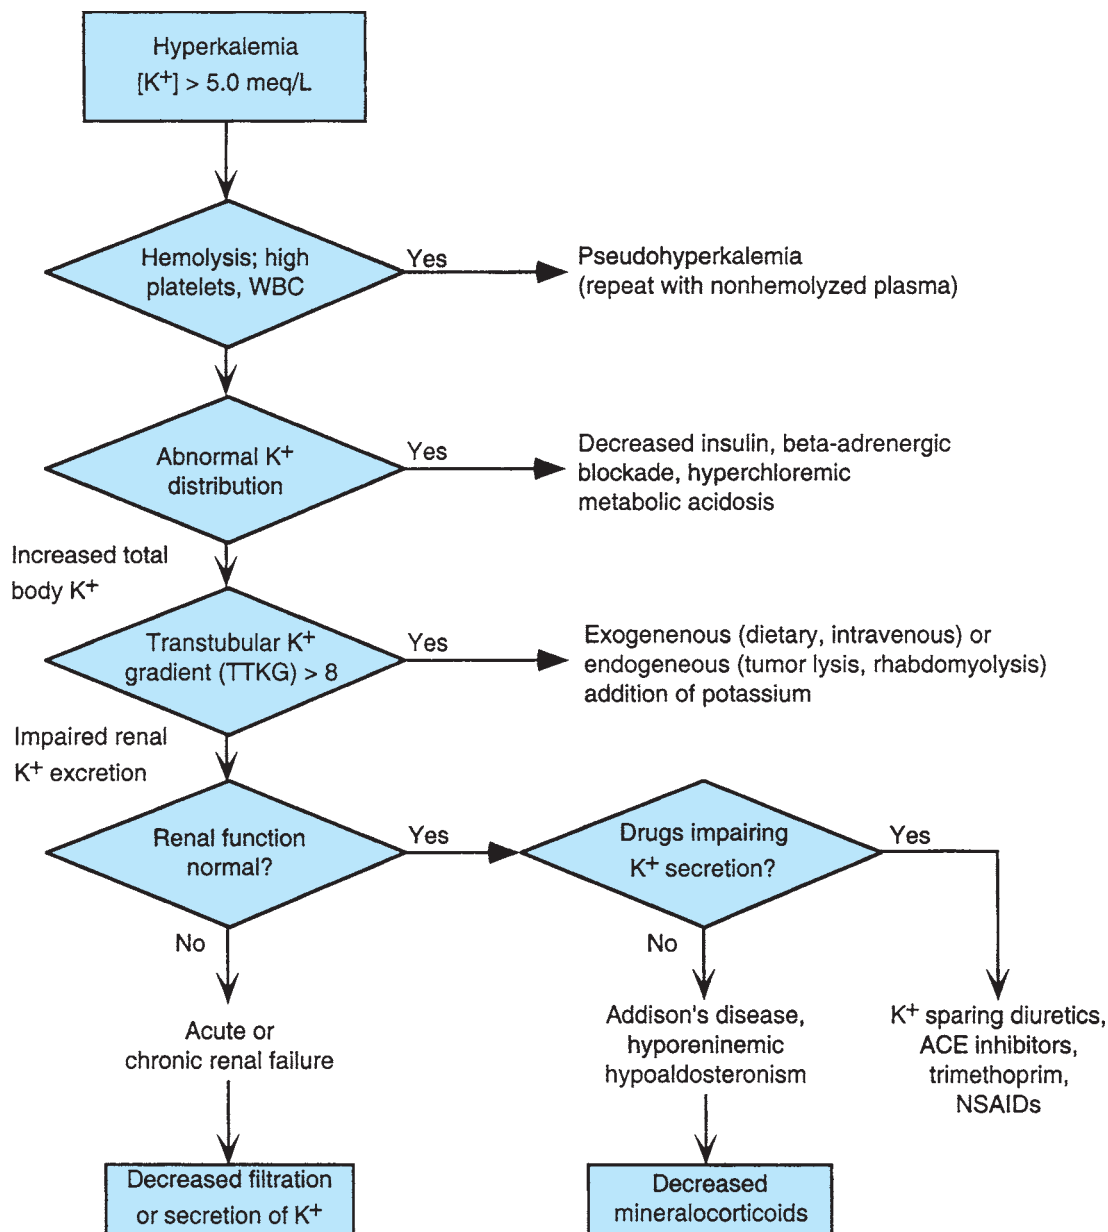

The medical history should be reviewed for medications that cause hyperkalemia, recently transfused blood, potential for tumor lysis syndrome, diabetes, renal failure, and other disorders. Intravenous solutions should be checked for inadvertent potassium administration. For critically ill patients, consideration of acute adrenal insufficiency is mandatory, especially if the patient had been receiving corticosteroids or has hypotension and hyponatremia.

Those at high risk for development of hyperkalemia include any patient receiving potassium supplementation or potassium-sparing diuretics, digitalis, beta-adrenergic blockers, trimethoprim, or ACE inhibitors. Patients with renal insufficiency (especially acute renal failure) or diabetes mellitus (especially type 1 diabetes) may develop hyperkalemia. Hyperkalemia sometimes can occur in patients who are sodium-restricted if they are allowed to use salt substitutes that contain primarily potassium chloride.

The most common associations of hyperkalemia in hospitalized patients are renal failure, drugs, and hyperglycemia. In one study, administration of potassium to correct hypokalemia was the most frequent cause of hyperkalemia.

B. Laboratory Findings—Hyperkalemia is diagnosed when plasma potassium concentration is greater than 5 meq/L. The ECG is an important indicator of severity of hyperkalemia, but electrocardiographic abnormalities were seen in only 14% of hospitalized patients with hyperkalemia in one study. Asymptomatic electrocardiographic changes occur as plasma $[K^+]$ rises, with increased height and sharper peaks of T waves seen first. The QRS duration then lengthens, and the P wave decreases in amplitude before disappearing as plasma $[K^+]$ rises. At very high plasma $[K^+]$, electrical activity becomes a broad sinelike wave preceding ventricular fibrillation or asystole.

Plasma sodium, chloride, glucose, and creatinine; urea nitrogen; arterial blood pH; P_{aCO_2} ; hematocrit; and platelet count should be determined to aid in establishing the cause of hyperkalemia. If the platelet count exceeds 1,000,000/ μ L, serum potassium may be falsely elevated as the blood clots and potassium is released from platelets; in such cases, plasma rather than serum potassium will reflect the true value in the body. In renal insufficiency, plasma creatinine and urea nitrogen are elevated. Urine potassium determination may be helpful in deciding whether renal potassium elimination is appropriate. The transtubular potassium gradient (see "Hypokalemia" above) can determine if the kidneys are contributing to hyperkalemia; a nonrenal cause is more likely if the gradient is greater than 10. Plasma sodium and chloride may provide evidence of adrenal insufficiency, but other tests of adrenocortical function should be performed. A very low plasma cortisol, for example, in the presence of hyperkalemia can be diagnostic of adrenal insufficiency. Arterial blood pH and plasma glucose are helpful in deciding on the approach to treatment of hyperkalemia.

▲ **Figure 2-4.** Clinical and laboratory approach to the diagnosis of hyperkalemia.

Treatment

Arrhythmias suspected of being due to hyperkalemia or electrocardiographic changes with plasma $[K^+]$ above the normal range (ie, >5 meq/L) should be treated aggressively, and the same is true if plasma $[K^+]$ is greater than 6 meq/L even if the ECG shows no evidence of hyperkalemia.

A. Calcium—Combination therapy is usually given to counter the effects of hyperkalemia on the heart and redistribute

potassium into cells. Calcium directly reverses the effects of potassium on the cardiac conduction system, although intravenous calcium chloride or calcium gluconate does not affect plasma potassium levels. One recommendation is to give slowly 5 mL of 5% calcium chloride (or 10 mL of calcium gluconate) intravenously every 1–2 hours as long as $[K^+]$ exceeds 6 meq/L and there are electrocardiographic abnormalities, but the number of doses should not exceed two or three. Calcium should be given cautiously in the presence of digitalis toxicity.

B. Redistribution of Potassium—Insulin has an immediate plasma $[K^+]$ lowering effect, but hypoglycemia ensues unless glucose is given simultaneously. Insulin can be given subcutaneously or by intravenous bolus or continuous infusion. One method is to give 1–2 ampules of 50% dextrose in water along with 5–10 units of intravenous insulin. Another method for severe hyperkalemia is to administer regular insulin intravenously at a rate of 1–2 units/h while 5% dextrose in water is given at a rate of 125 mL/h (8–10 units insulin in each liter of 5% dextrose in water). One should monitor electrolytes and glucose hourly and watch closely for hypoglycemia. The rate of administration of insulin and glucose can be adjusted accordingly.

Metabolic acidosis contributing to hyperkalemia, if present, can be ameliorated with sodium bicarbonate given intravenously. This treatment is not without hazard, with volume overload and hyperosmolality possible complications. Only enough NaHCO_3 should be given to reverse hyperkalemia, not completely correct acidemia. Treatment should begin with one ampule (about 44 meq NaHCO_3) given over several minutes. Another ampule can be given if needed in 15–30 minutes. Alternatively, two ampules can be added to 1 L of 5% dextrose in water for continuous intravenous administration (final sodium concentration about 90 meq/L) at 50–150 mL/h. This infusion can be stopped as soon as the plasma potassium concentration normalizes or in the event of fluid overload.

A few patients with hyperkalemia and renal failure have been treated with the beta-adrenergic agonist albuterol by nebulization. A modest transient reduction in plasma $[K^+]$ can be achieved even with standard bronchodilator doses, but the risks of arrhythmias and other potential problems suggest that this form of therapy should be used only when conventional therapy has failed or fluid overload is a concern.

C. Increased Excretion of Potassium—Facilitation of renal excretion mechanisms can help rid the body of excess potassium, but this route of excretion is usable only in patients whose renal potassium excretion is unimpaired. Furosemide increases distal tubule sodium delivery and promotes potassium secretion. Volume replacement with normal saline may be necessary if the patient begins with normal extracellular fluid volume. Mineralocorticoids increase renal potassium excretion, but in patients with a normal adrenal response, aldosterone levels are maximal. Therefore, mineralocorticoids such as fludrocortisone are useful only in patients with adrenal insufficiency or some other cause of depressed aldosterone.

In patients with impaired renal potassium excretion or to increase potassium elimination in any patient with hyperkalemia, increased nonrenal potassium excretion is indicated. A cation exchange resin designed for oral or rectal administration (eg, sodium polystyrene sulfonate) binds potassium in exchange for sodium. If the gastrointestinal tract is functional, 15–60 g mixed in 20–100 mL of water or sorbitol solution can be given orally; the dose can be repeated every 4–6 hours. The suspension also can be given as a retention enema.

Hemodialysis is an effective way of decreasing plasma potassium concentration, but hyperkalemia may return rapidly

after dialysis as potassium diffuses back out of the cells. Therefore, as much potassium removal as possible is indicated during hemodialysis if it is concluded that a large increase in total body potassium is present. Plasma potassium concentration should be carefully monitored during dialysis. Continuous venovenous hemofiltration and dialysis (CVVHD) is very effective, or peritoneal dialysis with dialysate containing no potassium can be used.

D. Other Treatment—Dietary potassium intake should be restricted. In practice, the diet should avoid high-potassium foods, but in ICU patients in whom sparing of body protein is a goal, at least 2.5 g (64 meq) of potassium daily is usually necessary to maintain acceptable protein intake. All intravenous infusions should be double-checked to make sure that potassium (sometimes in the form of phosphate as well as chloride) is not being given inadvertently. Potassium penicillin should be switched to sodium penicillin. The need for drugs contributing to potassium maldistribution, impaired excretion, metabolic acidosis, and renal insufficiency should be reevaluated and the drugs discontinued, if possible. These include ACE inhibitors, beta-adrenergic blockers, and potassium-sparing diuretics.

DISORDERS OF PHOSPHORUS BALANCE

Phosphorus is found in both inorganic (phosphate) and organic forms. Most of the body's store of phosphorus is in the bones (80%), and the vast majority of the remainder is, like potassium, distributed inside cells (muscles 10%) as organic phosphates. Only 1% is in the blood, and plasma phosphorus does not reflect the total body phosphorus. Organic phosphates play a major role in metabolic functions, especially in energy-producing reactions, as part of ATP and other cofactors. In the erythrocyte, 2,3-diphosphoglycerate (2,3-DPG) levels decrease with decreased plasma phosphorus concentration, leading to impaired tissue oxygen delivery. In the ICU, hypophosphatemia is associated with dysfunction of red blood cells, respiratory muscles, the heart, platelets, and white blood cells and is often due to acute ICU interventions in susceptible patients. Patients with hypophosphatemia may have heart failure, hemolysis, respiratory failure, and impaired oxygen delivery.

Plasma phosphorus is reported by the laboratory in milligrams of elemental phosphorus per deciliter, but phosphorus is largely in the form of inorganic phosphate in the divalent (HPO_4^{-2}) and monovalent forms ($\text{H}_2\text{PO}_4^{-}$). There are two major determinants of phosphorus balance in the body: the distribution of phosphorus compounds between intracellular and extracellular spaces and the daily intake compared with excretion. The total body store of phosphorus is great, and only a small proportion of total body phosphorus participates in intracellular reactions and shifts between cells and extracellular spaces.

The intracellular phosphorus concentration is considerably larger than the extracellular concentration. Factors that determine the distribution of phosphorus between the two compartments include the rate of glucose entry into cells and the presence of respiratory alkalosis. Glucose movement into cells, facilitated by insulin, traps phosphate intracellularly through phosphorylation of glucose and glycolytic intermediates. Acute respiratory alkalosis facilitates glycolysis, thereby reducing extracellular phosphorus concentration.

Phosphorus intake depends on the type of diet and the presence of active $1,25(\text{OH})_2$ -vitamin D_3 , which facilitates both calcium and phosphorus absorption in the gastrointestinal tract. Corticosteroids, dietary magnesium, hypothyroidism, and intestinal phosphate-binding drugs (eg, aluminum hydroxide and calcium carbonate) decrease phosphorus absorption. Net phosphate excretion is primarily through the kidneys by filtration and reabsorption. Because filtration is unregulated, reabsorption in the proximal tubules determines phosphorus excretion, and this mechanism is driven by proximal tubular sodium reabsorption. Thus there is enhanced phosphorus reabsorption in the face of increased proximal sodium reabsorption in volume-depleted states. However, proximal phosphorus reabsorption is also independently regulated by the parathyroid hormone level. This can lead to dissociation between sodium reabsorption and phosphorus reabsorption, as in hyperparathyroidism.

▶ Hypophosphatemia

ESSENTIALS OF DIAGNOSIS

- ▶ Plasma phosphorus <2.5 mg/dL; severe, <1.0 mg/dL.
- ▶ May have muscle weakness, including respiratory muscle weakness (failure to wean from respirator) and myocardial dysfunction.
- ▶ Evidence of impaired oxygen transport.
- ▶ Impaired platelet and leukocyte function. Hemolysis and rhabdomyolysis may occur with plasma phosphorus <1 mg/dL.

General Considerations

Hypophosphatemia is associated in the ICU mostly with a shift of extracellular phosphorus into cells and is seen as a consequence of acid-base disturbances and as a complication of drugs and nutritional support more often than as a primary problem. Acute hypophosphatemia should be anticipated in postoperative patients; in patients with chronic or acute alcoholism, diabetic ketoacidosis, or head trauma; and in patients receiving total parenteral nutrition or mechanical ventilation.

In theory, hypophosphatemia always results from a problem of maldistribution of total body phosphorus. This is so because of the very large quantity of phosphorus in the intracellular space plus the amount of phosphorus in bone, even in those with hypophosphatemia (ie, decreased plasma phosphorus and extracellular phosphorus). Thus even a state of “phosphate depletion” from increased losses and decreased intake is a problem of distribution because there must be decreased ability to mobilize and transfer phosphorus to the extracellular space coincident with depletion. Nevertheless, it is helpful to think of the pathophysiology of hypophosphatemia as being primarily redistribution, decreased intake, or increased excretion of phosphorus.

A. Redistribution of Phosphorus—In the ICU, the most common causes of hypophosphatemia are administration of insulin and glucose or acute hyperventilation. Glucose movement into cells (facilitated by insulin) and subsequent glycolysis produce phosphorylated intermediates that are trapped intracellularly. The most striking examples of rapid, severe falls in plasma phosphorus are seen in the treatment of diabetic ketoacidosis and in the refeeding syndrome. Diabetic ketoacidosis is associated with pretreatment extracellular phosphate loss from solute diuresis. The administration of insulin results predictably in hypophosphatemia as glucose and phosphate move into cells. The marked fall in plasma phosphate during enteral or parenteral refeeding of chronically malnourished individuals, including alcoholics, reflects low extracellular phosphorus from decreased intake followed by rapid movement of phosphate and glucose intracellularly.

Respiratory alkalosis also causes a shift of extracellular phosphorus into cells. This has been attributed to enhanced activity of the glycolytic enzyme phosphofructokinase at high pH, but this mechanism has been called into question because metabolic alkalosis of comparable degree has little effect on plasma phosphorus. Hypophosphatemia seen in salicylate toxicity, sepsis, and hepatic encephalopathy is probably secondary to hyperventilation.

B. Decreased Phosphorus Intake—Decreased intake of phosphorus is usually a chronic problem and is seen in ICU patients with preexisting diseases leading to decreased dietary intake of calcium, phosphorus, and vitamin D. In addition, binding of phosphorus in the gastrointestinal tract by antacids and specific phosphate-binding compounds prevents absorption and can lead to hypophosphatemia, especially

when the diet is limited in phosphorus content. Because most diets contain adequate phosphorus, low dietary intake of phosphorus is seen almost exclusively in patients who are not being fed at all.

C. Increased Excretion of Phosphorus—Among all patients, increased renal tubular excretion of phosphate is the most common cause of hypophosphatemia, primarily from subclinical hyperparathyroidism. In critically ill patients, renal phosphate excretion increases with solute diuresis and with the use of acetazolamide, a carbonic anhydrase inhibitor. Metabolic acidosis increases the release of inorganic phosphate into the extracellular space, resulting in increased renal excretion of phosphate, but this is not usually a cause of hypophosphatemia because phosphorus can be mobilized easily from the intracellular stores. Hemodialysis is a relatively inefficient way of removing phosphate; therefore, hypophosphatemia is an unusual complication of renal replacement therapy.

D. Physiologic Effects of Hypophosphatemia—Phosphorus in the form of phosphate plays an important role in intermediary metabolism, especially in intracellular energy production. Clinical consequences of hypophosphatemia are due to decreased production of ATP and erythrocyte 2,3-DPG. Erythrocyte inorganic phosphate concentration is directly related to plasma phosphorus, and inorganic phosphate is required for the conversion of glyceraldehyde 3-phosphate to 1,3-diphosphoglyceric acid, a key step in glycolysis. In hypophosphatemia, glycolytic intermediates preceding this enzymatic step accumulate and those following, including ATP and 2,3-DPG, decrease in concentration. Low 2,3-DPG increases the O₂ affinity of hemoglobin (left-shifted oxyhemoglobin curve), potentially impairing O₂ delivery to the tissues. Hemolysis is due to impaired ATP generation, probably in a way similar to erythrocyte glycolytic enzyme deficiencies such as pyruvate kinase deficiency. Impaired function of skeletal muscles, including respiratory muscles, and myocardium have been related to both decreased 2,3-DPG and decreased availability of phosphorus to the muscles. In one study, decreased respiratory and peripheral muscle phosphate concentrations were found in 50% of patients with COPD and respiratory failure compared with normal control individuals.

Clinical Features

Although most patients with hypophosphatemia are identified by routine monitoring of electrolytes, hypophosphatemia should be suspected in certain high-risk ICU patients, that is, those with preexisting total body or extracellular phosphorus depletion or a severe acute disorder causing redistribution of extracellular phosphorus (Table 2–10). The most likely candidates for symptomatic hypophosphatemia are those with combinations of mechanisms, such as patients with diabetic ketoacidosis with solute diuresis who are receiving insulin

Table 2–10. ICU patients at risk for hypophosphatemia.

Preexisting total body or extracellular phosphorus depletion

- Malnutrition
- Chronic increased renal phosphate loss
- Diabetic ketoacidosis (osmotic diuresis)
- Alcoholism
- Vitamin D deficiency
- Fat malabsorption
- Chronic antacid use

Acute redistribution of extracellular phosphorus

- Respiratory alkalosis
- Sepsis
- Salicylate toxicity
- Hepatic encephalopathy
- Toxic shock syndrome
- Glucose-insulin administration
 - Diabetic ketoacidosis
 - Refeeding syndrome
 - Hyperalimentation
 - Treatment of hyperkalemia

and malnourished alcoholics given glucose, insulin, and phosphate-binding antacids. Severely burned patients may have a combination of respiratory alkalosis, pain, sepsis, and increased tissue uptake of phosphate. Patients with severe head injury are reported to have hypophosphatemia and hypomagnesemia owing to excessive urinary losses.

A. Symptoms and Signs—Mild to moderate hypophosphatemia is usually asymptomatic. When hypophosphatemia is severe (plasma phosphorus <1.0 mg/dL), patients may complain of muscle weakness. Skeletal and cardiac muscles are involved primarily, and signs of weakness may be present in the respiratory muscles. Patients may have difficulty weaning from mechanical ventilation or may present with symptoms and signs of congestive heart failure. Rhabdomyolysis and hemolysis are uncommon features of severe hypophosphatemia. Although unusual, leukocyte dysfunction may result in an increased tendency to infection, and platelet dysfunction may contribute to bleeding.

CNS dysfunction has been attributed to hypophosphatemia, but consistent features have not been found. Findings have included changes in mental status, seizures, and neuropathy. Changes may be related to direct effects or may occur because of reduced CNS oxygen delivery.

B. Laboratory Findings—The diagnosis of hypophosphatemia is made when plasma phosphorus concentration is less than 2.5 mg/dL, but symptoms are not likely to appear until the plasma phosphorus concentration is less than 1.5 mg/dL. Other laboratory findings may include features of hemolysis, elevated creatine kinase, and qualitative platelet dysfunction (prolonged bleeding time) when plasma phosphorus is 0.5–1 mg/dL. For determining the

specific cause of hypophosphatemia, the clinical history is most useful; arterial blood gases and plasma glucose, electrolytes, and calcium may be helpful. Although useful in evaluation of chronic hypophosphatemia, urinary phosphorus measurement is seldom necessary in ICU patients.

Treatment

A. Assess Urgency of Treatment—In critically ill patients, development of severe hypophosphatemia may require immediate treatment if weakness involving the respiratory muscles precipitates respiratory failure. Generally, a plasma phosphorus concentration of less than 1–1.5 mg/dL should be treated immediately. This is especially important when a further decrease in phosphorus is anticipated, such as in the treatment of diabetic ketoacidosis. Supportive care is essential while severe hypophosphatemia is corrected.

B. Phosphorus Replacement—Recommendations for phosphorus repletion are often confusing because of the way elemental phosphorus and phosphate concentrations and amounts are expressed. At physiologic pH, inorganic phosphate anion exists almost entirely in the monovalent (H_2PO_4^-) and divalent (HPO_4^{2-}) forms (about 1:4 monovalent:divalent). This means that the use of milliequivalents is potentially misleading. Laboratories report plasma phosphorus as milligrams of elemental phosphorus per deciliter. To avoid confusion, calculations for repletion should be based on milligrams of elemental phosphorus or millimoles of phosphorus or phosphate (these are the same because there is one phosphorus atom for each phosphate regardless of valence). One millimole of phosphate or phosphorus is the same as 31 mg phosphorus.

Intravenous phosphate is given as sodium or potassium phosphate, available usually at a concentration of 93 mg phosphorus/mL (3 mmol/mL). The amount of phosphorus to be given is difficult to estimate because total body phosphorus may not be decreased (redistribution), and rapid phosphate shifts during treatment may resolve or worsen the problem. Therefore, close monitoring of plasma phosphorus and other electrolytes is necessary during repletion, especially if phosphate is given as the potassium salt.

In severe cases (plasma phosphorus <1.0 mg/dL), give 5–7 mg phosphorus/kg of body weight intravenous in 1 L of 5% dextrose in water (D_5W) over 4–6 hours. For a 60-kg adult, this would be approximately 400 mg phosphorus, or about 4 mL of sodium or potassium phosphate solution (3 mmol/mL) in the 1-L infusion. Alternatively, 1 g phosphorus (~10 mL of sodium or potassium phosphate [3 mmol/mL]) is added to 1 L D_5W and infused over 12–24 hours or until the serum phosphorus concentration is greater than 1.5 mg/dL. In less severe hypophosphatemia, an appropriate starting dose would be 2–4 mg/kg intravenously over 8 hours. Oral supplementation can be provided using potassium phosphate or mixtures of sodium and potassium phosphate.

Prevention of hypophosphatemia is important. In patients receiving intravenous glucose, phosphorus supplementation should be considered. Adult patients receiving parenteral hyperalimentation generally require about 1 g phosphorus daily, or approximately 12 mmol (372 mg) for every 1000 kcal provided.

Routine repletion of phosphorus in patients with diabetic ketoacidosis has been recommended because of the high frequency of hypophosphatemia reported during treatment with insulin infusions. It has been proposed that hypophosphatemia contributes to decreased oxygen delivery, insulin resistance, hyperchloremic acidosis, and other complications of diabetic ketoacidosis. However, improvement in intermediate or final outcome from routine phosphate replacement has not been demonstrated.

C. Complications of Treatment—Complications of excessive phosphate repletion include volume overload from sodium phosphate, hyperkalemia from potassium phosphate, precipitation of calcium phosphate in the face of hypercalcemia, and hypocalcemia. In older patients with renal insufficiency and small children, especially with fluid restriction, phosphate salts given for bowel preparation are associated with severe hyperphosphatemia, marked anion gap metabolic acidosis, and hypocalcemia.

▶ Hyperphosphatemia

ESSENTIALS OF DIAGNOSIS

- ▶ Plasma phosphorus >5 mg/dL.
- ▶ Usually no acute symptoms.
- ▶ Cardiac conduction system disturbances and features of hypocalcemia may occur.

General Considerations

Hyperphosphatemia as a clinical problem is most often the result of long-standing elevation of plasma phosphorus concentration to greater than 5 mg/dL, but acute elevation can have consequences owing to precipitation of calcium phosphate salts in the heart, kidneys, and lungs; rarely, acute cardiac conduction disturbances can occur. In addition, calcium phosphate precipitation results in acute hypocalcemia and its consequences.

Severe hyperphosphatemia is associated in the ICU with a shift of intracellular phosphorus out of cells and is seen when there is massive tissue breakdown. Rarely, in patients given large amounts of sodium phosphate as a cathartic or enema, severe anion gap metabolic acidosis may result. Patients in whom this has been reported are elderly or very young and often have renal insufficiency. More commonly, hyperphosphatemia is seen in chronic renal failure, where there is decreased ability to excrete phosphorus.

Hyperphosphatemia results from impaired excretion of phosphorus or increased addition of phosphorus to the extracellular space.

A. Impaired Phosphate Excretion—There is a large quantity of phosphorus in the intracellular space, as well as the phosphorus stored in bone, but the quantity of extracellular phosphorus is small. Normal cell turnover releases a steady quantity of phosphorus into the extracellular space that is taken back up into the cells or bone or excreted by the kidney. Impaired excretion primarily results from chronic renal insufficiency, and because parathyroid hormone facilitates renal phosphate excretion, hypoparathyroidism impairs renal phosphorus excretion even with normal renal function.

B. Redistribution of Phosphorus—A cause of hyperphosphatemia unique to critically ill patients is massive tissue breakdown, a form of “redistribution” of a large amount of intracellular phosphorus into the extracellular space. The most common form of tissue injury seen in the ICU is rhabdomyolysis from trauma or other muscle injury from infection, drugs, seizures, or metabolic problems. Tumor lysis syndrome, seen after chemo- or radiotherapy of highly responsive tumors (eg, lymphoma), releases large quantities of phosphorus as well as purines (to become uric acid) and potassium. Tumor lysis syndrome is seen uncommonly in patients with solid tumors, except those with extensive necrosis. Bowel necrosis from ischemia also may be associated with hyperphosphatemia. Renal insufficiency exacerbates hyperphosphatemia caused by redistribution of phosphorus. Because insulin and glucose drive phosphorus into cells, diabetics with insulin deficiency also may be more prone to hyperphosphatemia, but this is rarely significant.

C. Excessive Replacement of Phosphorus—Excessive replacement of phosphorus in patients with hypophosphatemia

may cause hyperphosphatemia. Factors that may lead to this situation include renal insufficiency and continued replacement of phosphorus after reversal of the cause of hypophosphatemia. Patients receiving total parenteral nutrition should be monitored closely because standard solutions may contain 300–500 mg phosphorus per liter. Enemas or oral bowel preparation products used prior to radiographic procedures or colonoscopy may contain a large quantity of sodium phosphate as an osmotic agent. If patients absorb some of this phosphate, severe hyperphosphatemia (plasma phosphorus >20 mg/dL) and anion gap metabolic acidosis have been reported.

Clinical Features

Patients at high risk for development of hyperphosphatemia are those with tissue injury and renal insufficiency (Table 2–11), especially in combination. Other patients in the ICU who may develop hyperphosphatemia include those receiving intravenous or oral phosphorus supplementation for treatment of hypophosphatemia, patients with decreased glomerular filtration because of extracellular volume depletion, those with chronic renal failure, and those given large amounts of oral phosphate salts.

A. Symptoms and Signs—Most patients with hyperphosphatemia of mild to moderate degree are asymptomatic. In more severe cases, if the calcium \times phosphorus product is greater than 60, the risk of ectopic calcification in various organs increases, including the heart, lungs, and kidneys. Acute problems from precipitation of calcium phosphate are mainly restricted to the development of cardiac conduction system disturbances such as heart block.

Acute hyperphosphatemia also can lead to hypocalcemia with development of tetany, seizures, cardiac arrhythmias, and hypotension. Plasma calcium should be monitored during treatment of both hypo- and hyperphosphatemia.

Table 2–11. ICU patients at risk for hyperphosphatemia.

Impaired excretion of phosphate
Chronic renal failure
Acute renal failure
Extracellular volume depletion
Hypoparathyroidism
Acute redistribution of intracellular phosphorus
Massive tissue breakdown
Rhabdomyolysis
Tumor lysis syndrome (lymphoma)
Exogenous phosphorus intake
Excessive treatment of hypophosphatemia
Increased dietary phosphorus (with renal insufficiency)
Excessive sodium phosphate enema or laxative use

Hypocalcemia results both from precipitation of calcium phosphate and from inhibition of renal 1 α -hydroxylase necessary for vitamin D activation.

B. Laboratory Findings—The diagnosis of hyperphosphatemia is most often made only by the laboratory finding of a plasma phosphorus concentration of greater than 5 mg/dL. The specific cause of hyperphosphatemia usually can be determined from the clinical history, but plasma creatinine and electrolytes should be obtained. Plasma uric acid and potassium are expected to be elevated in tumor lysis syndrome. In rhabdomyolysis, plasma creatine kinase and aldolase are elevated, and myoglobinuria may be present. In patients who have hyperphosphatemia from administration of phosphate salts, metabolic acidosis with a large anion gap can be found.

Treatment

A. Assess Urgency of Treatment—There is no absolute elevated plasma concentration of phosphorus that requires immediate treatment. Rapid treatment should be considered if there is evidence of a cardiac conduction disturbance such as heart block or evidence of symptomatic or severe hypocalcemia. Hypocalcemia in the presence of hyperphosphatemia should be treated by lowering the plasma phosphorus concentration rather than by administration of calcium because the latter action may worsen ectopic calcification.

B. Remove Phosphorus from the Body—Renal excretion of phosphorus depends on having an adequate glomerular filtration rate. Because phosphate reabsorption depends on proximal tubular sodium reabsorption, normal saline infusion in patients who can tolerate this treatment will enhance phosphate excretion. This should be avoided in patients with preexisting increased extracellular volume, congestive heart failure, and renal insufficiency.

Hemodialysis is effective in removing extracellular phosphate but has only a transient effect because of the small proportion of phosphorus in the extracellular fluid. Orally administered phosphate binders have only a mild acute effect, especially if patients are not being fed enterally. Calcium carbonate should be avoided in acute hyperphosphatemia because of the potential for raising the calcium \times phosphorus product. Non-calcium-, non-aluminum-containing phosphate binders are used acutely. For chronic administration, calcium carbonate or non-aluminum-containing phosphate binders are preferred.

C. Minimize Phosphorus Intake—Exogenous sources of phosphate should be discontinued, including total parenteral nutrition solutions and supplemental phosphorus given orally or intravenously. Dietary phosphorus can be minimized by prescribing a low-protein diet and avoiding dairy products that contain both calcium and phosphorus, but this may conflict with nutritional goals.

DISORDERS OF MAGNESIUM BALANCE

Magnesium is the most abundant intracellular divalent cation and, after calcium, the most common divalent cation in the body. The distribution of magnesium is similar to that of potassium, with the vast majority (99%) of magnesium residing inside cells. Consequently, plasma magnesium concentration does not reflect total body magnesium. Magnesium plays an important role in neuromuscular coupling, largely through its interaction with calcium. In the ICU, disorders of magnesium primarily reflect hypomagnesemia, with cardiac arrhythmias and other features similar to those of hypocalcemia. Among the causes of hypomagnesemia are drugs frequently used in critically ill patients such as amphotericin B, diuretics, and aminoglycoside antibiotics, but hypomagnesemia is also seen in malnutrition, chronic alcoholism, and malabsorption. In contrast, hypermagnesemia in ICU patients is relatively uncommon and almost always results from a combination of renal insufficiency and increased magnesium intake. On occasion, hypermagnesemia results from overzealous repletion of hypomagnesemia.

Magnesium Intake and Distribution

Magnesium is found in many foods, including green vegetables and meat products, and the normal diet is usually more than ample. Approximately 5 mg/kg per day of magnesium is required for normal magnesium balance. Magnesium is supplied as part of enteral feedings and is added to parenteral nutrition formulations. Factors that control gastrointestinal magnesium absorption are unclear, but about one-third of ingested magnesium is absorbed. The absorbed fraction decreases with increased ingestion, suggesting an active transport mechanism. Magnesium binds to fatty acids and oxalate in the gut, decreasing absorption. Like potassium, magnesium is distributed largely within cells, but the mechanisms controlling distribution do not seem to be controlled by circulating levels of hormones such as insulin or epinephrine or by acid-base status. About 25% of plasma magnesium is protein-bound.

Magnesium Excretion

Free magnesium is filtered and largely reabsorbed under steady-state conditions in the proximal nephron (a minor role), ascending loop of Henle (accounting for about 60–70%

of reabsorption), and the distal nephron (about 10%). The distal nephron, however, is the major site of fine regulation of magnesium excretion. Only about 100 mg magnesium is excreted per day even though as much as 2400 mg is filtered by the glomeruli, and reabsorption is increased in the face of magnesium deficiency. The driving force for magnesium reabsorption is the reabsorption of Na^+ and K^+ . As would be expected, drugs that interfere with sodium reabsorption interfere with magnesium reabsorption. Because the ascending portion of the loop of Henle accounts for a large fraction of magnesium reabsorption, loop-acting diuretics predictably have a potent magnesium-wasting effect.

Excess magnesium is excreted renally by decreased reabsorption. When plasma magnesium levels are elevated—as happens, for example, shortly after intravenous administration of a large quantity of magnesium salt—renal magnesium excretion increases. This is so in part because a lower proportion is protein-bound and in part because only a fixed amount rather than a fixed proportion of the larger filtered load is reabsorbed. Maximum magnesium excretion is limited by glomerular filtration, as would be expected from its renal handling.

Role of Magnesium

The major role of magnesium is as a cofactor for hundreds of identified enzymes that produce or require ATP, such as kinases, ATPase, and adenylyl cyclase. Disorders of magnesium may lead to impaired energy production, substrate utilization, and synthetic processes.

► Hypomagnesemia

ESSENTIALS OF DIAGNOSIS

- Plasma $[\text{Mg}^{2+}] < 1.7 \text{ mg/dL}$.
- Cardiac arrhythmias, refractory potassium deficiency.
- Features suggestive of hypocalcemia: tetany, weakness, increased deep tendon reflexes, altered mental status, and seizures.

General Considerations

Decreased plasma magnesium has serious consequences in critically ill patients, potentiating arrhythmias, interfering with potassium repletion, and causing neuromuscular weakness. However, mild to moderate hypomagnesemia is frequently unrecognized because routine plasma $[\text{Mg}^{2+}]$ levels are not always obtained. Some investigators have recommended that this test be included as part of daily electrolyte determinations whenever these are deemed necessary for patient care. The prevalence of hypomagnesemia in ICU patients has been estimated to be about 20–65%, and most of

Table 2–12. Risks for hypomagnesemia in ICU patients.

Increased loss of magnesium

Diuretic phase of acute tubular necrosis
Extrarenal loss
Diarrhea
Nasogastric suction or vomiting
Pancreatitis
Intestinal fistulas with external drainage

these patients are on the medical rather than surgical services. Hypomagnesemia is defined as a plasma magnesium concentration of less than 1.7 mg/dL, but about 25% of plasma magnesium is bound to albumin. While the plasma level reflects both bound and unbound magnesium, the clinical effects of magnesium, like those of calcium, are due to the unbound ion.

The mechanisms of hypomagnesemia can be divided into decreased intake and increased losses of magnesium, both renal and extrarenal in nature (Table 2–12).

A. Decreased Magnesium Intake—Decreased intake is an unusual cause of decreased $[\text{Mg}^{2+}]$, but patients with no oral intake who receive parenteral nutrition without magnesium supplementation can develop hypomagnesemia. More commonly, the diet contains sufficient magnesium, but intestinal causes of malnutrition interfere with its absorption. Alcoholism is often associated with hypomagnesemia, but it is likely that factors in addition to malnutrition play roles in causing low $[\text{Mg}^{2+}]$ in these patients, such as increased renal losses, vomiting, and diarrhea. In malabsorption syndromes, increased levels of free fatty acids in the intestinal lumen may bind magnesium in a poorly absorbable state.

B. Increased Loss of Magnesium—Increased losses of magnesium are most commonly due to renal magnesium wasting. Intrinsic renal parenchymal diseases primarily lead to hypermagnesemia, but relief of acute obstructive nephropathy (postobstructive diuresis), solute diuresis, and the diuretic phase of acute tubular necrosis sometimes lead to large amounts of magnesium excretion. In the ICU, renal magnesium wasting is most commonly secondary to drugs, including loop diuretics, cyclosporine, cisplatin, aminoglycosides, amphotericin B, pentamidine, and poorly absorbable anionic antibiotics such as ticarcillin and carbenicillin in large doses. These drugs, along with ethanol, decrease tubular magnesium reabsorption. Nonrenal losses of magnesium occur in association with intestinal bypass, sprue, malabsorption, severe diarrhea, short bowel syndrome, biliary fistulas,

and other mechanisms of fluid loss from the gastrointestinal tract. Hypomagnesemia is also found in association with diabetes mellitus, phosphate depletion, hyperparathyroidism, and thyrotoxicosis.

Several specific primary renal magnesium-wasting disorders are described. Gitelman's syndrome is due to a defect in the thiazide-sensitive sodium-chloride cotransporter and presents with hypocalciuria, hypomagnesemia, and hypokalemic metabolic alkalosis. Another is a syndrome of primary hypercalciuria, nephrocalcinosis, and renal tubular acidification defects.

Whether abnormally low plasma $[Mg^{2+}]$ can result from maldistribution of this cation between extracellular and intracellular spaces is debated. One possible cause of hypomagnesemia is vigorous refeeding after starvation. Both hypomagnesemia and hypocalcemia may be seen during acute pancreatitis, primarily from deposition of these cations into the tissue.

C. Hypomagnesemia and Acute Myocardial Infarction—

There is an association between hypomagnesemia and acute myocardial infarction that is not explicable by renal or other increased excretion of magnesium. Hypomagnesemia occurring with acute myocardial infarction persists for 5–12 days, and $[Mg^{2+}]$ then generally returns to normal. The association is strengthened by the finding that treatment with magnesium has a beneficial effect in such patients found to have decreased $[Mg^{2+}]$ by reducing the frequency and consequences of ventricular arrhythmias. The mechanism of hypomagnesemia is likely a shift in magnesium from the extracellular space.

Clinical Features

A. Symptoms and Signs—Hypomagnesemia has its own effects, but because it may be accompanied by hypokalemia, hypocalcemia, acid-base disturbances, clinical features may result from a composite of abnormalities. Cardiac arrhythmias are the most important complications of hypomagnesemia. Ventricular rhythms such as torsade de pointes, ventricular tachycardia, and ventricular fibrillation, as well as atrial tachycardia and atrial premature beats, can be seen. There is an association of increased arrhythmias with digitalis toxicity and hypomagnesemia. Acute myocardial infarction imposes a further arrhythmia risk when decreased plasma $[Mg^{2+}]$ is found. Hypocalcemia is strongly associated with hypomagnesemia. Tetany, positive Chvostek and Trousseau signs, seizures, weakness, and altered mental status may be seen.

Most patients with hypomagnesemia are identified by routine plasma $[Mg^{2+}]$ determinations, but the disorder should be anticipated in certain high-risk groups, that is, patients with hypocalcemia, acute myocardial infarction, congestive heart failure, alcoholism, acute pancreatitis, malnutrition, diarrhea, or seizures and those receiving diuretics, amphotericin B, or aminoglycosides.

B. Laboratory Findings—Hypomagnesemia is diagnosed when the plasma $[Mg^{2+}]$ is less than 1.7 mg/dL. In critically ill patients, $[Mg^{2+}]$ levels should be obtained when routine plasma electrolytes are needed. This probably means at least daily for most high-risk patients. In patients with hypomagnesemia, other electrolytes, plasma calcium and phosphorus, and urinary magnesium determinations may be helpful for diagnostic purposes.

Because magnesium is largely intracellular, plasma $[Mg^{2+}]$ may not reflect total body magnesium depletion. Red blood cell and leukocyte $[Mg^{2+}]$ concentrations do not offer much better sensitivity or specificity. Some studies have shown that a functional magnesium loading test can identify patients who may benefit from supplemental magnesium, including those with normal $[Mg^{2+}]$ levels. These patients may be identified by greater retention of magnesium (>70% of a loading dose of 30 mmol magnesium sulfate).

Two electrolyte disturbances are closely tied to hypomagnesemia and total body magnesium depletion: hypokalemia and hypocalcemia. Hypomagnesemia is seen in a large percentage of those with hypokalemia (40%). Although this may be due to similar renal handling of these cations or coincidental gastrointestinal losses, magnesium deficiency may be responsible for refractory potassium deficiency. Hypomagnesemia interferes with potassium movement into cells, leading to net potassium leakage out of cells, by inhibiting Na^+,K^+ -ATPase pumps. Intracellular potassium falls while intracellular sodium concentration rises. Refractory potassium deficiency results because administered potassium is unable to enter cells readily and therefore is excreted in the urine. Hypomagnesemia also stimulates renin release and thereby increases aldosterone, further enhancing potassium excretion.

Hypomagnesemia is also strongly linked with hypocalcemia and inappropriately low levels of parathyroid hormone. Parathyroid hormone release is impaired by hypomagnesemia, and the hormone has a reduced effect in the presence of hypomagnesemia. In fact, plasma $[Ca^{2+}]$ has been used to estimate the effective $[Mg^{2+}]$ concentration. Clinical findings of severe hypocalcemia, including Chvostek's sign and tetany, can be due both to hypomagnesemia and to the resulting hypocalcemia.

The ECG may show arrhythmias, but flattened T waves, widening of the QRS complex, PR-interval prolongation, and U waves may be seen in moderate to severe magnesium deficiency.

Treatment

Plasma magnesium measures both protein-bound and unbound magnesium, but more than 95% of magnesium in the body is found in the bones and intracellularly. In contrast to potassium, however, rarely are there instances of normal or high plasma $[Mg^{2+}]$ in patients with depletion of total body magnesium. This suggests that plasma $[Mg^{2+}]$ is a reasonable guide to deciding that total body magnesium is low

but perhaps not ideal for determining the degree of depletion. Fortunately, in the absence of decreased glomerular filtration, administered magnesium is readily excreted when plasma $[Mg^{2+}]$ is greater than 2 mg/dL, suggesting that repletion of magnesium is apt to be indicated and safe in almost all patients with $[Mg^{2+}]$ less than 1.5–1.7 mg/dL.

A. Assess Urgency of Treatment—Replacement of magnesium is indicated in patients having or anticipated to have serious cardiac arrhythmias owing to or contributed to by hypomagnesemia. Seizures, especially if not responsive to seizure medications, should receive immediate treatment with magnesium if hypomagnesemia is suspected. In high-risk groups, plasma $[Mg^{2+}]$ should be used as a guide, but even a mildly reduced plasma $[Mg^{2+}]$ may call for aggressive magnesium replacement therapy, especially for patients with myocardial infarction, digitalis toxicity, or congestive heart failure. If hypocalcemia is symptomatic and due to hypomagnesemia, repletion of magnesium may be more effective and safer than administration of calcium. Hypokalemia refractory to potassium administration may respond to magnesium replacement; an arrhythmia owing to hypokalemia or hypomagnesemia is an indication for urgent magnesium therapy.

B. Estimate Replacement Requirements—Estimation of total body magnesium deficiency is often inaccurate. In magnesium deficiency, the deficit ranges between 6 and 24 mg/kg of body weight. For a 60-kg adult with moderate magnesium deficiency (12 mg/kg), the deficit is about 720 mg. Because plasma levels may not reflect the magnitude of the deficit, replacement is usually initiated, and plasma $[Mg^{2+}]$ is followed with repeated measurements.

C. Magnesium Replacement—Intravenous magnesium sulfate ($MgSO_4$) can be given as 50% solution added to D_5W or normal saline. Each 1 mL of 50% solution contains 500 mg $MgSO_4$, or about 2 mmol (48 mg) of elemental magnesium.

In severe hypomagnesemia, 1–2 g of $MgSO_4$ (4–8 mmol) can be given over 20–30 minutes (2–4 mL of 50% solution of $MgSO_4$ in 50–100 mL of D_5W). This can be followed by 4–8 mmol magnesium over 6–8 hours and repeated as needed. It is not uncommon to find that patients need 25–50 mmol in 24 hours. It has been recommended that one should limit intravenous magnesium replenishment to 50 mmol in 24 hours except in severe life-threatening hypomagnesemia, although about 50% of intravenous magnesium will be excreted into the urine even in the presence of magnesium deficiency. Although plasma levels of Mg^{2+} , Ca^{2+} , and K^+ are useful for following replacement, some clinicians recommend following deep tendon reflexes. These reflexes disappear with hypermagnesemia, but usually only at very high toxic levels. Replacement doses of magnesium in patients with renal insufficiency should be reduced, and plasma $[Mg^{2+}]$ must be watched carefully.

Dietary intake of approximately 5 mg/kg per day (about 300 mg) of magnesium is required for normal magnesium

balance. Magnesium supplementation is not usually required in patients eating a reasonable diet or who are receiving enteral feeding formulas. Parenteral nutrition solutions should provide about 12 mmol/day (about 300 mg/day) of magnesium.

D. Correction of Cause of Hypomagnesemia—Patients with self-limited gastrointestinal tract losses will not require continued magnesium therapy, but renal magnesium wasting may be caused by required medications such as antibiotics, amphotericin B, and diuretics. In these patients, continued magnesium supplementation may be necessary.

▶ Hypermagnesemia

ESSENTIALS OF DIAGNOSIS

- ▶ Plasma $[Mg^{2+}] >2.7$ mg/dL: usually asymptomatic.
- ▶ Plasma $[Mg^{2+}] >7$ mg/dL: weakness, loss of deep tendon reflexes, and paralysis.
- ▶ Plasma $[Mg^{2+}] >10$ mg/dL: hypotension and cardiac arrhythmias.

General Considerations

In contrast to hypomagnesemia, increased $[Mg^{2+}]$ is seen in a limited number of disorders. The normal kidney's generous magnesium excretion capacity suggests that both increased intake of magnesium and decreased glomerular filtration rate are necessary for hypermagnesemia to develop. Hypermagnesemia in critically ill patients occurs occasionally, and impaired neuromuscular and cardiac function may result.

A. Increased Magnesium Intake—Increased intake alone is a rare cause of increased plasma $[Mg^{2+}]$. High intake of magnesium by the oral route is unusual and is almost never from dietary sources. Magnesium-containing antacids (eg, magnesium hydroxide) and laxatives (eg, magnesium citrate) provide the only likely sources of increased oral magnesium ingestion, but fatal cases of hypermagnesemia have resulted from these agents, especially in the elderly and those with renal failure. Excessive amounts of intravenous magnesium sulfate can be given inadvertently in the course of parenteral

nutrition or during replacement therapy, making close monitoring of plasma $[\text{Mg}^{2+}]$ mandatory. In the treatment of preeclampsia-eclampsia, large amounts of intravenous magnesium sulfate are sometimes given, with the goal of achieving a plasma $[\text{Mg}^{2+}]$ well above the usual normal range. Rarely, tissue breakdown (tumor lysis syndrome) can cause hypermagnesemia as intracellular magnesium is released.

B. Decreased Magnesium Excretion—Unbound magnesium is filtered, and the amount appearing in the urine represents what is not reabsorbed. In the presence of increased plasma $[\text{Mg}^{2+}]$, a larger quantity is non-protein-bound, increasing the amount filtered relative to the glomerular filtration rate. Magnesium is reabsorbed as a result of sodium reabsorption in proximal, loop of Henle, and distal sites. In the absence of enhanced sodium reabsorption, there is no change in the quantity of reabsorbed magnesium, and the net result in hypermagnesemia is increased renal excretion. However, any disorder impairing glomerular filtration has the potential for causing hypermagnesemia, including acute and chronic renal failure. An increase in sodium reabsorption, such as seen in volume-depleted states, may impair renal magnesium excretion by facilitating magnesium reabsorption.

Clinical Features

A. Symptoms and Signs—Effects of hypermagnesemia are nonspecific and include lethargy, weakness, and hyporeflexia. More severely increased Mg^{2+} levels are associated with loss of deep tendon reflexes, refractory hypotension (from interference with membrane calcium transport), cardiac arrhythmias, respiratory depression, and drowsiness.

Hypermagnesemia should be suspected in patients with renal insufficiency who are receiving magnesium-containing medications or oral or parenteral magnesium supplementation or replacement. Other high-risk critically ill patients include those receiving nephrotoxic drugs, those with hypotension or hypovolemia and oliguria, and those with preeclampsia-eclampsia or preterm labor receiving large doses of intravenous magnesium. Patients with chronic renal failure should have antacids containing magnesium restricted. Elderly patients with diminished renal function who use magnesium-containing antacids and laxatives or vitamins containing magnesium salts may have an increased incidence of hypermagnesemia.

B. Laboratory Findings—A plasma magnesium level over 2.7 mg/dL makes the diagnosis of hypermagnesemia. Other laboratory studies that should be obtained include other plasma electrolytes and plasma creatinine and urea nitrogen. Urinary magnesium may be of value in confirming that hypermagnesemia is due to increased intake of magnesium rather than decreased renal excretion.

Treatment

A. Hypermagnesemia Requiring Urgent Treatment—Patients who are symptomatic and who have plasma $[\text{Mg}^{2+}]$ greater than 8–10 mg/dL should be treated urgently. Most

commonly they will have muscle weakness or paralysis and hypotension, prompting evaluation and treatment. Intravenous calcium gluconate or calcium chloride will counter the effects of excessively high $[\text{Mg}^{2+}]$. The amount of calcium should be limited in the presence of renal failure if the plasma phosphorus concentration is elevated.

B. Decrease Intake of Magnesium—Magnesium-containing antacids and other agents should be discontinued. Intravenous fluids, especially parenteral nutrition fluids, should have magnesium removed.

C. Increase Magnesium Excretion—In patients with normal renal function who develop hypermagnesemia, even a large excess of magnesium will be excreted rapidly without intervention. The majority of patients with decreased glomerular filtration will not be able to increase excretion appreciably because they are limited by decreased filtration. Nevertheless, inhibition of ascending loop of Henle sodium reabsorption with furosemide may impair magnesium reabsorption somewhat. Patients who can tolerate volume expansion also should be given normal saline to facilitate magnesium excretion. In patients who have severe hypermagnesemia, greatly enhanced magnesium removal requires hemodialysis.

Topf JM, Murray PT: Hypomagnesemia and hypermagnesemia. *Rev Endocr Metab Disord* 2003;4:195–206. [PMID: 12766548]

DISORDERS OF CALCIUM BALANCE

Calcium is the most abundant divalent cation in the body. The vast majority (98%) of calcium is in the form of hydroxyapatite in the bone, and only a very small amount is in the extracellular fluid. Nevertheless, plasma and extracellular calcium has a major role in the control of neuromuscular coupling and contraction. Plasma calcium is regulated by a complex system of hormones, vitamins, and organ function and is closely tied to phosphorus and magnesium regulation. In the ICU, both hyper- and hypocalcemia are seen. Severe hypercalcemia is due primarily to malignant disorders; there are fewer patients who have severe hypercalcemia from hyperparathyroidism, vitamin D toxicity, sarcoidosis, and other disorders. Hypocalcemia is seen in patients with chronic or acute renal failure, hyperphosphatemia, hypomagnesemia, and drug treatment.

Physiologic Considerations

A. Calcium Intake—Dietary calcium has a wide range in adult patients. Calcium absorption from the intestinal tract is influenced by 1,25-dihydroxyvitamin D, but calcium uptake is also proportionate to calcium intake. Calcium is taken up primarily in the duodenum and jejunum. Calcium binding to phosphate and free fatty acids in the lumen to form insoluble salts will interfere with absorption.

B. Plasma Calcium—Plasma calcium is about 40% protein-bound to albumin and other plasma proteins, and a smaller

fraction (10%) is attached to various anions. Total plasma calcium concentration is normally about 9–10 mg/dL; therefore, ionized calcium concentration is normally about 4.5–5 mg/dL. An important cause of decreased total plasma calcium is hypoalbuminemia, but ionized calcium, the component important in symptomatic hypocalcemia, may not be reduced. One approximation is that for each decrease of 1 g/dL of albumin from normal, 0.2 mmol/L (0.8 mg/dL) is added to the plasma calcium as a correction factor for interpretation of the level. The degree of protein binding of calcium to plasma proteins is affected by plasma pH; acidosis increases and alkalosis decreases ionized calcium.

C. Renal Calcium Excretion—Free calcium is filtered and largely reabsorbed (>95%) under steady-state conditions in the proximal nephron (accounting for about 60% of reabsorption), the ascending loop of Henle, and the distal nephron. Although passive movement of calcium is largely responsible for calcium uptake in the proximal tubule, there is some active transport. In the loop of Henle, the driving force for calcium reabsorption is the reabsorption of Na^+ and K^+ , causing an electropositive gradient from lumen to extracellular space. Drugs that interfere with sodium reabsorption here, such as loop diuretics, interfere with calcium reabsorption and lead to increased calcium excretion. On the other hand, the action of thiazide diuretics in the distal tubule favors calcium reabsorption, increasing plasma calcium and decreasing calciuria. Under physiologic conditions, the normal kidneys can conserve calcium extremely well (<100 mg/day) and can increase excretion to very high levels in the face of hypercalcemia.

D. Regulation of Plasma Calcium—In contrast to magnesium, which does not appear to be under hormonal control, plasma calcium is regulated primarily by two interacting hormones: parathyroid hormone (PTH) and vitamin D ($1,25[\text{OH}]_2\text{D}_3$). These two hormones control the complex cycle of calcium between the intestinal lumen (dietary calcium), the large reserve of calcium in the bone, and renal excretion. They also play important roles in the regulation of phosphorus distribution, absorption, and excretion.

1. PARATHYROID HORMONE—Hypocalcemia stimulates release of PTH from the parathyroid glands. PTH binds to transmembrane receptors in bone and renal tubular cells and stimulates adenyl cyclase, resulting in increased intracellular cAMP levels. The effect of PTH is to mobilize calcium by bone resorption and, in the kidneys, to decrease calcium excretion, increase phosphate excretion, and stimulate increased synthesis of active vitamin D ($1,25[\text{OH}]_2\text{D}_3$). In the absence of PTH, patients can have severe hypocalcemia and hyperphosphatemia; in states of excess PTH from hyperplasia of the parathyroid glands, hypercalcemia and hypophosphatemia are noted.

2. VITAMIN D—Vitamin D_3 is a fat-soluble vitamin that is found in various amounts in the diet. Ultraviolet light stimulates some conversion of precursor substances to vitamin D_3 in the skin. The most active vitamin D compound is

$1,25(\text{OH})_2\text{D}_3$, which is synthesized by conversion of vitamin D_3 in two stages to $25(\text{OH})\text{D}_3$ by the liver and to $1,25(\text{OH})_2\text{D}_3$ by the kidneys. The rate of conversion of $25(\text{OH})\text{D}_3$ to $1,25(\text{OH})_2\text{D}_3$ is indirectly accelerated by hypocalcemia through the action of PTH on the kidneys. Active $1,25(\text{OH})_2\text{D}_3$ increases calcium and phosphorus absorption from the gastrointestinal tract and helps PTH mobilize calcium from the bone.

▶ Hypocalcemia (See Table 2-13)

ESSENTIALS OF DIAGNOSIS

- ▶ Plasma $[\text{Ca}^{2+}] < 8.5 \text{ mg/dL}$.
- ▶ Nervous system irritability, including altered mental status, focal and grand mal seizures, paresthesias, tetany, hyperreflexia, muscle weakness.
- ▶ Prolonged QT interval, cardiac arrhythmias.

General Considerations

Decreased plasma calcium can have serious consequences in critically ill patients, potentiating arrhythmias and seizures. However, most patients in the ICU with hypocalcemia (total $[\text{Ca}^{2+}] < 8.5 \text{ mg/dL}$) are asymptomatic. This is so because these patients have low plasma albumin levels, and the non-albumin-bound or ionized fraction of Ca^{2+} that participates in neuromuscular coupling is normal. Total plasma $[\text{Ca}^{2+}]$ can be “corrected” for hypoalbuminemia by adding 0.8 mg/dL to the measured total $[\text{Ca}^{2+}]$ for every 1 g/dL decrease in plasma albumin below 3.5 g/dL. If the value is above 8.5 mg/dL, ionized calcium is likely to be normal, except with extreme changes in pH. Ionized plasma calcium measurements can confirm this correction, if indicated.

Table 2-13. Risks for hypocalcemia in ICU patients.

Decreased intake of calcium

Malabsorption of calcium or vitamin D
Steatorrhea

Decreased PTH or decreased PTH effectiveness

Hypoparathyroidism, parathyroidectomy
Hypomagnesemia
Acute pancreatitis
Vitamin D deficiency
Chronic renal insufficiency

Other

Septic shock
Rhabdomyolysis
Acute hyperphosphatemia
Treatment of hypercalcemia
Hypoalbuminemia

There is an abundance of calcium in the body, but much of it is in poorly mobilized forms. When hypocalcemia occurs, there is failure of normal plasma calcium regulation. Calcium can leave the extracellular space when driven by reactions that deposit calcium in the bones and soft tissues or when there is insufficient PTH or $1,25(\text{OH})_2\text{D}_3$ to mobilize calcium from the bone. In the ICU, a few other factors may also lead to hypocalcemia—notably drugs and hyperphosphatemia.

A. Calcium Deposition—Hypocalcemia may be due to loss of plasma calcium by deposition of calcium salts in tissues. In critically ill patients, this may be seen in acute pancreatitis and rhabdomyolysis. Calcium is deposited in the form of calcium soaps (ie, poorly soluble salts of Ca^{2+} and fatty acids) in the case of pancreatitis or in other forms in damaged skeletal muscle. Most other patients with hypocalcemia from calcium deposition have hyperphosphatemia. In these patients, when the product of calcium \times phosphorus is greater than 60, calcium phosphate tends to deposit in soft tissues. An important cause of hypocalcemia is the tumor lysis syndrome, in which there is massive release of phosphorus into the blood. Hyperphosphatemia also may be seen in ICU patients in whom excessive phosphorus repletion is given to correct hypophosphatemia or from absorption of bowel preparation solutions containing sodium phosphate. Most patients with chronic renal failure will have some degree of hyperphosphatemia that facilitates hypocalcemia unless they are effectively treated with oral phosphate-binding agents and vitamin D supplementation. Rarely—less commonly than at one time believed—large amounts of blood transfusions have been associated with hypocalcemia, probably from chelation of Ca^{2+} by citrate used as an anticoagulant.

B. Decreased PTH or PTH Effect—Hypoparathyroidism is seen occasionally in the ICU but is rarely undiagnosed or unsuspected prior to admission. Low PTH levels are still seen occasionally after thyroid surgery when parathyroid glands are not preserved adequately. On the other hand, hypomagnesemia has an important effect of decreasing PTH release from parathyroids, contributing to hypocalcemia. There are rare congenital forms of PTH resistance.

In critically ill patients, hypocalcemia also may be due to a decreased effect of PTH action. Hypomagnesemia decreases the action of PTH on bone. Pancreatitis usually is thought to cause hypocalcemia from soft tissue deposition, but there also may be resistance to PTH in this disease. Vitamin D deficiency also interferes with the action of PTH.

C. Other Causes—Loop-acting diuretics such as furosemide may cause excessive calcium excretion by the kidneys, but this is rarely a cause of hypocalcemia alone because of effective counterregulatory mechanisms. Treatment of hypercalcemia with bisphosphonates, plicamycin, or calcitonin may lead to excessively low $[\text{Ca}^{2+}]$ —but again, this is rarely seen. Finally, patients with renal failure have hypocalcemia from a combination of mechanisms, including hyperphosphatemia and decreased conversion of $1,25(\text{OH})_2\text{D}_3$.

Clinical Features

A. Symptoms and Signs—Central and peripheral nervous system effects are the most common features of hypocalcemia. Altered mental status, including lethargy and coma, may be present. Seizures may be focal or generalized, and hypocalcemia may complicate a known seizure disorder. More often, hypocalcemia is manifested by tetany, paresthesias, and hyperreflexia. The Chvostek and Trousseau signs may be positive. When severe, hypocalcemia may result in muscle weakness. Hypocalcemia prolongs the QT interval on the ECG. Ventricular arrhythmias may be seen, including ventricular fibrillation.

Patients with chronic hypocalcemia may have manifestations of bone resorption of calcium and have features of the underlying disease leading to decreased plasma $[\text{Ca}^{2+}]$. For ICU patients, review of medications and recent conditions that may affect plasma $[\text{Ca}^{2+}]$ should be undertaken. Medications contributing to hypocalcemia include furosemide, phenytoin, calcium-lowering drugs such as plicamycin and bisphosphonates, blood transfusions, and phosphate therapy. Patients with renal failure (acute or chronic), rhabdomyolysis, pancreatitis, tumors, malnutrition, and gastrointestinal disorders are at risk.

B. Laboratory Findings—Hypocalcemia is diagnosed when the plasma $[\text{Ca}^{2+}]$ is less than 8.5 mg/dL after appropriate correction for low plasma albumin levels. In critically ill patients, $[\text{Ca}^{2+}]$ should be measured when routine plasma electrolyte determinations are needed. This probably means at least daily for most high-risk patients. In patients with hypocalcemia, plasma sodium, potassium, chloride, magnesium, phosphorus, amylase, and creatine kinase may be helpful for making a specific diagnosis.

Vitamin D levels in the blood can be measured, including $1,25(\text{OH})_2\text{D}_3$, if necessary. The PTH level can be interpreted properly only when compared with the normal range for the $[\text{Ca}^{2+}]$. In most cases of hypocalcemia in the ICU, these measurements are not necessary.

Treatment

A. Need for Treatment—Low plasma $[\text{Ca}^{2+}]$ calls for treatment if the patient is symptomatic, especially with very low $[\text{Ca}^{2+}]$ and tetany, arrhythmias, or seizures. Hypomagnesemia, because of multiple effects leading to hypocalcemia, is also a treatment priority and usually can be corrected with little risk of complications, except in patients with renal insufficiency.

Patients with decreased total plasma calcium but with hypoalbuminemia or pH changes sufficient to maintain a normal estimated ionized calcium do not require calcium replacement. Patients with both acute severe hyperphosphatemia and hypocalcemia represent a problem. Raising plasma calcium in the face of hyperphosphatemia may cause widespread calcium phosphate deposition. Only enough calcium to prevent or reverse cardiovascular complications should be given. It may be advisable to determine plasma ionized calcium in this situation for guidance. Acute hemodialysis to lower the plasma phosphorus concentration could be helpful.

B. Treatment of Severe Hypocalcemia—Treatment with intravenous calcium gluconate or calcium chloride is indicated. Calcium chloride may be less well tolerated than calcium gluconate, and calcium gluconate is recommended except during cardiac arrest or severe arrhythmias. Each compound is available in ampules containing 10 mL of 10% solution containing 93 mg Ca^{2+} for calcium gluconate and 273 mg Ca^{2+} for calcium chloride. For rapid intravenous infusion, give 1 ampule over 10–30 minutes. For persistent severe hypocalcemia, intravenous calcium gluconate can be given as 8–12 mg/kg (about 6–8 ampules of calcium gluconate) of Ca^{2+} over 6–8 hours.

During treatment, plasma [Ca^{2+}] should be followed, along with phosphorus and magnesium. The physical examination and ECG may be helpful in deciding when treatment should be slowed or changed to oral supplementation.

C. Correction of Cause of Hypocalcemia—Patients with pancreatitis and rhabdomyolysis may have transient hypocalcemia of varying duration followed by release of Ca^{2+} back into the extracellular space. Therefore, these patients should be monitored closely for development of normocalcemia or even rebound hypercalcemia. Patients with chronic renal failure with hypocalcemia may respond to vitamin D supplementation and dialysis. Hypoparathyroidism is treated with calcium supplementation and vitamin D.

► Hypercalcemia (See Table 2–14)

ESSENTIALS OF DIAGNOSIS

- ▶ Plasma [Ca^{2+}] >10.5 mg/dL.
- ▶ Altered mental status with confusion, lethargy, psychosis, and coma.
- ▶ Hyporeflexia and muscle weakness.
- ▶ Constipation, shortening of QT interval, and pancreatitis.
- ▶ Features of chronic hypercalcemia may be seen: bone changes, band keratopathy.
- ▶ May have features of underlying disease: hyperparathyroidism, malignancy, sarcoidosis, vitamin A toxicity.

Table 2–14. Risks for hypercalcemia in ICU patients.

Increased intake of calcium

- Calcium-containing antacids
- Milk-alkali syndrome
- Increased PTH or PTH effectiveness

Hyperparathyroidism

- Vitamin D intoxication
- Hypercalcemia of malignancy
- PTH-related peptide

Increased vitamin D conversion

Bone destruction

Cytokines

Others

- Thiazide diuretics
- Immobilization
- Thyrotoxicosis
- Granulomatous diseases (vitamin D conversion)

General Considerations

Hypercalcemia is a frequent cause of admission to the ICU, as well as a complication of a variety of disorders. Most often hypercalcemia is identified by a routine plasma calcium level ($[\text{Ca}^{2+}] >10.5 \text{ mg/dL}$), but severe hypercalcemia with altered mental status is a medical emergency. Patients may be admitted to the ICU for management, especially for close monitoring of intravascular fluid therapy. Severe hypercalcemia is almost always due to malignancy, including solid tumors, lymphoma, and multiple myeloma. Causes of more mild hypercalcemia include granulomatous diseases such as sarcoidosis, tuberculosis, and fungal diseases and hyperparathyroidism.

The mechanisms of hypercalcemia, like hypocalcemia, reflect the large amount of Ca^{2+} flux between the gastrointestinal tract, bone, kidneys, and extracellular space. Hypercalcemia is the result of failure of the regulatory mechanisms for calcium, including inability to suppress PTH normally, or excessive mobilization of calcium by an abnormally produced PTH-like compound or vitamin D. PTH activates or stimulates osteoclasts that mobilize calcium from bone. Vitamin D primarily increases calcium absorption from the gastrointestinal tract.

A. Primary Elevation of Parathyroid Hormone—

Hypercalcemia in primary hyperparathyroidism is caused by unregulated PTH secretion from parathyroid adenoma or hyperplasia. In the past, patients were identified when symptomatic from renal stones, bone pain, or symptoms of hypercalcemia. These patients are now identified most often from routine screening laboratory tests that include plasma [Ca^{2+}]. Diagnosis is made by the finding of PTH levels that are inappropriately high in the presence of elevated plasma [Ca^{2+}].

B. Abnormal PTH-like Substance—Malignancy is the most frequent cause of severe hypercalcemia. Although several mechanisms of tumor hypercalcemia have been identified, the most important is release by the tumor of a peptide that has structural homology with PTH, called *parathyroid hormone-related peptide* (PTHrP). The effects of PTHrP are similar to those of PTH, causing increased plasma calcium and decreased plasma phosphorus. Hypercalcemia from this substance is seen in bronchogenic carcinoma and many other malignancies. Hypercalcemia in malignant disease is also caused by other factors, including bony metastases with bone destruction and the effects of cytokines, including interleukins and transforming growth factor β (TGF- β).

C. Abnormal Production of Vitamin D—Excessive administration or ingestion of vitamin D can cause hypercalcemia, but this does not occur immediately. Toxic doses of vitamin A also may cause hypercalcemia. Macrophages within granulomas may synthesize $1,25(\text{OH})_2\text{D}_3$. Although sarcoidosis is the best known entity associated with hypercalcemia, tuberculosis, berylliosis, and fungal diseases may behave similarly. In some patients with granulomatous diseases, hypercalciuria is more common than hypercalcemia. This is probably so because both elevated Ca^{2+} and vitamin D inhibit PTH release. In the absence of elevated PTH, renal calcium excretion is high, resulting in hypercalciuria without hypercalcemia. Both Hodgkin's and non-Hodgkin's lymphoma can produce $1,25(\text{OH})_2\text{D}_3$.

D. Other Causes—Patients recovering from acute pancreatitis or rhabdomyolysis can have a rebound of plasma Ca^{2+} levels as Ca^{2+} is released back into the extracellular space. Milk-alkali syndrome results from ingestion of calcium and antacids by a patient with renal failure and is associated with the unusual combination of hypercalcemia and hyperphosphatemia. Hypercalcemia can be seen rarely as a manifestation of hyperthyroidism. Thiazide diuretics decrease renal calcium excretion. Immobilization does not cause hypercalcemia but exacerbates hypercalcemia owing to other mechanisms.

Clinical Features

Most patients with hypercalcemia of mild degree are identified by routine plasma $[\text{Ca}^{2+}]$ determinations on screening laboratory tests.

A. Symptoms and Signs—Hypercalcemia affects mental status, including lethargy, confusion, and psychosis. Patients may have absent deep tendon reflexes and muscle weakness. A major complaint may be constipation, and bowel sounds usually are decreased. Polyuria and impaired urinary concentrating ability (nephrogenic diabetes insipidus) are consequences of hypercalcemia. The ECG may show a shortened QT interval. Arrhythmias may be precipitated in patients receiving digitalis. Hypercalcemia is associated with and may be a causal factor in peptic ulcer disease and pancreatitis.

Hypercalcemia should be suspected in patients with malignancies of the breast, prostate, lung, kidney, liver, and head and neck. Patients with multiple myeloma may have hypercalcemia as well. Sarcoidosis, tuberculosis, fungal infections, and other granulomatous diseases may be associated with significant hypercalcemia, but rarely is plasma $[\text{Ca}^{2+}]$ high enough to cause severe symptoms.

Other symptoms and signs are related to the underlying disease, especially with long-standing hyperparathyroidism (eg, renal stones, fractures, bony deformities, band keratopathy, and conjunctivitis). Patients with hypercalcemia of malignancy usually do not have evidence of long-term hypercalcemia but may have findings related to the primary or metastatic tumor.

B. Laboratory Findings

A plasma calcium concentration over 10.5 mg/dL makes the diagnosis of hypercalcemia. Other laboratory studies that should be obtained include plasma phosphorus, other electrolytes, and creatinine and urea nitrogen. In hypercalcemia, polyuria may result from inability to concentrate the urine. Renal calcification and obstructive uropathy from renal stones may lead to renal insufficiency.

For severe hypercalcemia, treatment can be initiated without knowledge of the underlying cause. However, specific diagnosis may be helped by obtaining a PTH level. Assays for PTH and PTHrP are available to distinguish primary hyperparathyroidism from hypercalcemia of malignancy mediated by PTHrP. Vitamin D levels are rarely needed for work-up of hypercalcemia.

Treatment

A. Need for Treatment—Patients with mild hypercalcemia need not be treated immediately or aggressively unless symptomatic. Severe hypercalcemia ($[\text{Ca}^{2+}] >12\text{--}13$ mg/dL) should be treated even if asymptomatic, and hypercalcemia of any degree with symptoms, especially altered mental status or seizures, should be treated vigorously. Treatment is directed at lowering plasma $[\text{Ca}^{2+}]$ by increased renal excretion and by decreasing mobilization from the bone stores.

In patients with symptomatic or severe hypercalcemia, a four-pronged approach is used: expansion of extracellular volume, furosemide, calcitonin, and pamidronate.

B. Increased Excretion of Calcium—Unbound plasma calcium is filtered and largely reabsorbed. Calcium reabsorption is closely tied to sodium reabsorption in the proximal nephron and loop of Henle. Expansion of extracellular volume with 0.9% NaCl decreases passive proximal reabsorption of calcium. Loop diuretics are given both to prevent volume overload and to inhibit active sodium and passive calcium reabsorption in the loop of Henle. In severe hypercalcemia, intravenous 0.9% NaCl should be given at a rate of 200–300 mL/h or more. Patients with cardiac disease and the elderly may be unable to tolerate these large volumes, and pulmonary edema

may develop. In such patients, central venous pressure or pulmonary artery wedge pressure measurements may be necessary.

Because calcium absorption is coupled with sodium reabsorption in the ascending loop of Henle, furosemide increases calcium excretion. Furosemide can be given in a dosage of 20–60 mg intravenously every 2–6 hours as needed to maintain urine output. Furosemide is also useful to maintain natriuresis in patients given large volumes of intravenous NaCl. In patients given large doses of furosemide, hypokalemia and hypomagnesemia may be problems. Thiazide diuretics should not be given because these drugs inhibit renal calcium excretion in the distal tubule.

Plasma calcium concentration usually will begin to decline within a few hours with the combination of furosemide and normal saline, as long as 0.9% NaCl is given at a sufficient rate.

C. Decreased Mobilization of Calcium from Bone—

Bisphosphonates are very effective agents used for the management of hypercalcemia and have low toxicity. These drugs bind to bone hydroxyapatite and inhibit osteoclast activity for a prolonged period. Their action is moderately rapid, with onset within 2 days and maximum effect at about 1 week. Plasma $[Ca^{2+}]$ falls even while urinary $[Ca^{2+}]$ decreases. With bisphosphonates, a large proportion of patients will have return of $[Ca^{2+}]$ to the normal range regardless of the cause of hypercalcemia.

Pamidronate is given as a single dose of 60 or 90 mg intravenous over 24 hours, with 60–100% of patients having a normal plasma $[Ca^{2+}]$ 10–13 days later. The higher dose is given for more severe hypercalcemia (>13.5 mg/dL). Patients with renal insufficiency should be given a smaller dose of pamidronate. Side effects of pamidronate are minor. However, in fewer than 2% of patients, systemic inflammatory reactions, ocular inflammation, and osteonecrosis of the maxilla and mandible may occur. The calcium-lowering effect may last 2–4 weeks, although the effect may be shorter and less pronounced when treating malignant hypercalcemia. Newer bisphosphonates, including oral agents, are used mostly for mild hypercalcemia or to prevent osteoporosis or hypercalcemia.

Calcitonin (calcitonin-salmon, 4 IU/kg IM as a starting dosage) has a slight and short-term effect but can be used in the initial phase of therapy. It is nontoxic and acts most quickly of all these agents. Calcitonin promotes renal excretion of calcium, inhibits bone resorption, and inhibits gut absorption of calcium. The effect of calcitonin diminishes within a few days, but other treatments are likely to be effective by then.

Plicamycin blocks bone resorption of calcium. It can be given to any patient with hypercalcemia but is used most often in hypercalcemia of malignancy. The usual dose is 25 μ g/kg in 50 mL D_5W intravenous over 3–6 hours. $[Ca^{2+}]$ begins to decline at about 24 hours and normalizes in about 60% of patients. Plicamycin should not be used in

the presence of severe renal or liver failure or thrombocytopenia. It is much less often used since the advent of the bisphosphonates.

There are some limited data on gallium nitrate for the treatment of hypercalcemia of malignancy. Studies indicate that it is as effective as pamidronate and has few side effects. It may be particularly useful in specific kinds of tumors or in those whose hypercalcemia is refractory to other treatment.

D. Other Therapy—Hemodialysis is very effective in lowering plasma $[Ca^{2+}]$ in patients who have inadequate renal function or who cannot tolerate forced diuresis. Corticosteroids have a role in hypercalcemia mediated by elevated vitamin D (in granulomatous disorders) and in multiple myeloma. The effect is not immediate because corticosteroids probably decrease absorption of calcium from the gut by interfering with vitamin D activation. While intravenous sodium phosphate has a predictable calcium-lowering effect, this treatment is used rarely at present because of the precipitation of calcium phosphate in soft tissues. On the other hand, oral sodium phosphate therapy is effective in forming insoluble calcium phosphate deposits in the gut.

ACID-BASE HOMEOSTASIS & DISORDERS

▶ Pathophysiology

Arterial pH is reflected by the relative concentrations of bicarbonate (HCO_3^-) and carbon dioxide (CO_2) in the blood. While this system does not provide very strong buffering, the ability to adjust these variables makes this system an important component of acid-base regulation. Plasma bicarbonate is controlled principally by renal conservation or excretion of bicarbonate and hydrogen ion; CO_2 , largely by pulmonary ventilation. Decreased arterial pH is called *acidemia*, and increased arterial pH is called *alkalemia*. The disturbances responsible for these changes are *acidosis* and *alkalosis*, respectively, and these changes are defined as “metabolic” (owing to primary increase or decrease in HCO_3^-) or “respiratory” (owing to primary increase or decrease in CO_2).

Acid-Base Buffering Systems

The major acid-base buffering system in the blood involves carbon dioxide and bicarbonate. Carbon dioxide, bicarbonate, and carbonic acid are interconverted according to the following reaction:

The relationship between the species that define pH is known as the *Henderson-Hasselbalch equation*:

$$\text{pH} = 6.1 + \log \frac{[\text{HCO}_3^-]}{0.03 \times \text{PaCO}_2}$$

Under normal conditions, the balance between these components is tightly controlled. Within 95% confidence limits, the pH of the arterial blood is between 7.35 and 7.43. For PaCO_2 , the limits are 37 and 45 mm Hg. Bicarbonate concentration normally varies between 22 and 26 meq/L. If hydrogen ions are added to the blood, the reaction shifts rightward, with production of CO_2 and water. Normally, the CO_2 so produced is eliminated rapidly by the lungs.

The bicarbonate–carbon dioxide buffering system is the major extracellular buffer. Other minor extracellular buffer systems also contribute to stabilization of the pH. After extracellular buffering occurs, a second intracellular phase takes place over the next several hours. The main intracellular buffer systems include hemoglobin, protein, dibasic phosphate, and carbonate in bone. The ratio of extracellular to intracellular buffering is approximately 1:1 unless the acid load is very large or continues over a long period of time. Contribution by both the extracellular and intracellular buffers means that an exogenous acid load (or deficit) has a volume of distribution approximately equal to that of the total body water (50–60% of ideal body weight).

Finally, both bicarbonate and CO_2 act as a “dynamic” buffering system. For usual buffers, the addition or removal of hydrogen ion, for example, is countered by corresponding opposite effects of the buffer components. This minimizes pH change at the expense of consumption of some of the buffer components, limiting the maximum buffering capacity. For the bicarbonate- CO_2 system, however, physiologic mechanisms greatly increase the buffer capacity. Metabolic acidosis can be countered by decreased arterial PaCO_2 , whereas a respiratory acidosis is countered by increased plasma bicarbonate. Because the lungs can eliminate a vast amount of CO_2 per day, this is a very powerful buffering component. Similarly, the kidneys can eliminate bicarbonate if necessary or can regenerate bicarbonate at quite high rates.

Renal Handling of Bicarbonate

The kidneys perform two major functions in acid-base homeostasis. First, they reclaim filtered bicarbonate by secreting hydrogen ions. Within the cells of the proximal tubule, carbonic anhydrase facilitates conversion of CO_2 and water into protons and bicarbonate ions. The bicarbonate is returned to the blood, whereas the hydrogen is secreted into the proximal tubule, where it combines with tubular bicarbonate to re-form CO_2 and water. The result is a net reclamation of bicarbonate; 80–85% is reabsorbed in the proximal convoluted tubule, with lesser amounts in the loop of Henle (5%), the distal tubule (5%), and the collecting system (5%).

In addition to bicarbonate, the anions of other acids are filtered by the glomeruli. The formation of these acids in the body results in an equimolar decrease in bicarbonate. The most important of these anions is monohydrogen phosphate. When hydrogen ion, secreted by the proximal tubules, combines with monohydrogen phosphate, it forms dihydrogen phosphate (H_2PO_4^-), which is a weak acid with a $\text{p}K_a$ of 6.8. The lowest pH attainable in the proximal tubule is approximately 4.5. Because the $\text{p}K_a$ of this acid is within the tubular physiologic range for pH, it can be re-formed and excreted. When acids can be excreted by this process, they are referred to as *titratable acids*. The net effect is the regeneration of a bicarbonate anion to be added to the blood.

On the other hand, acids with $\text{p}K_a$ values lower than 4.5 (such as sulfuric acid, which is formed as a metabolic product of some amino acids) cannot be regenerated in this way. Therefore, excess hydrogen ions secreted into the proximal tubule must be excreted bound to another buffer to permit the continued formation of bicarbonate by the tubular cells. Tubular cells deaminate glutamine, and ammonia diffuses into the proximal tubules. Ammonia reacts with hydrogen ion produced in the distal tubule to form ammonium ion (NH_4^+), which is excreted as NH_4Cl . Ammonium excretion can increase from its normal level of 35 meq/day to over 300 meq/day in the face of severe acidemia. Three to five days are required before maximum excretion of ammonium is achieved. As ammonium excretion increases, plasma bicarbonate concentration rises, as does urinary pH. Because a greater absolute quantity of hydrogen ions can be excreted in buffered (ammonium-rich) urine, urinary pH does not always reflect the extent of renal acidification. Both ammonia production and proton secretion in the proximal tubules are increased by acidemia and decreased by alkalemia.

Loss of acidic fluids (eg, in vomiting) or increase in alkali (eg, antacid ingestion) in the body causes a reduction in hydrogen ion concentration and an increase in plasma bicarbonate and pH. About two-thirds of the alkaline load is buffered in the extracellular space, whereas only one-third enters the intracellular compartment. At the same time, there is a modest shift of potassium into the cells, resulting in a decline in potassium concentration of approximately 0.4–0.5 meq/L for each 0.1 unit increase in pH. The acute response to an infusion of bicarbonate is an increase in PaCO_2 , which results from combination with H^+ , and the release of CO_2 . The pulmonary response to chronic alkalemia is inhibition of the respiratory drive. This causes a rise in PaCO_2 of about 0.5 mm Hg for each 1 meq/L increase in the plasma bicarbonate concentration.

The kidney is able to excrete large amounts of excess bicarbonate under normal physiologic conditions. Increased concentration of bicarbonate in the glomerular ultrafiltrate, in combination with elevated pH of the blood perfusing the cells of the proximal tubules, decreases renal reabsorption and creates alkaline urine. Titratable acid and ammonia excretion are rapidly reduced.

However, both hypovolemia (volume-contraction alkalosis) and hypokalemia can compromise the kidney's ability to excrete bicarbonate. Three mechanisms are responsible: (1) Decreased glomerular filtration rate (GFR) caused by hypovolemia, despite an elevated plasma bicarbonate, decreases the amount of filtered bicarbonate, (2) proximal tubular reabsorption of HCO_3^- is stimulated by hypovolemia and hypokalemia, and (3) increased aldosterone concentration, produced by hypovolemia, encourages paradoxically increased bicarbonate reabsorption.

Respiratory Acid-Base Changes

Chemoreceptors normally maintain the PaCO_2 between 37 and 45 mm Hg as long as pH is near normal. Lung disease, chest wall abnormalities, neurologic disease, or trauma may interfere with pulmonary excretion of CO_2 and cause hypercapnia. Both stimulation of ventilation and other mechanisms cause hypocapnia. An acute change in PaCO_2 produces a change in blood pH within several minutes.

Because of "mass action," plasma bicarbonate falls by about 0.25 meq/L for each 1 mm Hg decrease in PaCO_2 (acute respiratory alkalosis) and increases by 0.1 meq/L for each 1 mm Hg increase in PaCO_2 during acute respiratory acidosis. Eventually, the kidneys respond to the change in PaCO_2 by increasing bicarbonate reabsorption from the proximal tubules, compensating for a rise in PaCO_2 , or decreasing bicarbonate reabsorption if PaCO_2 is low. Plasma bicarbonate concentration increases by an average of 0.5 meq/L for each 1 mm Hg increase in PaCO_2 during chronic hypercapnia. Chronic hypercapnia stimulates ammonia production and increases urinary ammonium excretion. Occasionally, pH becomes slightly alkaline owing to excessive renal bicarbonate production and retention. Hypocapnia appropriately increases urinary bicarbonate excretion and transiently reduces urinary net acid secretion. The increased excretion of bicarbonate also results in kaliuresis and a decline in plasma potassium concentration. In the steady state, the plasma bicarbonate concentration falls by about 0.5 meq/L for each 1 mm Hg decrease in PaCO_2 .

Classification of Acid-Base Disorders

Acid-base disorders are classified according to whether there is a primary abnormality in plasma bicarbonate concentration, plasma PaCO_2 , or both. Abnormal pH owing to altered bicarbonate concentration with PaCO_2 changes in response to the primary disorder is referred to as either *metabolic acidosis* or *metabolic alkalosis*. When the defect in pH is due primarily to altered PaCO_2 , the condition is referred to as either *respiratory acidosis* or *respiratory alkalosis*. A change in HCO_3^- brings about a compensatory change in PaCO_2 , and a primary change in PaCO_2 stimulates a compensatory adjustment in plasma HCO_3^- . The compensatory changes may take minutes (PaCO_2) or hours to days (HCO_3^-) to reach a steady state.

Simple acid-base disorders occur when there is a primary change either in the bicarbonate concentration or in the PaCO_2 with an appropriate (normal) secondary change in the other

parameter (Table 2–15 and Figure 2–5). When values do not follow these rules, a complex (mixed) acid-base disorder exists. Mixed acid-base disorders include all possible combinations. For example, a patient may develop metabolic acidosis and respiratory acidosis simultaneously. Another patient may have a combination of respiratory alkalosis and metabolic acidosis. Some patients who have toxicity from excessive salicylates will develop metabolic acidosis along with respiratory alkalosis.

It is helpful in evaluating acid-base disorders to follow some general rules. First, disorders are identified by the direction of the pH change. That is, any patient with a low pH (acidemia) must have at least metabolic acidosis, respiratory acidosis, or both. If both PaCO_2 and HCO_3^- contribute to either acidemia or alkalemia, then the patient must have two (or more) problems. Third, because compensatory mechanisms are never sufficient to restore the pH to normal, any patient with a normal pH (about 7.40) and appreciably abnormal PaCO_2 and HCO_3^- must have at least two primary acid-base disturbances. For example, acidemia with a decreased HCO_3^- concentration and a reduced PaCO_2 is most often a simple metabolic acidosis with respiratory compensation. However, if the pH is very close to 7.40, then respiratory compensation is abnormally excessive, and a second primary disturbance, respiratory alkalosis, should be suspected.

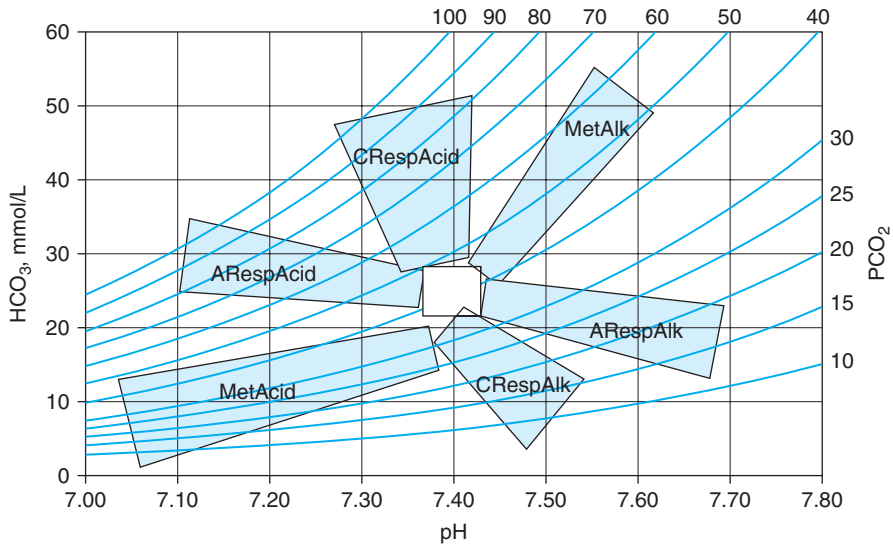

Figure 2–5 will help in determining whether appropriate compensation is present. Location of a patient's position on the diagram will suggest if a mixed acid-base problem is present. The areas shown represent 95% confidence intervals for single acid-base problems (labeled). If a point falls outside an area, then it is less likely to be a single acid-base problem, and a mixed acid-base disturbance (with two or more processes) should be suspected. General rules for the identification and verification of disorders are listed in Tables 2–15 and 2–16.

Current Controversies and Unresolved Issues

Most clinicians currently understand and manage acid-base disorders in what have been termed *traditional* frameworks. The two most commonly used are either the PaCO_2 -plasma HCO_3^- system or, recognizing that plasma HCO_3^- reflects both

Table 2–15. Identification of acid-base disorders.

I. Confirm that pH, PaCO_2 , and $[\text{HCO}_3^-]$ are compatible: Henderson-Hasselbalch equation Acid-based nomogram
II. Identify the primary disturbance: 1. Arterial pH to identify acidemia or alkalemia 2. Change in PaCO_2 , HCO_3^- , or both to determine whether respiratory, metabolic or both.
III. Determine whether the disorder is simple or complex: Acid-base nomogram Anion gap

▲ Figure 2-5. Acid-base nomogram showing the relationship between pH and HCO₃⁻. The curved lines are isopleths of Pco₂. The shaded areas represent the approximate 95% confidence limits of the normal respiratory and metabolic compensations for a single primary acid-base disturbance (MetAcid = metabolic acidosis; MetAlk = metabolic alkalosis; ARespAcid = acute respiratory acidosis; ARespAlk = acute respiratory alkalosis; CRespAcid = chronic respiratory acidosis; CRespAlk = chronic respiratory alkalosis). Points in the center area show normal pH, Pco₂, and HCO₃⁻. Points with an abnormal pH, Pco₂, or HCO₃⁻ outside the shaded areas are more likely to be compatible with mixed acid-base disturbances.

“metabolic” and “respiratory” changes, systems that express plasma HCO₃⁻ changes as base excess or deficit or standard bicarbonate. In recent years, these frameworks have been challenged by a physical-chemical approach that reaches similar clinical conclusions but suggests different mechanisms for acid-base disorders. This approach, sometimes called the

strong ion difference, may have important implications for such entities as dilutional acidosis, correction of metabolic alkalosis, detection of subtle metabolic acidosis, and prognosis in the ICU. Some studies have shown that the strong ion difference concept improves diagnosis and therapy of acid-base disorders, but this remains unresolved.

Table 2-16. Approximate expected response for a single acid-base disturbance.

	For Each	Expected Change
Acute respiratory acidosis	Increase in Pco ₂ by 1 mm Hg	[HCO ₃ ⁻] increases by 0.1 mmol/L
Chronic respiratory acidosis		[HCO ₃ ⁻] increases by 0.5 mmol/L
Acute respiratory alkalosis	Decrease in Pco ₂ by 1 mm Hg	[HCO ₃ ⁻] decreases by 0.25 mmol/L
Chronic respiratory alkalosis		[HCO ₃ ⁻] decreases by 0.5 mmol/L
Metabolic acidosis	Decrease in [HCO ₃ ⁻] by 1 mmol/L	Pco ₂ decreases by 1.25 mm Hg
Metabolic alkalosis	Increase in [HCO ₃ ⁻] by 1 mmol/L	Pco ₂ increases by 0.5 mm Hg

▶ Metabolic Acidosis

ESSENTIALS OF DIAGNOSIS

- ▶ Decreased plasma $[\text{HCO}_3^-]$ with appropriately decreased Paco_2 (simple metabolic acidosis), but metabolic acidosis may be part of a mixed acid-based disturbance.
- ▶ Evidence that low plasma $[\text{HCO}_3^-]$ is primary problem (and not due to compensation for hypocapnia).
- ▶ May present with peripheral vasodilation, depressed cardiac contractility in severe acidosis, fatigue, weakness, stupor, and coma.

General Considerations

Metabolic acidosis results from a primary reduction in plasma bicarbonate concentration, usually accompanied by a compensatory decrease in Paco_2 . Compared with respiratory acid-base disorders, the degree of Paco_2 compensation in metabolic acidosis depends only slightly on whether the condition is acute or chronic. The normal compensatory response is to maximize renal reabsorption of bicarbonate. In a recent study, ICU patients with metabolic acidosis regardless of etiology had a poorer outcome than those without.

A useful classification for metabolic acidosis uses the *anion gap*. The anion gap is calculated as

$$\text{Anion gap} = [\text{Na}^+] - ([\text{HCO}_3^-] + [\text{Cl}^-])$$

The normal value for the anion gap is 12 ± 4 meq/L. The anion gap is equal to the difference between “unmeasured” anions and “unmeasured” cations. In normal subjects, unmeasured anions include albumin (2 meq/L), phosphate (2 meq/L), sulfate (1 meq/L), lactate (1–2 meq/L), and the anions of weak acids (3–4 meq/L). The predominant unmeasured cations include calcium (5 meq/L), magnesium (2 meq/L), and certain cationic immunoglobulins. Some clinicians recommend making a correction to the calculated anion gap by correcting for plasma albumin (add to calculated anion gap 2.8 times $[4 - \text{plasma albumin in g/dL}]$).

The anion gap widens most commonly because of increased unmeasured anions, but occasionally widening is due to decreased unmeasured cations. In metabolic acidosis,

an increased anion gap indicates that a strong acid is present that dissociates into hydrogen ion and an “unmeasured” anion. On the other hand, failure of the kidneys to generate sufficient bicarbonate results in metabolic acidosis in which chloride, a “measured” anion, is the predominant anion. Therefore, the anion gap does not widen. This classification divides metabolic acidosis, therefore, into those with an increased anion gap and those without an increase in the anion gap. The latter are often called *hyperchloremic metabolic acidosis*.

While challenged by some investigators, an additional calculation may be helpful. Because an increase in anion gap must be due to the addition of a strong acid, the increase in the anion gap must be equal to the fall in plasma bicarbonate. Thus, adding the numerical increase in anion gap to the measured plasma bicarbonate estimates the plasma bicarbonate “before” the anion gap acidosis occurred. If the sum is below normal (22–26 meq/L), then a preexisting low plasma bicarbonate can be assumed (ie, metabolic acidosis or chronic respiratory alkalosis). On the other hand, if the calculated sum is greater than 26 meq/L, then the preexisting plasma bicarbonate can be assumed to be high (ie, chronic respiratory acidosis or metabolic alkalosis). This estimate is not perfect, but if the clinical situation fits, it may allow the identification of mixed acid-base disturbances that otherwise might be missed.

Normal Anion Gap Metabolic Acidosis

Hyperchloremic metabolic acidosis occurs from one of four mechanisms: (1) dilution of extracellular buffer (bicarbonate) by bicarbonate-free solutions, (2) addition of net hydrochloric acid, (3) a defect in renal acidification, or (4) renal excretion of large quantities of nonchloride anions with reabsorption of chloride. Dilutional acidosis occurs when patients are rapidly infused with a solution devoid of buffering compounds. For example, a large volume of normal saline is given to resuscitate a trauma victim or patient with hypovolemic shock. Dilutional acidosis is usually mild; plasma bicarbonate is rarely less than 15 meq/L. In response, the kidneys correct the situation by maximizing urine acidification and natriuresis to normalize the extracellular volume. Saline-based crystalloids are avoided by some clinicians who favor lactated Ringer’s solution for large volume replacement. In some trials, small differences in hemodynamic variables and degree of acidemia have been noted.

Administration of dilute hydrochloric acid for treatment of severe metabolic alkalosis is rarely needed, but excess hydrochloric acid will result in hyperchloremic metabolic acidosis. More commonly, bicarbonate is lost as a result of gastrointestinal losses from diarrhea or fluids from fistulas. Regeneration of bicarbonate in the lower gastrointestinal tract accounts for net addition of hydrogen ion to blood without adding an unmeasured anion. When loss of bicarbonate is severe, extracellular volume depletion, electrolyte imbalances, and stimulation of aldosterone and renin ensues. In response

to such conditions, net renal acid excretion increases, with a tendency for urine pH to rise because of ammonium production.

Failure of normal urinary acidification increases bicarbonate losses. This condition, called *renal tubular acidosis*, leads to metabolic acidosis because the kidneys are unable to compensate for normal acid production or fail to reabsorb normal amounts of filtered bicarbonate. At least four subtypes of renal tubular acidosis exist, differentiated on the basis of the primary tubular abnormality. These differ in the site of abnormality (proximal or distal tubule), mechanism, and ease of correction with alkali therapy. In the absence of renal failure, these are relatively rare disorders, except for type 4 renal tubular acidosis. This disorder, commonly seen in diabetics, is caused by deficiency of aldosterone and is identified by mild metabolic acidosis in association with hyperkalemia. Treatment is not always needed and involves replacement of mineralocorticoid function with fludrocortisone. Hyperchloremic metabolic acidosis can be caused by acetazolamide, a carbonic anhydrase inhibitor and diuretic. Acetazolamide inhibits proximal tubular bicarbonate reabsorption; the result is metabolic acidosis with inappropriate loss of renal tubular bicarbonate, a drug-induced renal tubular acidosis.

Patients with diabetic ketoacidosis (DKA) almost always will present with an anion gap metabolic acidosis. Because, however, the anions of the keto acids β -hydroxybutyrate and acetoacetate are readily excreted in the urine, the anion gap may not persist in patients who are able to maintain

adequate glomerular filtration. Thus a small fraction of those with DKA will present with an anion gap increase that is smaller than the decrease in plasma bicarbonate. That is, there is both anion gap and non-anion gap metabolic acidoses. While unusual at the start of DKA, this feature is seen in as many as 80% of patients during treatment. The mechanism is the urinary loss of anions of the keto acids while bicarbonate regeneration is too slow to correct for the earlier loss of bicarbonate. Several days are sometimes required for the bicarbonate to return to normal.

Anion Gap Metabolic Acidosis

The major causes of metabolic acidosis with elevated anion gap are listed in Table 2–17. Except for uremia, they all occur acutely and are due to overproduction or administration of a strong acid that dissociates into a hydrogen ion and an “unmeasured” anion. Unlike renal tubular acidosis, renal mechanisms for acid handling are intact but are unable to keep pace with the extent of acid production.

A. Lactic Acidosis—Lactic acidosis occurs in a number of situations in critically ill patients, including shock, diabetes, renal failure, liver disease, sepsis, drug intoxication, severe volume depletion, and hereditary metabolic abnormalities. Transient lactic acidosis is a feature of grand mal seizures. Patients with liver disease have difficulty removing lactate. An uncommon complication of nonnucleoside reverse transcriptase inhibitors is lactic acidosis with hepatic

Table 2–17. Common metabolic acidoses with increased anion gap.

Type	Mechanism	Unmeasured Anion	Treatment Approach
Lactic acidosis	Decreased perfusion (shock) Drugs Seizures Exercise	Lactate	Treat underlying disorder
Diabetic ketoacidosis	Diabetes (type 1 or type 2), insufficient insulin	β -Hydroxybutyrate, acetoacetate	Insulin, fluid replacement
Alcoholic ketoacidosis	Acute ethanol ingestion		Fluid replacement, glucose
Salicylate	Ingestion	Salicylate, lactate	Alkaline diuresis, hemodialysis
Ethylene glycol	Ingestion	Glycolate	Hemodialysis, alcohol dehydrogenase inhibitors, ethanol
Methanol	Ingestion	Formate	Hemodialysis, alcohol dehydrogenase inhibitors, ethanol
Uremia	Renal failure	Inorganic acid anions (sulfate, phosphate)	NaHCO_3 , dialysis

steatosis. A proposed mechanism is inhibition of mitochondrial DNA synthesis with impaired oxidative phosphorylation and resulting lactic acidosis. Metformin is reported to be a rare cause of lactic acidosis. Identification and correction of the underlying process are essential to the management of this disorder. Specific therapy for this and other causes of metabolic acidosis will be discussed subsequently.

B. Ketoacidosis—Ketoacidosis is most commonly due to poorly controlled diabetes mellitus, occasionally in those with heavy ethanol consumption in the absence of food intake (alcoholic ketoacidosis), and during starvation. In all cases, keto acids (β -hydroxybutyrate and acetoacetate) derived from oxidation of fatty acids in the liver accumulate. In alcoholic ketoacidosis, β -hydroxybutyrate and lactate levels rise more than acetoacetate, and blood glucose concentrations are usually only minimally elevated. Starvation produces mild ketoacidosis accompanied by mild renal wasting of sodium, chloride, potassium, calcium, phosphate, and magnesium. In all three conditions, unmeasured anions elevate the anion gap.

C. Uremia—In chronic renal insufficiency, hyperchloremic metabolic acidosis may occur initially owing to impaired ammonia generation and decreased ammonium excretion. When the GFR falls below 20 mL/min, excretion of fixed acids is impaired, adding an anion gap acidosis. Usually a mixed anion gap/non-anion gap metabolic acidosis is seen in chronic renal failure.

D. Poisons—Ingestion of ethylene glycol (radiator antifreeze), methanol, and excessive salicylic acid may give rise to anion gap metabolic acidosis. Ethylene glycol is oxidized by alcohol dehydrogenase to glycolic acid, which is the major acid found in the blood. Further oxidation produces oxalic acid, with resulting sodium oxalate crystals precipitating in the urine. Lactic acid may be present if circulatory shock develops. Methanol is oxidized to formaldehyde and formic acid. Although salicylate is itself a weak acid, it probably produces its major effect by inducing simultaneous lactic acidosis. Isopropyl alcohol ingestion is sometimes thought to cause an anion gap metabolic acidosis, but oxidation of this alcohol produces acetone and no strong acid. The management of poisoning is discussed in greater detail in Chapter 36.

Clinical Features

A. Symptoms and Signs—The physical findings associated with mild acidemia are nonspecific and may reflect the underlying disease or associated conditions. As acidosis worsens, increased respiratory rate and tidal volume (Kussmaul respiration) provide partial respiratory compensation. Peripheral vasodilation occurs and produces palpable cutaneous warmth. Paradoxical venoconstriction increases central pooling and may result in pulmonary edema. Cardiac contractility may decrease below a pH of 7.10 and may result in reduced blood pressure or shock. CNS depression produces

fatigue, weakness, lethargy, and ultimately stupor and coma, but CNS disturbances are much more common with respiratory acidosis at similar pH.

Metabolic acidosis is associated with poorer prognosis in the ICU possibly because it is now recognized that low pH induces release of nitric oxide and inflammatory mediators regardless of the cause of acidemia.

B. Laboratory Findings—The anion gap calculation separates those with anion gap metabolic acidosis from those with non-anion gap acidosis, so plasma sodium, chloride, and bicarbonate must be measured. Because pH determines the severity of metabolic acidosis and not plasma bicarbonate, an arterial blood gas determination is essential.

In patients with an increased anion gap, the unmeasured anion sometimes can be identified. Serum lactate levels are elevated (>2 – 3 meq/L) when lactic acidosis is the cause of a high anion gap acidosis. DKA is often accompanied by hypokalemia, hypomagnesemia, and hypophosphatemia, along with hyperglycemia. The ratio of keto acids present depends on the intracellular redox potential (NADH:NAD ratio). Because the commonly used nitroprusside reaction measures only the acetoacetate, tests for ketones may be negative if the β -hydroxybutyrate:acetoacetate ratio is very high. Alcoholic ketoacidosis presents with similar laboratory findings to DKA, except that glucose is only minimally elevated. Because β -hydroxybutyrate is the predominant keto acid, testing for ketones may be negative. With starvation, decreased serum concentrations of sodium, chloride, potassium, calcium, phosphate, and magnesium may be present. Ingestion of ethylene glycol or methanol causes an increased osmolal gap that persists until the toxic alcohol is metabolized.

Laboratory tests in a patient with hyperchloremic non-anion gap acidosis may help to distinguish renal causes from a nonrenal cause such as diarrhea. Calculation of the urine anion gap ($[\text{Na}^+] + [\text{K}^+] - [\text{Cl}^-]$) may be helpful. The normal urine anion gap is negative because of the presence of ammonium, an unmeasured cation. The urine anion gap becomes more negative as the ammonium concentration increases, which is seen in hyperchloremic metabolic acidosis caused by diarrhea or some other extrarenal mechanism. On the other hand, the urine anion gap becomes positive when ammonium excretion fails to increase or if there is bicarbonaturia indicative of renal tubular acidosis. Findings associated with ingestions are specific to the toxin and are discussed in Chapter 36. The specific anion is usually not measured when, for example, one of the commonly ingested toxic alcohols is present. Of note, isopropyl alcohol ingestion is associated with ketonemia but does not cause metabolic acidosis. When uremia is the cause, increases in serum potassium, serum urea nitrogen, and serum creatinine are typically observed.

Differential Diagnosis

The history and careful questioning regarding drug intake and use are essential in determining the cause of the acidosis.

When ingestion is suspected, microscopic examination of the urine looking for oxalate crystals may aid in the diagnosis of ethylene glycol ingestion. Similarly, visual impairment, nausea and vomiting, and disordered CNS functioning are characteristic of methanol ingestion. A history of insulin requirement and use—along with the blood glucose concentration— aids in the diagnosis of DKA. Differentiation between hyperchloremic acidosis and renal tubular acidosis is aided by calculation of the urine anion gap and the presence or absence of diarrhea.

Treatment

A. Assessment of the Need for Therapy—Whenever metabolic acidosis is present, a diligent search should be made for its underlying cause. Therapy directed toward treatment of the primary disorder is instituted. Correction of fluid and electrolyte disturbances is key in patients with DKA or with lactic acidosis owing to hypovolemic, septic, or cardiogenic shock and in patients with various toxic ingestions.

There are few data supporting improved patient outcome with treatment directed specifically at the metabolic acidosis in patients with anion gap acidosis, including DKA and lactic acidosis. However, there are few or no randomized trials in patients with severe acidemia. Thus, when acidemia is acute and the pH falls below 7.00, directed therapy should be considered. For pH values between 7.00 and 7.20, the need to treat should be individualized based on such considerations as the patient's level of stability and the presumed cause of the disturbance. There is experimental evidence that bicarbonate therapy of acute lactic acidosis may promote further lactate production and actually worsen the situation. Furthermore, bicarbonate buffering yields considerable carbon dioxide that produces severe local respiratory acidosis. However, because severe acidosis acts as a myocardial and circulatory depressant, treatment should be considered if there is evidence of circulatory impairment and other factors have been addressed.

When acidosis is chronic, as with uremia or the renal tubular acidosis syndromes, the need for treatment should be based on the patient's overall status and the presence of signs and symptoms related to the acidosis, as well as the absolute arterial pH itself.

B. Treatment—If treatment is indicated for severe metabolic acidosis, intravenous sodium bicarbonate is the preferred agent. It is most commonly supplied in 50-mL ampules containing 44.6 meq of HCO_3^- . The amount of bicarbonate required is based on the degree of acidemia. Because the administered base will partition equally between intracellular and extracellular spaces, dosing is based on total body water (approximately one-half the total body weight) and the extent of the acidemia. Typically, one-half the bicarbonate required to completely correct the deficit is administered acutely, with the rest given by slow intravenous infusion over the ensuing 8–12 hours. For example, if a 70-kg patient has a bicarbonate concentration of 14 meq/L, the amount of bicarbonate administered acutely can be calculated as follows:

$$[\text{HCO}_3^-] \text{ deficit} = \text{normal concentration} - \text{present concentration} = (24 - 14) = 10 \text{ meq/L}$$

$$\text{Distribution volume} = \text{total body water} \times 0.5 \\ = 70 \times 0.5 = 35 \text{ L}$$

$$\text{Dose} = \text{deficit} \times \text{distribution} \times 0.5 \text{ (to correct half the deficit)} = 10 \times 35 \times 0.5 = 175 \text{ meq}$$

Some laboratories calculate base deficit from blood gas values. The base deficit is an approximation of base (or bicarbonate) depletion secondary to metabolic causes. The base deficit usually is reported as a positive number. It is negative when a base excess is present. The base deficit can be used to calculate the amount of bicarbonate required according to the following equation:

$$[\text{HCO}_3^-] \text{ required} = \text{base deficit} \times 0.4 \\ \times \text{body weight (kg)}$$

The amount of sodium bicarbonate required to completely correct the deficit is then halved to arrive at an appropriate dose.

Because of the considerable intracellular buffering of hydrogen ion in severe acidosis, the bicarbonate volume of distribution can be underestimated. Thus the improvement in pH may be less than expected. However, because of the risks of excessive bicarbonate therapy and the greatest benefit seen in correcting severe acidosis, the goal is to correct pH to more than 7.20 and often to much less than that (see below).

Bicarbonate must be administered with extreme care in patients with potentially compromised respiratory status because the combination of HCO_3^- with excess H^+ will yield H_2O and CO_2 . Acute respiratory acidosis may occur. On the other hand, if the metabolic acidosis is chronic or well compensated by respiratory mechanisms, rebound alkalosis can follow bicarbonate administration. Because bicarbonate is administered as the sodium salt and given in high concentration, both volume overloading and hyperosmolality can result.

Current Controversies and Unresolved Issues

No issue in critical care medicine remains more controversial and less resolved than the administration of bicarbonate in acute metabolic acidosis. Animal studies support both a benefit of bicarbonate in severe acidosis and numerous complications of such therapy. Human studies are limited because, although inconclusive, they have not randomized patients with severe acidosis. It is very likely that the outcome of patients with metabolic acidosis is more closely linked to the underlying disease than to the severity of acidemia. In the words of some investigators, there is no evidence that bicarbonate therapy improves the outcome for any patient with an acute anion gap metabolic acidosis (DKA or lactic acidosis).

A small increase in pH in patients with severe metabolic acidosis can be associated with significant improvement in the function of physiologic systems. Because a patient with a very low serum bicarbonate (2–4 meq/L) will have a substantial increase in pH when the bicarbonate reaches 6–8 meq/L, one approach is to treat only those who have very severe metabolic acidosis and administer only a relatively small amount of sodium bicarbonate. In theory, this patient will have the greatest potential benefit, less generation of carbon dioxide, and minimal risks of volume overload and hyperosmolality.

Another approach has been to use non-CO₂-generating buffering agents. A mixture of carbonate and bicarbonate has been given experimentally. This product, called *carbicarb*, generates a smaller amount of CO₂ for the degree of buffering, but clinical experience is limited. There are studies using tris(hydroxymethyl)aminomethane (THAM) as a buffering agent. This compound, which also does not produce CO₂ during use, may be a useful alkalinizing agent if further studies demonstrate its value.

▶ Metabolic Alkalosis

ESSENTIALS OF DIAGNOSIS

- ▶ Alkalemia with increased plasma [HCO₃⁻].
- ▶ Lethargy and confusion progressing to seizures in severe cases.
- ▶ Ventricular and supraventricular arrhythmias.
- ▶ Impaired oxygen delivery because of increased hemoglobin affinity for oxygen.

General Considerations

Metabolic alkalosis consists of the triad of increased [HCO₃⁻], increased pH, and decreased plasma chloride concentration.

The principal mechanisms leading to metabolic alkalosis include (1) addition of bicarbonate to the plasma, (2) loss of hydrogen ion, (3) volume depletion, (4) chronic use of chloruretic diuretics, and (5) potassium depletion.

Pathophysiology

A. Addition of Bicarbonate—Addition of bicarbonate is an unusual cause of metabolic alkalosis but may occur with prolonged administration of high amounts of alkali (milk-alkali syndrome) or after therapy with solutions that contain bicarbonate, carbonate, acetate, lactate, or citrate. In normal adults, up to 20 meq/kg per day of bicarbonate may be administered without significantly altering plasma pH.

When calcium and vitamin D intakes are high, as in the milk-alkali syndrome, nephrocalcinosis causes renal insufficiency and diminishes GFR. This reduced renal capacity permits the retention of bicarbonate and increases pH. High concentrations of acetate in hyperalimentation fluids may be an unsuspected cause in critically ill patients. When the GFR is normal, elevated plasma bicarbonate results in the presentation of increased bicarbonate to the proximal tubules, which reduces bicarbonate reabsorption and causes bicarbonaturia.

B. Vomiting—Prolonged emesis and nasogastric suction are the most common causes of loss of hydrogen ion leading of metabolic alkalosis in critically ill patients. Parietal cells produce hydrochloric acid from carbonic acid, and for each proton secreted into the gastric lumen, one molecule of bicarbonate is returned to the blood. Reduction in intravascular volume stimulates renal sodium reabsorption with loss of potassium. Avid sodium reabsorption is accompanied by chloride reabsorption, and when chloride is depleted, bicarbonate is reabsorbed. This counterproductive response results in a paradoxical aciduria when urine should be maximally alkaline in response to metabolic alkalosis.

C. Volume Depletion—Volume depletion accompanies many types of chronic metabolic alkalosis. Volume depletion may generate and certainly maintains metabolic alkalosis. In response to volume depletion, renin and aldosterone production are increased, and these stimulate renal tubular sodium reabsorption and potassium secretion. Furthermore, because hydrogen ion secretion by the α -intercalated cells of the collecting tubules is sensitive to the concentration of aldosterone, hyperreninemia also increases bicarbonate reabsorption in the distal tubules.

Thiazide and loop diuretics are important causes of volume depletion and metabolic alkalosis, but there are important additional factors with these drugs. Sodium delivery to the distal tubule is increased, stimulating increased hydrogen and potassium secretion. As extracellular volume falls, renin secretion further enhances renal hydrogen and potassium losses. Hypokalemia stimulates ammoniogenesis and increases ammonium excretion with further loss of hydrogen

ion. Thus additional bicarbonate is generated, and metabolic alkalosis is created and sustained by the combined effects of increased distal tubular sodium delivery, elevated aldosterone levels, and hypokalemia. Administration of saline and potassium increases GFR and repairs the hypokalemia, permitting excretion of the accumulated bicarbonate.

There has been ongoing debate about the specific role of chloride ion compared with volume repletion alone. Earlier experiments seemed to demonstrate that replacement of volume deficit with non-chloride-containing solutions led to prompt bicarbonaturia and resolution of the metabolic alkalosis. However, more recently, administration of chloride-containing solutions corrected the alkalosis (bicarbonaturia) despite insufficient volume replacement, suggesting a key role for chloride. This is why some patients with metabolic alkalosis who have volume depletion and hypokalemia are variably termed *volume-responsive* or *chloride-responsive*.

D. Potassium Depletion—Potassium depletion results in a shift of hydrogen ions into the cells, raising pH. However, potassium depletion increases renal ammonia generation and reduces potassium secretion in the distal nephron, stimulating bicarbonate generation and reabsorption. A combination of potassium depletion and mineralocorticoid excess is associated with marked refractory metabolic alkalosis.

E. Other Causes—Some nonreabsorbable anions (eg, penicillin and carbenicillin anion) promote tubular secretion of hydrogen and potassium by increasing luminal electronegativity. The metabolic alkalosis produced can be repaired readily by administering NaCl and potassium. A related cause is seen in the ICU and follows carbohydrate refeeding after starvation ketoacidosis. During the period of starvation, renal production of bicarbonate in response to the acidemia helps to maintain pH. However, when refeeding is instituted, ketones are converted into bicarbonate, thereby producing metabolic alkalosis. Coexisting potassium and volume depletion will maintain the alkalosis unless sodium chloride and potassium are provided.

Other common causes of metabolic alkalosis, categorized by physiology and response to NaCl or KCl infusion, are listed in Table 2-18. On rare occasions, a patient requiring critical care will present with hypervolemia, mild to moderate hypertension, hypokalemia, metabolic alkalosis, and primary hypersecretion of aldosterone. A similar situation may be seen with administration of mineralocorticoids or corticosteroids with mineralocorticoid activity. These metabolic alkalosis states are associated with hypervolemia, so they are not volume- or chloride-responsive. Rarely, adult patients with Gitelman's syndrome will be seen in the ICU. The defect is located in the thiazide-sensitive NaCl cotransporter in the distal tubule, resulting in a thiazide diuretic-like syndrome of hypokalemia, metabolic alkalosis, hypocalciuria, and hypomagnesemia.

Table 2-18. Causes of metabolic alkalosis.

I. Exogenous bicarbonate administration: Bicarbonate, citrate, acetate, lactate Milk-alkali syndrome
II. Volume contraction + potassium depletion (saline-responsive) Gastrointestinal loss (emesis, gastric suction, villous adenoma) Renal loss (loop and thiazide diuretics) Posthypercapnic states Nonreabsorbable anions (ketones, penicillin, carbenicillin) After treatment for lactic acidosis or ketoacidosis Carbohydrate refeeding after starvation Hypokalemia, hypomagnesemia
III. Volume expansion + potassium deficiency (not saline-responsive) High renin (malignant hypertension, renin-secreting tumor) Low renin (primary hyperaldosteronism, adrenal enzymatic defects, Cushing's disease)

Clinical Features

A. Symptoms and Signs—Symptoms and physical findings with mild metabolic alkalosis are nonspecific and usually are related more closely to the underlying disorder than to the acid-base disturbance itself. Review of the patient's medical record with particular attention to medications received and fluid balance will often aid in determining the origin of alkalemia. On physical examination, a difference between supine and sitting blood pressures may reveal hypovolemia. Hypertension suggests hypervolemia. When both hypertension and metabolic alkalosis are present, a history of glucocorticoid or mineralocorticoid use or endogenous aldosterone production should be considered.

A decrease in minute ventilation is usually noted in moderate cases of metabolic alkalosis. If preexisting pulmonary disease is present, CO₂ retention may result in severe hypercapnia. As alkalemia progresses, the ionized calcium concentration decreases and produces neuromuscular findings similar to those of hypocalcemia. Initial lethargy and confusion give way to obtundation and seizures as the alkalemia worsens. Patients may complain of paresthesias and muscle cramps. The Chvostek and Trousseau signs may be present. In severe cases, respiratory muscle paralysis may develop.

Alkalemia acts as a negative inotrope, with the change in blood pressure depending on the degree of hypo- or hypervolemia. Furthermore, the increase in pH lowers the arrhythmia threshold, with supraventricular and ventricular arrhythmias predominating. There are no electrocardiographic abnormalities specific for alkalemia, although the presence of arrhythmias should alert the clinician to the potential severity of the acid-base disturbance.

B. Laboratory Findings—An increase in plasma [HCO₃⁻] may be present with either chronic respiratory acidosis or

metabolic alkalosis. The arterial pH is essential to make the distinction. Comparison of the PaCO_2 with the nomogram in Figure 2–5 will aid in determining whether any respiratory compensation is appropriate or whether a mixed acid-base disorder is present.

Once it has been determined that simple metabolic alkalosis is present, further evaluation will determine the cause of the disorder. Plasma potassium is almost always decreased. The magnitude of total body potassium depletion cannot be estimated precisely from the plasma potassium. Hyponatremia is common in hypovolemic disorders, which are ultimately responsive to saline infusion.

A useful distinction can be made by separating metabolic alkaloses into those that are chloride-sensitive (sometimes called *volume-* or *saline-responsive*) and those that are non-chloride-sensitive. Chloride- or volume-sensitive patients are volume-depleted, hypokalemic, and will respond to chloride or volume administration (see above). The latter group is usually volume overloaded and will worsen or fail to improve with chloride-containing solutions or volume repletion.

These groups can be distinguished by measurement of urine chloride. Volume contraction usually is accompanied by concentrated urine with a low sodium concentration. However, if metabolic alkalosis develops, high renal tubular bicarbonate concentrations may encourage sodium to be spilled into the urine. Thus there is a paradoxically high urine sodium and fractional excretion of sodium despite volume depletion. However, urine chloride can be relied on in this situation. A low urine $[\text{Cl}^-]$ (<10 meq/L) indicates potential volume-responsive or chloride-responsive metabolic alkalosis. On the other hand, diuretics will confuse this picture because both urine sodium and urine chloride will be increased despite the hypovolemia. Hypomagnesemia from gastrointestinal and renal losses is observed occasionally in this situation.

When primary hyperaldosteronism is the cause of metabolic alkalosis, urinary sodium and chloride outputs are approximately equal to intake and in the range of 100–200 meq/L. Volume expansion and hypertension are usually present.

Differential Diagnosis

Once a high plasma bicarbonate is identified, the most important distinction must be made between metabolic alkalosis and chronic respiratory acidosis with renal compensation. Diuretic therapy may superimpose additional metabolic alkalosis on top of chronic respiratory acidosis, which further increases the $[\text{HCO}_3^-]$ and actually may result in an alkaline pH. Noting increased concentrations of sodium and chloride in the urine prior to discontinuation of diuretic therapy is a useful tool. When simple metabolic alkalosis is present, the distinction between chloride-responsive and chloride-unresponsive disorders should be made.

Treatment

It has become clear that alkalemia in critically ill patients is associated with poor outcome, just as acidemia is linked to decreased survival. The underlying disease in all situations must be addressed to slow or reverse the cause of metabolic alkalosis. The decision to treat is based on both the severity of alkalemia and the risks of complications.

A. Saline-Responsive Metabolic Alkalosis—Mild alkalemia (pH 7.40–7.50) is well tolerated and does not require treatment unless preexisting cardiac or pulmonary disease complicates the situation. If the alkalemia worsens (pH >7.60), or if findings consistent with cardiac, pulmonary, or neuromuscular complications appear, treatment is indicated.

The key to therapy is restoration of normal circulating blood volume and repair of the associated hypokalemia. Potassium replacement can be estimated from the extent of the potassium deficit. The volume of normal saline required should be infused so that one-half the deficit is replaced within 8 hours and the remainder within the ensuing 16 hours. As discussed earlier, there is evidence that chloride-containing solutions stimulate a more marked bicarbonaturia, leading to more rapid correction of the alkalosis. Therefore, volume repletion preferentially should be with NaCl and KCl solutions.

In unusual situations, acetazolamide, an inhibitor of carbonic anhydrase, can be used to correct metabolic alkalosis as long as the patient is not volume-depleted. This situation is encountered rarely, and the drug will exacerbate both volume depletion and hypokalemia. Acetazolamide, 250–500 mg, can be given orally and repeated if necessary with close monitoring of plasma potassium. Very rarely, if alkalemia is extremely severe, dilute hydrochloric acid (0.1 mol/L) can be infused into a central vein. The quantity required can be calculated from the plasma bicarbonate concentration. Assuming that the volume of distribution of bicarbonate is that of total body water (one-half body weight), the amount of HCl required is calculated as follows:

$$\text{HCl required (meq)} = ([\text{HCO}_3^-] - 24) \times 0.5 \times \text{weight (kg)}$$

One-half the calculated dose should be given over the first 4–8 hours, with the remainder infused over the next day. Hyperkalemia is a major potential complication of this therapy. Several other acidifying agents have been used, including ammonium chloride, arginine monohydrochloride, and lysine monohydrochloride. The latter two should not be given because of the very high risk of hyperkalemia, sometimes fatal, associated with large and rapid shifts of potassium out of the cells.

B. Saline-Resistant Metabolic Alkalosis—These disorders are encountered rarely and may result from reversible (drug-induced) causes or abnormal endogenous secretion of aldosterone. In both cases, mineralocorticoids lead to sodium retention and potassium excretion despite elevated extracellular volume and hypokalemia.

Therapy of these disorders should be aimed at identifying the source of the aldosterone or other mineralocorticoid. When the condition follows excessive administration of mineralocorticoids, their use should be stopped. If the patient has excessive aldosterone secretion from an adrenal adenoma, medical management with an inhibitor of aldosterone (eg, spironolactone) may play a role until more definitive therapy can be planned.

► **Respiratory Acidosis**

ESSENTIALS OF DIAGNOSIS

- ▶ Acidemia with increased P_{aCO_2} and near-normal (acute) or appropriately elevated $[HCO_3^-]$ (chronic).
- ▶ Fatigue, weakness, confusion, and headaches.
- ▶ If severe, lethargy, stupor, and coma.
- ▶ Decreased cardiac contractility, pulmonary artery hypertension, and splanchnic vasodilation.

General Considerations

Elevated P_{aCO_2} (hypercapnia) with resulting acidemia is termed *respiratory acidosis*. After going into solution, dissolved CO_2 turns into hydrogen ion and bicarbonate. The major problem in acute hypercapnia is that dissolved CO_2 can rapidly produce tissue acidosis because CO_2 diffuses easily into tissues and cells. This is particularly important at the blood-brain barrier, such that the pH of CSF falls rapidly after an acute increase in P_{aCO_2} .

Hypercapnia is usually attributed to lung disease, such as COPD. However, hypercapnia can be produced either by an increase in the production of CO_2 without compensatory elimination or by constant production with decreased elimination. The second mechanism is usually seen in patients with COPD or restrictive pulmonary disease, in those with a severely deformed chest wall or neuromuscular weakness, after trauma, and following anesthesia, where either the respiratory mechanics or the drive for CO_2 elimination are compromised.

Increased CO_2 production is not uncommon because CO_2 output follows metabolic rate, and patients in the ICU are frequently hypermetabolic. What is unusual, however, is failure of the ventilatory control mechanisms to respond to the increase in CO_2 production by stimulating ventilation and maintaining P_{aCO_2} at a constant value.

Common causes of respiratory acidosis among critically ill patients are listed in [Table 2–19](#), and there is

additional discussion of hypercapnic respiratory failure in Chapter 12.

An acute change in P_{aCO_2} produces a blood pH change within minutes. There is a small rise in plasma bicarbonate concentration owing to acute “mass action” shifts. The predicted response of $[HCO_3^-]$ is an increase of approximately 0.25 meq/L for each 1 mm Hg increase in P_{aCO_2} . More marked changes in plasma bicarbonate concentration suggest that a mixed acid-base disturbance is present.

Hypercapnia stimulates renal ammonia production and increases urinary ammonium excretion because of an increase in local P_{aCO_2} and because of the fall in pH. Urine pH decreases appropriately as newly generated bicarbonate is added to the blood in exchange for acidifying the urine. An increase in bicarbonate absorptive capacity also occurs so that increased quantities of filtered bicarbonate can be reabsorbed completely. Once equilibrium has been reached after several days, the plasma bicarbonate concentration should increase by about 0.5 meq/L for each 1 mm Hg increase in P_{aCO_2} . Arterial pH actually may become slightly alkalemic because of the avid retention of bicarbonate; this is one situation in which “complete” correction may occur and may not represent a mixed acid-base disturbance.

Clinical Features

A. Symptoms and Signs—There are no symptoms or signs specific to mild respiratory acidosis. Findings are usually

Table 2–19. Causes of respiratory acidosis.

Acute	Chronic
Airway obstruction Emesis with aspiration Bronchospasm Laryngospasm	Airway obstruction Chronic obstructive pulmonary disease
Respiratory center depression General anesthesia Sedative or narcotic over-dose Head injury	Respiratory center depression Chronic sedative overdose Obesity (Picwickian syndrome) Brain tumor
Circulatory collapse Cardiac arrest Pulmonary edema	
Neurogenic causes Cervical spine injury Guillain-Barré syndrome Myasthenic crisis Drugs (paralytic agents, organophosphates)	Neurogenic causes Multiple sclerosis Muscular dystrophy Amyotrophic lateral sclerosis Myxedema Posttraumatic diaphragmatic paralysis Phrenic nerve injury
Restrictive defects Hemothorax or pneumothorax Flail chest ARDS	Restrictive defects Hydrothorax or fibrothorax Ascites Obesity

related to the underlying cause, such as COPD, obesity-hypoventilation syndrome, CNS disease, or severe hypothyroidism. When airway obstruction is the cause, patients may present with shortness of breath and labored breathing. If respiratory center depression is the cause, slow and shallow or even apneustic breathing may be noted. As discussed in Chapter 12, patients may have tachypnea or hyperpnea (increased minute ventilation) despite hypercapnia (alveolar hypoventilation).

In cases of marked respiratory acidosis, fatigue, weakness, and confusion are present. In milder cases, patients may complain of headache. Physical findings are nonspecific and include tremor, asterixis, weakness, incoordination, cranial nerve signs, papilledema, retinal hemorrhages, and pyramidal tract findings. The syndrome of pseudotumor cerebri (increased CSF pressure and papilledema) may be simulated by respiratory acidosis. Coma begins at levels of CO_2 that vary from 70–100 mm Hg depending on arterial pH (pH <7.25) and the rate of increase of PaCO_2 . It is critical to remember that almost all patients with hypercapnia will have concomitant hypoxemia unless they are receiving supplemental oxygen.

B. Laboratory Findings—Respiratory acidosis is manifested by acidemia and elevated PaCO_2 in the presence of an appropriate $[\text{HCO}_3^-]$ (see Figure 2–5). Because renal ammonia production and hydrogen ion secretion are stimulated, urine pH falls. In chronic respiratory acidosis, plasma pH may be very close to normal as bicarbonate concentration rises in compensation. A mild increase in potassium secretion occurs, although hypokalemia is not inevitable.

Treatment

The key to management of respiratory acidosis is correction of its primary cause (see Chapter 12). For some patients, this will require endotracheal intubation and mechanical ventilation or noninvasive positive-pressure ventilation.

Restoration of pH and PaCO_2 should take place over several hours if the respiratory acidosis is chronic to prevent alkalemia. The compensatory increase in plasma bicarbonate in response to hypercapnia may take hours to days to be eliminated if the PaCO_2 is immediately corrected to normal. This results in a form of “metabolic alkalosis” that requires renal elimination of bicarbonate to a normal value. In many patients, overcorrection of chronic hypercapnia to normal is not advised because these patients have poor lung or ventilatory function. When mechanical ventilation is removed, they will be unable to maintain sufficient ventilation to keep the PaCO_2 at the lower level, resulting in recurrence of severe acute respiratory acidosis.

In general, there is no role for respiratory stimulant drugs except in a few circumstances. Administration of antagonists to opiates or benzodiazepines may be helpful if respiratory depression from these agents is suspected.

Current Controversies and Unresolved Issues

Acute hypercapnia and respiratory acidosis almost always can be reversed effectively by increasing minute ventilation until the underlying disorder can be treated (eg, COPD, neuromuscular weakness, etc.). It is now recognized that excessively high tidal volume may be associated with damage to the lungs, prolonged hospitalization, and increased mortality. Therefore, low tidal volume strategies are recommended (see Chapter 12). The consequence is mild to moderate hypercapnia in some of these patients. The bulk of the evidence from large studies suggests that such hypercapnia is well tolerated and rarely associated with complications. In fact, some studies have suggested that hypercapnia is not merely a consequence that must be tolerated but that it actually may be instrumental in improving outcomes of patients with acute lung injury (eg, ARDS). For example, in ARDS, a tidal volume of 6 mL/kg was associated with lower mortality than 12 mL/kg. However, in the patients randomized to 12 mL/kg, the odds ratio for mortality was 0.14 in those who were hypercapnic compared with those with a normal PaCO_2 .

While there have been limited studies of the effects of ameliorating the fall in pH during so-called permissive hypercapnia, it remains to be seen if preventing the fall in pH with bicarbonate or other buffers is beneficial, hazardous, or neither. Nonbicarbonate buffers may be preferred to avoid generation of additional CO_2 .

▶ Respiratory Alkalosis

ESSENTIALS OF DIAGNOSIS

- ▶ Alkalemia with decreased PaCO_2 and normal or appropriately decreased $[\text{HCO}_3^-]$.
- ▶ Anxiety, irritability, vertigo, and syncope.
- ▶ Flattened ST segments or T waves.
- ▶ Tetany in severe cases.

General Considerations

A primary decrease in arterial PCO_2 (hypocapnia) indicates respiratory alkalosis. By definition, alveolar hyperventilation is synonymous with hypocapnia. The most common causes

of hyperventilation include hypoxemia, CNS disorders, pulmonary disease, and excessive mechanical ventilation. Patients who are anxious, pregnant, have liver failure, or are toxic from salicylates often will hyperventilate. A few patients seem to have primary hyperventilation of unknown mechanism. In the ICU, hyperventilation may be an early feature of sepsis. Hyperventilation resulting in respiratory alkalosis must be distinguished from the low PaCO_2 seen as compensation for metabolic acidosis. In both, PaCO_2 is reduced and plasma HCO_3^- is low. The difference is that in respiratory alkalosis, low PaCO_2 is primary and pH is above normal, whereas in metabolic acidosis, pH is in the acidic range and low HCO_3^- is the primary disturbance.

The principal compensatory response for respiratory alkalosis is renal elimination of bicarbonate, which takes several hours to days to complete. Hypocapnia itself reduces bicarbonate reabsorption from the proximal tubule, but hydrogen ion secretion in the distal nephron is also decreased, resulting in loss of tubular bicarbonate. Increased delivery of bicarbonate from the proximal tubule stimulates a marked kaliuresis. In the steady state, plasma bicarbonate concentration falls by about 0.5 meq/L for each 1 mm Hg decrease in PaCO_2 during chronic respiratory alkalosis, and there is a smaller decrease in plasma bicarbonate with acute respiratory alkalosis. The arterial pH therefore is corrected toward normal but not to normal.

Clinical Features

A. Symptoms and Signs—Severe hyperventilation may result in tetany that is clinically indistinguishable from the hypocalcemic variety except that total plasma calcium and the ionized fraction of calcium are normal. Hyperventilation also may decrease blood pressure and cerebral perfusion, which can cause increased irritability, anxiety, and inability to concentrate. Occasionally, awake patients will complain of vertigo and experience syncope. Other features are those of the underlying disorder leading to respiratory alkalosis. Patients with severe damage to the midbrain may have central neurogenic hyperventilation. Prolonged respiratory alkalosis may have adverse effects on patients with head injury despite transient reduction in intracranial pressure acutely largely because of decreased oxygen delivery and unloading in the brain. Interestingly, respiratory but not metabolic alkalosis may impair fluid resorption from lungs with pulmonary edema.

B. Laboratory Findings—The hallmark of respiratory alkalosis is the presence of alkalemia (pH >7.44) and decreased PaCO_2 in the presence of normal or decreased HCO_3^- . The extent of plasma bicarbonate reduction depends on the duration of the respiratory disorder and the effectiveness of the kidneys. The nomogram in Figure 2–5 may aid in determining whether the respiratory alkalosis is occurring alone or is a mixed disorder. Most patients with chronic respiratory alkalosis will have a decline in plasma bicarbonate of

0.5 meq/L for each 1 mm Hg decrease in PaCO_2 . Mild hyponatremia and hypochloremia often are present. Hypophosphatemia owing to excess renal phosphate wasting seems to be more marked with respiratory alkalosis than in metabolic alkalosis.

For patients with central neurogenic hyperventilation, evaluation may include CT scan or MRI of the head. Drug ingestions (particularly salicylates) can be investigated with a toxicology screen or blood salicylate determination.

Because hypoxemia appropriately may stimulate respiratory drive and cause respiratory alkalosis, the adequacy of arterial oxygenation must be assessed.

C. Electrocardiography and Electroencephalography—

Electrocardiographic changes may include ST-segment or T-wave flattening or inversion. Alterations in the QRS complex also have been reported. Electroencephalographic studies are usually normal but may show an increase in the number of slow high-voltage waves.

Differential Diagnosis

The most important differential is metabolic acidosis with respiratory compensation. As described earlier, in metabolic acidosis, the blood pH is less than 7.38, whereas respiratory alkalosis is associated with alkalemia. Mixed or combined disturbances are often seen with respiratory alkalosis—notably salicylate overdose, which may cause primary metabolic acidosis and primary respiratory alkalosis simultaneously.

Treatment

A. Correction of Underlying Disorder—The key to treatment is identification and management of underlying disorders. If the patient is hypoxemic, the inspired oxygen concentration may need to be increased. Anemia also may be contributory and may be helped by blood transfusion. Other potentially reversible causes include sepsis and liver failure. Severe CNS disorders may cause respiratory alkalosis.

B. Mechanical Ventilation—Probably the most common cause of respiratory alkalosis among critically ill patients is iatrogenic hyperventilation owing to excessive mechanical ventilation. Strict attention to blood gases and examination of trends over several days usually will disclose this problem. If the ventilator has been set to deliver too much minute ventilation and the patient is not triggering, reducing the respiratory rate and tidal volume will cause a marked and predictable fall in pH. One reasonable goal is to reduce minute ventilation just until the patient begins to trigger spontaneous ventilation. At this point, pH is likely to be near normal.

On the other hand, if the patient is already triggering the mechanical ventilator, that is, choosing the respiratory rate, then he or she is generating the primary drive for hyperventilation. In most of these cases, changing the settings on the

ventilator will not affect the patient's spontaneous respiratory rate. Hyperventilation sometimes can be moderated by increasing paradoxically the inspiratory flow rate or tidal volume.

Clinicians often opt for intermittent mandatory ventilation to treat respiratory alkalosis; controlled trials have shown that this is ineffective. Adding dead space to the ventilator circuit tubing should not be done. In rare circumstances, severe respiratory alkalosis that cannot be managed in any other way may require paralyzing the patient and controlling the PaCO_2 and pH.

Transfusion Therapy

Elizabeth D. Simmons, MD

3

The discovery of the ABO and Rh blood groups and the development of nontoxic anticoagulant-preservative solutions for blood storage during the first half of the 20th century made it possible for human blood to be widely used as lifesaving therapy in critically ill patients. Subsequent refinements in cross-matching and the development of sophisticated screening tests for transmissible diseases have made blood transfusion a safe and often lifesaving form of therapy. Because of the wide range of potential adverse effects of transfusion therapy, however, the clinician must have a clear understanding of the indications, efficacy, and complications of blood component therapy.

BLOOD COMPONENTS

In modern transfusion practice, blood is separated into various components (see Table 3–1), and individual components are selected for transfusion based on the needs of the patient. Blood component therapy is superior to whole blood replacement because it concentrates those portions of blood a patient needs, thereby increasing efficiency and minimizing volume and subsequent transfusion requirements—as well as increasing the efficiency of blood banking by putting donated blood to maximal and optimal use.

► Red Blood Cells

The products available for replacement of red blood cells are listed in Table 3–1. Homologous packed red blood cells from volunteer donors are transfused most often. Leukocyte-poor red blood cells are prepared by a variety of techniques to remove at least 70% of leukocytes. Washing red blood cells in saline removes most plasma proteins and some leukocytes and platelets. Red blood cells frozen in liquid nitrogen with glycerol as a cryoprotective agent can be stored for up to 10 years. Extensive washing after thawing removes most plasma proteins and cellular debris. Neocytes (young red blood

cells) can be prepared by differential centrifugation or cell separators and have a longer circulating life span than standard red cells, but they are rarely used. Directed donations of red blood cells from ABO- and Rh-compatible individuals who are appropriately screened may be substituted for homologous red blood cells at the patient's request. Autologous red blood cells may be collected preoperatively, by perioperative blood salvage, or by acute normovolemic hemodilution to decrease homologous red blood cell use.

Indications

Red blood cell transfusions are indicated to promote oxygen delivery in patients who are actively bleeding, for symptomatic anemia unresponsive to conservative management, or when time does not permit alternative treatment. Red blood cell transfusions also may be useful for improving the bleeding tendency of a severely anemic patient with platelet dysfunction (eg, uremia) or severe thrombocytopenia.

The decision to transfuse red blood cells should be made only after consideration of several factors. The age and general condition of the patient and the presence of coexisting cardiac, pulmonary, or vascular conditions will influence the patient's ability to tolerate acute blood loss or chronic anemia. The degree and chronicity of the anemia are also important determinants of the physiologic responses to anemia. Finally, the cause of the anemia must be considered because alternative therapy (eg, iron sulfate, vitamin B₁₂, folate, or epoetin alfa [erythropoietin]) may eliminate the need for transfusions altogether.

A. Chronic Hypoproliferative Anemia—Chronic anemia is accompanied by several physiologic adaptations that enhance oxygen delivery despite a reduced red blood cell oxygen-carrying capacity. Increased cardiac output, increased intravascular volume, and redistribution of blood flow to vital organs maintain organ function. Tissue extraction of oxygen occurs over a wide range of hemoglobin concentrations and is

Table 3-1. Blood component therapy.

Products Available	Indications for Transfusion
Red Blood Cells (RBC)	
Homologous packed RBC	Promote oxygen delivery for patients with active bleeding or severe anemia; improve bleeding tendency in severely anemic patients with platelet dysfunction; replace sickle RBC with normal RBC by exchange transfusion.
Leukocyte-poor RBC	Reduce febrile reactions; prevent HLA alloimmunization and CMV infection in potential transplant recipients or those requiring chronic platelet transfusions.
Irradiated RBC	Reduce graft-versus-host disease.
Washed RBC	Substitute for homologous RBC in patients sensitive to a plasma component; avoid transfusion of anti-A and anti-B antibodies when O-negative blood is used in patients who are type A, B, or AB.
Frozen RBC	Preserve autologous RBC; maintain store of rare blood types.
Neocytes	Increase efficacy of individual transfusion for patients with transfusion-dependent anemia.
Directed donor RBC	After screening and informed consent, may be substituted for volunteer RBC at patient request.
Autologous RBC	Decrease or eliminate need for homologous RBC in patients undergoing elective surgical procedures or obstetric delivery.
Platelets	
Random donor platelets	Treat or prevent bleeding associated with severe thrombocytopenia or platelet dysfunction; replace platelets lost with massive bleeding; treat excessive bleeding associated with cardiopulmonary bypass.
Platelet pheresis	Decrease exposure to infectious agents.
Leukocyte-poor platelets	Reduce febrile reactions; reduce HLA alloimmunization for patients requiring chronic platelet transfusions.
Irradiated platelets	Reduce graft-versus-host disease.
HLA-matched platelets	Treat bleeding associated with thrombocytopenia in patients who are refractory to platelet transfusions due to HLA sensitization.
Plasma and Derivatives	
Fresh frozen plasma (FFP)	Correct coagulation factor deficiencies in bleeding patients or those who require invasive procedures if concentrated or recombinant product not available; treat TTP/HUS, protein-losing enteropathy in infants; antithrombin III deficiency; C-1 esterase inhibitor deficiency.
Fresh plasma (liquid plasma)	Same as FFP, except does not contain factors V and VIII.
Cryoprecipitate-poor plasma	Correct coagulation factor deficiencies other than VIII, XIII, fibrinogen, vWF; may be indicated for treatment of refractory TTP.
Cryoprecipitate	Correct severe hypofibrinogenemia; may be useful for treatment of bleeding associated with uremia; provides factors VIII and XIII, fibrinogen, and vWF.
Granulocytes	
Stimulated leukapheresis	Treat severe bacterial infections unresponsive to antibiotics in patients with prolonged, severe neutropenia or congenital neutrophil dysfunction; may be indicated in the management of neonatal sepsis.

enhanced by a rightward shift in the oxyhemoglobin dissociation curve (owing to increased erythrocyte 2,3-DPG production and the Bohr effect). Additional responses to anemia include increased erythropoietin production and early release of young red blood cells into the circulation. These adaptive responses allow most individuals to tolerate severe decreases

in oxygen-carrying capacity. Therefore, red blood cell transfusions are rarely necessary for patients with chronic anemia who have hemoglobin concentrations above 7 g/dL unless significant cardiopulmonary disease is present, and transfusions may result in circulatory overload if given rapidly or in excessive quantity.

B. Acute Blood Loss—In contrast, physiologic responses may be inadequate to maintain organ function and hemodynamic stability following acute blood loss, even with apparently normal hemoglobin concentration, because it takes time for mobilization of extracellular fluid into the intravascular space and for increased production of erythrocyte 2,3-DPG. However, a healthy young person generally tolerates 500–1000 mL of acute blood loss without red blood cell transfusion, and intravascular volume can be replenished with crystalloid solutions. Acute blood loss of 1000–2000 mL usually can be managed with volume replacement alone, but red blood cell transfusions are necessary occasionally. More than 2 L of acute blood loss usually will require red blood cell transfusion. Other clinical factors are important. For example, because of the vasodilatory effects of anesthesia, intraoperative blood loss of more than 500 mL may require red blood cell transfusion to maintain hemodynamic stability, and burn patients often require vigorous blood product support because of volume depletion through denuded body surfaces.

C. High-Risk Patients—Any condition that impairs the patient's ability to increase intravascular volume, heart rate, stroke volume, or blood flow can result in poor tolerance of chronic anemia or acute blood loss (eg, patients with cardiovascular disease, volume depletion from diuretics or gastrointestinal losses, vascular fluid redistribution, and elderly patients). In these circumstances, transfusion may be necessary in patients with physiologic signs of inadequate oxygenation despite higher hemoglobin concentrations than in normal individuals with adequate physiologic reserves. The use of objective scoring systems (such as the APACHE II [Acute Physiology and Chronic Health Evaluation II] and the multiorgan dysfunction scores) to stratify patients according to severity of illness may be useful for determining which critically ill patients may benefit from a restrictive transfusion approach.

Studies have demonstrated that patients younger than 55 years of age with less severe illness may have improved outcomes using a lower hemoglobin threshold (<7 g/dL) for transfusion compared with more liberal use of transfusion (<10 g/dL). This lower threshold for transfusion appears to be at least as safe in older patients and those with more severe disease as well.

Exceptions include those with acute bleeding (discussed earlier) or myocardial ischemia. Although baseline anemia in patients with acute myocardial infarction is associated with adverse outcomes, including increased mortality, there is no clear evidence that a liberal blood transfusion strategy (ie, hemoglobin <10 g/dL as a trigger for transfusion) improves outcomes. Available clinical data are inadequate to make a firm recommendation regarding the hemoglobin threshold for transfusion for these patients; therefore, decisions about red blood cell transfusions must be individualized.

D. Hemolytic Anemia—Red blood cell transfusions are indicated in the management of some patients with a variety

of severe and symptomatic hemolytic anemias. Patients with markedly symptomatic antibody-mediated hemolytic anemias may require red blood cell transfusion until definitive therapy is effective. Autoantibodies are often reactive with all donor red blood cells in vitro such that cross-matching is impossible. Transfusion of ABO- and Rh-compatible red blood cells is usually safe in these patients; the blood bank can perform an extended cross-match to identify units with the least degree of in vitro hemolysis. Patients with cold-reacting antibodies (usually IgM) should receive blood through a blood warmer if transfusion is necessary.

E. Sickle Cell Anemia—Patients with sickle cell anemia may require red blood cell transfusion (and, in selected cases, partial or complete exchange transfusion) for management of specific complications, including splenic sequestration and aplastic crises (with rapidly falling hemoglobin concentration), recurrent priapism, chronic unremitting osteomyelitis, severe leg ulcers, pneumonia, or pulmonary sequestration crises. Red blood cell transfusion is also indicated for such patients undergoing major surgery, particularly those undergoing orthopedic procedures. Simple preoperative transfusion to achieve hematocrit levels of about 30% appears to be as effective as regimens aimed at reducing the fraction of hemoglobin S to 30% of total hemoglobin (by exchange transfusion or multiple transfusions over time) and is associated with fewer transfusion-related complications. Patients with sickle cell anemia are not candidates for autologous donation and transfusion.

Exchange transfusion is also indicated in the management of acute central nervous system infarction or hemorrhage (followed by chronic transfusion therapy to prevent recurrent strokes). Chronic prophylactic transfusion reduces the risk of initial stroke in children with sickle cell disease who have abnormal cerebrovascular blood flow on Doppler ultrasonography; however, alloimmunization (even with phenotypically matched, leukocyte-depleted red blood cells), iron overload, and infections complicating chronic transfusion programs have limited the acceptance of this approach. Furthermore, the duration of transfusion required to prevent stroke is unclear. Recent studies demonstrate that the risk of stroke increases once chronic transfusions are stopped.

Routine transfusion during pregnancy should be avoided. Patients with severe, symptomatic sickle cell anemia or those suffering recurrent painful crises may require periodic transfusion during pregnancy. Likewise, routine transfusion is not indicated in the management of painful vaso-occlusive sickle cell crises and should be reserved for patients with symptomatic anemia. Patients with sickle cell anemia appear to be unusually susceptible to the development of alloantibodies (see “Complications of Transfusion”), which limits the utility of chronic transfusion programs. The use of blood from racially matched donors that has been screened for selected minor blood group antigens may prevent alloimmunization in patients requiring chronic transfusion therapy, but this approach awaits confirmation.

F. Perioperative Transfusion—Transfusion is rarely indicated for patients undergoing noncardiac surgery who have hemoglobin values greater than 7–8 g/dL and no risk factors for myocardial ischemia. However, elderly patients with hematocrits less than 28% (hemoglobin of approximately 9 g/dL) may be at risk for myocardial ischemia during surgery, especially if tachycardia is present. In these patients—and others at risk for myocardial ischemia—a hemoglobin value of less than 10 g/dL probably warrants transfusion. The threshold for intraoperative transfusion depends on many factors, such as the presence of hemorrhage or coagulopathy, hemodynamic instability, and ischemic electrocardiographic changes.

G. Unacceptable Indications—Red blood cell transfusions should not be used to enhance a patient's general sense of well-being, to promote wound healing, or to expand vascular volume when oxygen-carrying capacity is adequate.

▶ Red Blood Cell Transfusion Requirements

There is no single hemoglobin threshold that is universally appropriate for determining transfusion requirements. The amount of red blood cells to be transfused should be determined by the clinical status of the patient rather than by the hemoglobin concentration. In patients who are actively bleeding, crystalloid volume repletion is essential. Hemodynamic instability, symptoms and signs of impaired organ function, rate of blood loss, and response to transfusion should be used to determine how much blood should be transfused. Patients with chronic anemia should receive only the amount of red blood cells necessary to reverse symptoms and signs. Patients with self-limited anemia (eg, transient blood loss, hemolysis, or marrow suppression) or those for whom alternative therapy is available (eg, nutritional deficiencies, anemia of renal failure) should receive red blood cells only when an immediate need for increased oxygen-carrying capacity is present, such as during myocardial ischemia, heart failure, impaired central nervous system oxygenation, hypotension, or other evidence of tissue hypoxia. The patient should be reevaluated after each unit of red blood cells is transfused rather than giving an arbitrary or predetermined number of units. Volume overload following red blood cell transfusion in patients with chronic severe anemia may eliminate any benefit of increasing the oxygen-carrying capacity and must be monitored carefully.

When untreatable chronic anemia is present (eg, bone marrow failure or chronic severe hemolytic anemia), red blood cell transfusions must be given conservatively to delay long-term treatment complications such as alloimmunization, infections, and iron overload. Red blood cell transfusions may be administered more liberally in the treatment of anemia associated with severe thrombocytopenia or platelet dysfunction (eg, acute leukemia or uremic bleeding episodes) because the salutary effect of increased hematocrit on platelet function may decrease platelet transfusion requirements and lessen clinical bleeding.

▶ Platelets

Platelet products available are listed in Table 3–1. The choice of platelet product depends on the underlying condition of the patient (eg, acute reversible thrombocytopenia versus chronic thrombocytopenia) as well as the local availability of supplies. Pooled random-donor platelets or single-donor platelets obtained by apheresis are the usual products transfused for correction of severe thrombocytopenia. Filtration or irradiation with ultraviolet B depletes donor platelets of leukocytes, and these are equally effective strategies for preventing alloantibody-mediated refractoriness to platelet transfusions. Such leukodepletion is appropriate for patients likely to require repeated platelet transfusions (eg, acute leukemia, aplastic anemia, and other bone marrow failure states). Leukocyte depletion performed shortly after collection of platelets also may decrease the risk of febrile reactions by preventing in vitro accumulation of cytokines, which are released during storage. Single-donor platelets decrease the total number of donor exposures and may reduce the risk of transfusion-transmitted infections but do not appear to offer additional benefit over filtration or irradiation for prevention of alloimmunization.

Product availability often will determine whether pooled platelets or single-donor platelets are transfused. Whenever possible, ABO type-specific platelets should be used; however, because platelets have a limited storage period, they are not always available. A decreased response to platelet transfusion may result from the use of ABO-incompatible platelets, but the most significant risk occurs when ABO-incompatible plasma is infused (ie, type O donor, type A or B recipient), resulting in hemolysis (estimated risk 1:9000–1:6600). Apheresis units may increase this risk by increasing the dose of incompatible plasma. If type-specific platelets are not available, pooled platelets are preferable to single-donor platelets. Washing the platelets to remove plasma may help to minimize exposure to incompatible plasma. Although platelets do not carry Rh antigens, platelets from Rh-negative donors should be used for transfusion in Rh-negative women of childbearing years to prevent sensitization from contaminating red blood cells.

Indications

Platelet transfusions are indicated for treatment of bleeding associated with thrombocytopenia or intrinsic platelet dysfunction. Platelet transfusions are also indicated in the management of massive bleeding if severe thrombocytopenia develops. Patients undergoing cardiopulmonary bypass may require platelet transfusions if excessive bleeding occurs because of thrombocytopenia and decreased platelet function induced by the bypass procedure. Other surgical procedures in thrombocytopenic patients generally require prophylactic platelet transfusions to maintain adequate perioperative platelet counts for at least 3 days ($>50,000/\mu\text{L}$ for major procedures; $>30,000/\mu\text{L}$ for minor procedures). Prophylactic

platelet transfusions are also indicated for severely thrombocytopenic (eg, $<10,000/\mu\text{L}$ platelets) patients undergoing intensive chemotherapy for acute leukemia; the threshold for transfusion may be higher in the presence of fever, infection, or drugs that cause platelet dysfunction.

Factors that determine the risk of serious bleeding owing to thrombocytopenia include the cause and severity of thrombocytopenia, the presence of vascular defects, the functional status of the patient's platelets, and the presence of other hemostatic defects. Severe anemia also may contribute to bleeding in patients with thrombocytopenia or platelet dysfunction. Because of the increased functional capacity of younger platelets in patients with decreased platelet survival, decreased production of platelets carries a higher risk of serious bleeding at any given platelet count than thrombocytopenia owing to destruction, consumption, or hypersplenism. Typical bleeding manifestations related to the level of thrombocytopenia are shown in Table 17–8. If bleeding is out of proportion to a given platelet count, other contributing factors to bleeding should be investigated.

The risk of bleeding in patients with disorders of platelet function likewise depends on the cause and severity of the disorder and whether vascular defects, other hemostatic abnormalities, or severe anemia is present. Bleeding time is the most widely used test of platelet function, and although it is useful in the diagnosis of certain disorders (eg, von Willebrand's disease, hereditary platelet disorders), prolonged bleeding time in the absence of a history of bleeding is not a reliable predictor of subsequent bleeding. A prolonged bleeding time in the absence of thrombocytopenia or severe anemia in a bleeding patient, however, may indicate the presence of platelet dysfunction.

The efficacy of platelet transfusions can be assessed by observing a sustained rise in platelet count in a patient who has stopped bleeding. Patients with thrombocytopenia owing to decreased production of platelets are most likely to experience a significant, sustained increase in platelet count following platelet transfusion. Patients with increased destruction of platelets and those who have hypersplenism usually do not achieve a significant increase in platelet count after transfusion, and any increase that occurs is usually transient. Similarly, patients with massive platelet consumption owing to bleeding will have a suboptimal increase in platelet count following transfusion. Hemorrhage owing to platelet dysfunction can be controlled with platelet transfusions only if the defect is intrinsic to the platelet (eg, aspirin ingestion, cardiopulmonary bypass, inherited platelet disorders) rather than extrinsic (eg, von Willebrand's disease or uremia).

Platelet transfusions are minimally useful in the treatment of thrombocytopenia owing to decreased platelet survival and should not be given unless severe life-threatening bleeding occurs. Platelet transfusions may be harmful in patients with thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP-HUS) despite the presence of thrombocytopenia, presumably owing to accelerated thrombosis in vital organs. Because platelet survival is short in this disorder, platelet transfusions usually are ineffective in controlling

hemorrhage. The diagnosis of TTP-HUS should be suspected in a patient with severe thrombocytopenia and hemolysis with schistocytes on peripheral blood smear (microangiopathic hemolytic anemia) with or without associated central nervous system dysfunction, renal dysfunction, or fever. Patients with heparin-associated thrombocytopenia also may suffer increased thrombotic complications if platelets are transfused. Platelet transfusions should be administered to these patients only when the risk of death from bleeding outweighs the potential risk of clinical deterioration from transfusion.

Platelet Transfusion Requirements

The quantity of platelets to be transfused depends on the source of the platelets, the cause and degree of thrombocytopenia, and the observed response to transfusions. The usual initial amount transfused is 6–8 units of random-donor platelets or 1 unit of single-donor apheresis product. Platelet packs should contain a minimum of 5.5×10^9 platelets per unit.

The response to platelet transfusions should be determined by obtaining a platelet count 1 hour after transfusion and daily thereafter and by observing the effect on control of bleeding. The 1-hour count should increase by about 5000–10,000 per unit of random-donor platelets or 30,000–50,000 per unit of single-donor platelets. Stored homologous platelets survive about 3 days in thrombocytopenic patients. The 1-hour count and subsequent platelet survival will be reduced in patients with increased destruction or hypersplenism. These measurements will help to determine the magnitude of the benefit to be expected from subsequent transfusions. If only a minimal response occurs, or if the platelet rise is short-lived, subsequent prophylactic transfusions should be withheld. However, in patients with severe thrombocytopenia owing to destruction or hypersplenism who have serious bleeding, platelet transfusions may be warranted. In any patient, if clinical bleeding does not improve despite platelet transfusion, other causes of bleeding should be evaluated and the utility of subsequent platelet transfusions in such patients reassessed.

The underlying cause of thrombocytopenia or platelet dysfunction should be determined so that specific therapy to reverse the process can be given if available. Alternatives to platelet transfusions in bleeding patients with thrombocytopenia or platelet dysfunction are set forth in Table 3–2.

► Plasma

Plasma products available are listed in Table 3–1. Fresh frozen plasma (FFP) is prepared by separating plasma from red blood cells (after collection of whole blood or during plasmapheresis) and freezing it within 6 hours after collection at -18°C or colder. It can be stored for up to 1 year and is thawed over 20–30 minutes prior to administration. Activities of coagulation factors are adequate for 24 hours after thawing. Fresh plasma and plasma recovered from outdated blood products are used for preparation of plasma

Table 3–2. Alternatives to platelet transfusions.

Alternative	Possible Indications
High-dose IgG	Life-threatening bleeding in immune-mediated thrombocytopenia (ITP).
Anti-D immune globulin	Treatment of bleeding in ITP in Rh-positive patients.
Desmopressin (DDAVP)	Bleeding associated with platelet dysfunction, uremia, von Willebrand's disease.
Antifibrinolytic agents (eg, aminocaproic acid)	Excessive bleeding without evidence of thrombotic diathesis or hematuria.
Estrogens	Bleeding associated with uremic platelet dysfunction.
Red cell transfusions	Severe anemia associated with thrombocytopenia or platelet dysfunction.
Erythropoietin	Bleeding in anemic, uremic patients.
Corticosteroids	ITP, possibly thrombotic thrombocytopenic purpura-hemolytic uremic syndrome (TTP-HUS).
Splenectomy	Refractory ITP, severe hypersplenism, possibly TTP.
Immunosuppressives, chemotherapy, danazol, vinca alkaloids, interferon alpha, protein-A immunoadsorption, rituximab	Refractory ITP.
Plasma infusion or exchange	TTP-HUS.

derivatives (eg, immunoglobulin, cryoprecipitate, albumin, coagulation factor concentrates). Fresh plasma may be used as an alternative to FFP for replacement of coagulation factors other than factors VIII and V.

Cryoprecipitate-poor plasma is the supernatant plasma remaining after preparation of cryoprecipitate and contains adequate quantities of all coagulation factors except fibrinogen, factors VIII and XIII, and von Willebrand factor. Solvent-detergent treatment of plasma (S/D plasma) inactivates lipid-enveloped viruses and has been licensed recently by the Food and Drug Administration (FDA) to minimize the risk of transfusion-transmitted infections and allergic reactions in the management of coagulopathies and thrombotic thrombocytopenic purpura (TTP). The highest-molecular-weight von Willebrand factor multimers are reduced in S/D plasma, enhancing its efficacy in the

treatment of TTP, but protein S and plasmin inhibitor levels are also variably reduced, potentially causing venous thromboembolism (low protein S) or excessive bleeding (low plasmin inhibitor). Numerous other derivatives of plasma are now available; **Table 3–3** outlines some of these products and their therapeutic uses.

Table 3–3. Therapeutic products derived from plasma.

Plasma Derivative	Therapeutic Use
Fibrin glue (human fibrinogen combined with bovine thrombin)	Prevent surgical oozing with topical use
Albumin (heat-treated)	Hypoalbuminemia in nephrotic syndrome
Plasma-derived factor VIII concentrate	Hemophilia A*
Humate-P	von Willebrand's disease
Prothrombin complex concentrate	Coagulation inhibitors, factor X and prothrombin deficiencies
Activated factor IX concentrates (Autoplex, FEIBA)	Factor VIII inhibitors
Plasma-derived factor IX concentrate	Hemophilia B*
Fibrinogen concentrate	Hypofibrinogenemia
Factor VII concentrate	Factor VII deficiency
Factor XI concentrate	Factor XI deficiency
Factor XIII concentrate	Factor XIII deficiency
Antithrombin III concentrate	Thrombosis in antithrombin III deficiency
C1 esterase inhibitor concentrate	Angioedema
α_1 -Antitrypsin concentrate	Prevent lung damage in α_1 -antitrypsin deficiency
Protein C and S concentrate	Severe protein C or S deficiency
Intravenous immunoglobulin	Immunodeficiency states; immune cytopenias, Kawasaki syndrome, Guillain-Barré syndrome, dermatomyositis
Immune serum globulin	Passive immunization against hepatitis A, measles, poliomyelitis, varicella, rubella

*Recombinant products are available as an alternative to plasma-derived product; see Chapter 17.

Indications

The major indication for plasma transfusion is correction of coagulation factor deficiencies in patients with active bleeding or in those who require invasive procedures. Isolated congenital factor deficiencies (eg, factor II, V, VII, X, XI, or XIII) may be treated with plasma (FFP for factor V deficiency, FFP or fresh plasma for the remainder) if factor-specific concentrate is unavailable. Multiple acquired factor deficiencies complicating severe liver disease and disseminated intravascular coagulation (DIC) and, if associated with significant bleeding, may be treated with FFP. However, excessive volume expansion or decreased survival of coagulation factors may decrease the usefulness of FFP in these conditions. Vitamin K deficiency and warfarin therapy result in a functional deficiency of factors II, VII, IX, and X, and parenteral vitamin K administration will reverse these deficiencies within about 24 hours. If immediate correction is necessary because of active bleeding, plasma can be given. Massively bleeding patients requiring transfusion of red blood cells greater than 100% of normal blood volume in less than 24 hours may become deficient in multiple coagulation factors, and plasma is indicated if a demonstrable coagulopathy develops following massive transfusion and bleeding continues. However, bleeding in such patients is more often due to thrombocytopenia than coagulation factor deficiencies, so prophylactic administration of plasma usually is not indicated.

Other indications for treatment with plasma include antithrombin III deficiency in patients at high risk for thrombosis or who are unresponsive to heparin therapy, severe protein-losing enteropathy in infants, severe C1 esterase inhibitor deficiency with life-threatening angioedema, and TTP-HUS.

Plasma exchange therapy, with removal of undesirable plasma substances and reinfusion of normal plasma, appears to be effective alone or as an adjunct in the management of TTP-HUS, cryoglobulinemia, Goodpasture's syndrome, Guillain-Barré syndrome, homozygous familial hypercholesterolemia, and posttransfusion purpura. Plasma exchange may be of value in some patients with chronic inflammatory demyelinating polyneuropathy, cold agglutinin disease, autoimmune thrombocytopenia, rapidly progressive glomerulonephritis, and systemic vasculitis. Rarely, patients with alloantibodies, pure red blood cell aplasia, warm autoimmune hemolytic anemia, multiple sclerosis, or maternal-fetal incompatibility may benefit from therapeutic plasma exchange.

Plasma should not be administered for reversal of volume depletion or to counter nutritional deficiencies (except severe protein-losing enteropathy in infants) because effective alternatives are available. Purified human immunoglobulin has replaced plasma in the treatment of humoral immunodeficiency. Patients with coagulation factor deficiencies who are not bleeding or not in need of invasive procedures likewise should not be treated with plasma. Patients with mild coagulation factor deficiencies (ie, prothrombin time <16–18 s,

partial thromboplastin time <55–60 s) are unlikely to have bleeding in the absence of an anatomic lesion, and even with surgery or other invasive procedures, these patients may not have excessive bleeding. Therefore, prophylactic administration of plasma should be discouraged in such patients.

Plasma Transfusion Requirements

ABO type-specific plasma should be used to prevent transfusion of anti-A or anti-B antibodies. Rh-negative donor plasma should be administered to Rh-negative patients to prevent Rh sensitization from contaminating red blood cells (particularly important for women of childbearing years).

The amount of plasma must be individualized. In the treatment of coagulation factor deficiencies, the appropriate dose of plasma must take into account the plasma volume of the patient, the desired increase in factor activity, and the expected half-life of the factors being replaced. The average adult patient with multiple factor deficiencies requires 2 to 9 units (about 400–1800 mL) of plasma acutely to control bleeding, with smaller quantities given at periodic intervals as necessary to maintain adequate hemostasis. Control of bleeding and measurement of coagulation times (prothrombin time and partial thromboplastin time) should be used to determine when and if to give repeated doses of plasma. Smaller amounts of plasma usually are sufficient for treatment of isolated coagulation factor deficiencies.

Plasma infusion and plasma exchange for treatment of TTP-HUS usually necessitate very large quantities of plasma—up to 10 units per day (or even more)—for several days until the desired clinical response is achieved. The precise dose of plasma required to treat hereditary angioedema is unknown; 2 units is probably adequate, and a concentrate is now available to treat C1 esterase inhibitor deficiency.

► Cryoprecipitate

Preparation

When FFP is thawed at 4°C, a precipitate is formed. This cryoprecipitate is separated from the supernatant plasma and resuspended in a small volume of plasma. It is then refrozen at –18°C and kept for up to 1 year. The supernatant plasma is used for preparation of other plasma fractions (eg, coagulation factor concentrates, albumin, and immunoglobulin). Each bag of cryoprecipitate (about 50 mL) contains approximately 100–250 mg of fibrinogen, 80–100 units of factor VIII, 40–70% of the plasma von Willebrand factor concentration, 50–60 mg of fibronectin, and factor XIII at one and one-half to four times the concentration in FFP.

Indications

Cryoprecipitate is indicated in patients with severe hypofibrinogenemia (<100 mg/dL) for treatment of bleeding episodes or as prophylaxis for invasive procedures. It may be

useful in the treatment of severe bleeding in uremic patients unresponsive to desmopressin and dialysis. Cryoprecipitate also can be used to make a topical fibrin glue for use intraoperatively to control local bleeding and has been used in the removal of renal stones when combined with thrombin and calcium.

Purified factor VIII concentrates or recombinant factor VIII products are preferred over cryoprecipitate in the management of hemophilia A because of the lower risk of infectious disease transmission, as well as fewer other complications (eg, allergic reactions to other plasma or cryoprecipitate constituents). Antihemophilic factor–von Willebrand factor complex (human), dried, pasteurized (Humate-P), a concentrate rich in von Willebrand factor, is now preferred over cryoprecipitate in the treatment of von Willebrand's disease when treatment with desmopressin is inadequate or unsuitable. Likewise, factor XIII concentrate is available for treatment of bleeding owing to factor XIII deficiency.

Cryoprecipitate is not indicated for bleeding owing to thrombocytopenia, for bleeding owing to multiple coagulation factor deficiencies unless severe hypofibrinogenemia is present, or for bleeding owing to unknown cause. It is not indicated for treatment of patients with deficiencies of factors VIII and XIII or von Willebrand factor in the absence of bleeding or the need for invasive procedures.

Administration

ABO type-specific cryoprecipitate is thawed and pooled into the desired quantity and administered intravenously by infusion or syringe. In treatment of bleeding owing to hypofibrinogenemia, the goal of therapy is to maintain the fibrinogen concentration above 100 mg/dL. Two to three bags per 10 kg of body weight will increase the fibrinogen concentration by about 100 mg/dL. Maintenance doses of one bag per 15 kg of body weight can be given daily until adequate hemostasis is achieved. When hypofibrinogenemia is due to increased consumption (eg, DIC), larger and more frequent doses may be required to control bleeding.

▶ Granulocytes

Granulocyte concentrates (see Table 3–1) are prepared by automated leukapheresis from ABO-compatible donors stimulated several hours before collection with corticosteroids. Granulocytes have decreased function if refrigerated or agitated, so these concentrates should be given as soon as possible after collection (preferably within 6 hours; never after 24 hours). Granulocytes do not survive prolonged storage and so must be prepared before each transfusion.

Indications

The indications for granulocyte transfusions are controversial. Severe neutropenia (<500/ μ L) is associated with a

marked increase in the risk of bacterial and fungal infections. Most authorities agree that granulocyte transfusions are most likely to be helpful in patients with documented bacterial or fungal infections unresponsive to antibiotics accompanied by prolonged severe neutropenia when bone marrow recovery is expected in 7–10 days or in patients with congenital severe granulocyte dysfunction complicated by life-threatening fungal infections. Granulocyte transfusions also may be of value in the treatment of neonatal sepsis, although this remains controversial.

Granulocyte transfusions are not helpful for preventing infections in neutropenic patients, in treating infections associated with transient neutropenia, or in treating fevers and neutropenia not associated with documented infection. Patients who are unlikely to recover bone marrow function (eg, those with aplastic anemia or refractory acute leukemia) appear to derive less benefit than patients who will recover ultimately (eg, those with acute leukemia following successful chemotherapy). Granulocyte transfusions should be used with caution in patients receiving amphotericin B and in those with pulmonary infiltrates because of the potential for adverse pulmonary events.

Administration

Granulocytes should be administered as soon as possible after collection from a corticosteroid-stimulated ABO-compatible donor. The minimal dose recommended is $2\text{--}3 \times 10^{10}$ granulocytes per transfusion, infused slowly under constant supervision. Daily transfusions should be administered for at least 4 days and perhaps longer until the infection is controlled.

Complications

Granulocyte transfusions are associated with numerous adverse effects, including febrile reactions (25–50%), alloantibodies (human leukocyte antigen [HLA] and neutrophil-specific), cytomegalovirus (CMV) infections if granulocytes from seropositive donors are given to seronegative patients, pulmonary reactions, and graft-versus-host disease (preventable with irradiation of the product). These complications—as well as the development of more effective antibiotics and more effective antileukemic therapy—have diminished the occasions for use of granulocyte transfusions over the last decade. Human recombinant cytokines, such as granulocyte colony-stimulating factor (Filgrastim; G-CSF) and granulocyte-macrophage colony-stimulating factor (Sargramostim; GM-CSF) can be used to decrease the severity and duration of neutropenia in patients receiving chemotherapy for nonmyeloid malignancies and even in selected patients with myeloid malignancies.

▶ Coagulation Factors

Available coagulation factor products, indications, dosing, alternatives, and complications are discussed in Chapter 17.

BLOOD COMPONENT ADMINISTRATION

► Informed Consent

Before elective transfusion of any blood component is undertaken, the patient should be informed of the benefits of transfusion, the potential risks of transfusion, and the alternatives to transfusion. The patient should be given the opportunity to ask questions about the recommended transfusion, and consent should be obtained before proceeding. Informed consent also should be obtained from competent patients in emergency situations. Many states have passed laws requiring informed consent prior to elective transfusion, including providing the patient with the option of autologous donation, where appropriate (usually for elective surgical procedures).

► Patient Identification

The identity of the patient should be verified when obtaining specimens for cross-match, and blood collected should be labeled immediately with the patient's name and hospital identification number, dated, and signed by the phlebotomist. At the time of transfusion, the label on the unit should be compared with the name and identification number on the patient's bracelet. There should be no discrepancies in spelling or medical record number. Rigid adherence to these practices eliminates the great majority of major acute hemolytic transfusion reactions.

► Preparation of Blood Components

Potential donors are screened with a questionnaire prior to donation to eliminate donors with identifiable risk factors for complications in both the donor and the recipient. After collection, donor blood is screened for the presence of infectious diseases or their markers, including VDRL, hepatitis B surface antigen and core antibody, hepatitis C, HIV-1 and -2, HTLV-1 and -2 antibodies, hepatitis C and HIV-1 RNA, and occasionally, CMV antibody. The ABO and Rh types of donor and recipient red blood cells are determined, and the sera of both donor and recipient are screened for clinically significant alloantibodies to the major red blood cell antigens. If donor red blood cells appear to be Rh-negative, they are typed further to exclude a weakly reactive Rh-positive variant (weak D, D^u). Recipient serum is incubated with donor red blood cells to detect antibodies that may react with donor red cells (the "cross-match"). Some patients have autoantibodies that react with virtually all red blood cells. In these situations, the *in vitro* cross-match should be performed with multiple type-specific donor samples to find red blood cells with the least *in vitro* incompatibility.

► Administration

All blood components should be administered through a standard blood filter to trap clots and other large particles

into any accessible vein or central venous catheter. When leukocyte-depleted red blood cells or platelets are desired, third-generation leukoreduction filters may be used if filtration has not been performed in the laboratory. Red blood cells should not be administered by syringe or by automatic infusion pump because forcible administration may cause mechanical hemolysis, but other cellular components and plasma derivatives may be administered by pumps. Nothing should be added to the blood component (eg, medications, hyperalimentation) or administered through the same line as the component. Only physiologic saline solution should be administered through the same line and may be used to dilute red blood cells and thus promote easier flow. Hypotonic solutions (5% dextrose in water) may cause hemolysis, and solutions containing calcium (Ringer's lactate) may initiate coagulation. These should not be administered through the same line with blood components.

Blood components should be administered slowly for the first 5–10 minutes while the patient is under observation, and the patient should be reassessed periodically throughout the transfusion process for adverse effects. Blood components should not be kept at room temperature for more than 4 hours after the blood bag has been opened. If a slower infusion rate is necessary to avoid circulatory overload, the unit may be divided into smaller portions. Each portion should be refrigerated until used, and each then can be administered over 4 hours. Catheter size should be sufficiently large to allow blood to be administered within the 4-hour time period (generally 20 gauge or larger). Use of very small gauge catheters will impede flow, especially of packed red blood cells, and should be reserved for pediatric patients, who require much smaller volumes of blood. A blood warmer should be used for transfusion of patients with cold-reacting antibodies to prevent acute hemolysis.

COMPLICATIONS OF TRANSFUSION

► Red Cell Antibody-Mediated Reactions

Acute Reactions

Acute hemolytic transfusion reactions are almost always due to human error, resulting in transfusion of incompatible blood, and are preventable by rigid adherence to a standardized protocol for collecting, labeling, storing, and releasing all blood involved in transfusion. When incompatible red blood cells are transfused, recipient antibodies directed against donor red blood cells may cause acute intravascular hemolysis. ABO incompatibility is most common because anti-A and anti-B antibodies are naturally occurring, but other antibodies owing to prior sensitization can cause acute hemolytic reactions.

Acute hemolytic transfusion reactions range in severity from mild, clinically undetected hemolysis to fulminant, fatal events. Back pain, chest tightness, chills, and fever are the most common complaints in conscious patients. If the patient is unconscious (eg, under general anesthesia), hypotension, tachycardia, or

fever may be the first clue, followed by generalized oozing from venipuncture and surgical sites. Since the severity of acute hemolytic transfusion reactions is related to the amount of incompatible blood given, it is vital to recognize early warning symptoms and signs to minimize sequelae of such a transfusion.

Complications of acute hemolytic transfusion reactions include cardiovascular collapse, oliguric renal failure, and DIC. Massive immune-complex deposition, stimulation of the coagulation cascade, and activation of vasoactive substances are the main pathophysiologic mechanisms underlying these complications, with subsequent decreased perfusion and hypoxia resulting in tissue damage. The degree of damage is related to the dose of incompatible blood received.

Any transfusion complicated by even apparently mild findings such as fever or allergic symptoms should be stopped. The identity of the patient and the label on the unit should be verified quickly. If the patient has never been transfused or has never had any adverse reaction to prior transfusions, even a minor febrile reaction should prompt an evaluation for incompatibility. The remainder of the unit of blood and additional samples (anticoagulated and coagulated) from the patient should be sent to the blood bank for repeat cross-match and direct antiglobulin testing. Patient plasma and urine should be examined for hemoglobin. It may be useful to check serum bilirubin and haptoglobin levels for evidence of hemolysis.

If acute hemolysis has occurred, the patient should be managed with aggressive supportive care. Vital signs should be monitored and intravenous volume support provided to maintain adequate blood pressure and renal perfusion for at least 24 hours following acute hemolysis. Loop or osmotic diuretics may be used in combination with intravenous fluids to maintain renal perfusion and urine output over 100 mL/h. Renal and coagulation status should be monitored clinically and with appropriate laboratory tests. DIC may occur and occasionally requires treatment with factor replacement. It is important to remember that an adverse reaction to an incompatible unit of red blood cells does not obviate the initial need for the transfusion. Therefore, transfusion with compatible red blood cells should be undertaken to provide the oxygen-carrying capacity the patient required prior to the transfusion.

In a patient who had been transfused previously and has had prior febrile reactions, the decision to evaluate each subsequent febrile reaction may be difficult. At a minimum, verification of the identity of the unit and the patient always should be performed. Whether to initiate the entire evaluation for hemolysis will depend on the clinical circumstances. When in doubt, it is safer to stop the transfusion and perform a complete evaluation before continuing. Alternatively, if judged safe to continue without further evaluation, antipyretics may be used to lessen or prevent subsequent reactions.

Delayed Reactions

Hemolysis occurring about 1 week after red blood cell transfusion may occur when the initial cross-match fails to detect recipient antibodies to donor red blood cell antigens. Prior

sensitization by transfusion or pregnancy to red blood cell antigens other than ABO may result in a transient rise in antibodies directed against those antigens. The antibody titer may wane to undetectable levels in as little as a few weeks. A second exposure prompts an anamnestic rise in antibody titer to a level sufficient to cause hemolysis.

The clinical manifestations of delayed hemolytic transfusion reactions are generally mild, with a fall in hematocrit accompanied by a slight increase in indirect bilirubin and lactic dehydrogenase levels about 1 week after transfusion. A repeat cross-match will demonstrate a “new” antibody. With some exceptions, hemolysis is extravascular and mild, without the serious sequelae that may follow acute hemolytic reactions. No specific therapy is necessary, but if indicated clinically, further transfusion should be given with red blood cells negative for the antigen. The blood bank should maintain a permanent record of the antibody, and all future red blood cell transfusions should be with antigen-negative blood. The patient should be informed of the antibody and of the need for screening of all future transfused red blood cells to avoid another such reaction. The patient also should be monitored for the development of other antibodies following subsequent transfusions.

Alloimmunization

Alloantibodies to red blood cell antigens other than ABO may occur in some recipients of red blood cell transfusions. Since there are over 300 red blood cell antigens, virtually all red blood cell transfusions expose the recipient to foreign antigens. Most antigens are not immunogenic, however, and rarely result in development of alloantibodies. Factors that influence the development of alloantibodies include the immunogenicity of the antigen, the frequency of the antigen in the population, the number of transfusions given, and the tendency of the recipient to form antibodies.

Because of the time required for the primary antibody response, alloantibodies do not complicate the sensitizing transfusion. Subsequent cross-match procedures will detect most clinically significant alloantibodies, but the development of multiple alloantibodies may make it difficult to find compatible units for transfusion-dependent recipients. Delayed hemolytic transfusion reactions may occur if the antibody is not detectable at the time of subsequent cross-match procedures. Red blood cell phenotyping may be useful for transfusion-dependent patients who demonstrate a tendency for antibody formation. When significant differences in the frequency of antigens exist between donor and recipient populations, empiric transfusion of red blood cells negative for certain antigens may be useful (eg, Duffy antigen-negative red blood cells for sickle cell patients) to prevent alloimmunization.

▶ Infectious Complications of Transfusions

Current transfusion techniques minimize the risk of transmission of many potential pathogens (Table 3–4). The major factors that decrease the risk of transmission of disease

Table 3-4. Infectious complications of transfusion therapy.

Infection	Clinical Significance/Incidence
Viruses	
Hepatitis A	Rarely transmitted because of short period of viremia and lack of carrier state (1 in 1,000,000 units transfused)
Parvovirus B19	Estimated risk is 1 in 10,000 units transfused. Infection clinically insignificant except in pregnant women, patients with hemolytic anemia or who are immunocompromised.
Esptein-Barr virus	Rarely transmitted because of immunity acquired early in life.
Cytomegalovirus	Clinically significant transfusion complication in low-birth-weight neonates or immunocompromised hosts. Markedly reduced by use of CMV-seronegative donors for all blood component therapy or by leukodepletion of blood products for CMV-negative recipients at high risk.
HTLV-1, HTLV-2	Estimated risk is 1 in 250,000 to 1 in 2,000,000 units transfused. Blood stored for more than 14 days and noncellular components are not infectious. Twenty to forty percent of recipients receiving infected blood become infected with virus; infection may lead to T cell lymphoproliferative disorder or myelopathy after long latency period. Donors are screened for both viruses.
Hepatitis B	Estimated risk is 1:50,000 to 1:150,000 units transfused. Usually causes anicteric and asymptomatic hepatitis 6 weeks to 6 months after transfusion. Ten percent become chronic carriers at risk for cirrhosis. All donors screened with surface antigen and core antibody.
Delta agent	Cotransmitted with hepatitis B, found primarily in drug abusers or patients who have received multiple transfusions. Superinfection of hepatitis B surface antigen carriers may result in fulminant hepatitis or chronic infectious state. Screening for hepatitis B eliminates the majority of infectious donors.
Hepatitis C	Previously the leading cause of posttransfusion hepatitis; donors are now screened, with estimated risk 1:600,000. Infection may be asymptomatic but 85% become chronic, 20% develop cirrhosis, and 1-5% develop hepatocellular carcinoma.
Hepatitis G (GB virus C)	Viremia may be present in 1-2% of donors, but no clear evidence that virus causes disease. Coinfection with HIV associated with prolonged survival. No approved screening test.
HIV	Screening program has been highly successful in eliminating transfusion-associated HIV disease; high risk donors excluded from donation; all donors tested for HIV antibody and p24 antigen. Estimated risk is 1:1,900,000 units transfused. Most recipients of infected blood develop HIV infection.
West Nile virus	Most infections mild but 1:150 infected will have severe illness with CNS involvement. Rare (146-1233:1,000,000 donations).
Bacteria	
Environmental contaminants	Closed, sterile collection techniques, use of preservatives and refrigeration, and natural bactericidal action of blood ensures extremely low risk, but improper storage or contamination with pathogens that survive refrigeration may result in serious bacterial infection.
Donor-transmitted	Asymptomatic carriers of certain bacteria may transmit infection; <i>Yersinia enterocolitica</i> is most common (<1:1,000,000) and is highly fatal. Other organisms (salmonella, brucella) associated with chronic carrier state are transmitted less often. Platelet concentrates carry higher risk (1:1000-1:2000) due to high storage temperature (most common organisms are staphylococcus, klebsiella, serratia); pooled platelets have greater risk than single-donor apheresis units. New standards to detect bacterial contamination of stored platelets should reduce this risk.
Spirochetes	
Syphilis	Short viability period (96 hours) in storage and donor screening with VDRL/RPR virtually eliminates possibility of transmission.
Lyme disease	<i>Borrelia burgdorferi</i> viable much longer than <i>Treponema pallidum</i> , but the period of blood culture positivity is associated with symptoms that preclude donation. No reported cases from transfusion.

(continued)

Table 3-4. Infectious complications of transfusion therapy. (continued)

Infection	Clinical Significance/Incidence
Parasites	
Malaria	Rare complication in USA (<0.25:1,000,000 units collected) because of exclusion from donation of asymptomatic individuals who have traveled to endemic areas within 1 year, or who have history of malaria or use of anti-malarial prophylaxis, or who are former residents of endemic areas for 3 years. Unexplained fever 7-50 days after transfusion should prompt consideration of posttransfusion malaria.
Chagas' disease	<i>Trypanosoma cruzi</i> mainly a transfusion hazard in Central and South America, but immigration to the USA may result in increased incidence. No screening test currently available.
Babesiosis	Endemic to northeastern USA. Causes mild malaria-like illness. Major risk to asplenic or immunocompromised recipients. No screening test currently available.
Toxoplasmosis	Infrequent hazard of granulocyte transfusion in immunosuppressed hosts.
Prions	
Variant Creutzfeldt-Jakob disease (vCJD, "mad cow disease")	Two possible cases of transfusion-associated v-CJD have been reported in the United Kingdom. The FDA has recommended excluding from donation individuals who spent a significant amount of time or received blood transfusions in endemic areas (United Kingdom, France, certain other parts of Northern Europe) between 1980 and 1986; or those who used bovine insulin during this time period.

include a closed, sterile system of collection of blood, proper storage and preservation of blood products, and screening. Standards for detecting bacterial contamination of platelets have been adopted recently by the American Association of Blood Banks. Screening includes obtaining historical information from potential donors to identify risk factors for infectious diseases and performing tests to identify carriers of known transmissible agents (see above) and those at high risk of being carriers. Current screening practices reduce the incidence of but do not eliminate entirely the transmission of infectious disease by blood transfusion. Characteristics of agents transmissible by blood include the ability to persist in blood for a prolonged period in an asymptomatic potential donor and stability in blood stored under refrigeration. Table 3-4 sets forth the major clinical features of transfusion-transmitted infectious diseases.

▶ Nonhemolytic, Noninfectious Complications

Nonhemolytic, noninfectious transfusion reactions account for more than 90% of adverse effects of transfusions and occur in approximately 7% of recipients of blood components. Major features of these unwanted complications are listed in Table 3-5.

Of particular importance in the critical care setting is transfusion-related acute lung injury (TRALI), which has emerged as the leading cause of transfusion-related death in the United States. This syndrome occurs within 4-6 hours of transfusion and is very similar clinically to the acute respiratory distress syndrome (ARDS). The pathophysiology of

TRALI is not known but is suspected to be related to donor antineutrophil antibodies or to transfusion of substances that activate recipient neutrophils in susceptible patients. TRALI appears to be more common after cardiac bypass surgery, during initial treatment for hematologic malignancies, following massive transfusion in organ recipients, and in patients receiving plasma for warfarin reversal or thrombotic thrombocytopenic purpura. Treatment with aggressive supportive care results in recovery in most patients within 72 hours, but the reported mortality rates of 5-25% underscore the need for selecting patients appropriately for transfusion therapy.

CURRENT CONTROVERSIES & UNRESOLVED ISSUES

▶ Perioperative Transfusion

The need for transfusion in the perioperative period should be determined by individual patient characteristics and by the type of surgical procedure rather than by hemoglobin level alone. Chronic mild to moderate anemia does not increase perioperative morbidity and by itself is not an indication for preoperative red blood cell transfusion. Intraoperative and postoperative blood loss should be managed first with crystalloids to maintain hemodynamic stability. Red blood cells should not be administered unless there is hemodynamic instability or the patient is at high risk for complications of acute blood loss (eg, coronary or cerebral vascular disease, congestive heart failure, or significant valvular heart disease). Patients who are at high risk or are

Table 3–5. Noninfectious complications of transfusion.

Complication	Clinical Manifestations, Pathogenesis, Prevention, and Treatment Strategies
Febrile-associated transfusion reaction (FATR)	Occurs in 0.5–3% of transfusion. Rigors or chills followed by fever during or shortly after transfusion due to prior sensitization to WBC or platelet antigens, or to pyrogenic cytokines released during storage. Prevent with antipyretics or leukocyte depletion of blood components.
Transfusion-related acute lung injury (TRALI)	Noncardiogenic pulmonary edema with fevers, chills, tachycardia, and diffuse pulmonary infiltrates shortly after transfusion, due to leukocyte incompatibility. Resolves in 1–4 days; rarely results in respiratory failure. Occurs in 1:5000–1:1323 transfusions.
Allergic reactions	Occurs in 1–3% of transfusions. Urticaria, pruritus, bronchospasm, or frank anaphylaxis due to recipient sensitization to a cellular or plasma element. Rarely, due to allergy to medication donor is taking. If severe, evaluate recipient for IgA deficiency (2% of population). Leukocyte depletion or washed red cells may be necessary for subsequent transfusions.
Transfusion-associated circulatory overload (TACO)	Common following transfusion for chronic anemia or when patient has impaired cardiovascular reserve. Prevent by transfusing only when clearly indicated, using the minimum amount of blood required to reverse symptoms, and carefully reassessing patient after each unit. Treat with oxygen, diuretics, and, rarely, phlebotomy (save units for reinfusion if necessary).
Dilutional effects	Transfusing with more than one blood volume or red blood cells with dilute platelets and coagulation factors. Replacement indicated only for clinical bleeding.
Hypocalcemia	Due to citrate intoxication following massive transfusion. Treat only if symptomatic.
Hyperkalemia	May occur in patients with preexisting renal insufficiency and hyperkalemia or in neonates. Use of fresh blood or washed red cells decreases potassium load for these patients.
Hypothermia	After massive transfusion of refrigerated blood, hypothermia may cause cardiac arrhythmias. Refrigerated blood may accelerate hemolysis in patients with cold agglutinin disease. Prevent by warming blood.
Immune modulation	Mechanisms and clinical significance unclear for immunosuppression that follows transfusion; enhances results following renal transplantation; possible deleterious effect on outcome after colorectal cancer surgery; possible increased susceptibility to bacterial infections.
Graft-versus-host disease	Immunocompetent donor T lymphocytes may engraft if the recipient is markedly immunosuppressed or if closely HLA-related. Symptoms and signs include high fever, maculopapular erythematous rash, hepatocellular damage, and pancytopenia 2–30 days after transfusion. Usually fatal despite treatment with immunosuppressives. Prevent by irradiating all blood components with 2500 cGy for immunocompromised recipients or when donor is first-degree relative.
Iron overload	Multiple transfusions in the absence of blood loss lead to excess accumulation of body iron with cirrhosis, heart failure, and endocrine organ failure. Prevent by decreasing total amount of red cells given, using alternatives to red cells whenever possible, using neocytes, and modifying diet to decrease iron absorption. Iron chelation indicated for patients with chronic transfusion dependence if prognosis is otherwise good.
Posttransfusion purpura	Acute severe thrombocytopenia about 1 week after transfusion due to alloantibodies to donor platelet antigen (usually P1A1). Self-limited, but treatment with steroids, high-dose IgG, plasmapheresis, or exchange transfusion recommended to prevent central nervous system hemorrhage. Platelet transfusions are ineffective even with compatible platelets. Pathogenesis poorly understood.
Miscellaneous	Increased supply of complement may accelerate hemolysis in paroxysmal nocturnal hemoglobinuria or make angioedema worse in patient with C1 esterase inhibitor deficiency. Increased blood viscosity may occur in patients with Waldenström's macroglobulinemia, polycythemia, or leukemia with high white blood cell count. Sudden deterioration may follow platelet transfusion in patients with TTP-HUS or heparin-induced thrombocytopenia.

unstable should be transfused on a unit-by-unit basis to maintain adequate perfusion of vital organs and to stabilize vital signs. It is reasonable to transfuse stable perioperative patients who have hemoglobin values around 7–8 g/dL if there are no significant risk factors for ischemia; in patients

who are elderly, unstable, or at higher risk for ischemia, a higher threshold (eg, 10 g/dL) is probably safer.

Alternatives to homologous red blood cell transfusions in the perioperative period include autologous red blood cells donated in advance of elective surgery, acute normovolemic

hemodilution, and intraoperative blood salvage. Preoperative autologous red blood cell donations are desirable whenever elective surgery likely to require red blood cell transfusion is planned and the patient is medically suitable for donation. Epoetin alfa (erythropoietin) use may enhance collection in patients with anemia or those likely to require large amounts of red blood cell transfusions. However, autologous donation is not without problems. Although autologous donation may decrease the use of allogeneic blood from an ever decreasing donor pool, thus reserving it for emergencies, about half the autologous blood collected is discarded, which is both wasteful and costly. Preoperative autologous donation may increase the risk of ischemic events, thereby outweighing the potential decrease in infectious risks, particularly in patients undergoing cardiovascular bypass surgery. In addition, collection of autologous blood preoperatively increases the risk of postoperative anemia and actually may increase the need for perioperative transfusion. Transfusion of autologous blood is also associated with some of the same risks as allogeneic blood (eg, administrative errors leading to ABO mismatch and hemolysis, bacterial contamination, volume overload, and reactions to preservatives). Therefore, criteria for transfusion of autologous units should be the same as those for transfusion of homologous red blood cells to avoid these unnecessary potential complications.

Acute normovolemic hemodilution may be suitable for patients undergoing surgical procedures with a significant risk of intraoperative bleeding (>20% of blood volume) who have baseline hemoglobin levels greater than 10 g/dL and who do not have severe ischemic heart disease or critical aortic stenosis. Phlebotomy with volume replacement by crystalloid is performed immediately after anesthetic induction. Blood lost intraoperatively results in loss of fewer red blood cells because of the lowered hematocrit, and subsequent reinfusion of the phlebotomized blood can restore oxygen-carrying capacity, if necessary. Perioperative allogeneic transfusion requirements following acute normovolemic hemodilution or preoperative autologous donation appear to be about the same when compared directly in certain types of surgery, but there are some advantages favoring hemodilution. It is less costly because no testing is performed on the blood, the risks of bacterial contamination related to storage or ABO mismatch owing to administrative error are reduced because the blood never leaves the operating room, and surgery does not have to be delayed to allow time for autologous donation.

Intraoperative blood salvage may be indicated for patients undergoing procedures with substantial blood loss or when transfusion is impossible (eg, patients who refuse blood transfusions and patients with rare blood groups or multiple red blood cell alloantibodies). Reinfusion of blood salvaged from the surgical field can reduce the requirement for standard homologous and autologous blood transfusions. Relative contraindications include the presence of infection, amniotic fluid or ascites in the operative field, malignancy, or the use of topical hemostatic agents in the

field from which blood is salvaged. It has not been demonstrated, however, that use of salvaged blood decreases the need for allogeneic transfusion, and it may be expensive if automated cell-washing devices are used. The main value of intraoperative salvage is that blood is immediately available if rapid blood loss occurs.

Postoperative salvage from chest or pericardial tubes or from drains also may provide blood for autologous transfusion if persistent bleeding occurs. However, because the fluid collected is dilute (therefore providing a small volume of red blood cells for reinfusion), depleted of coagulation factors, and may contain cytokines, it is not clear how effective or safe reinfusion of recovered fluid is. Clinical trials have yielded conflicting results about the benefits of this procedure.

► Directed Donations

Transfusions from ABO- and Rh-compatible family members or friends are frequently requested because of concerns about the safety of homologous transfusion. There is no evidence that directed donations are safer than volunteer donations, however, and some evidence exists that they may be less safe because blood from directed donors has a higher prevalence of serologic markers of infections than blood from volunteer donors. The patient and potential directed donors should be informed of the increased risk of transmission of infectious disease when directed donations are used. If the patient accepts this risk, potential donors should be given every opportunity to inform the blood bank of any conditions that would preclude use of their blood. Directed donations are not available immediately for transfusion because laboratory screening procedures are the same as for volunteer donor blood and require about 72 hours to complete. Blood donated from first-degree relatives should be irradiated prior to transfusion to prevent graft-versus-host disease, which can occur when the donor and recipient are closely HLA-matched.

► Increasing Blood Product Safety

Several strategies have been proposed and implemented to further decrease the risk of transfusion-related infections. Solvent/detergent-treated pooled plasma is now available commercially for treatment of coagulopathies and thrombotic thrombocytopenic purpura. Viruses with lipid envelopes are inactivated; however, there is concern that use of these products will result in transmission of viruses that do not have lipid envelopes. Plasma can be frozen and stored for a year, allowing for retesting beyond the window period between infection and serologic conversion of plasma donors prior to releasing the units for transfusion. Inactivation of viruses by exposure to psoralen and ultraviolet A irradiation (PUVA) can reduce the levels of HIV and hepatitis viruses, inactivate bacteria, and eliminate the problem of immunomodulation

owing to transfused lymphocytes. However, any toxicity from exposure of blood products to psoralen derivatives must be determined before this approach can be recommended. In addition, viability of platelets may be affected by PUVA.

Exposure of blood products to gamma irradiation (2500 cGy) results in inactivation of donor leukocytes, rendering them incapable of participation in the immune response. Graft-versus-host disease, a rare complication of blood transfusion that can occur in immunocompromised hosts or when the donor and recipient are closely related, can be prevented by irradiation of cellular blood components prior to transfusion. Alloimmunization, which can lead to poor response to subsequent platelet transfusions, also can be prevented with irradiation.

► Patients Who Refuse Blood Transfusion

Even after extensive counseling regarding the risks and benefits of transfusion, some patients refuse some or all blood products even under life-threatening circumstances. Courts have affirmed the right of individuals to refuse medical care in part (eg, transfusions) without relinquishing the right to receive other care. This is true also for surrogate decision makers for adults who are not competent to make their own medical decisions. In such situations, it is important to determine how adamant the patient is in refusing to accept blood products and to have the patient affirm that refusal in writing, if possible, even if death is imminent. Patients who have previously refused blood products should not be transfused if subsequently unable to give consent (eg, under general anesthesia). In an emergency, courts generally have granted permission to physicians to transfuse a patient over a family member's objections if no prior refusal by the patient has been documented and the patient is incompetent to give consent. It is preferable to avoid transfusions, however, rather than to obtain court permission to transfuse against a patient's or the family's wishes. Every effort should be made to treat existing anemia or acute blood loss with alternative therapy—volume expansion, erythropoietin (epoetin alfa), and (hematinics, iron, vitamins)—whenever possible. Careful surgical technique, meticulous hemostasis, and reliance on aggressive volume support have eliminated the need for transfusion during many major surgical procedures in patients who refuse blood transfusion therapy.

► Epoetin Alfa (Erythropoietin)

Recombinant human erythropoietin is available as epoetin alfa for the treatment of anemia owing to renal disease, for AIDS patients on zidovudine therapy with transfusion-dependent anemia, and for anemia associated with cancer or cancer chemotherapy. It also may be useful in the treatment of the anemia of chronic disease. Erythropoietin may be useful to augment autologous donations of red blood cells

preoperatively even in the absence of anemia and may decrease the need for transfusion perioperatively when autologous blood is not collected. Because the cost of the drug is substantial, patient selection and modification of dosage will improve cost-effectiveness of this therapy. Those who will benefit most from preoperative erythropoietin treatment have baseline hematocrits between 33% and 39%, with expected blood loss of 1000–3000 mL. If more blood loss is anticipated, autologous donation in addition to erythropoietin may be needed to prevent preoperative polycythemia. Erythropoietin therapy also may improve the efficacy of acute normovolemic hemodilution.

Data on whether erythropoietin reduces the need for red blood cell transfusion and decreases the total amount of blood transfused in critically ill patients with anemia are inconclusive. Its use does not appear to reduce mortality or other serious events. Treatment with erythropoietin is associated with an increase in thromboembolic events in ICU patients, even among those who are not considered high risk (eg, renal failure, prior thromboembolic disease), and in those who reach excessively high hemoglobin concentrations (>12 g/dL).

► Massive Transfusion

Administration of a volume of blood and blood components equal to or exceeding the patient's estimated blood volume within a 24-hour period is accompanied by complications not often seen during transfusion of smaller volumes.

Deficiencies of platelets and clotting factors may occur, especially if extensive tissue injury or DIC is present. However, prophylactic replacement with platelets or plasma results in unnecessary transfusions for many patients. It is preferable to base the decision to replace platelets and clotting factors on clinical criteria such as a generalized bleeding diathesis and laboratory abnormalities (platelet count and clotting times).

Clinically significant citrate (anticoagulant) intoxication is rare even with massive transfusions. Prophylactic calcium administration is not indicated, with the possible exception of patients with severe hepatic dysfunction or heart failure in whom citrate metabolism may be impaired. Hyperkalemia occurs rarely following even massive blood transfusion. In fact, hypokalemia occurs more frequently as a result of metabolic alkalosis, which occurs as citrate is metabolized to bicarbonate. Interventions should be based on serum potassium levels. Although banked blood is acidic, massive transfusion does not complicate the lactic acidosis present in a patient with severe blood loss because improved tissue oxygenation results in metabolism of lactate and citrate to bicarbonate. Therefore, prophylactic administration of sodium bicarbonate is inadvisable in the massively transfused patient. The clinical significance of the low 2,3-DPG found in stored red blood cells appears to be minor because many other factors determine tissue oxygenation, including pH, tissue perfusion, hemoglobin concentration, and temperature. There

appears to be no advantage in transfusing fresh red blood cells over stored cells.

Hypothermia may result from massive transfusion of refrigerated blood and may impair cardiac function. Warming of blood prior to transfusion is recommended to prevent this complication. Microembolization of particulate debris in stored blood probably does not have any clinical significance. The use of microaggregate filters rather than standard blood filters has not been proven to be beneficial.

A significant potential hazard of massive transfusion is unrecognized acute hemolytic transfusion reaction. Many of the clinical signs and symptoms observed in the acutely bleeding patient are identical to those of an acute hemolytic event. Most fatal hemolytic transfusion reactions occur in emergency settings both because of the difficulty in recognizing such reactions and because of the higher potential for human error in emergency situations. Strict attention to details of specimen labeling and patient identification and recognition of signs such as hemoglobinuria, fever, and generalized oozing from DIC can minimize the risks and complications of such reactions.

Emerging Technologies

Several biotechnology products are under development as potential alternatives to blood products. Blood substitutes (eg, cell-free hemoglobin solutions and perfluorocarbon emulsions) may serve as alternative oxygen carriers in patients undergoing surgery, following massive trauma, or for patients who refuse blood products. New erythropoiesis stimulants may offer more rapid correction of anemia. Recombinant coagulation factors can reduce exposure of patients with severe clotting disorders or inhibitors to infectious agents. Synthesis of important molecules in blood eventually may offer specific therapy for disorders currently treated with blood products (eg, the metalloprotease implicated in the pathogenesis of thrombotic thrombocytopenic purpura could offer targeted therapy in place of the massive plasma infusion that is currently the mainstay of treatment). Embryonic stem cells have the capacity to produce all blood cells and eventually may lead to a new source of cells for blood transfusion. All these biotechnologic approaches hold the promise of decreasing our dependence on blood products, therefore conserving this resource and decreasing serious complications associated transfusion, but considerations of cost and safety must be balanced against their potential benefits.

▶ Pretransplant Transfusion Therapy

Use of HLA-related blood donors may induce immune tolerance to donor antigens following organ transplant, therefore improving allograft survival. However, better methods of immunosuppression have decreased the clinical importance of pretransplant blood transfusion. In contrast, blood transfusion prior to bone marrow transplantation—particularly

in patients with aplastic anemia—appears to decrease its success, especially if HLA-related donors are the source of blood.

▶ Use of Non-Cross-Matched Blood in Emergency Situations

In the absence of unusual antibodies, complete cross-matching takes approximately 30–60 minutes. In most cases of acute hemorrhage, initial management with crystalloid is sufficient to maintain perfusion and hemodynamic stability. Occasionally, a delay in red blood cell transfusion poses a substantial risk to the patient, as in sudden massive blood loss or less massive blood loss occurring in a patient with myocardial or cerebral ischemia. In these circumstances, transfusion with non-cross-matched type O, Rh-negative blood or ABO-compatible blood tested with an abbreviated cross-match (5–20 minutes) may be necessary. Since Rh-negative blood is often in short supply, Rh-positive blood may be given to women beyond childbearing years or to males if emergent transfusion is required. If the recipient's blood type is known, unmatched blood of the same group may be used. Patients with group AB blood may receive either group A or group B cells. Type-specific plasma is preferred when plasma transfusion is necessary because naturally occurring anti-A or anti-B antibodies (or both) are present in plasma from all donors except those with type AB red cells, independent of prior sensitization. When type-specific plasma is not available, patients with type O blood can receive plasma of any type, but patients with types A and B can receive plasma only from AB donors. Patients with type AB blood can receive type-specific plasma only.

The disadvantages of using non-cross-matched blood include the possible transfusion of incompatible blood owing to clinically significant antibodies to blood groups other than ABO, transfusion of anti-A and anti-B antibodies from plasma accompanying type O, Rh-negative red blood cells, and depletion of the supply of group O blood. Whenever possible, transfusion of cross-matched, type-specific blood should be used. ABO group-specific partially cross-matched blood is preferred over type O blood to avoid transfusion of ABO-incompatible plasma. Non-cross-matched type O blood should be reserved for truly extreme emergencies. A blood sample from the patient always should be obtained prior to any transfusion for complete cross-matching for subsequent transfusions and to aid in the evaluation of transfusion reactions.

▶ Conservation of Blood Resources

Conserving blood resources is one of the goals of the National Blood Resource Education Program of the National Institutes of Health. Recently, several controlled clinical trials examining the impact of transfusion on outcomes in a wide-variety of clinical settings have been performed. These trials

serve to promote rational use of blood products for the benefit of patients as well as protecting the limited supply of blood from waste. These trials have clearly influenced transfusion practices in well-defined clinical situations. There are many situations, however, where no empirical data exist, and the clinician must determine the benefits of transfusion on an individualized basis. Massive repeated transfusion in patients with uncorrectable vascular defects or who are terminally ill—and platelet and plasma transfusions for patients without demonstrated response to such transfusions—may deplete the blood supply without substantially improving the outcome for those patients.

The medical team caring for a patient with massive uncontrollable bleeding or a terminal illness should make every effort to discuss the limits of care with the patient and family members, to establish long-term treatment goals and expectations, and to decide when continued blood transfusion is no longer of benefit to the patient. In addition, family members should be strongly encouraged to donate blood to help replace some of the units used. Ineffective therapy should not be given prophylactically (eg, daily platelet transfusions in patients with consumptive thrombocytopenia without bleeding or plasma therapy in patients with multiple severe coagulation deficiencies not corrected with large doses of plasma).

Pharmacotherapy*

Darryl Y. Sue, MD

Critically ill patients are almost always given many different drugs. For example, patients may require broad-spectrum antibiotics, vasopressor agents, and antiarrhythmics. At the same time, clinicians often must give sedatives and muscle relaxants to patients in order to tolerate mechanical ventilation, and there is strong evidence that ICU outcome is improved by empirical prophylaxis for GI bleeding with proton pump inhibitors or other antacids and prophylaxis for deep venous thrombosis with heparin.

One estimate is that ICU patients receive twice as many different drugs as other hospitalized patients. It is no wonder, therefore, that medication errors, a major focus of hospital safety improvement, are increased in ICU patients. In fact, an error in preparation, dosage, or rate of infusion has been found in as many as 10% of intravenous medications. Furthermore, complex changes in pharmacokinetics and pharmacodynamics are seen frequently in these patients, necessitating consideration of dosage, interaction, and organ function.

Pharmacokinetics is the movement of a drug through the body over time and is defined by the following: absorption, distribution, metabolism, and elimination—basically, how the patient affects a drug. *Pharmacodynamics* is the relationship between drug concentration and drug effect—or how a drug affects the patient. Both pharmacokinetic and pharmacodynamic changes compared with baseline occur in critical illness and the management of patients in the ICU.

PHARMACOKINETIC PARAMETERS

The most important pharmacokinetic parameters are clearance and volume of distribution. The disposition of a drug, once it has entered the body, depends on both clearance (CL) and the volume of distribution (V_d). Clearance is proportional to the rate at which a drug is eliminated from the body.

*Jennifer H. Cupo Abbott, PharmD, and Maria I. Rudis, PharmD, were the authors of this chapter in the second edition.

Volume of distribution is a theoretical volume that relates the concentration in the plasma to the total amount of drug in the body. The elimination half-life ($t_{1/2}$) depends on the preceding independent variables and is described by the following mathematical relationship:

$$t_{1/2} = (0.693 \times V_d / CL)$$

Hence either decreased clearance or an expanded volume of distribution will result in an increased pharmacologic half-life. A practical understanding of this mathematical relationship is essential for developing optimal dosing regimens in the critically ill patient.

PHARMACOKINETIC CONSIDERATIONS

► Absorption

Drug absorption is influenced by a variety of factors, including the site of absorption, the amount metabolized before reaching the systemic circulation (“first-pass” effect for orally administered drugs), and drug interactions. In critical illness, the site of absorption is of utmost importance. The extent of oral absorption—bioavailability—may be diminished as a result of low cardiac output or shunting of blood from the mesentery to the peripheral circulation. In patients who are in the ICU for a longer duration, intestinal atrophy and motility dysfunction may play a role. While highly encouraged in suitable patients, enteral nutritional support may cause inadvertent malabsorption of some orally administered medications. Therefore, therapeutic “failures” may be due to inadequate bioavailability rather than absence of effect at the intended receptor site. Acutely ill patients may have decreased perfusion of sites of parenteral administration of drugs. These patients may have poor or unreliable absorption of subcutaneously or intramuscularly administered medications. In general, the intravenous route is preferred for critical medications, and oral, subcutaneous, or intramuscular administration should be avoided.

Distribution

The distribution of drugs in the body depends on factors such as blood flow, body composition, and plasma protein binding (Table 4-1). For a single-compartment model, initial plasma concentration (before elimination) equals the dose of drug given divided by the apparent volume of distribution. In normal subjects, the volume of distribution of a drug is generally well described and usually is related to some measure of patient size (eg, total body water for a water-soluble drug and extravascular volume for a large molecule). However, volume of distribution is strongly influenced by drug lipid solubility, protein binding, and intra- versus extracellular partitioning.

In critical illness, fluid overload can increase a patient's volume of distribution significantly, and insufficiently effective drug concentrations may result. For drugs with extensive tissue distribution (eg, digoxin), the volume of distribution is approximately 500 L, or several times actual body weight. Thus it is unlikely that changes in fluid status can affect the distribution of digoxin significantly. For drugs apparently distributed largely into extracellular

water, however, drug concentrations can be affected. It is not uncommon for a critically ill patient to gain several kilograms of extracellular water (ECW). Because this space is roughly 20% of body weight, or about 12 L in a 60 kg adult, gaining even 2 L of ECW would reduce expected concentration of such a drug by 15–20%. A drug such as gentamicin exhibits concentration-dependent killing of bacteria. A peak level of 25 µg/kg (dose = 5–7 mg/kg, normal $V_d = 0.25$ L/kg) is expected. However, V_d in critically ill patients may be as high as 0.6 L/kg, resulting in a much lower than expected serum level.

Body composition and the lipophilicity of a given drug are also important factors to consider. In general, lipophilic agents such as diazepam readily distribute into fat. For these agents, dosing should be based on total body weight. Since most agents used in the ICU setting are not lipophilic, such as pressors and most antimicrobials, it may be more accurate to use ideal body weight in dosing calculations. However, an increasingly important question is how to adjust medication dosages for obese patients because the volume of distribution likely will change. Considerations include unexpected changes in the proportion of adipose tissue compared with total body weight, thereby changing estimates of total body and extracellular water, and sometimes the difficulty in obtaining accurate scaled weights. Analgesics, including opiates, and sedatives should be titrated to desired clinical effect in the absence of studies of weight-adjusted dosing. Antibiotic dosing should be guided by therapeutic drug monitoring when possible, adjusting for both desired antimicrobial effect and toxicity. Low-molecular-weight heparin is a special situation because the effect when dosed as milligrams per kilogram is no longer predictable in the obese patient; in this case, measurement of factor Xa activity may be useful.

Protein binding is another important determinant of distribution. Only the unbound fraction of a drug can diffuse or be transported into tissues. Thus the influence of protein binding is a limiting factor in drug distribution for highly bound drugs (see Table 4-1). Serum pH, often abnormal in critically ill patients, also may affect the degree of protein binding of drugs. Phenytoin is a highly protein-bound drug (~90%). The remaining 10% circulates as unbound or “free” drug and is the fraction responsible for the pharmacologic effect. If a patient with normal albumin has a phenytoin level of 12 mg/L, the free fraction would be approximately 1.2 mg/L. However, with decreased serum albumin, as is found in patients with CNS trauma or those with end-stage liver disease, less serum protein is available to bind phenytoin. The laboratory reports total phenytoin concentrations, which includes bound and unbound drug. In a patient with hypoalbuminemia, the total phenytoin level will be unchanged, but the percentage of “free” drug (ie, pharmacologically available) will increase. For example, a patient with a serum albumin of 2 g/dL and a measured phenytoin plasma concentration (C_{meas}) of 12 mg/L has more free drug, resulting in an adjusted phenytoin plasma concentration (C_{adj}) of 24 mg/L.

Table 4-1. Protein binding.

Drug	Protein-Bound
Amphotericin B	90–95%
Ceftriaxone	93–96%
Chlordiazepoxide	94–97%
Clindamycin	93%
Diazepam	84–98%
Erythromycin	96%
Ethacrynic acid	95%
Furosemide	91–99%
Haloperidol	90–92%
Heparin	>90%
Hydralazine	90%
Lorazepam	90%
Midazolam	94–97%
Nafcillin	70–90%
Nifedipine	89–92%
Oxacillin	89–94%
Phenytoin	90%
Prochlorperazine	90%
Rifampin	84–91%
Vecuronium	60–90%
Verapamil	90%

 \end{aligned}$$

The uremia accompanying renal failure also displaces phenytoin from its binding sites because endogenous competitors for binding accumulate. It is important to recognize that malnourished patients and those with renal failure will have a lower than normal “therapeutic range” for phenytoin. For this reason, it is clinically more relevant to monitor free phenytoin concentrations or to use these values in calculation of dosage adjustments.

► Drug Clearance (Elimination)

With limited exceptions, most pharmacologic agents are eliminated either renally or hepatically, but drug clearance is considered the effect of all pathways of elimination taken together. Since multiorgan dysfunction is commonly encountered in critically ill patients, drug accumulation and toxicity are of concern. Specific dosage adjustment is often required in the setting of renal or hepatic impairment. Some of the most frequently used agents with predominantly renal elimination are listed in [Table 4-2](#). Most antimicrobials, including aminoglycosides, vancomycin, beta-lactams, and fluoroquinolones, are eliminated primarily via the kidneys.

Table 4-2. Drugs with primarily renal elimination.

Antimicrobials		
Acyclovir	Ciprofloxacin	Meropenem
Amikacin	Fluconazole	Penicillin G
Ampicillin	Flucytosine	Piperacillin
Cefazolin	Ganciclovir	Ticarcillin-clavulanate
Cefepime	Gatifloxacin	Tobramycin
Cefotetan	Gentamicin	Trimethoprim-sulfamethoxazole
Cefoxitin	Imipenem-cilastatin	Vancomycin
Ceftazidime	Levofloxacin	
Ceftizoxime		
Antihypertensives		
Diazoxide		
Methyldopa		
Nitroprusside		
Antiarrhythmic agents		
Bretylium		
Digoxin		
Procainamide		
Miscellaneous drugs		
Ranitidine		
Pancuronium		

Although some dosage adjustment is needed when these antimicrobials are used in critically ill patients with renal failure, studies have found both under- and overdosing of antimicrobial agents because of renal function considerations. Importantly, the initial concentration of an antimicrobial drug is related to its dose and volume of distribution, not its elimination. Therefore, the “first dose” of an antimicrobial need not be adjusted for renal failure, only subsequent doses. Failure to recognize this concept leads to a delay in achieving desired therapeutic levels.

Other drugs with primarily renal elimination used in the critical care setting are the low-molecular-weight heparins. Currently, dosage of enoxaparin is reduced 25–50% for patients with a creatinine clearance of less than 30 mL/min, but not for mild or moderate renal insufficiency. Some practitioners advocate monitoring factor Xa activity for these patients. Some drugs have mixed routes of elimination and require adjustment for both renal and hepatic function for proper dosing.

Renal Dysfunction

Medications used in the ICU are often eliminated by the kidneys, and dosages are adjusted in the face of renal insufficiency. Common causes of renal insufficiency in the ICU include chronic kidney disease, acute renal failure from shock or hypoperfusion, exposure to nephrotoxic drugs, and obstructive uropathy.

Several studies have demonstrated that dosing of renally excreted drugs (cleared by glomerular filtration) is improved when creatinine clearance rather than serum creatinine concentration alone is used to estimate renal function. This is especially true in the elderly and those who are underweight, in whom a “normal” serum creatinine concentration (0.8–1 mg/dL) may be associated with significantly reduced renal function. Less commonly, patients with rhabdomyolysis produce more than the expected amount of creatinine; in these patients, elevated serum creatinine may not indicate decreased glomerular filtration rate (GFR). Rarely, some medications interfere with creatinine secretion, further dissociating the relationship between serum creatinine and GFR.

When the serum creatinine level is known, an estimate of creatinine clearance can be obtained to assist with dosage adjustment using the Cockcroft-Gault equation:

$$\frac{(140 - \text{age}) \times \text{weight (in kg)}}{72 \times \text{serum creatinine}}$$

(For females, multiply the numerator by a factor of 0.85.)

Although this equation and several others are used frequently in ICU patients and generally are better estimates than serum creatinine alone, some studies demonstrate that they are far from perfect. In fact, even short-term collections

of urine for calculation of creatinine clearance are less accurate than 12- or 24-hour collections, probably because of variability in GFR over time.

For patients requiring hemodialysis, it is essential to know the extent to which drugs can be removed by dialysis. Knowledge of pharmaceutical properties such as hydrophilicity, molecular weight, plasma protein binding, and volume of distribution (Table 4-3) can help to distinguish agents that are dialyzable. Low-molecular-weight, water-soluble drugs with low protein binding are highly dialyzable. If they have a small volume of distribution, then an appreciable amount of the drug can be eliminated by dialysis. Conversely, drugs with extensive tissue distribution such as digoxin or the calcium channel blockers and highly lipophilic drugs are not affected by dialysis. Other important considerations for drug clearance include the duration and type of dialysis. Short dialysis sessions are less likely to remove significant amounts of drug. New forms of dialysis are more efficient and remove drugs previously thought to be minimally dialyzable. Hemodialysis with high-flux filters removes significant amounts of vancomycin, previously considered not to require replacement for drug lost to dialysis. Continuous renal replacement therapy is a much more efficient process than conventional hemodialysis and equates to a clearance of approximately 30 mL/min for creatinine, but not clearly comparable for other drugs. It is essential to review the medication regimen closely when patients are dialyzed with high-flux filters or are switched from hemodialysis to continuous renal replacement because the dosages of some drugs will have to be increased.

Table 4-3. Drugs significantly removed by hemodialysis.

Antimicrobials		
Aminoglycosides	Ceftazidime	Meropenem
Ampicillin	Chloramphenicol	Metronidazole
Cefazolin	Ciprofloxacin	Penicillin G
Cefepime	Gatifloxacin	Piperacillin
Cefotaxime	Imipenem-cilastatin	Quinupristin-dalfopristin
Cefotetan	Levofloxacin	Trimethoprim-sulfamethoxazole
Cefoxitin	Linezolid	
Ceftazidime		
Antihypertensives		
Diazoxide		
Methyldopa		
Nitroprusside		
Antiarrhythmic agents		
Bretylium		
Digoxin		
Procainamide		
Miscellaneous drugs		
Ranitidine		
Pancuronium		

Hepatic Dysfunction

Liver failure is a common problem in the ICU and may be due to chronic liver disease (eg, cirrhosis or hemochromatosis) or acute liver disease (eg, acute hepatitis, drug-induced hepatitis, alcohol, or toxins). Some drugs require dosage adjustment in hepatic insufficiency (Table 4-4). However, most commonly used tests of “liver function” describe the degree of liver damage and not the liver’s capacity for drug elimination. Determining the degree of hepatic dysfunction is difficult because no quantitative equations exist. Laboratory tests of hepatic synthetic function (eg, prothrombin time, serum albumin, and conjugated bilirubin) are most predictive of drug elimination. For drugs metabolized by the liver, the route of metabolism is important in determining the effects of liver disease on drug clearance. Some enzyme systems are remarkably well preserved even in end-stage liver disease. Drugs such as lorazepam that are metabolized primarily by conjugation with glucuronic acid are minimally affected in cirrhosis, so little dosage adjustment is required. For drugs whose clearance depends on oxidative metabolism (eg, metronidazole, theophylline, opioids, and sedative-hypnotics), cirrhosis reduces their elimination. Generally speaking, acute liver disease (eg, hepatitis) does not alter drug clearance significantly.

Congestive heart failure may cause hepatic congestion and decreased hepatic blood flow and decrease hepatic elimination of drugs. The hepatic clearance of theophylline, for example, is markedly reduced in patients with congestive heart failure (CHF). Patients with chronic liver disease frequently have hypoalbuminemia, thereby reducing the amount of drug protein binding. For such highly protein-bound drugs as phenytoin, the proportion of free unbound drug rises with hypoalbuminemia.

Table 4-4. Drugs requiring dosage adjustment in severe hepatic insufficiency.

Analgesics	Antimicrobials
Acetaminophen	Cefoperazone
Opioids	Ceftriaxone
Salicylates	Chloramphenicol
Antiarrhythmics	Clindamycin
Lidocaine	Erythromycin
Quinidine	Isoniazid
Verapamil	Metronidazole
Anticonvulsants	Nafcillin
Phenobarbital	Rifampin
Phenytoin	Sedative-hypnotics
Antihypertensives	Chlordiazepoxide
Hydralazine	Diazepam
Labetalol	Midazolam
Nitroprusside	Miscellaneous
	Haloperidol
	Theophylline

▶ Therapeutic Drug Monitoring

Agents with a narrow therapeutic index have only a small difference between serum drug concentrations that produce therapeutic and toxic effects, and monitoring of serum drug concentrations is recommended (Table 4–5). Examples of agents with low therapeutic indices are the aminoglycosides, digoxin, theophylline, and phenytoin.

In many ICUs, routine blood samples are collected at a set time. For therapeutic drug monitoring, this may not be acceptable because the time the sample is drawn must be related to the time since the last dose of the drug was given. First, for some drugs, an estimate of peak concentration is desired. This level should be obtained after distribution of the dose into the volume of distribution is achieved. For example, digoxin levels should be drawn about 4–6 hours after administration in order to distribute into its very large V_d . If peak aminoglycoside or vancomycin levels are sought, these are usually reached at 30 minutes to 1 hour after administration. Second, sometimes the “trough,” or lowest, value before administration of the next dose is wanted. Obviously, the sample is drawn just prior to administration. Finally, for many drugs, dosing is predicted by formulas or nomograms that use serum levels at designated times (eg, aminoglycosides and vancomycin), such as 4–10 hours after dosing. Drug distribution is also of concern following dialysis. It is important to allow at least 3 hours to elapse after dialysis to obtain drug levels to allow for redistribution of drug from other tissues into the main compartment (eg, intravascular space). This is illustrated also in the case of hemodialysis for a toxic

ingestion of lithium. A lithium level of 10 meq/L (therapeutic level is 0.5–2 meq/L) obtained before dialysis may decrease to 1 meq/L immediately after hemodialysis. However, a third level obtained 3–4 hours after dialysis may rebound to a toxic level of 5 meq/L, showing evidence of redistribution from the CNS back into the main compartment. This indicates the need for longer or more frequent hemodialysis.

Phenytoin serum levels are often used to adjust dosing. Phenytoin is eliminated by first-order kinetics at low serum levels, but elimination is saturable at higher levels, even within the therapeutic range. Therefore, at these levels, small increases in dosing may result in unexpectedly high levels. Ethanol is eliminated by alcohol dehydrogenase and obeys zero-order kinetics; thus a constant fall in serum level with time is expected, usually 30–40 mg/dL per hour.

▶ Drug Interactions

Given the number of drugs prescribed for critically ill patients, the potential for drug interactions is high. Drug interactions may occur as a result of pharmacodynamic, pharmaceutical, or pharmacokinetic effects. Pharmacodynamic interactions result from the drugs actions and may enhance or antagonize a drug's effects. Pharmaceutical interactions can result from a number of causes, one of which is the relationship between two drugs. The most striking interactions are pharmacokinetic, which occur when one drug affects the absorption, distribution, or clearance of another.

Pharmacodynamic Interactions

Pharmacodynamic drug interactions can result in synergistic, additive, or antagonistic pharmacologic effects. A beneficial additive effect would be observed in a patient with poorly controlled hypertension who receives a second antihypertensive agent from a different class and then achieves optimal blood pressure control. Synergistic combinations are noted when the resulting pharmacologic effect with combination therapy is greater than the expected sum of drug effects. This phenomenon occurs infrequently and is best described for antimicrobial combinations. A beta-lactam antimicrobial (eg, piperacillin or ceftazidime) in combination with an aminoglycoside may be more effective than a beta-lactam alone and results in a lower incidence of acquired bacterial resistance in the treatment of infections with aerobic gram-negative organisms. On the other hand, antagonism may be encountered when beta-blockers reverse the pharmacologic benefit of beta-agonists in patients with chronic obstructive pulmonary disease (COPD). While some beta-blockers such as atenolol are more cardioselective at lower doses, they still have the potential to antagonize bronchodilators such as albuterol and salmeterol. The concomitant use of antimicrobials from the same class also carries the potential for antagonism. For example, some beta-lactams induce production of beta-lactamase. The combination of a strongly inducing beta-lactam with a labile compound

Table 4–5. Therapeutic ranges for drugs commonly used in critical care.

Drug	Therapeutic Range
Amikacin	Peak: 25–35 mg/L Trough: <10 mg/L
Amiodarone	0.8–2.8 mg/L
Gentamicin, tobramycin	Peak: 8–12 mg/L Trough: <1 mg/L
Digoxin	1–2 µg/L
Lidocaine	1–5 mg/L
Phenobarbital	10–30 mg/L
Phenytoin	10–20 mg/L
Procainamide	4–8 mg/L
<i>N</i> -Acetylprocainamide	<30 mg/L
Salicylates	100–300 mg/L
Theophylline (in COPD)	8–10 mg/L
Vancomycin	Trough: 5–15 mg/L

(eg, piperacillin) for the treatment of infections owing to *Enterobacter* species has been shown to produce antagonism *in vitro* and in animal models of infection. Hence double beta-lactam combinations that include a strong inducer should be avoided.

Pharmaceutical Interactions

Pharmaceutical interactions may be caused by drug incompatibilities or drug adsorption to catheters and to intravenous administration materials. For example, intravenous administration of nitroglycerin requires special equipment to decrease the likelihood of adsorption. The complexity of drug regimens in the critically ill patient coupled with limited intravenous access makes intravenous drug compatibility a significant issue. Although a great deal is known about the compatibility of drug combinations, there are still many potential combinations for which no such information is available.

Pharmacokinetic Interactions

Although pharmacokinetic interactions occur as a result of alterations in drug absorption, distribution, metabolism, or elimination, the effects on drug metabolism are the most clinically significant. A commonly seen absorption interaction occurs when fluoroquinolones are administered concomitantly with antacids, causing decreased quinolone bioavailability. Similarly, enteral feeding should be withheld 2 hours before and after the administration of oral phenytoin formulations because of the decreased and delayed absorption of phenytoin that occurs.

Drug interactions owing to altered distribution also may occur. When two drugs compete for binding sites on plasma proteins or tissues, the unbound or free serum concentration of one or both drugs may increase. Although this theoretically may increase a drug's effect, the enhanced pharmacologic effect is usually transient because more unbound drug is now available for elimination by the liver and kidney. Thus the clinical significance of protein-binding displacement interactions is minimal unless there is concomitant hepatic or renal disease. However, warfarin and phenytoin may be transiently displaced by a number of drugs.

Pharmacokinetic drug interactions are frequently due to altered metabolism involving the cytochrome P450 (CYP) enzyme system, which is largely responsible for oxidative metabolism of drugs by the liver. These enzymes are a superfamily of microsomal drug-metabolizing enzymes that degrade endogenous substances, chemicals, toxins, and medications. The primary ones responsible for drug metabolism are CYP3A4, CYP2D6, CYP1A2, and CYP2C. Examples of commonly used drugs that are inducers and inhibitors of CYP are shown in Table 4–6. The most potent drugs likely to be encountered are phenobarbital, phenytoin, and rifampin, with subsequently more rapid metabolism and lower serum levels for cimetidine, phenytoin, theophylline, warfarin, corticosteroids, and quinidine. Cigarette smoking and chronic ethanol use also increase CYP activity. This explains why alcoholics may require surprisingly high doses of sedatives (eg, diazepam and midazolam) or analgesics. CYP induction does not occur immediately, but usually takes at least several days. Therefore, effects of CYP may be immediate (eg, in a

Table 4–6. Examples of cytochrome P450 (CYP) induction or inhibition by drugs.

Drug Affected	CYP Inducer/Inhibitor	Effect
Benzodiazepines (alprazolam)	Inhibitor Azole antifungal (fluconazole, itraconazole, ketoconazole)	Increased benzodiazepine concentration
Cyclosporine	Inducer Rifampin, rifabutin, phenobarbital, phenytoin Inhibitor Erythromycin, azole antifungal	Decreased cyclosporine levels Increased cyclosporine levels
Theophylline	Inhibitor Fluoroquinolone Inducer Cigarette smoking	Increased theophylline levels Decreased theophylline levels
Warfarin	Inducer Phenobarbital Inhibitor Cimetidine	Decreased warfarin levels Increased warfarin levels

chronic smoker) or delayed (eg, after starting a potential CYP inducer in the hospital). Drugs that inhibit CYP systems may behave differently than those that are inducers because the former can act immediately on CYP. The most common CYP inhibitors in the ICU are allopurinol, amiodarone, cimetidine, erythromycin, and fluconazole.

The importance of CYP induction and inhibition depend on the therapeutic indices of the drugs whose metabolism are affected. The narrower the therapeutic window (level providing therapeutic effect compared with the level resulting in toxic effect), the greater is the likelihood that a CYP inhibitor will lead to toxicity or an inducer will cause subtherapeutic levels.

► Adverse Effects & Drug Toxicities

Drugs may adversely affect all organ systems, but the kidney, liver, heart, CNS, and vascular system are most frequently affected. In critically ill patients with multiple medical problems, it can be quite difficult to isolate drug toxicity as the sole cause of organ failure. Some drug toxicities are dose-dependent, so attention to dosing and elimination is important, as well as to drug interactions that may increase drug levels (eg, inhibition of cytochrome P450 enzymes). Other adverse effects are allergic and depend on the host response and prior exposure. For some adverse effects, the patient may be more susceptible for genetic or other reasons (long QT syndrome).

Nephrotoxicity

The most common causes of drug-induced nephrotoxicity are listed in Table 4-7. Nephrotoxicity in critically ill patients may be due to drug-induced causes or to hypoperfusion. Because the mortality rate for ICU patients with acute renal failure approaches 80%, efforts should be directed at removing all potential causes of nephrotoxicity. Adequate fluid resuscitation and maintenance of renal perfusion are of paramount importance for preventing prerenal acute renal failure. Appropriate intravascular volume status and pretreatment with *N*-acetylcysteine or sodium bicarbonate decrease the risk of nephrotoxicity from radiocontrast agents.

Despite adequate preventive measures, up to 20% of all cases of acute renal failure may be associated with drug toxicity. Drug-induced toxicity may take the form of acute tubular necrosis, interstitial nephritis, or glomerulonephritis. Of those drugs associated with acute tubular necrosis, the most notable are the aminoglycosides and amphotericin B. With once-daily dosing of aminoglycosides (5–7 mg/kg per day) and proper therapeutic drug monitoring, the incidence of acute tubular necrosis is reduced significantly. Novel amphotericin B formulations as well as the increased use of other antifungals (eg, azoles and echinocandins) reduce the risk of nephrotoxicity. Interstitial nephritis and glomerulonephritis

Table 4-7. Nephrotoxic drugs.

Acute tubular necrosis
Acyclovir

ACE inhibitors
Cyclosporine
NSAIDs
Tacrolimus

are due to hypersensitivity reactions or immune-complex formation. The most common drugs leading to interstitial nephritis are antibiotics, even though the most likely culprit, methicillin, is no longer used.

Hepatotoxicity

While a number of drugs have been associated with altered liver function tests, these changes are usually reversible on discontinuation of the offending agent. Since acute hepatic injury is classified according to morphology, drug-induced hepatic injury may cause either direct hepatocellular necrosis, cholestasis, or a mixed presentation of both (Table 4-8). Some drug combinations such as rifampin and isoniazid, amoxicillin and clavulanic acid, and trimethoprim and sulfamethoxazole also may increase the possibility of hepatotoxic reactions. This may occur because one agent alters the metabolism of the other, leading to the production of toxic metabolites. Phenytoin induces both hepatic necrosis and cholestasis in association, producing an immune response manifested by a rash, eosinophilia, atypical lymphocytosis, and serum IgG antibodies against phenytoin.

An increasingly important source of drug-induced hepatotoxicity is the use of herbal drugs. These may not be disclosed

Table 4–8. Hepatotoxic drugs.

Type of Hepatic Injury	Drug
Hepatocellular	Acetaminophen
	Allopurinol
	Amiodarone

Verapamil	

by patients without specific questioning. Toxicity may be hepatocellular or cholestatic in nature. Some herbs may inhibit or induce the CYP system (eg, St. John’s wart induces CYP3A4, reducing concentrations of cyclosporine A), and several herbal drugs affect metabolism of warfarin.

Cardiac Toxicity

Many drugs used in the ICU have potentially adverse cardiac effects. These include drugs that cause tachycardia (eg, beta-adrenergic agonists, dopamine, and theophylline), bradycardia (eg, beta-adrenergic blockers and certain calcium channel blockers), myocardial depression, and arrhythmias (eg, digoxin, theophylline, and, surprisingly, antiarrhythmic drugs).

An important but unusual adverse effect is drug-induced prolonged QT interval syndrome, sometimes associated with a chaotic ventricular tachycardia (torsade de points). Both cardiac and noncardiac drugs have been associated with this syndrome, including quinidine and procaineamide; antipsychotic drugs; antibiotics such as macrolides, fluoroquinolones, and ketoconazole; histamine-1-antihistamines; and other drugs. In some cases, patients receiving multiple drugs develop interactions that increase serum levels of the contributing agent. It should be noted that some such drugs have been withdrawn from the market because of the risk of prolonging the QT interval. Drug-induced prolonged QT syndrome and torsade de points are more common in women, those with heart disease and electrolyte disorders, and those with familial long QT syndrome. In one study, one or more of these risk factors were present in the majority of patients who had drug-induced torsade de points.

Electrolyte Abnormalities

Drugs may be associated with a variety of electrolyte and acid-base abnormalities. Some of the effects are predictable, such as hypokalemia induced by thiazide diuretics, furosemide, glucocorticoids, insulin, and beta-adrenergic agonists and hyperkalemia from spironolactone, triamterene, or angiotensin-converting enzyme (ACE) inhibitors. On the other hand, less often expected are hyperkalemia with heparin, potassium penicillin G, and trimethoprim. Hyponatremia may be a feature of thiazide diuretic administration. Amphotericin B is associated with hypokalemia, hypomagnesemia, and renal tubular acidosis.

MEDICATION ERRORS & PREVENTION IN THE ICU

Reduction of medical errors is the focus of many hospital quality improvement plans, and medication errors usually make up the vast majority of medical errors. In the ICU, attention to medication administration is very important, and systems to reduce errors have been shown to be effective.

Medication errors arise at any point—from ordering to administration. The most common errors are those of dosing without due consideration for the patient’s age, size, renal or hepatic function, or drug interactions. More rare is administration of the wrong medication; this can result from transcription errors or failure to match the medication with the patient. Because critically ill patients often have multiple clinicians participating in their care and multiple medications

prescribed, it is not surprising that there may be duplication of medication orders, inadvertent administration of two drugs for the same purpose, and unrecognized drug interactions.

Systems for minimizing medication errors in the ICU depend on careful, timely, and regular review of medications and reconciliation of orders with administered medications. Standardized intravenous mixtures, protocols for drug administration (eg, sedation guidelines and IV insulin and heparin protocols), computerized order entry, and automated review of potential drug interactions are effective tools.

5

PHYSIOLOGIC EFFECTS OF ANESTHESIA IN THE CRITICALLY ILL

Many critically ill patients undergo surgery and anesthesia before or after admission to the ICU. To take care of these patients perioperatively, an understanding of the physiologic effects of anesthesia is essential.

Anesthetics produce their primary effects by acting on the CNS. They also elicit a variety of physiologic changes throughout the body. The physiologic reserve of critically ill patients is limited because of concurrent or preexisting pathophysiologic disorders. Such individuals thus are more susceptible to physiologic derangements than normal and more apt to develop complications during the recovery period.

Recovery from the influences of anesthesia requires careful observation and specialized management. Since patients may be labile and vulnerable during this stage, they may stay in the postanesthetic care unit (PACU) until they have regained consciousness. The function of the PACU is to provide close monitoring of vital functions and to ensure prompt recognition of problems owing to anesthesia and surgery. The same functions can be served in the ICU as well.

► Anesthesia & the Airway

Soft Tissue Obstruction

Under the influence of residual anesthesia and muscle relaxant effects, airway obstruction is a common and potentially catastrophic complication in the immediate postanesthesia period. It usually results from soft tissue obstruction by the tongue and laryngopharyngeal structures when recovery from neuromuscular function is incomplete. It can be detected by physical signs and symptoms with or without abnormal blood gas measurements. Management includes hyperextension of the head, chin lift–jaw thrust maneuvers, insertion of an oropharyngeal or nasopharyngeal airway, or positive-pressure ventilation.

Laryngospasm

As the patient is emerging from anesthesia, the vocal cords are sensitive and prone to develop spasms if blood or secretions accumulate in the area of the larynx. This may result in hypoxia, hypercapnia, and respiratory arrest if not corrected promptly. Suctioning corrects the problem in most cases. If spasms persist, positive-pressure ventilation by mask with or without small doses (10–20 mg) of succinylcholine may be necessary. Endotracheal reintubation is seldom required.

Laryngoedema

Edema of the laryngeal structures may occur following extubation after anesthesia. It is usually due to use of an oversized endotracheal tube or traumatic intubation, fluid overload, or allergic reaction. In women, it may be caused by preeclampsia. It usually responds best to high humidity and nebulized racemic epinephrine. Corticosteroids may be beneficial.

Aspiration

Recovery of laryngopharyngeal function may be incomplete after anesthesia with muscle relaxant drugs. Prolonged placement of the endotracheal tube may further aggravate the situation. With an incompetent larynx, aspiration may occur following vomiting or regurgitation.

► Cardiovascular Effects of Anesthesia

Anesthesia may disrupt homeostatic regulation of the cardiovascular system by a variety of mechanisms.

Inhalation Anesthesia

A. Blood Pressure Response—All currently used inhalation anesthetics (ie, halothane, enflurane, isoflurane, desflurane, and sevoflurane) cause dose-dependent reduction in mean arterial blood pressure. The decrease in blood pressure is due primarily to a decrease in cardiac output by

myocardial depression with halothane and enflurane and a decrease in peripheral vascular resistance with isoflurane, desflurane, and sevoflurane.

B. Cardiac Effects—All inhalation anesthetics shift the left ventricular function curve downward and to the right, indicating depression of myocardial contractility. This may be due to a direct action of anesthetics on cardiac cells or on postganglionic receptors on the myocytes. The drugs may inhibit the slow Na^+ - Ca^{2+} channels and reduce Ca^{2+} influx. The degree of depression varies with different agents and concentrations. There is a consistent decrease in stroke volume as well as cardiac output, whereas the heart rate response may vary. All agents decrease the slope of phase 4 and phase 0 depolarizations and increase the action potential duration at minimum alveolar concentrations.

C. Peripheral Resistance Effects—All inhalation agents cause vasodilation and decrease peripheral resistance, but to different degrees. This effect may be due to the direct vasodilating effects on vascular smooth muscle as well as the result of decrease in sympathetic vasoconstrictor tone. Anesthetics may interfere with the movement of Ca^{2+} across the vascular endothelial membranes and within the smooth muscle cells.

D. Cardiovascular Reflexes—Inhalation anesthetic agents depress homeostatic reflex regulation of the cardiovascular system. The baroreceptor reflex is attenuated or blocked via either a central or a peripheral effect. The cardiac chronotropic response is also blunted by higher anesthetic doses.

Narcotic Anesthesia

A. Cardiac Effects—Depression in myocardial contractility has been demonstrated in a variety of isolated heart muscle preparations using different opioids in concentrations much higher than those attained clinically. Opioid receptors may not be involved in this effect. It is not preventable with naloxone pretreatment.

With the exception of meperidine, opioids cause bradycardia by stimulation of vagal preganglionic neurons in the medulla oblongata. They also may cause direct depression of the sinoatrial node at very high doses. Bradycardia can be reversed by naloxone or atropine.

B. Peripheral Resistance Effects—Aside from histamine release, morphine may cause vasodilation of both resistance and capacitance vessels through direct local effects on vascular smooth muscle or the central vasomotor center. The degree of this effect is determined by the specific opioid, the rate of injection, the baseline status of the patient, and compensatory responses. The vascular effects of morphine may not involve opioid receptors or narcotic action. Clinically, opioid-induced vasodilation occurs predominantly in patients who are critically ill or in those with underlying cardiac disease with elevated sympathetic tone.

Anesthesia with opioids in high doses (morphine, 1–3 mg/kg; fentanyl, 50–150 $\mu\text{g}/\text{kg}$) normally causes little hemodynamic

change and is well tolerated by patients with poor cardiovascular function. However, the potential risk of myocardial depression and peripheral vasodilation with opioids should not be underestimated. Adding nitrous oxide or benzodiazepines to high doses of fentanyl may produce hypotension owing to myocardial depression or peripheral vasodilation.

Regional Anesthesia

Local anesthetic agents inhibit the excitation-conduction process in peripheral nerves. In sufficient tissue concentration, they may affect the heart and smooth muscles of blood vessels, resulting in hemodynamic depression.

A. Direct Effects—All local anesthetics produce a dose-related decrease in velocity of atrial conduction, atrioventricular conduction, and ventricular conduction. Lidocaine decreases the maximum rate of depolarization, action potential duration, and effective refractory period. Bupivacaine, etidocaine, and tetracaine, which are highly potent local anesthetics, tend to decrease conduction velocity through various parts of the heart at relatively low concentrations. An extremely high concentration of local anesthetics will depress spontaneous pacemaker activity in the sinus node, resulting in sinus bradycardia and sinus arrest.

All local anesthetics essentially exert a dose-dependent negative inotropic action. High doses of bupivacaine are cardiotoxic. A biphasic peripheral vascular effect of local anesthetic agents may be observed, with vasoconstriction followed by vasodilation in high concentration.

B. Indirect Effects—Spinal or epidural anesthesia is associated with sympathetic blockade that may result in profound hypotension owing to peripheral vasodilation. The higher the spinal level of the blockade, the lower is the blood pressure.

Below the T5 dermatomal level, epidural anesthesia is not usually associated with significant cardiovascular changes. From T5 to T1, it produces about a 20% decrease in blood pressure. At T1 or above, bradycardia and a fall in cardiac output may develop as a result of blockade of cardiac sympathetic accelerator nerves. In addition to peripheral vasodilation, myocardial contractility is depressed. Hypovolemic patients are more susceptible to sympathetic blockade; profound hypotension may occur when the preload is too low. High epidural anesthesia may decrease coronary and hepatic blood flow and may alter normal autoregulation of cerebral and renal blood flow as well.

► Anesthesia & the Respiratory System

Inhalation Anesthesia

A. Control of Ventilation—In general, all volatile anesthetics decrease ventilation in a dose-related manner. When the patient is allowed to breathe spontaneously, the decrease in tidal volume reflects the depth of anesthesia. Although

anesthesia reduces metabolism and thus CO_2 production, it also increases dead space. Postoperative hypoventilation may occur under the residual effect of anesthesia on the respiratory center with resulting hypercapnia and hypoxemia.

With the exception of ether, all inhalation anesthetics cause not only a rise in resting PaCO_2 but also a diminished responsiveness of ventilation to added CO_2 . This shifts the CO_2 response curve downward and to the right, causing hypoventilation in the immediate postanesthesia period. Doxapram, which produces respiratory stimulation via peripheral carotid chemoreceptors, may be useful, but mechanical ventilation until the residual anesthesia effect completely wears off is the best treatment.

In general, inhalation anesthetics depress the hyperventilation response to hypoxemia by acting directly on the carotid body. This hypoxic ventilatory response is impaired in a dose-related manner; however, the dose required is much smaller than that required for depressing the hypercapnic ventilatory response. In the immediate postoperative period, the patient may fail to respond to hypoxemia by increasing ventilation because of impairment of this defense mechanism by residual anesthetic agent.

1. RESPONSE TO LOADING AND STIMULATIONS—In a conscious person, inspiratory effort increases when external resistance is imposed. This response is markedly depressed by anesthesia. Under the influence of anesthetics, patients with chronic obstructive pulmonary disease in particular may fail to increase ventilation when airway resistance is increased.

Ventilation increases with surgical stimulation during anesthesia. When all stimulation ceases at the conclusion of the procedure, spontaneous breathing may diminish or stop.

2. APNEA THRESHOLD—The *apnea threshold* is the PaCO_2 level at which spontaneous ventilatory effort ceases. The difference between the PaCO_2 during spontaneous breathing and during apnea is generally a constant value of 5–9 mm Hg, independent of anesthetic depth. When PaCO_2 is too low as a result of prolonged hyperventilation during anesthesia, postoperative hypoventilation or apnea can occur and lead to hypoxemia.

3. POSTHYPERVENTILATION HYPOXEMIA—Following prolonged anesthesia with hyperventilation, the body stores of CO_2 are depleted. Refilling CO_2 stores leads to low PaCO_2 and hypoventilation. Hypoxemia may occur if supplemental oxygen is not provided.

B. Mechanics of Respiration—General anesthesia and muscle paralysis have a significant impact on respiratory mechanics that may lead to impaired gas exchange.

1. FUNCTIONAL RESIDUAL CAPACITY—With induction of general anesthesia, functional residual capacity is reduced by about 500 mL within 30 seconds. The mechanisms of this effect remain unclear. Increased elastic recoil of the lung, decreased outward recoil of the chest wall, and peripheral alveolar atelectasis owing to absorption or hypoventilation

in the dependent portions of the lung are the most likely underlying mechanisms. Other possibilities include trapping of gas distal to the closed airways, increased activity of expiratory or decreased activity of inspiratory muscles, and increased thoracic or abdominal blood volume, alone or in combination.

Twenty-four hours after recovery from anesthesia—particularly following upper abdominal surgery—functional residual capacity continues to fall to the lowest value (70–80% of the preoperative level). It takes about 7–10 days to return to the preoperative volume. When closing capacity exceeds functional residual capacity, regions with a low ventilation-perfusion (\dot{V}/\dot{Q}) ratio develop, leading to atelectasis, shunting, and impaired gas exchange. Widening of the alveolar-arterial PO_2 gradient and some degree of hypoxemia are not uncommon in the immediate postoperative period.

2. COMPLIANCE OF THE LUNG AND CHEST WALL—The compliance of the total respiratory system and lungs is reduced. The pressure-volume curve shifts rightward, following induction of general anesthesia. This may be due to a decrease in functional residual capacity, an increase in recoil of the lung, and paralysis of the diaphragm. The reduction in total compliance results in a need for greater airway pressures to inflate the lungs to a given volume under anesthetic influence. A restrictive ventilatory pattern with impaired gas exchange may occur during the recovery period.

3. AIRWAY RESISTANCE—Following induction of general anesthesia and endotracheal intubation, pulmonary resistance may be doubled. The size of the airway may be altered by the decrease of lung recoil, and bronchial smooth muscle tone may be diminished by some anesthetics. The pressure-flow relationship is affected, and dynamic compliance is also decreased.

4. INTRAPULMONARY GAS DISTRIBUTION—Changes in the vertical pleural pressure gradient secondary to alterations in the shape or pattern of chest wall motion during anesthesia may influence the intrapulmonary distribution of inspired gas. In contrast to the awake state, preferential ventilation of the nondependent lung occurs in patients under general anesthesia. This redistribution does not depend on the use of muscle paralytic agents. Abnormal gas distribution and \dot{V}/\dot{Q} mismatching may exist when there is a residual effect of anesthetics or muscle relaxant.

5. POSTOPERATIVE VITAL CAPACITY—The characteristic pulmonary function profile following abdominal or thoracic surgery is a restrictive pattern with markedly reduced inspiratory capacity and vital capacity. Patients usually breathe with a shallow volume at a higher rate and cough ineffectively. The vital capacity is reduced by 50–70% of preoperative values immediately after upper abdominal surgery and remains depressed for 7–10 days. Only moderate or minimal reduction in vital capacity is observed following extremity surgery. If not improved, this defect of pulmonary mechanics may lead to atelectasis and pneumonia

during the postoperative period. Although residual effects of anesthetics and muscle relaxants may have some contribution during the immediate postoperative period, the reduction of vital capacity appears to be more related to surgical pain and the noxious reflex, which limit excursion of the diaphragm more than the anesthesia itself.

6. DIAPHRAGMATIC FUNCTION—Normally, the muscles of the chest wall, the diaphragm, and the abdominal muscles have important roles in the regional distribution of inhaled gases. Anesthesia and muscle paralysis have a significant impact on the mechanics of the chest wall, particularly the diaphragm, causing irregularities of gas distribution and exchange. Both anesthesia and muscle paralysis move the diaphragm cephalad in the recumbent and decubitus positions at the end of expiration. This is of greatest significance for the dependent parts of the diaphragm, for which abdominal pressure has the greatest influence. While displacement of the diaphragm during spontaneous inspiration is maximal in dependent regions and minimal in nondependent regions, the relationship is reversed during paralysis with mechanical ventilation. Regional gas volume and distribution are in proportion to diaphragmatic movement. In states of anesthesia and paralysis, the anteroposterior diameters of both the rib cage and the abdomen decrease while the transverse diameters increase. Compliance of the rigid thoracic compartment increases, and that of the abdomen and diaphragm decrease. The persistent tonic activity of the diaphragm throughout expiration is also abolished, and the motion of the diaphragm becomes passive. In contrast to active breathing, displacement of the diaphragm and the associated gas distribution will be different. Mismatch of ventilation and perfusion may be exaggerated.

C. Pulmonary Gas Exchange—Under general anesthesia, oxygen consumption normally decreases by approximately 10%. This may decline to 25% of normal depending on the fall in body temperature. It is raised substantially if shivering occurs. The production of CO_2 fluctuates with oxygen consumption. While it is not uncommon to mechanically hyperventilate a paralyzed patient, hypoventilation usually occurs during anesthesia with spontaneous breathing. Diffusing capacity for carbon monoxide remains unaltered, indicating that transfer across the alveolar-capillary membrane is not affected. Studies on gas exchange indicate the occurrence of ventilation-perfusion mismatching during anesthesia. The increase in $P(A-a)\text{O}_2$ gradient may be due to increased perfusion of regions with low \dot{V}/\dot{Q} ratio or increased shunt (or both). The increase in alveolar dead space appears to be a result of the relative maldistribution of ventilation.

D. Pulmonary Circulation—Normally, hypoxic pulmonary vasoconstriction is a powerful physiologic response. The mechanism is triggered by regional alveolar hypoxia (low PAO_2 or low $\text{P}\dot{\text{V}}\text{O}_2$), which causes precapillary pulmonary arterial constriction. The increase of vascular tone in the hypoxic area diverts blood flow to areas of higher oxygen

tension. This optimizes ventilation-perfusion matching in the lung and thus reduces venous admixture and maintains better gas exchange. All three currently used inhalation anesthetics inhibit hypoxic pulmonary vasoconstriction in a dose-dependent manner. This special effect of volatile agents may contribute to the inefficiency of oxygen exchange during anesthesia.

E. Diffusion Hypoxemia and Absorption Atelectasis—At the conclusion of inhalation anesthesia, when the patient starts to breathe spontaneously, diffusion hypoxemia may occur. Since nitrous oxide is 30 times more soluble than nitrogen, it will rapidly diffuse from the pulmonary capillary blood and dilute the inspired alveolar air. This causes a reduction in PAO_2 that can be corrected with supplemental oxygen.

When high concentrations of oxygen are used during anesthesia, the lung units with low ventilation-perfusion ratios may become unstable and collapse. This absorption atelectasis may widen the PAO_2 - PaO_2 gradient, particularly when ventilation is shallow and inadequate.

Narcotic Anesthesia

All opioid agonists produce a dose-dependent depression of ventilation by acting on the central respiratory center. The ventilatory effects of opioids include a decreased respiratory rate, decreased minute ventilation, increased arterial CO_2 tension, and decreased ventilatory response to CO_2 . Although equianalgesic doses of opioids are likely to produce equivalent depression of ventilation, the peak effects and durations are determined by the pharmacokinetics of each drug. Depression of ventilation is augmented and prolonged in elderly and debilitated patients and in the presence of other CNS depressants. Airway reflexes are blunted, as is the hypoxic ventilatory response. Additionally, fentanyl may cause chest wall rigidity and compromise ventilatory function.

Regional Anesthesia

Diaphragmatic function is usually preserved even with high spinal anesthesia as long as the cervical portion of the spinal cord is not involved. With paralysis of the thoracic cage, the patient may appear to experience an incoordinate breathing pattern with paradoxical abdominal respiration even though ventilatory function is well maintained at the 75–85% level. The blockade of intercostal nerves leads to abdominal muscle paralysis that may limit the ability to cough and clear secretions. When anesthetics reach the cervical region or fourth ventricle, total apnea develops.

► Anesthesia & Body Temperature

Hypothermia may occur with general anesthesia. Not only are the thermoregulatory centers depressed by anesthetic agents, but the interior and exterior of the body are also exposed to a cool environment for hours. In addition, the

peripheral vasodilatory effect associated with most types of anesthesia can aggravate heat loss and further decrease body temperature. Although hypothermia lowers total body oxygen consumption, severe depression may be fatal. Other complications of hypothermia include myocardial dysfunction, cardiac dysrhythmia, coagulopathy, and acidosis. Shivering during recovery may increase oxygen consumption as much as fourfold. During rewarming, circulatory collapse can occur if adequate fluid replacement is not provided to offset increased vascular capacitance.

► Effects of Neuromuscular Blockade

Neuromuscular blocking agents are used commonly in anesthesia to facilitate surgical procedures. Because of paralysis or weakness of skeletal muscles, such blockade has a significant influence on ventilation and airway maintenance if a residual effect persists during the recovery period. Neuromuscular blocking agents are classified as depolarizing or nondepolarizing depending on their effects at the neuromuscular junction. Depolarizing agents form strong attachments to the postsynaptic cholinergic receptor and result in persistent depolarization and paralysis. Nondepolarizing drugs bind competitively to postsynaptic cholinergic receptors and prevent acetylcholine from activating sodium channels. Residual neuromuscular blockade must be antagonized before extubation—otherwise, airway patency as well as respiratory function may be compromised postoperatively. If not reversed completely, residual neuromuscular blockade may persist into the recovery period. Recovery is monitored by peripheral nerve stimulators using a train-of-four test. There are essentially two patterns of blockade: (1) Phase 1 (depolarizing) block is produced by succinylcholine and is associated with sustained tetanus, equal train-of-four responses (muscle responses to four consecutive 2-Hz electrical nerve stimuli), and absence of posttetanic potentiation, which refers to enhanced twitch responses after tetanic stimulation. (2) Phase 2 block is caused by nondepolarizing agents or the prolonged use of succinylcholine and is characterized by tetanic fade and fade of the train-of-four responses and posttetanic potentiation. Both can recover spontaneously. Nondepolarizing agents may be reversed with anticholinesterases such as edrophonium, neostigmine, or pyridostigmine. Persistent phase 1 block requires continuous ventilatory support.

AIRWAY MANAGEMENT

In the ICU, airway management is a common challenge in daily practice. For critical care physicians, its importance cannot be overemphasized. A number of techniques must be mastered, ranging from merely lifting the chin to emergency tracheostomy. Physicians confronted with airway problems must decide whether to intervene. This requires rapid assessment of several factors such as the duration of hypoxia, the current status of the airway and ventilation, the presence of

jaw clenching, cervical spine stability, prior difficulties with intubation, and available equipment and skills. Contingency plans for various potential airway emergencies must be in place and familiar to all ICU personnel. The risk of irreversible hypoxic damage always should dictate priorities in the decision algorithm. Gloves and goggles are indicated for personal protection during manipulations of the airway.

► Secure a Patent Airway

Partial or complete obstruction of the airway results in ventilatory failure, hypoxemia, hypercapnia, and death. The first priority in management of any critically ill patient is establishment of airway patency. In the ICU, this may be accomplished urgently for cardiopulmonary resuscitation or electively for mechanical ventilation.

Mechanical Maneuvers

Whenever the airway is compromised at the pharyngolaryngeal area owing to tongue or soft tissue occlusion, the chin lift–jaw thrust maneuver is useful initially to maintain patency, particularly in conjunction with insertion of oral or nasal airways. These techniques for temporary opening of the airway can be performed easily in any unconscious patient. They are commonly followed by mask ventilation and endotracheal intubation.

It is essential to exclude cervical spine injury by appropriate x-rays at the time of a patient's arrival in the unit so that further neurologic damage can be avoided in case emergent intubation is required. Neck lift and head tilt maneuvers are contraindicated in patients with cervical spine injury. Chin lifting or jaw thrusting may be performed while the neck is maintained in the neutral position.

Clearing of vomitus, secretions, blood, and foreign bodies should be done immediately when necessary to ensure an open airway. If the risk of aspiration is high and the spine is stable, the patient should be placed in the lateral position. Adequate suction devices, including large-bore rigid and flexible cannulas, always should be available.

Artificial Airways

Artificial airways are useful when the obstruction is above the laryngopharynx. They keep the tongue from falling back and aid in removal of secretions from the posterior pharynx. Oropharyngeal and nasopharyngeal airways are used commonly. Selection of an airway of appropriate size is required to achieve optimal effect. Oral airways may prevent undesirable clenching of the teeth. Nasal airways usually are better tolerated by agitated and semiconscious patients. Lubrication with local anesthetics prior to airway insertion can be helpful. Nasal airways are contraindicated in patients with suspected basilar skull fractures or coagulopathies because they may cause severe bleeding from the nasal mucosa.

Intermediate Airways

Intermediate airways include the esophageal obturator airway, the esophageal gastric tube airway, the pharyngeal-tracheal lumen airway, and the esophageal-tracheal combitube. The first two are designed to occlude only the esophagus, whereas the latter two can be inserted into either the trachea or the esophagus. These devices are designed to establish an airway rapidly, but they fail to control the airway completely. Because of the latter shortcoming, they are not often used in the ICU.

Laryngeal Mask Airway (LMA)

The laryngeal mask airway (LMA) is designed to provide a secured patent airway by inserting variable sizes of cuffed tubes into the larynx. It has the advantages of not requiring laryngoscopy and easy insertion. However, it is contraindicated in patients with risk of aspiration. It has been used widely for anesthesia in spontaneously breathing patients. It also has proved to be useful in emergency airway management during difficult airway and cardiopulmonary resuscitation (CPR) situations. The practical use of an LMA in critical care unit is not well evaluated yet.

Brain A et al: The intubating laryngeal mask: Development of new device for intubation of the trachea. *Br J Anaesth* 1997;79:699–703. [PMID: 9496198]

▶ Endotracheal Intubation

Endotracheal intubation is indicated if the chin lift–jaw thrust maneuver fails to establish or secure a patent airway, if the patient is obtunded and aspiration is a concern, if positive-pressure mechanical ventilation is required, if tracheobronchial secretions cannot be cleared, or if complete control of the airway is desirable. In critically ill patients, use of the esophageal obturator airway and its variants should be limited to situations in which endotracheal intubation has been unsuccessful and no other methods are available.

Any maneuver involving movement of the neck should be avoided in cases of confirmed or suspected cervical spine injury. However, if the patient sustains apnea or severe hypoxemia despite conservative management, immediate endotracheal intubation may become necessary. Oral endotracheal intubation may be attempted if stability of the neck can be maintained. The risk of further damage must be balanced by the overall risk to the patient's life owing to failure to secure an airway. If time permits, fiberoptic nasotracheal intubation should be the first choice in such situations. Blind nasotracheal intubation is the alternative when a skilled operator with the necessary equipment for fiberoptic intubation is not available or when the oral approach is contraindicated, impossible, or difficult. Nevertheless, a careful orotracheal approach is common practice.

▶ Special Considerations in Airway Management

Neuromuscular Blocking Agents

At the time of intubation, jaw clenching induced by neurologic dysfunction in various disease states can obstruct the oral passage and prevent not only access to the larynx but also clearing of secretions, vomitus, blood, and foreign bodies. Even though jaw clenching usually will subside when severe hypoxia develops, the risk of irreversible cerebral damage is very high if a patent airway cannot be established immediately. Rather than attempting intubation with force, neuromuscular blocking agents are indicated to overcome jaw clenching and facilitate intubation.

Time Factors

Irreversible brain damage can result within minutes if apnea is not corrected. The period of apnea that can be sustained without brain damage depends on the degree of preoxygenation and the patient's oxygen consumption, hemoglobin concentration, cardiac output, and functional residual capacity. Patients with low reserves can tolerate only brief periods of apnea. Without preoxygenation, the customary maximum interval of allowable apnea during intubation is 30 seconds. The interval can be extended to minutes in a healthy young person who has been preoxygenated. Ventilation with a mask that provides 100% oxygen is strongly recommended before attempts at intubation are repeated. Prolonged and multiple attempts at intubation can injure the airway and cause decompensation of the cardiorespiratory system, including hypoxemia, arrhythmia, bradycardia, asystole, laryngospasm, bronchospasm, and apnea. An oxygen saturation monitor (pulse oximeter) and atropine should be available.

Endotracheal Tube Size

In adults, cuffed endotracheal tubes of different internal diameters (6.5–9 mm) should be available. Tubes with diameters of 7–8 mm are usually appropriate for females, whereas slightly larger tubes (7.5–8.5 mm) are appropriate for males. A slightly smaller tube (by 0.5 mm in each case) is usually adequate for nasal intubation. Tubes that are too large will cause laryngeal injury, particularly after prolonged intubation; tubes that are too small will increase airway resistance and the work of breathing. An endotracheal tube with a minimum internal diameter of 8 mm is advisable if bronchoscopy is anticipated. The cuff should be checked for any leak beforehand. After tube placement, the cuff should be inflated with the minimum volume necessary to prevent air leak around the tube. Breath sounds should be checked bilaterally immediately after tube placement, and the position of the tube should be checked by x-ray. When the tube is placed correctly, it is secured with tape and a bite block or oral airway to protect it from damage or crimping.

Improper Positioning

Esophageal placement of the endotracheal tube, if unrecognized, is a lethal complication. Unfortunately, esophageal intubation may not be detected immediately. Auscultation of breath sounds bilaterally is useful but not always reliable. Absence of breath sounds, increasing abdominal girth, or gurgling during ventilation in conjunction with desaturation and cyanosis should alert one to the possibility of esophageal intubation. End-tidal CO₂ measurement has become the best means of confirming proper placement of the endotracheal tube in most instances. The colorimetric end-tidal carbon dioxide detector is used frequently in non-OR facilities to confirm the right placement of endotracheal tube by color changes. However, its use in arrested patients, who have no blood circulation to the lung, is not valid. A flexible fiberoptic bronchoscope, if available, is also helpful to ensure proper positioning under direct vision.

If a tube that is too long is inserted, main stem bronchus intubation results. This occurs most commonly on the right side. If unrecognized, one-sided intubations can cause atelectasis of the opposite lung, hypoxemia owing to shunting, and an increased risk of barotrauma of the ipsilateral lung. Asymmetric breath sounds and chest movements are common findings. The tube should be withdrawn about 2–3 cm beyond the point where equal breath sounds are first heard. Chest radiographs are useful to confirm tube placement but do not always exclude main stem intubations.

Other than esophageal and main stem bronchus intubations, complications following nasal endotracheal intubation include epistaxis, nasal necrosis, retropharyngeal laceration, mediastinal emphysema, and intracranial placement of the tube. Nasal sinusitis is common and may be a cause of sepsis.

Persistent Air Leak

Persistent air leak around an endotracheal tube may result in hypercapnia and hypoxemia secondary to inadequate ventilation. The leak may be due to damage to the balloon itself or to the pilot balloon. Other causes include tracheomalacia or malposition of the cuff at or above the vocal cords. Repositioning the tube or replacement with a tube of appropriate size is required.

Surgical Airway

When endotracheal intubation is impossible or has failed after several attempts, operative creation of an airway becomes imperative. Options include needle cricothyrotomy, surgical cricothyrotomy, and tracheostomy. Jet ventilation may be used initially with needle cricothyrotomy; however, adequate alveolar ventilation is not ensured, and a formal airway is usually required in less than 45 minutes. Surgical cricothyrotomy will rapidly stabilize and secure the airway, but pressure effects will lead to necrosis if the endotracheal tube is not removed within several days.

Airway Management in Patients Requiring Prolonged Ventilation

The use of high-volume, low-pressure cuffs has greatly reduced the incidence of tracheal injury from intubation. However, damage to the laryngeal area has been a continuing problem. Tubes with high-pressure, low-compliance cuffs should be avoided or replaced. Monitoring of the cuff pressure is useful but not reliable because it does not reflect the lateral tracheal wall pressure and may fluctuate when high pressures are used to overcome poor lung compliance. Conversion to a tracheostomy is indicated when endotracheal intubation is prolonged and laryngeal damage is a concern. Other relative indications include patient comfort, easier nursing care, and facilitation of suction.

The time limit for change is debated. Three weeks is the empirical limit. Recently, earlier tracheostomy has been advocated.

PAIN MANAGEMENT IN THE ICU

Pain control in the ICU has improved significantly over the last decade with greater understanding of neurophysiologic mechanisms, anatomic pathways, causes of pain perception, and clinical pharmacology. In a sense, pain serves as a means for detection of tissue damage, for prevention of further harm, and for promotion of healing through rest. Postoperative or posttraumatic pain, however, may have no such useful purpose and may in fact be detrimental and cause complications in many organ systems. The goal of pain management in the ICU is to minimize discomfort and promote faster recovery of normal function.

► Anatomic Pathways & Physiology of Pain

Pain is perceived through the nociceptors at nerve endings throughout the body. The impulses in response to mechanical, thermal, and certain chemical stimuli are transmitted through A, δ , and C fibers to the neuraxis at the dorsal horn of the spinal cord. The marginal layer cells in lamina I and the wide-dynamic-range neurons in lamina V are activated and send projections to the nociceptive areas of the thalamus. The spinothalamic tract is the predominant but not the only pathway. Others project to the reticular formation, mid-brain, hypothalamus, and limbic forebrain structures. Impulses finally reach the cortex, where perception of pain is completed. Cells in the substantia gelatinosa modulate both segmental and descending input and exert an inhibitory effect on thalamic projection cells in the dorsal horn. Some visceral pain may pass through visceral afferents.

► Pathophysiology of Pain

Perception of pain at the neuraxis provokes both segmental reflexes and central responses. Segmentally, it causes a marked increase in local skeletal muscle tension, which not

only impairs normal function but also intensifies pain. Centrally, the sympathetic nervous system is activated, and this leads to an increase in overall sympathetic tone, thereby increasing cardiac output, blood pressure, and cardiac work load. Cardiac metabolism—as well as whole body metabolism—and oxygen consumption are augmented. Tachypnea, ileus, nausea, bladder hypotonicity, and urinary retention are not uncommon.

Pain itself—as well as the associated anxiety and apprehension—also aggravates the hypothalamic neuroendocrine response. There are increased secretions of catabolic hormones such as catecholamines, adrenocorticotropic hormone (ACTH), cortisol, antidiuretic hormone (ADH), aldosterone, and glucagon. Secretion of anabolic hormones such as insulin and testosterone is decreased. Persistent pain, if uncorrected, will result in a catabolic state and negative nitrogen balance.

► Pain & Respiratory Dysfunction

The incidence of postoperative pulmonary complications varies from 5–28%. Most of these complications are related to inappropriate control of postoperative pain. Pulmonary function can be affected significantly depending on the site and extent of surgery or trauma. Derangement of ventilation-perfusion relationships occurs, followed by abnormal gas exchange and hypoxemia. Surgery and postoperative pain cause involuntary splinting and reflex muscle spasm of the abdominal and thoracic muscles. Excursions of the diaphragm are markedly limited, particularly when ileus develops. Furthermore, in an attempt to minimize pain, the patient refrains from deep breathing and coughing. Pulmonary status deteriorates, and some patients progress to atelectasis and pneumonia. When narcotics are given in sufficient quantity, respiratory depression results. Apnea can occur in severe cases. Adequate monitoring and therapeutic facilities always should be available.

► Analgesia with Opioids

Intravenous Opioid Analgesia

Opioid analgesics alone or in combination with adjuvant agents such as nonsteroidal anti-inflammatory drugs (NSAIDs) have been used conventionally for pain relief. They are effective if prescribed properly. However, patients are frequently undertreated. The minimum effective analgesic dosage varies widely in different patients. Therefore, the dose of opioid should be individualized and titrated as needed.

The absorption of opioids following intramuscular or oral administration is variable. The intravenous route is usually appropriate for patients in the ICU because an effective plasma concentration level can be achieved promptly. Not uncommonly, small doses (3–5 mg) of morphine or other equally potent opioids are given for pain relief. Continuous

infusion of small doses of morphine (0.1 mg/min) avoids peaks and valleys in plasma concentration and provides effective relief of pain in most instances.

Patient-controlled analgesia (PCA) allows the patient to self-administer a preset amount of opioid intravenously as needed. A lock-out interval can be set to prevent overdosage. PCA permits the patient to titrate his or her own analgesic requirements and maintains a relatively steady level of minimum effective analgesic concentration. PCA is generally well accepted by patients. Overall, it provides smoother and more adequate analgesia accompanied by relief of fear and anxiety. It improves pulmonary function in postoperative patients, reduces nocturnal sleep disturbances, and decreases the overall drug requirement. The patient must be thoroughly instructed about the device in order to maximize its advantages.

The ideal agent for PCA in the ICU should have a rapid onset, a predictable efficacy, a relatively short duration of action with minimal side effects (particularly on cardiopulmonary function), and no tendency to cause tolerance or dependency. A typical prescription of PCA with morphine is a loading dose of 2–10 mg over 15–30 minutes, followed by a patient-triggered bolus (1–2 mg) via the PCA pump programmed with a lock-out interval of 5–15 minutes. This regimen may be changed based on the patient's responses. Total doses and effective therapeutic concentrations cannot be predicted. Individualization is necessary.

The combination of PCA with continuous infusion has the advantage of providing a baseline plasma level of analgesic while allowing titration of boluses to overcome varying acute changes in the threshold of pain perception.

Epidural and Intrathecal Opioids

The use of epidural and intrathecal opioids for pain relief in the ICU has increased recently. Epidural and intrathecal narcotics act mainly on spinal receptors and produce long-lasting pain relief with relatively small amounts of drug. The major advantage of this modality over local anesthesia is that sympathetic and motor nerves are not blocked.

Morphine, a highly hydrophilic drug, has been shown to spread rostrally to reach the fourth ventricle and brain stem in about 6 hours following epidural administration. There are two phases of respiratory depression. The earlier phase reflects the rise of serum levels through absorption from epidural veins. It commonly occurs 20–45 minutes after an injection. The second phase coincides with rostral spread and appears approximately 6–10 hours after injection. It causes a decrease in respiratory rate. The risk of delayed respiratory depression rises greatly if opioid is given systemically at the same time.

Fentanyl, a lipophilic agent, also travels cephalad through the cerebrospinal fluid (CSF) but extends less than morphine. When given by lumbar epidural catheter, it may not be equianalgesic with morphine for thoracic pain. It tends to have fewer side effects than morphine, and most

can be reversed with naloxone. These include nausea and vomiting (17–34%), pruritus (11–24%), and urinary retention (22–50%).

Epidural morphine has a relatively slow onset, prolonged action, and delayed occurrence of respiratory depression. Fentanyl has a rapid onset and short duration of action and is not uncommonly used for continuous epidural infusion. The addition of epinephrine to epidural narcotics is not recommended because of the increased incidence of side effects.

Intermittent epidural administration of opioids has the drawback of peak and trough concentrations, so patients may suffer unacceptable pain before adequate analgesia is restored. Continuous infusion, PCA, or a combination of both may provide better pain control in certain situations.

The epidural route has been used more commonly than the intrathecal route for postoperative pain control. Potential risks, complications, and monitoring requirements are similar for the two techniques. Because of spinal cord toxicity, not all drugs used epidurally are safe for intrathecal use. Compared with regional anesthesia, epidural or intrathecal narcotics provide highly effective pain relief with no direct effects on hemodynamics and motor function. However, they may be less effective than regional anesthesia in blocking nociceptive perception and the associated metabolic and neuroendocrine reactions.

▶ Local Anesthetic Analgesia

Postoperative or posttraumatic pain control also can be managed with long-acting local anesthetics. Brachial plexus block, intercostal block, other peripheral nerve blocks, intrapleural block, and local infiltration of the wound area are available. When feasible, continuous infusion may be more effective and reliable.

Regional Analgesia

Regional analgesia with local anesthetic agents generally provides better pain relief than opioids because anesthetic agents block both the afferent and the efferent pathways of the reflex arc. This minimizes neuroendocrine and metabolic responses to noxious stimuli. Nevertheless, when local anesthetics are administered epidurally or intrathecally, care must be exercised to minimize side effects such as hypotension and limb paralysis or weakness secondary to sympathetic and somatic nerve blockade. A proper combination of opioids and local anesthetics may achieve the ideal goal of adequate analgesia with minimum metabolic and physiologic changes.

Local Anesthetic Agents

Local anesthetics produce both sensory and motor block when a sufficient quantity is deposited near neural tissue. They are used in the ICU to provide anesthesia and analgesia through spinal, epidural, field, nerve block, or intravenous techniques.

Local anesthetics are classified as esters (eg, tetracaine, chlorprocaine, and procaine) or amides (eg, lidocaine, bupivacaine, and ropivacaine) depending on the chemical bond of their alkyl chain. The ester local anesthetics are metabolized by plasma cholinesterase, and the amide local anesthetics are metabolized by the liver. The actions of local anesthetics are affected by multiple factors, including lipid solubility, pK_a , protein binding, metabolism, and local vasoactivity. Onset of block depends on the availability of the nonionized form of the drug, which is determined by its pK_a and the tissue pH. The extent of binding to membrane protein and the time of direct contact with the nerve fiber affect its duration of action. Epinephrine (1:200,000) is frequently added to local anesthetic solutions to reduce their absorption and prolong the duration of action through local vasoconstriction.

Allergic reactions to local anesthetics are rare and more likely to occur with esters than with amides. High plasma concentrations of local anesthetics from either excessive absorption or inadvertent overdose lead to severe side effects. Hypotension, direct myocardial depression, arrhythmias, and cardiac arrest are potentially lethal complications. Perioral numbness, restlessness, vertigo, tinnitus, twitching, and seizures are common manifestations that involve the nervous system.

A. Lidocaine—Lidocaine is currently the most widely used local anesthetic in the ICU because it has a low incidence of side effects, a rapid onset of action, and an intermediate duration of action. It has a volume of distribution of 90 L, a clearance rate of 60 L/h, a distribution half-life of 57 seconds, and an elimination half-life of 1.6 hours. It is metabolized in the liver by oxidative dealkylation.

Lidocaine is used to provide pain control in spinal, epidural, caudal, nerve, and field blocks, as well as in Bier block anesthesia (IV regional block). Lidocaine in concentrations of 2–4% has been used topically in the nose, mouth, laryngotracheobronchial tree, esophagus, and urethra. Lidocaine concentrations of 0.5–1.5% are used for local infiltration. An intravenous bolus of lidocaine (1.5 mg/kg) is useful to attenuate the increase of intracranial pressure and blood pressure during laryngoscopy and endotracheal intubation.

Systemic toxicity occurs when plasma concentrations of lidocaine are above 5–10 $\mu\text{g/mL}$. Doses of 6.5 mg/kg can cause CNS toxicity.

B. Bupivacaine—Bupivacaine, commonly used in obstetric epidural and spinal anesthesia, is highly protein-bound and produces intense analgesia of prolonged duration but is relatively slow in onset. It has a volume of distribution of 72 L, a clearance rate of 28 L/h, a distribution half-life of 162 seconds, and an elimination half-life of 3.5 hours. It is metabolized primarily in the liver.

Bupivacaine is used commonly in neuraxial anesthesia and for nerve blocks. CNS toxicity occurs with plasma concentrations of 1.5 $\mu\text{g/mL}$. Clinically, doses exceeding 2 mg/kg may cause systemic toxicity. Cardiac toxicity owing to severe

Table 5–1. Commonly used local anesthetics.

Agent	Half-Life (hours)	Use	Maximum Single Dose
Amides			
Bupivacaine	3.5	Epidural, spinal infiltration	3 mg/kg
Ropivacaine	3.5	Epidural, spinal, caudal, infiltration nerve block	NA
Etidocaine	2.6	Epidural, caudal, infiltration, nerve block	3 (4) ¹ mg/kg
Lidocaine	1.6	Epidural, caudal, infiltration, nerve block	4.5 (7) ¹ mg/kg
Mepivacaine	1.9	Epidural, caudal, infiltration, nerve block	4.5 (7) ¹ mg/kg
Esters			
Procaine	0.14	Spinal, infiltration, nerve block	12 mg/kg

¹Maximum dose with epinephrine.

myocardial depression may be fatal. Levobupivacaine, an isomer of bupivacaine, causes less cardiotoxicity. Other less commonly used agents include etidocaine, mepivacaine, chlorprocaine, and procaine (Table 5–1).

C. Ropivacaine—Ropivacaine is one of the amide group of local anesthetics. It is 94% protein bound with a steady-state volume of distribution of 41 ± 7 L and is metabolized extensively in the liver. Approximately 37% of the total dose is excreted in the urine. Unlike most other local anesthetics, the presence of epinephrine has no major effect on either the time of onset or the duration of action. At blood concentrations achieved with therapeutic doses, changes in cardiac conduction, excitability, refractoriness, contractility, and peripheral vascular resistance are minimal. Ropivacaine may cause depression of cardiac contractility. Although both are considerably more toxic than lidocaine, the cardiac toxicity of ropivacaine is less than that of bupivacaine.

▶ Nonsteroidal Anti-Inflammatory Drugs

NSAIDs are a group of compounds with heterogeneous structures that relieve pain, lower fever, and decrease inflammatory reactions. The mechanism of their actions remains unclear but may involve an inhibitory effect on prostaglandin synthesis. They are useful for management of mild to moderate pain. Compared with opioids, they have both the advantages and the disadvantages of analgesia but without producing changes in sensorium or ventilatory depression and without the possibility of dependency. NSAIDs cause

platelet dysfunction and prolong bleeding time. They may produce gastric erosions and hemorrhage. Other adverse effects include interstitial nephritis, renal hypoperfusion, somnolence, nausea and vomiting, and palpitations.

Until recently, because of a lack of parenteral formulations, the use of NSAIDs in the ICU was limited. The advent of ketorolac tromethamine, which can be given parenterally, has made this class of agents more conveniently available for critically ill patients.

Ketorolac tromethamine has no direct effect on opiate receptors. It is a potent analgesic with a ceiling effect. IM doses of 30–90 mg have analgesic efficacy comparable with that of 10 mg of morphine. After IM injection, maximum plasma concentrations are achieved within 45–60 minutes.

Ketorolac tromethamine is highly protein bound and metabolized primarily by hepatic conjugation. Excretion is through the kidney. It is nonaddicting and has no effect on ventilation. Its side effects are similar to those of other NSAIDs. It should be avoided in patients with renal dysfunction and bleeding tendencies.

▶ Analgesia & Anesthesia for Bedside Procedures

Excision of Eschar in Burn Patients; Wound Debridement and Dressing Changes

The first excision may be performed without anesthesia on the fifth or sixth day following the burn. This is carried to the point of pain or bleeding and identifies the areas of second- and third-degree burn. Anesthesia with IM ketamine at up to 3–4 mg/kg or intravenous ketamine at up to 1–2 mg/kg is satisfactory for subsequent excisions. The patient is usually semiresponsive, whereas respiratory function and the gag and cough reflexes are preserved. Emergence nightmares may occur and can be reduced by giving diazepam or midazolam (IM or IV) during induction of and emergence from ketamine anesthesia. Increased sympathetic activity following ketamine administration may be beneficial in critically ill patients with circulatory depression.

Cardioversion

In cases of elective cardioversion such as atrial flutter or atrial fibrillation, there is usually sufficient time to premedicate the patient to provide a period of amnesia or hypnosis. Intravenous diazepam, 5–10 mg, or midazolam, 2–3 mg, is effective and safe. Methohexital, a short-acting barbiturate, 1 mg/kg intravenous, is also useful. Thiopental (50–100 mg) and propofol (0.5–1 mg/kg) also have been used. Narcotics alone are not sufficient. Supplemental oxygen and equipment for intubation and ventilation should be available.

MUSCLE RELAXANTS IN INTENSIVE CARE

Neuromuscular blocking agents (Table 5–2) are used frequently in the ICU. Their major drawbacks are the lack of titratable agents and the difficulty with bolus techniques.

Table 5-2. Commonly used muscle relaxants.

Drug	Loading Dose	Maintenance Dose	Time of Onset	Duration of Action	Complications
Succinylcholine	1-2 mg/kg	Not recommended	0.5-1 min	5-10 min	Vagolytic, prolonged
Pancuronium	0.1 mg/kg	0.3-0.5 µg/kg/min	3 min	45-60 min	Minimal histamine release
Atracurium	0.5 mg/kg	3-10 µg/kg/min	1.5-2 min	20-60 min	Weak histamine release
Vecuronium	0.1 mg/kg	1-2 µg/kg/min	2-3 min	25-30 min	None
Cisatracurium	0.2-0.3 mg/kg		2-3 min	30-40 min	None
Doxacurium	0.05 mg/kg		4 min	30-160 min	None
Pipecuronium	0.15 mg/kg	Supplemental dose guided by twitch monitor	3 min	45-120 min	None
Mivacurium	0.15 mg/kg		2 min	15-20 min	Weak histamine release
Rocuronium	0.6 mg/kg	0.075-0.225 mg/kg	1-1.5 min	20-30 min	None

This, coupled with inadequate monitoring, may result in inappropriate blockade and markedly delayed recovery. Nowadays, the availability of bedside intravenous pumps, nerve stimulator monitors, and intermediate-acting nondepolarizing agents has redefined their role in ICU management. Recent reports of prolonged paralysis, muscle weakness from neuromuscular junction dysfunction, and muscle atrophy following long-term treatment with neuromuscular blocking agents should alert the clinician to serious potential consequences. Whenever prolonged use of neuromuscular blocking agents is planned, the balance of benefits and complications should be carefully assessed.

There are some circumstances in critical care in which neuromuscular blocking agents are indicated but not indispensable. These include endotracheal intubation, postoperative reawakening with shivering, the presence of delicate vascular anastomoses, the need for protection of wounds with tension, tracheal anastomosis, increased intracranial pressure, insertion of invasive vascular catheters in agitated patients, and facilitation of mechanical ventilation. In other specific areas (eg, neurosurgical intensive therapy, management of tetanus, and severe status epilepticus), neuromuscular agents can either provide protection of the patient or facilitate procedures and management. Neuromuscular blocking agents in these situations are beneficial but not essential. If adequate sedation and analgesia are provided, the need for relaxants is frequently diminished. In most instances, muscle relaxation is required only when sedation and analgesia fail to achieve adequate ventilation or other therapeutic goals. Anxiety, apprehension, and confusion, together with pain and discomfort, often make patients agitated, combative, and more apt to fight against the ventilator. It is essential to provide appropriate levels of sedation and pain relief before and after a trial of neuromuscular blocking agents. Adequate intravenous administration of narcotics, either by bolus or by continuous infusion,

accompanied by benzodiazepines, usually obviates the need for neuromuscular blocking agents.

Once paralysis is induced, the feeling of total dependency and helplessness can lead to extreme anxiety and fear. This psychosomatic impact must not be ignored. Sedation with narcotics or benzodiazepines is mandatory.

► Muscle Relaxants in Mechanical Ventilation

Only rarely does a mechanically ventilated patient require neuromuscular blockade. Therapy should be instituted to make certain that the patient is properly sedated and free from pain before blockade is considered. The use of muscle relaxants is indicated for patients who have very poor thoracic or lung compliance, those who are fighting the ventilator, and those at increased risk of barotrauma from high airway pressures. If total control of ventilation is required with modalities such as an inverted I:E ratio or high-minute-volume ventilation or hypoventilation with permissive hypercarbia, muscle relaxants may be required.

Before initiating neuromuscular blockade, the patient-ventilator system should be thoroughly reviewed and evaluated. Any sudden development such as pulmonary edema, pneumothorax, or an obstructed endotracheal tube can cause contraction of the respiratory muscles, resulting in uncoordinated, asynchronous breathing. On the other hand, the ventilator settings may no longer be appropriate. Adjustments in tidal volume, inspiratory flow rate, ventilator triggering sensitivity, or mode of ventilation often can avoid the need for neuromuscular blockade.

If there is no apparent change in the patient's clinical status, and if adjustments in the mechanical ventilator fail to improve the situation, attention should be directed to the need for adequate sedation and analgesia.

▶ Depolarizing Agents

Succinylcholine

Succinylcholine is the only clinically available depolarizing neuromuscular blocking agent in the United States. It has a uniquely rapid onset (30–60 seconds) and a short duration of action (5–10 minutes). It acts as a false transmitter of acetylcholine by avidly binding to postsynaptic cholinergic receptors, resulting in persistent depolarization and muscle paralysis. Succinylcholine also stimulates all cholinergic receptors, including autonomic ganglia, postganglionic cholinergic nerve endings, and the acetylcholine receptors of the vascular system, which causes changes in blood pressure and heart rate. A peculiar bradycardia may occur after repeated bolus doses of succinylcholine, especially in children, when the interval of injections is shorter than 4–5 minutes. Use of succinylcholine in a hypoxic patient may cause irreversible sinus arrest. Muscle fasciculations from sustained depolarization following succinylcholine can increase serum K^+ by 0.5–1 meq/L and produce arrhythmias. This induced hyperkalemia is enhanced 24 hours after burns or with long-term paraplegia or hemiplegia. Succinylcholine should be avoided in these situations. Otherwise, succinylcholine remains the preferred choice of muscle relaxant for intubation in acute trauma patients.

Based on the fact that succinylcholine causes hyperkalemic cardiac arrhythmia and even arrest more frequently in pediatric patients with undiagnosed myopathy, the Food and Drug Administration (FDA) issued a warning on the succinylcholine package insert. Now the use of succinylcholine in children is only by indications, such as immediate airway security, by most anesthesiologists. Severe fasciculations also may increase intragastric pressure, resulting in regurgitation and aspiration. Succinylcholine also may trigger malignant hyperthermia.

Succinylcholine is rapidly hydrolyzed by pseudocholinesterase in the plasma to succinylmonocholine, a relatively inactive metabolite. In patients with low levels of pseudocholinesterase or atypical cholinesterase enzyme, prolonged relaxation can occur. Furthermore, when very large doses of succinylcholine are used, a phase 2 competitive block, which is similar to nondepolarizer block, may develop.

Succinylcholine is used in the ICU mainly for endotracheal intubation, especially when jaw clenching or muscle tone makes laryngoscopy difficult or impossible. The usual dose of succinylcholine is 1–2 mg/kg IV. This drug is particularly useful in critically ill patients with a full stomach, for whom a rapid-sequence intubation technique is needed.

▶ Nondepolarizing Neuromuscular Blocking Agents

Nondepolarizing neuromuscular blocking agents bind in a competitive manner principally to postsynaptic cholinergic receptors at the neuromuscular junctions, where they prevent depolarization by acetylcholine.

Pancuronium

Pancuronium bromide, a bisquaternary aminosteroid, used to be the principal muscle relaxant in critical care. It is a long-acting nondepolarizing agent, water-soluble, highly ionized, and excreted mainly through the kidney. Its clearance depends on the glomerular filtration rate. It is also metabolized and broken down into less active hydroxyl metabolites in the liver. The elimination half-life of pancuronium is 90–160 minutes, which is greatly prolonged by hepatic or renal failure.

Pancuronium is administered intravenously as a bolus of 0.1 mg/kg. Onset of complete relaxation is 3–5 minutes, and the duration of action is 45–60 minutes. Unlike monoquaternary relaxants, pancuronium causes histamine release. In large doses, because of vagolytic and sympathomimetic effects, it may cause increases in heart rate and blood pressure. Prolonged paralysis can occur after relatively large doses of pancuronium, particularly in patients with renal or hepatic dysfunction.

Atracurium

Atracurium is a nondepolarizing muscle relaxant with an intermediate duration of action. It has the unique property of being hydrolyzed through the Hoffman degradation mechanism. Renal or hepatic disease does not prolong its short elimination half-life (19 minutes). Laudanosine, its metabolite, causes cerebral irritation in high doses in several animal species. This has not been noted clinically, however, even after prolonged use of atracurium. The route of laudanosine elimination is not known for certain, but it seems that renal failure itself will not affect metabolic accumulation significantly.

For intravenous administration, 0.5 mg/kg is given in adults. The onset of action is 1.5–2 minutes, with peak relaxation in 3–5 minutes. The duration of action is 20–60 minutes. There are no cumulative effects.

Administration of atracurium should be slow and adequate in amount because rapid intravenous injection with a large bolus may result in histamine release and hypotension. Clinically, in most instances, recovery is rapid and complete once the infusion is stopped. Because of its relatively mild cardiovascular and cumulative effects, atracurium by continuous infusion appears to be useful when prolonged neuromuscular blockade is required.

Cisatracurium

Cisatracurium is a stereoisomer of atracurium with higher potency and no histamine release and thus more cardiovascular stability. It has replaced the original atracurium because of these advantages. Like atracurium, it is particularly indicated in patients with compromised hepatic and/or renal functions. The dose for intubation is 0.2–0.3 mg/kg, with onset in 3 minutes.

Mivacurium

Mivacurium is the only short-acting nondepolarizing muscle relaxant currently available. It is metabolized by plasma

cholinesterase. In some procedures, mivacurium can replace succinylcholine if short duration of muscle relaxation is needed and succinylcholine is contraindicated. Renal and hepatic patients have prolonged action of mivacurium because of decreased plasma cholinesterase in those patients. It can cause histamine release and thus is not suitable for hemodynamically unstable patients. The dose for intubation is 0.1–0.15 mg/kg, with recovery in 15 minutes.

Vecuronium

Vecuronium is a shorter-acting monoquaternary steroidal analogue of pancuronium. It is classified as an intermediate-duration nondepolarizing muscle relaxant. Because it causes no vagolytic effects and does not provoke histamine release, its use is associated with marked cardiovascular stability. The metabolism and excretion of vecuronium are mainly through the liver, although about 15–25% is excreted by the kidneys. The elimination half-life is 70 minutes. The metabolite 3-desacetyl vecuronium has about half the potency of the parent compound.

The intravenous dose of vecuronium for adults is 0.1 mg/kg. Onset of action is 2–3 minutes, peak relaxation occurs within 3–5 minutes, and the duration of action is 25–30 minutes. Continuous infusion of vecuronium is recommended for prolonged paralysis in patients with cardiovascular instability. A lower dose should be used in patients with hepatic or renal failure. In patients with cardiac failure, modification of the dose is not required.

In patients with normal renal and liver function, recovery of neuromuscular function occurs rapidly when the infusion is stopped, even after large doses. However, in patients with renal and hepatic failure, the effect may be more variable and the duration of action unpredictable.

Rocuronium

Depending on the dose, rocuronium is a nondepolarizing neuromuscular blocking agent with a rapid to intermediate onset. With rocuronium 0.6 mg/kg, good to excellent intubating conditions can be achieved within 2 minutes in most patients. The duration of action of rocuronium at this dose is approximately equivalent to the duration of other intermediate-acting neuromuscular blocking drugs. Generally, there are no dose-related changes in mean arterial pressure or heart rate associated with injection. The rapid-distribution half-life is 1–2 minutes, and the slower-distribution half-life is 14–18 minutes. Rocuronium is eliminated primarily by the liver. Patients with liver cirrhosis have a marked increase in volume of distribution, resulting in a plasma half-life that is approximately twice that of patients with normal liver function. Currently, rocuronium is used commonly to replace succinylcholine when rapid-sequence intubation is needed or when succinylcholine is contraindicated.

Doxacurium and Pipecuronium

Doxacurium and pipecuronium are as long-acting as pancuronium but are associated with better cardiovascular stability. Clinical experience with their use in the ICU is limited. Both doxacurium and pipecuronium are obsolete in clinical use owing to their lack of titratability compared with other relaxants.

► Complications of Use of Muscle Relaxants

Psychosomatic Effects

When paralysis is imposed without adequate explanation and sedation, severe psychosomatic stress and crisis may result. If both muscle relaxants and sedatives are appropriately titrated, the goal of management can be maintained in a cooperative and well-sedated but easily arousable patient.

Suppression of Cough Reflex

When all the respiratory muscles are paralyzed, the cough reflex is suppressed. Endotracheal suctioning may provoke no response or only an ineffective cough. Retention of secretions can precipitate atelectasis and lead to pneumonia.

Neuromuscular Dysfunction and Prolonged Paralysis

When controlled ventilation is indicated, prolonged use (>48 hours) of neuromuscular blocking agents is often necessary. Aside from delayed recovery from paralysis, there is evidence that some degree of neuromuscular dysfunction can occur. Clinically, these types of neuromuscular dysfunction range from generalized weakness, paresis, and areflexia to persistent flaccid paralysis for days or months. There are generally no sensory disturbances after discontinuation of relaxants.

Long periods of iatrogenic immobilization lead to disuse atrophy. Pathologic changes of motor endplates and muscle fibers have been demonstrated. Electrodiagnostic studies show evidence of neurogenic and myopathic abnormalities, as well as transmission disturbances at the neuromuscular junction. Unless strongly indicated, the duration of relaxation should be as short as possible. Range-of-motion exercises may help to prevent atrophy and contracture.

► Monitoring with a Peripheral Nerve Stimulator

Without objective monitoring of responses, overdosing of muscle relaxants is not uncommon. During surgical anesthesia, train-of-four stimuli are used to detect the degree of muscle relaxation. In the ICU, paralysis with total ablation of twitches of a train-of-four is usually not necessary. The use of peripheral nerve stimulators is helpful to titrate the requirement of neuromuscular blocking agents.

▶ Reversal of Neuromuscular Blockade

While there is no specific antagonist for depolarizing agents, nondepolarizing neuromuscular blockade can be reversed with intravenously administered anticholinesterase drugs. The commonly used anticholinesterases include edrophonium (0.5 mg/kg), neostigmine (0.05 mg/kg), and pyridostigmine (0.2 mg/kg). Anticholinergic agents such as atropine (0.01 mg/kg) or glycopyrrolate (0.008 mg/kg) are usually given simultaneously to offset the stimulation of muscarinic receptors.

A new reversal agent, cyclodextrin (Sugammadex), a large-molecule sugar derivative, has proven significant reversibility immediately after even large doses of steroid nondepolarizer (eg, rocuronium and vecuronium) and will come to clinical use soon. The need for succinylcholine will be decreased significantly if cyclodextrin is available clinically.

Naguib M: Sugammadex: Another milestone in clinical pharmacology. *Anesth Analg* 2007;104:575–81. [PMID: 17312211]

SEDATIVE-HYPNOTICS FOR THE CRITICALLY ILL

Critically ill patients are constantly exposed to an unusual and frequently noxious environment that includes pain, noise, tracheal suctioning, sensory overload or deprivation, isolation, immobilization, physical restraints, lack of communication, and sleep deprivation. These unpleasant experiences can lead to anger, frustration, anxiety, and mental stress. This may result in a diagnosis of ICU psychosis unless organic and pharmacologic causes are excluded.

Sedative-hypnotic medications are used frequently to calm the patient or induce sleep for therapeutic or diagnostic purposes. Because of associated side effects, stable cardiopulmonary function must be ensured prior to administration. Furthermore, because individual responses may vary greatly among patients—and even in the same patient at different stages of illness—dosage should be adjusted carefully. The conventional categories of sedative-hypnotic agents are the benzodiazepines, barbiturates, and narcotics. The ideal agent for use in the ICU should have a rapid onset of action, a predictable duration of action, no adverse effects on cardiovascular stability or respiratory function, a favorable therapeutic index, no tendency toward accumulation in the body, ease of administration, and available antagonists.

▶ Benzodiazepines

Benzodiazepines (Table 5–3) produce sedation, anxiolysis, and muscle relaxation. They also have anticonvulsant activity. Flumazenil is the specific antagonist for benzodiazepines at a dosage of 1 mg slowly intravenously up to a total dose of 3 mg.

Diazepam

Diazepam binds to specific benzodiazepine receptors in cortical limbic, thalamic, and hypothalamic areas of the CNS, where it enhances the inhibitory effects of γ -aminobutyric acid (GABA)

Table 5–3. Commonly used benzodiazepines.

Agent	Intravenous Dose	Duration of Action
Diazepam	2–10 mg	4–6 hours
Lorazepam	0.04 mg/kg	6–10 hours
Midazolam	0.1 mg/kg	0.5–2 hours

and other neurotransmitters. Following an intravenous dose, its onset of action is within 1–2 minutes. Maximum effect is achieved in 2–5 minutes, and the duration of action is 4–6 hours. Diazepam is redistributed initially into adipose tissue and is metabolized in the liver by microsomal oxidation and demethylation. Its active metabolites are excreted by the kidney with a half-life of 45 hours. The IM route should not be used because of poor bioavailability from unpredictable absorption. Abscesses may form at the injection site.

Diazepam is used to produce sedation and amnesia for reduction of anxiety and unpleasant stress. It is also useful for anticonvulsion, muscle relaxation, cardioversion, endoscopy, and management of drug or alcohol withdrawal.

For relief of anxiety in adults, an intravenous bolus injection of 2–10 mg is given slowly. This can be repeated every 3–4 hours if necessary. When used for cardioversion, 5–15 mg is administered intravenously 5–10 minutes before the procedure. For status epilepticus, 5–10 mg is administered intravenously and repeated every 10–15 minutes up to a maximum dose of 30 mg. For acute alcohol withdrawal, 5–10 mg is given intravenously every 3–4 hours as necessary.

Diazepam can cause prolonged dose-related drowsiness, confusion, and impairment of psychomotor and intellectual functions. Paradoxical excitement can occur. Hypotension, bradycardia, cardiac arrest, respiratory depression, and apnea have been associated with rapid parenteral injection, particularly in elderly and debilitated patients. Allergic reactions have been reported. Irritation at the infusion site and thrombophlebitis may occur.

Lorazepam

Lorazepam acts on benzodiazepine receptors in the CNS and enhances the chloride channel gating function of GABA by promoting binding to its receptors. The resulting increase in resistance to neuronal excitation leads to anxiolytic, hypnotic, and anticonvulsant effects. Lorazepam is highly lipid soluble and protein bound. It can be administered both intravenously and intramuscularly. The onset of action following intravenous injection is within 1–5 minutes, with a peak at 60–90 minutes. The duration of action is 6–10 hours. Seventy-five percent of the dose is conjugated in the liver and excreted in the urine. The elimination half-life is 12–20 hours.

Lorazepam is useful for the management of anxiety with or without depression, stress, and insomnia. It can be used for preoperative sedation as well as status epilepticus.

The common dosage for IV or IM administration is 0.04 mg/kg. Normal maximum doses are 2 mg intravenously and 4 mg intramuscularly. The dose needs to be individualized to minimize adverse effects. For status epilepticus, 0.5–2 mg may be given intravenously every 10 minutes until seizures stop.

Side effects of drowsiness, ataxia, confusion, and hypotonia are extensions of the drug's pharmacologic effects. Cardiovascular depression, hypotension, bradycardia, cardiac arrest, and respiratory depression have been associated with parenteral use of lorazepam, especially in elderly and debilitated patients. Caution and adjustment of doses are required when administering this drug to patients with liver or kidney dysfunction.

Midazolam

Midazolam, an imidazole benzodiazepine derivative, exerts its sedative and amnestic effect through binding of benzodiazepine receptors. It is two to three times as potent as diazepam. Its onset of action begins within 1–2 minutes after an IV or IM dose. Its duration of action is 0.5–2 hours. Midazolam reaches its peak of action rapidly (3–5 minutes) and has a plasma half-life of 1.5–3 hours. Its high lipid solubility results in rapid redistribution from the brain to inactive tissue sites, yielding a short duration of action. Metabolism is by hepatic microsomal oxidation with renal excretion of glucuronide conjugates. The drug's half-life can be extended up to 22 hours in patients with liver failure. It is water soluble and can be administered intravenously or intramuscularly. Pain and phlebitis at injection sites are seen less frequently than with other benzodiazepines.

Midazolam is indicated for sedation, to creation of an amnesia state, for anesthesia induction, and for anticonvulsant treatment. It has become the benzodiazepine of choice for sedation in the ICU. Midazolam can be administered intravenously or intramuscularly at a rate of 0.1 mg/kg to a maximum dose of 2.5 mg/kg. Alternatively, intermittent doses of 2.5–5 mg may be given every 2–3 hours. A rate of 1–20 mg/h or 0.5–10 µg/kg per minute can be used for continuous intravenous infusion.

Midazolam may cause unexpected respiratory depression or apnea, particularly in elderly and debilitated patients. In combination with some narcotics, midazolam may cause myocardial depression and hypotension in relatively hypovolemic patients. Monitoring of cardiopulmonary function is required.

▶ Barbiturates

The barbiturates possess sedative-hypnotic activities without analgesia.

Thiopental

This ultra-short-acting barbiturate is a potent coma-inducing agent. It blocks the reticular activating system and depresses the CNS to produce anesthesia without analgesia. It quickly crosses the blood-brain barrier and has an onset of action

within 10–15 seconds after an intravenous bolus, a peak effect within 30–40 seconds, and a duration of action of only 5–10 minutes. This initial effect on the CNS disappears rapidly as a result of drug redistribution. Thiopental is metabolized by hepatic degradation, and the inactive metabolites are excreted by the kidney. The elimination half-life is 5–12 hours but can be as long as 24–36 hours after prolonged continuous infusion. In sufficient doses, thiopental can cause deep coma and apnea but poor analgesia. It also produces a dose-related depression of myocardial contractility, venous pooling, and an increase in peripheral vascular resistance. Thiopental reduces cerebral metabolism and oxygen consumption.

Thiopental is used for induction of general anesthesia but is also useful for sedation, particularly in patients with high intracranial pressures or seizures. It is also useful for short procedures such as cardioversion and endotracheal intubation.

For induction of anesthesia, an intravenous bolus of 3–5 mg/kg is given over 1–2 minutes. Individual responses are sufficiently variable that the dose should be titrated to patient requirements as guided by age, sex, and body weight. In patients with cardiac, hepatic, or renal dysfunction, dose reduction is required. Slow injection is recommended to minimize respiratory depression. Convulsions usually can be controlled with a dose of 75–150 mg. When continuous infusion is required, the maintenance dose is 1–5 mg/kg per hour of 0.2% or 0.4% concentration. After prolonged continuous use, thiopental will become a long-acting drug.

Side effects of thiopental include respiratory depression, apnea, myocardial depression with hypotension, laryngospasm, bronchospasm, arrhythmias, and tissue necrosis with extravasation. Thiopental is contraindicated in patients with porphyria or status asthmaticus and in those with known hypersensitivity to barbiturates.

▶ Opioids (Narcotics)

Opioids (Table 5–4) have the advantage of possessing both analgesic and sedative effects.

Table 5–4. Commonly used intravenous opioids.

Agent	Usual Initial Intravenous Dose	Duration of Action
Morphine	3–5 mg	2–3 hours
Meperidine	25–50 mg	2–4 hours
Fentanyl	2–3 µg/kg	0.5–1 hours
Sufentanil	0.1–0.4 µg/kg	20–45 minutes
Alfentanil	10–15 µg/kg	30 minutes
Remifentanyl	1–2 µg/kg	<10 minutes

Opioid Agonists

Opioid agonists acting at stereospecific opioid receptors at the level of the CNS are associated with dose-related sedation in addition to their pain-relieving effects. Titration to patient response is advisable. Alterations in sensorium such as nervousness, disorientation, delirium, and hallucinations can occur. It is essential to maintain a balance between the patient's comfort and level of awareness. Opioids can cause peripheral vasodilation, but their use has rarely been associated with clinically significant cardiovascular effects. Unlike local anesthetics, opioids do not block noxious stimuli via the afferent nerve endings or nerve conduction along peripheral nerves.

Opioid agonists include morphine, meperidine, methadone, fentanyl, sufentanil, alfentanil, and remifentanil, as well as other drugs. Each produces particular pharmacologic effects depending on the types of receptors stimulated.

A. Morphine—Morphine, a pure agonist of opioid receptors, produces analgesia through its action on the CNS. It also can induce a sense of sedation and euphoria. Its volume of distribution is 3.2–3.4 L/kg, its distribution half-life is 1.5 minutes, and its elimination half-life is 1.5 hours in young adults. Elimination is prolonged up to 4–5 hours in the elderly. It has an onset of action within 1–2 minutes, a peak action at 30 minutes, and a duration of action of 2–3 hours. Morphine is metabolized primarily in the liver by conjugation with glucuronic acid. It is excreted principally through glomerular filtration. Only 10–50% is excreted unchanged in the urine or in conjugated form in the feces.

Morphine is used widely for the management of moderate to severe pain. A number of administration routes are available. These include the epidural, intrathecal, IM, and IV routes (by bolus injection such as PCA). Morphine is also very useful for sedation, particularly in patients with some pain. Other indications are myocardial infarction and pulmonary edema.

Since absorption following IM or SQ administration is unpredictable, the intravenous route is preferable in critically ill patients. The initial intravenous dose is 3–5 mg. This may be repeated every 2–3 hours as necessary to titrate effect. For maintenance, it can be given by continuous infusion at a rate of 1–10 mg/h.

Morphine causes respiratory depression through direct action on the pontine and medullary respiratory centers. It decreases the response to CO₂ stimulation. Respiratory depression, which is dose-dependent, occurs shortly after intravenous injection but may be delayed following IM or SQ administration. In therapeutic doses, morphine produces little change in the cardiovascular system other than occasional bradycardia and mild venodilation. It also causes nausea and vomiting, bronchial constriction, spasm at the sphincter of Oddi, constipation, and urinary urgency and retention. In patients with renal, hepatic, or cardiac failure, smaller doses at less frequent intervals may be necessary. Respiratory depression can be treated with naloxone, 0.4–2 mg intramuscularly or intravenously.

B. Meperidine—Meperidine, a phenylpiperidine derivative opioid agonist, is one-tenth as potent as morphine and has a slightly faster onset and shorter duration of action. Meperidine is metabolized in the liver by demethylation to normeperidine, which is an active metabolite. It has a distribution half-life of 5–15 minutes, an elimination half-life of 3–4 hours, and a duration of action of 2–4 hours. Meperidine can cause direct myocardial depression and histamine release. It may increase the heart rate via a vagolytic effect. Overdosage of meperidine may depress ventilation. Compared with morphine, meperidine produces less biliary tract spasm, less urinary retention, and less constipation. It is useful as an analgesic for short procedures that produce moderate to severe pain. It is also used to induce sedation.

For intravenous administration, the initial dose is 25–50 mg every 2–3 hours as necessary. For IM injection, 50–200 mg is given initially and repeated every 2–3 hours if required. Ventilatory depression can be reversed with naloxone. Other side effects include histamine release, hypotension, nausea and vomiting, hallucinations, psychosis, and seizures.

C. Methadone—Methadone is a synthetic mu-agonist opioid. Absorption from the stomach is fast, but the onset is slow. It is metabolized by the liver without active metabolites, so there is no need to reduce dose in renal failure patients. The elimination half-life is about 22 hours, but metabolism varied in each person, requiring careful titration to avoid accumulation and side effects. The initial dose is 5–10 mg PO bid to tid. Methadone is used initially for detoxication of opioid addiction, but now its use is emerging for the treatment of chronic pain and cancer pain. Respiratory depression is the most serious complication, especially when it is combined with benzodiazepines.

D. Fentanyl—Fentanyl, a highly lipid-soluble synthetic opioid agonist, crosses the blood-brain barrier easily. It is 75–125 times more potent than morphine as an analgesic. It has a rapid onset of action (<30 seconds), a short duration of effect, a plasma half-life of 90 minutes, and an elimination half-time of 180–220 minutes. Initially, fentanyl is redistributed to inactive tissue sites such as fat and muscle. It is eventually metabolized extensively in the liver and excreted by the kidneys.

When fentanyl is administered in repeated doses or by continuous infusion, progressive saturation occurs. As a result, the duration of analgesia—as well as ventilatory depression—may be prolonged. Fentanyl does not cause histamine release and is associated with a relatively low incidence of hypotension and myocardial depression. It has been used widely in balanced anesthesia for cardiac patients.

Fentanyl is indicated for short, painful procedures such as orthopedic reductions and laceration repair. The initial intravenous dose is 2–3 µg/kg over 3–5 minutes for analgesia. The dosing interval is 1–2 hours. A reduced dose and an increase in dosing interval may be necessary in hepatic or renal disease.

Ventilatory depression is a potential complication following fentanyl. Muscle rigidity, difficult ventilation, and respiratory failure can develop and call for administration of naloxone.

E. Sufentanil—Sufentanil, a thienyl analogue of fentanyl, has high affinity for opioid receptors and an analgesic potency 5–10 times that of fentanyl. Its lipophilic nature permits rapid diffusion across the blood-brain barrier followed by quick onset of analgesic effect. The effect is terminated by rapid redistribution to inactive tissue sites. Repeated doses of sufentanil can cause a cumulative effect. Sufentanil has an intermediate elimination half-time of 150 minutes and a smaller volume of distribution. It is metabolized rapidly by dealkylation in the liver. Metabolites are excreted in urine and feces.

Sufentanil is given intravenously in doses of 0.1–0.4 µg/kg to produce a longer period of analgesia and less depression of ventilation than a comparable dose of fentanyl. Sufentanil may cause bradycardia, decreased cardiac output, and delayed depression of ventilation.

F. Alfentanil—Alfentanil, a highly lipophilic narcotic, has a more rapid onset and a shorter duration of action than fentanyl. The onset of action after intravenous administration is 1–2 minutes. Because of the agent's low pH, more of the nonionized fraction is available to cross the blood-brain barrier. The serum elimination half-life of alfentanil is about 30 minutes because of redistribution to inactive tissue sites and metabolism. The drug is metabolized in the liver and excreted by the kidney.

Continuous intravenous infusion of alfentanil does not lead to a significant cumulative effect. Alfentanil does not cause histamine release and thus tends not to cause hypotension and myocardial depression. It can be used in patients with chronic obstructive pulmonary disease or asthma. Respiratory depression can occur with large doses.

The initial dose for intravenous injection is 10–15 µg/kg over 3–5 minutes, repeated every 30 minutes as needed. For maintenance, continuous infusion is given at a rate of 25–150 µg/kg per hour. Reduction of dosage and increase in dosing interval are required in hepatic and renal dysfunction. Muscle rigidity and respiratory depression may develop following administration of alfentanil.

G. Remifentanyl—Remifentanyl is an ultra-short-acting synthetic opioid. It is metabolized by hydrolysis of blood and tissue cholinesterase. Because of its rapid metabolism, the administration of remifentanyl has to use continuous infusion. It has very little accumulative effect even after prolonged infusion. Combination of propofol and remifentanyl infusion provides a controllable and rapid-recovery regimen for either anesthesia or sedation in the OR as well as in the ICU. Hypotension can occur if remifentanyl is given in a large dose or too fast.

Opioid Agonist-Antagonists

Opioid agonist-antagonists bind to opioid receptors and produce limited pharmacologic responses to opioids. They are effective analgesics but lack the efficacy of subsequently administered opioid agonists. The advantage of this group of drugs is the ability to provide analgesia with limited side effects, including ventilatory depression and physical dependence.

A. Butorphanol—Butorphanol, acting on different opioid receptors, has agonist and antagonist effects. It may be used for control of acute pain. However, in comparison with equianalgesic doses of morphine, it may cause similar ventilatory depression. It is metabolized in the liver to an inactive form that is largely eliminated in the bile. The onset of analgesia is within 10 minutes following IM injection, peak activity is within 30–60 minutes, and the elimination half-life is 2.5–3.5 hours. Following intravenous doses, butorphanol may increase mean arterial pressure, pulmonary wedge pressure, and pulmonary vascular resistance. It is useful for postoperative or traumatic pain of moderate or severe degree.

For the average adult, the usual intravenous dose is 0.5–2 mg every 3–4 hours as required. Butorphanol also may be given by IM injection at dosage of 1–4 mg every 3–4 hours as indicated. Side effects include dizziness, lethargy, confusion, and hallucinations. Butorphanol may increase the cardiac workload, which limits its usefulness in acute myocardial infarction or coronary insufficiency and congestive heart failure.

B. Buprenorphine—Buprenorphine is derived from the opium alkaloid thebaine. It has 50 times the affinity of morphine for the mu receptors and is a powerful analgesic drug. It is highly lipid soluble and dissociates slowly from its receptors. After IM administration, analgesia occurs within 15–30 minutes and persists for 6–8 hours, with a plasma half-life of 2–3 hours. Two-thirds of the drug is excreted unchanged in the bile and one-third in the urine as inactive metabolites. A buprenorphine dose of 0.3–0.4 mg is equivalent to 10 mg morphine.

Buprenorphine is indicated for the control of moderate to severe pain such as that of myocardial infarction, cancer, renal colic, and postoperative or posttraumatic discomfort. For IM or IV administration, 0.3–0.4 mg buprenorphine is given every 6–8 hours as needed. Drowsiness, nausea, vomiting, and depression of ventilation are common side effects. The duration of ventilatory depression may be prolonged and resistant to antagonism with naloxone.

Toombs JD, Kral LA: Methadone treatment for pain states. *Am Fam Physician* 2005;71:1353–8. [PMID: 15832538]

▶ Opioid Antagonists

Pure opioid antagonists act by a competitive mechanism in which they bind to receptors, making them unavailable to the agonist. Naloxone is the single agent used clinically.

Naloxone

Naloxone, a synthetic congener of oxymorphone, competitively displaces opioid agonists from the mu receptors and thus reverses opioid-induced analgesia and ventilatory depression. Following intravenous administration, naloxone has a rapid onset of effect (within 2 minutes) and a relatively short

duration of action (30–45 minutes). For this reason, repeated doses or continuous infusions are usually required for sustained antagonist effects. Naloxone is metabolized in the liver by conjugation, with an elimination half-life of 60–90 minutes. Naloxone is used most commonly for the treatment of opioid-induced ventilatory depression and opioid overdose.

Intravenous doses of 1–4 $\mu\text{g}/\text{kg}$ are given to reverse opioid-induced ventilatory depression. Boluses of 0.4–2 mg (intravenously, intramuscularly, or subcutaneously) may be repeated every 2–3 minutes up to a total dose of 10 mg. Continuous infusion of 5 $\mu\text{g}/\text{kg}$ per hour may reverse ventilatory depression without affecting analgesia.

Reversal of analgesia, nausea, and vomiting can occur following naloxone administration when it is given to antagonize ventilatory depression. Larger doses of naloxone have been associated with increased sympathetic activity manifested by tachycardia, hypertension, pulmonary edema, and cardiac arrhythmias.

▶ Haloperidol

Haloperidol, a butyrophenone antipsychotic agent, produces rapid tranquilization and sedation of agitated or violent patients. The mechanism of action is unclear, although it may be related to antidopaminergic activity. Onset of action is 5–20 minutes when haloperidol is given intravenously or intramuscularly. Peak action is at 15–45 minutes, although the duration of effect is highly variable (4–12 hours). Haloperidol is metabolized in the liver and excreted through the kidneys. The plasma half-life is 20 hours. Haloperidol causes few hemodynamic or respiratory changes.

For control of agitated patients, administration begins with IV or IM doses of 1–2 mg. This dosage can be increased to 2–5 mg every 8 hours. The dose may be doubled every 30 minutes until the patient is calmed. Maintenance dosage depends on individual response. As much as 50 mg over 1–2 hours has been used.

Haloperidol can cause extrapyramidal reactions and is absolutely contraindicated in patients with Parkinson's disease. Other complications include neuroleptic malignant syndrome, hypotension, seizures, and cardiac arrhythmias. Haloperidol also may antagonize the renal diuretic effect of dopamine.

▶ Intravenous Anesthetics

Propofol

Propofol, an isopropylphenol, is used increasingly for sedation and induction of general anesthesia. Following intravenous administration, it produces unconsciousness within 30 seconds. In most cases, recovery is more prompt and complete than recovery from thiopental and without residual effect. Redistribution and liver metabolism are responsible for rapid clearance of propofol from the plasma. Elimination seems not to be affected by renal or hepatic dysfunction. The

plasma half-life is 0.5–1.5 hours. Propofol has been used by continuous infusion without excessive cumulative effect. Hemodynamically, it may cause hypotension, especially in hypovolemic or elderly patients or those with heart failure. Propofol can produce transient ventilatory depression or apnea following rapid intravenous boluses.

In the ICU, propofol may be used for brief procedures such as cardioversion, endoscopy, and endotracheal intubation and for sedation of agitated, anxious patients. The dosage for sedation is 1–3 mg/kg per hour; for anesthesia, the dosage is 5–15 mg/kg per hour.

Propofol may cause ventilatory and cardiovascular depression, particularly if given rapidly or in large amounts. It has been noted to increase the prothrombin time. After high-dose and long-term infusion, rhabdomyolysis, metabolic acidosis, and renal failure had been reported. Hypertriglyceridemia had been mentioned but has not been substantially related to propofol infusion.

Ketamine

Ketamine, a phencyclidine derivative, produces dissociative anesthesia with profound analgesia and hypnosis. In contrast to inhalation anesthetics, ketamine is characterized by slightly increased skeletal muscle tone, normal pharyngeal and laryngeal reflexes with a patent airway, and cardiovascular stimulation secondary to sympathetic discharge. It has a rapid onset of action (intravenously, less than 1 minute; intramuscularly, 15–30 minutes). Its volume of distribution is 3 L/kg, and its distribution half-life is 15–45 minutes. Ketamine is eliminated by hepatic biotransformation, with a plasma half-life of 2–3 hours. With doses lower than those needed for dissociative anesthesia, ketamine induces analgesia comparable with that achieved with the opioids. It also produces bronchodilation.

In the ICU, ketamine is useful as a sole anesthetic or analgesic agent for relatively short diagnostic and surgical procedures that do not require muscle relaxation. It has been used for treatment of persistent status asthmaticus. It is one of the agents of choice for the care of burn patients. An IV dose of 2 mg/kg or an IM dose of 10 mg/kg may be used to produce surgical anesthesia. For maintenance, 10–30 $\mu\text{g}/\text{kg}$ per minute is given by continuous infusion. Ketamine at a dosage of 0.2–0.3 mg/kg produces analgesia with little change in the level of consciousness. It is particularly useful in patients who have cardiovascular depression and are in constant pain.

Transient emergence hallucinations, excitement, and delirium have been associated with ketamine administration in 5–30% of patients. Stimulation of the cardiovascular system may cause tachycardia, hypertension, and increased myocardial oxygen consumption. Other side effects include nystagmus, nausea, paralytic ileus, increased skeletal muscle tone, and slight elevation in intraocular pressure. Severe respiratory depression or apnea may occur following rapid intravenous administration of high doses. Ketamine is contraindicated in patients with increased intracranial pressure because it augments cerebral blood flow and oxygen consumption.

MALIGNANT HYPERTHERMIA

ESSENTIALS OF DIAGNOSIS

- ▶ History of exposure to agents known to trigger malignant hyperthermia.
- ▶ Development of muscle rigidity.
- ▶ Signs of hypermetabolic activity with hyperthermia.
- ▶ Confirmation by muscle biopsy with caffeine-halothane contracture test.

General Considerations

Malignant hyperthermia is a syndrome characterized by a paroxysmal fulminant hypermetabolic crisis in both skeletal and heart muscle. Massive heat is generated and overwhelms the body's normal dissipation mechanisms. It is a complication uniquely associated with anesthesia. Almost any anesthetic agent or muscle relaxant may trigger malignant hyperthermia. Halothane and succinylcholine are the most common offenders. Malignant hyperthermia can occur at any time perioperatively—before, during, or after the induction of anesthesia.

The incidence of malignant hyperthermia is difficult to assess because of various regional distributions. It is estimated to occur in 1:50,000 adults and 1:15,000 children undergoing general anesthesia.

Pathophysiology

Malignant hyperthermia is a genetically predisposed syndrome transmitted as an autosomal dominant trait with reduced penetrance and variable expressivity. The precise cause has not been fully elucidated. The central pathophysiologic event is a sudden increase in intracellular Ca^{2+} concentration in skeletal and perhaps also cardiac muscles triggered by causative agents. This may be due to any of the following mechanisms singly or in combination: increased release of Ca^{2+} from the sarcoplasmic reticulum, inhibition of calcium uptake in the sarcoplasmic reticulum, defective accumulation of calcium in mitochondria, excessive calcium influx via a fragile sarcolemma, and exaggeration of adrenergic activity.

The excessive myoplasmic calcium activates ATPase and phosphorylase, thus causing muscle contracture and a massive increase in oxygen consumption, CO_2 production, and heat generation. The toxic concentrations of calcium within mitochondria uncouple oxidative phosphorylation that leads to increased anaerobic metabolism. The production of lactate, CO_2 , and heat is accelerated. Membrane permeability increases when the ATP level eventually falls. This allows K^+ , Mg^{2+} , and PO_4^{2-} to leak from and calcium to flow into myoplasm. As a result, severe respiratory and metabolic acidosis develops, followed by dysrhythmias and cardiac arrest.

Rhabdomyolysis, hyperkalemia, and myoglobinuria are common consequences of muscle damage.

Clinical Features

A. Symptoms and Signs—Unexplained tachycardia (96%) and tachypnea (85%) are usually the earliest and most consistent—but nonspecific—signs of malignant hyperthermia. The patient also may present with profuse sweating, hot and flushed skin, mottling and cyanosis, arrhythmias, and hypertension or hypotension. During anesthesia, the canister of CO_2 absorbent is overheated. Evidence of increased muscle tone may appear in the form of marked fasciculations or sustained muscle rigidity.

A rapid rise of body temperature (1°C per 5 minutes) is a classic but relatively late sign. The magnitude and duration of fever directly affect the mortality rate. Conventionally, the diagnosis of malignant hyperthermia is based on the clinical triad of (1) a history of exposure to an agent or stress known to trigger the episode, (2) development of muscle rigidity, and (3) signs of hypermetabolic activity with hyperthermia. However, 20% of patients may never manifest any perceptible hyperthermia or muscle rigidity. Signs of pulmonary edema, acute renal failure, myoglobinuria, disseminated intravascular coagulation, and cardiovascular collapse may occur subsequently.

B. Laboratory Findings—Respiratory and metabolic acidosis with hypercapnia is the characteristic finding on arterial blood gas analysis. Clinically, a sudden marked increase in end-tidal CO_2 is the best early clue to the diagnosis. Hypoxemia, hyperkalemia, hypermagnesemia, myoglobine-mia, hemoglobinemia, and increases in lactate, pyruvate, and creatine kinase may be seen.

C. Special Tests—The diagnosis can be confirmed by muscle biopsy with the caffeine-halothane contracture test. Clinically, rapid resolution after treatment with dantrolene is highly suggestive.

Genetic testing for a ryanodine receptor on chromosome 19q13.2 is the major locus of malignant hyperthermia susceptibility, but there are several other loci, and a high mutation rate has been identified.

Currently, there are six malignant hyperthermia diagnostic centers in the United States for performing contracture and genetic testing. The Malignant hyperthermia Hotline (1-800-644-9737) is available 24 hours a day for consultation.

Complications

Late complications of malignant hyperthermia involve multiple organ systems (Table 5-5).

Treatment

Early diagnosis and prompt drug treatment cannot be overemphasized. To be effective, dantrolene must be given

Table 5-5. Late complications of malignant hyperthermia.

Site	Complication
Heart	Increase in myocardial oxygen consumption, decrease in myocardial contractility, decrease in cardiac output, hypotension, dysrhythmia, and cardiac arrest.
Lungs	Pulmonary edema.
Central nervous system	Cerebral edema and hypoxia, convulsion, of, coma, brain death, and increased sympathetic activity.
Kidneys	Acute renal failure, myoglobinuria, and hemoglobinuria.
Hematologic system	Disseminated intravascular coagulopathy, hemolysis.
Liver	Increased hepatic enzyme activity.
Musculoskeletal system	Muscle edema and necrosis.

before tissue ischemia occurs. Hyperthermia must be controlled as quickly as possible. Standard supportive and cooling measures should be started immediately and simultaneously with the administration of dantrolene.

The treatment of malignant hyperthermia should proceed as follows:

1. Immediately discontinue all possible triggering agents if any are still in use.
2. Perform intubation and start hyperventilation with 100% oxygen.
3. Initiate active cooling by internal and external measures; use intravenous refrigerated saline, iced saline lavage of the stomach or rectum, surface cooling with a thermal blanket, ice or alcohol, and fans.
4. Dantrolene sodium is the only specific drug for treatment of malignant hyperthermia. A hydantoin derivative, it acts by inhibiting the release of calcium from the sarcoplasmic reticulum. Intravenous dantrolene should be started at a rate of 1–2 mg/kg. Warming the preservative-free sterile water to fasten dissolving dantrolene is recommended. Repeat the same dose every 15–30 minutes up to 10–20 mg/kg, if necessary, until signs of improvement become evident. Response is indicated by slowing of the heart rate, resolution of arrhythmia, relaxation of muscle tone, and decline in body temperature. Because retriggering may occur, dantrolene should be continued for 24–48 hours.
5. Fluid resuscitation, diuretics, procainamide, and bicarbonate should be used as indicated.
6. Continue to monitor the patient closely.

Prognosis

The mortality and morbidity rate, high 2 decades ago (70%), is now much lower (10%) because of earlier diagnosis and effective treatment.

Nutrition

6

John A. Tayek, MD

NUTRITION & MALNUTRITION IN THE CRITICALLY ILL PATIENT

In the critically ill patient, nutritional status plays a key role in recovery. The extent of muscle wasting and weight loss in the ICU is inversely correlated with long-term survival. However, because conventional nutritional therapy of malnourished critically ill patients has not been demonstrated to produce anabolism, blunting of the catabolic state may be the more effective strategy. The use of conventional nutritional support and the role of newer nutritional adjunctive techniques used in the critical care setting will be discussed in this chapter.

► Metabolic & Nutritional Changes During Critical Illness

Acute-Phase Response

The acute-phase response to sudden illness or trauma is one of the most basic features of the body's defenses against injury. Phylogenetically, this response could be considered the most primitive one that occurs, and it is similar for insults owing to trauma, burns, or infections. It includes alterations in amino acid distribution and metabolism, an increase in acute-phase protein synthesis, increased gluconeogenesis, reductions in serum iron and zinc levels, and increased serum copper and ceruloplasmin levels. Fever and negative nitrogen balance follow as a consequence of these changes.

Changes in levels of cytokines and hormones occur as part of the acute-phase response. For example, an infectious process in the lung will attract monocytes that will be transformed into macrophages at the site of infection. These macrophages will secrete proteins known as cytokines and other peptides that attract other white blood cells and initiate the inflammatory response common to many types of injury. These cytokines include tumor necrosis factor- α

(TNF- α) and interleukins 1–32. TNF- α and other cytokines circulate to the liver, where they inhibit albumin synthesis and stimulate the synthesis of acute phase proteins, including (1) C-reactive protein, which promotes phagocytosis and modulates the cellular immune response, (2) α_1 -antichymotrypsin, which minimizes tissue damage from phagocytosis and reduces intravascular coagulation, and (3) α_2 -macroglobulin, which forms complexes with proteases and removes them from circulation, maintains antibody production, and promotes granulopoiesis. TNF- α and some of the interleukins also circulate to the brain, where they are responsible for induction of fever and initial stimulation of adrenocorticotrophic hormone release with a subsequent rise in serum cortisol.

Hormonal Changes

A. Insulin Resistance—As a result of severe injury, many patients develop the syndrome of insulin resistance with hyperglycemia even though they had no history of diabetes prior to the injury. Patients with new-onset diabetes, defined as two random blood glucose determinations greater than 199 mg/dL or two fasting blood glucose determinations greater than 125 mg/dL, have an increased hospital and ICU mortality compared to known diabetics. Hospital mortality increased 3–16% in new-onset diabetic patients compared with known hospitalized diabetic patients. ICU mortality is increased threefold in this group of patients (30% versus 10%). New-onset diabetic patients had the same level of injury as the known diabetics. The higher mortality may be due to the proinflammatory effect of an elevated glucose concentration.

Both the injury response and the septic state are associated with a decrease in whole body glucose oxidation and an increase in the fasting hepatic glucose production rate. Recently, it has been demonstrated that the elevated blood glucose in sepsis and injury is due to an overproduction of glucose by the liver.

The rise in serum cortisol is one of the many factors responsible for the development of insulin resistance. Insulin resistance is easy to diagnose because the injured patient will develop an elevated blood glucose level (fasting >125 mg/dL or nonfasting >199 mg/dL). In addition to cortisol, elevations in catecholamines, glucagon, and growth hormone in the injured patient also contribute to the development of insulin resistance. All these hormones increase the rate of hepatic glucose production.

Increased catecholamine levels are a direct response to the injury via secretion of these hormones by the adrenal gland and sympathetic ganglia throughout the body. Glucagon and growth hormone levels increase in response to the injury. Both hormones are known to increase hepatic glucose production.

B. Thyroid Hormones—As a normal response to injury, the body's ability to convert the stored form of thyroid hormone, thyroxine (T_4), into the active form, triiodothyronine (T_3), becomes impaired. There is increased conversion of T_4 to an inactive thyroid hormone known as *reverse* T_3 (rT_3) rather than T_3 . This may have evolved as an energy-saving response during severe injury or illness to reduce the known contribution of T_3 to increased resting energy expenditure. Thus the syndrome of low T_3 (sick euthyroid syndrome) seen in acute illness is an adaptive strategy that reduces the normal effects of T_3 on resting energy expenditure.

In clinical trials, normalization of T_3 values by replacement of thyroid hormone in cardiovascular surgery patients has been accomplished without noted harm. However, in critically ill patients, the administration of T_3 should not be provided until clinical trials are performed to document an improved clinical outcome.

Catabolism and Urine Urea Nitrogen

As part of the injury response resulting in protein breakdown, critically ill adult patients may lose about 16–20 g of nitrogen (in the form of urea) in the urine per day—compared with about 10–12 g/day in normal individuals. In some septic patients, losses have been noted to be as high as 24 g of urinary urea nitrogen per day. The loss of 1 g of urinary urea nitrogen is equal to the nitrogen contained in 6.25 g protein. This amount of protein is equal to approximately 1 oz of lean body mass. As one can calculate, the loss of 16 g nitrogen as urinary urea therefore is equal to the loss of about 1 lb of skeletal muscle or lean body mass per day.

Specific areas of loss of lean body mass may result in functional impairment of the respiratory muscles (including the diaphragm), heart muscle, and gastrointestinal mucosa, thus contributing to the development of respiratory failure, heart failure, and diarrhea. Rapid development of malnutrition can occur in the critically ill patient as a result of these large daily losses of lean body mass. The patient who enters the ICU at 100% of ideal body weight (IBW) usually will not survive a weight loss greater than 30%. However, because

large changes in intravascular and extravascular fluid may occur in critically ill patients, body weight needs to be correlated with loss in lean body mass (estimated from urinary creatinine) to confirm that any weight changes are not just due to changes in fluid volume.

The injury response is associated with an increase in both protein synthesis and protein degradation, as determined by either stable or radioactive amino acid tracer infusion studies. In contrast to increased whole body protein synthesis, skeletal muscle protein synthesis is usually reduced, so the increased whole body protein synthesis may be due to production of acute-phase proteins, leukocytes, complement, and immunoglobulins. Leukocytes have a 4–6-hour half-life during infection, so adequate nutritional support is important for their replacement and function. It has been estimated that the average adult can break down and resynthesize up to 400 g protein per day.

Conventional Total Parenteral Nutrition and Loss of Lean Body Mass

It has been demonstrated that conventional total parenteral nutrition (TPN) given at a rate of 39 kcal/kg per day and 1.8 g/kg per day of protein did not stop the loss of lean body mass in acute illness. Despite this aggressive feeding regimen, critically ill patients lost an average of 24 g nitrogen (1.5 lb of lean body mass) per day over a 10-day period, resulting in a 15-lb loss of lean body mass. These patients were able to increase the fat content of their bodies by about 5 lb over this same period, but they were unable to increase lean body mass. It was concluded that conventional TPN in this study was able to ameliorate the overall nitrogen and lean body mass loss but was not able to produce a net protein anabolism. Because of the inability of conventional TPN to stop progressive loss of lean body mass in acute illness, several anabolic agents (eg, insulin, anabolic steroids, and growth hormone) have been or may be studied in the future to see if they can prevent the loss of lean body mass and its functional consequences.

▶ Nutritional Assessment & Prediction of Outcome

Nutritional Markers

Conventional nutritional assessment in the critically ill patient is of limited value. Daily weights in critically ill patients are helpful more for the determination of fluid changes and less for the determination of actual loss of lean body mass. The 24-hour urine urea nitrogen measurement is the single best determination of the severity of the injury response, but it cannot be used in those who have oliguric renal failure. Daily measurement of urine urea nitrogen is inexpensive and provides a good marker of catabolism that may not be detected from systemic signs such as tachycardia, tachypnea, or fever. Unfortunately, the severity of the

catabolic response to injury is the same in malnourished and nonmalnourished patients. Therefore, the absolute urine urea nitrogen content does not indicate who is initially more malnourished.

Protein requirements for critically ill patients can be estimated by the use of the 24-hour urinary urea loss. Add 4 g to the quantity of urinary urea (in grams) to get an estimate of total nitrogen losses (in grams). For example, if the urine urea nitrogen is 12 g per day, add 4 g to equal 16 g of nitrogen loss per day. Multiply this amount by 6.25 to determine the protein requirement per day (16 g nitrogen \times 6.25 g protein/g of nitrogen = 100 g of protein per day). Adjustments should be made based on the urinary urea loss + 4 g + additional nitrogen losses estimated if there are severe stool, skin, or fistula losses.

Serum Albumin

The serum albumin level is one of the best predictors of malnutrition because it provides the clinician with an index of visceral and somatic protein stores in most medical illnesses. Exceptions include anorexia nervosa and congenital analbuminemia (rare). Serum albumin level rarely increases during most hospital stays because of albumin's 21-day half-life. Thus, while serum albumin is a marker of initial nutritional status, serum transferrin (7-day half-life) or, better yet, prealbumin (1-day half-life) responds more rapidly to nutritional support. Either one can be used to monitor sequential measurements, which would reflect improvements in nutritional intake and status.

Albumin is a 584-amino-acid protein with a net negative charge of 19, permitting transport of many compounds. Large portions of the plasma's calcium, magnesium, zinc, bilirubin, many drugs (eg, anticoagulants, antibiotics, etc.), and free fatty acids are transported bound to albumin. Approximately 40% of whole body albumin reserves (4–5 g/kg) are intravascular, and albumin is responsible for about 76% of the colloid oncotic pressure of the plasma. Patients with normal serum albumin levels have less wound edema, and the inflammatory phase of wound healing is shortened.

A. Causes of Hypoalbuminemia—Except for the rare patient with analbuminemia, hypoalbuminemia results from an increase in plasma volume; an increase in skin, urine, or stool losses of albumin; an increase in albumin degradation; loss into ascites; or a reduction in albumin synthesis. Bed rest is associated with an approximately 7% increase in plasma volume and an equal reduction in serum albumin. In patients who are hypoalbuminemic, plasma volume can increase by 18% with bed rest. Because the skin stores approximately 20% of the total albumin mass, excessive losses of albumin occur with burns and subsequent exudative losses. Massive losses of protein can occur in the nephrotic syndrome, in which 60% to as much as 90% of the protein lost in the urine is albumin. Gastrointestinal losses of protein can vary markedly, and the amount of albumin normally degraded and lost in the stool is not known. In addition,

large amounts can be lost into ascites fluid. A third factor contributing to the development of hypoalbuminemia is impaired albumin synthesis in the liver. Albumin is synthesized in the hepatocyte as a larger precursor, preproalbumin, containing 24 additional amino-terminal amino acids referred to as the *signal peptide*. The preproalbumin undergoes two sequential cleavages within the rough endoplasmic reticulum within 3–6 minutes of initial formation and is transported to the Golgi apparatus within 15–20 minutes for subsequent vesicular release. Albumin synthesis is inhibited by severe protein and calorie deprivation, ethanol, severe liver disease, malabsorption, early forms of injury, burns, infections, cancer cachexia, and aging.

B. Albumin Synthesis—The rate of albumin synthesis (normally 150 mg/kg per day) is stimulated by (1) reduction in colloid oncotic pressure, (2) antibiotic treatment, (3) glucocorticoid therapy in cirrhosis, and (4) amino acid administration. Albumin synthesis was increased to 350 mg/kg per day in a small group of patients with idiopathic tropical diarrhea following 2 weeks of tetracycline therapy. In a small group of patients with cirrhosis, prednisolone, 60 mg daily for 2 weeks, was associated with an increase of albumin synthesis from 130 to 260 mg/kg per day.

In one study, albumin synthesis is more stimulated (240 mg/kg per day) after 300 kcal of amino acid administration than after 400 kcal of glucose administration (160 mg/kg per day). Furthermore, albumin synthesis is higher (360 mg/kg per day) when providing a total of 700 kcal/day rather than only 300 kcal/day (albumin synthesis rate 240 mg/kg per day) for the same protein intake (1 g/kg per day).

There is a positive correlation between albumin synthesis rate and serum concentrations of leucine, isoleucine, valine, and tryptophan. It appears that the albumin synthesis rate in cancer cachexia is also responsive to isonitrogenous amounts of a branched-chain-enriched amino acid solution. In one study, cancer patients increased albumin synthesis from 100 to 190 mg/kg per day as a result of increased administration of leucine, isoleucine, and valine (branched-chain amino acids). These observations imply that providing a diet rich in tryptophan, leucine, isoleucine, and valine may stimulate albumin synthesis.

Nutritional Predictors of Outcome

Serum albumin is an excellent predictor of survival (Table 6–1). At least 22 studies to date have shown that a below-normal serum albumin level can be used to predict disease outcome in many groups of patients. Thirty-day mortality rates for a total of 2060 consecutive medical and surgical admissions were reported at a Veterans Affairs hospital. The investigators found that 24.7% of the patient population had a low albumin, defined as less than 3.4 g/dL. The 30-day mortality rate for hypoalbuminemic patients was 24.6% compared with 1.7% in patients with normal serum albumin levels. The investigators also demonstrated an excellent correlation between serum albumin levels and 30-day mortality rates. In

Table 6–1. Serum albumin and increased mortality risk in various published studies.

Diagnosis or Study Group	n	Normal Serum Albumin (g/dL) ¹	Mortality, Normal Serum Albumin	Mortality Low Serum Albumin	Relative Mortality Risk of Low Serum Albumin
Medical and surgical patients	500	3.5	1.3%	7.9%	6.1
Critically ill	55	3.0	10.0%	76.0%	7.6
Surgical patients	243	3.5	4.7%	23.0%	4.9
Hodgkin's disease	586	3.5	1.0%	10.0%	10.0
Malnutrition	92	3.5	8.0%	40.0%	5.0
Colorectal surgery	83	3.5	3.0%	28.0%	9.3
Alcoholic hepatitis	352	3.5	2.0%	19.8%	9.9
Cirrhosis	139	2.9	32.0%	52.0%	1.6
Lung cancer	59	3.4	49.0%	85.0%	1.7
Heart disease	7,735	4.0	0.4%	2.3%	6.1
Multiple myeloma	23	3.0	25.0%	50.0%	2.0
Trauma	34	3.5	15.4%	28.6%	1.9
Sepsis	199	2.9	0.7%	15.9%	22.7
Pneumonia	456	3.5	2.1%	8.3%	4.0
Pneumonia	38	3.0	0.0%	10.0%	—
VA Hospital	152	3.5	3.3%	7.8%	7.8
VA Hospital	2,060	3.5	1.7%	14.5%	14.5
CABG/Cardiac valve surgery	5,156	2.5	0.2%	0.9%	5.7
Preoperative (VA hospital)	54,215	3.5	2.0%	10.3%	5.1
Beth Israel Hospital	15,511	3.4	4.0%	14.0%	3.5

Stroke	225	3.5	20.0%	55.0%	2.7

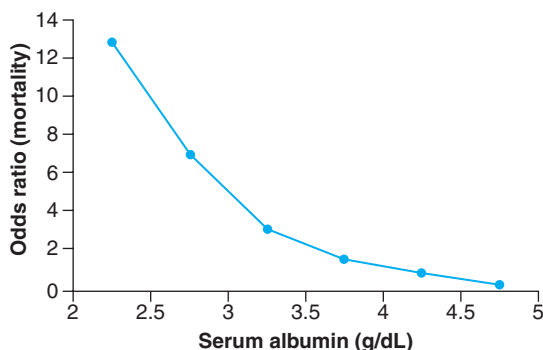

¹Serum albumin, g/dL, separating normal and low albumin groups for each study.

a recent meta-analysis, for each 1.0-g decrease in serum albumin concentration, the odds ratio for mortality increased by 137%. However, the relationship between albumin concentration and mortality is not linear. In 13,473 patients on hemodialysis, for example, mortality increased in an exponential fashion as serum albumin decreased. If one sets the risk for death equal to 1 at an albumin level of 4.25 g/dL, then the risk for death drops to 0.47 if the serum albumin is greater than 4.4 g/dL. In contrast, the odds ratio for mortality increases 12.8-fold for patients with an albumin level less than 2.5 g/dL as compared with baseline.

A simplified formula for estimating the relative risk of death in patients with chronic renal insufficiency is $128/(\text{albumin}^3)$, where albumin is in grams per deciliter. A serum albumin level of 4 g/dL has a twofold risk of death,

and a serum albumin level of 2 g/dL has a 16-fold risk of death (Figure 6–1).

In a large group (54,215) of surgical patients, there also was an exponential increase in 30-day mortality as albumin decreased. For example, 30-day mortality was 1% in patients with a normal concentration (albumin >4.6 g/dL), and mortality increased to 29% with an albumin concentration of less than 2.1 g/dL. The relationship between surgical mortality and serum albumin concentration also was exponential. A simplified equation to estimate the risk of mortality could be used, where mortality is equal to $60/\text{albumin}^2$. Surgical patients with an albumin level of 1 g/dL have an approximate 60% mortality. In comparison, surgical patients with an albumin level of 4.5 g/dL have a 3% mortality.

▲ **Figure 6-1.** In patients undergoing hemodialysis, lower serum albumin is a predictor of increased mortality. The risk of death (odds ratio) is increased 12.5-fold in the group with the lowest albumin concentration.

In addition to the use of serum albumin, the patient's caloric intake predicts survival. Patients provided with an adequate caloric intake (1632 versus 671 kcal/d) have an eightfold reduction in mortality (11.8% versus 1.5%). At the same albumin concentration (<3.0 g/dL), survival is longer in those who have a normal energy and protein intake. This is also true for patients with advanced liver cirrhosis. In comparison, a recent, very large study in which additional calories were provided to patients with stroke failed to demonstrate reduced mortality. However, in a recent meta-analysis, all-cause mortality was reduced from 13.7% to 9.7% when patients received supplement feeding.

In summary, serum albumin concentration and energy intake in critically ill patients provide the clinician with tools to help predict recovery or demise. Albumin levels should be monitored at regular intervals (weekly) and caloric intake should be determined daily in patients who are ill and at risk for malnutrition. Once hypoalbuminemia is documented, albumin measurement is not an ideal indicator of nutritional repletion because it returns to normal slowly (half-life 21 days) and lags behind other laboratory indices of nutritional status such as transferrin (half-life 7 days), prealbumin (half-life 1 day), insulin-like growth factor-1 (IGF-1; half-life 20 hours), and retinol-binding protein (half-life 4 hours). Albumin replacement itself does not reverse the metabolic process that the hypoalbuminemic state represents. The reduced level of protein reserves in the patient and the severity of the metabolic injury are the two most important determinants of serum albumin level.

► Features of Malnutrition in Critical Illness

Symptoms and Signs

It is important to ask patients if they have been able to maintain appetite and body weight over the last several months. A history of recent hospitalization is important because of the

common development of protein malnutrition during a hospital stay. Physical examination should include an estimate of muscle mass, noting especially a loss of temporalis muscle mass, “squaring off” of the deltoid muscle, and loss of thigh muscle mass. Measurement of body weight should be standard on all ICU admissions, and weight should be followed on a daily basis. Daily weights are facilitated in the ICU by use of beds with built-in scales. Although it can be argued that body weight is not a good marker of nutritional status in the ICU—and this may be true for many patients—body weight is also useful as a marker of changes in fluid status.

Laboratory Findings

Up to 50% of hospitalized surgical and medical patients have either hypoalbuminemic malnutrition or marasmic-type malnutrition. Hypoalbuminemic (protein) malnutrition is diagnosed by finding reduced serum albumin or other protein (eg, transferrin, prealbumin, etc.) level. Serum albumin is used most commonly. Marasmic malnutrition is identified in anyone who has lost 20% or more of usual body weight over the preceding 3–6 months or who is at less than 90% of ideal body weight. Marasmic malnutrition is starvation without injury; protein malnutrition always accompanies injury (eg, trauma, sepsis, inflammation, or cancer). Of these two types of malnutrition, hypoalbuminemic malnutrition is the most common. Hypoalbuminemia was associated with a 4-fold increase in dying and a 2.5-fold increased risk of developing a nosocomial infection and sepsis. Table 6-1 shows that a low serum albumin level predicts a significant increase in mortality rate in a variety of types of patients and diseases.

Delayed Hypersensitivity

Delayed hypersensitivity, as measured by skin testing, is frequently abnormal or absent (anergic) in patients with hypoalbuminemic malnutrition. When five appropriate antigens are used for testing delayed hypersensitivity in such patients, failure to respond to more than one antigen was associated with an 80% 2-year mortality rate compared with an overall 35% mortality rate. In another study of over 500 patients, anergy was associated with a fivefold increase in numbers of deaths in trauma patients and a sixfold increase in septic patients.

Lean Body Mass

The use of body weight as an index of muscle mass in ICU patients is very difficult because of fluid shifts that occur in the extracellular compartment. Body weight can be divided into three compartments: extracellular mass, lean body mass, and fat mass. Extracellular fluid is known to increase as a result of critical illness even in well-nourished individuals, but the degree of increase in extracellular fluid is greater in

the malnourished. Much of this is accounted for by fluid shifts into the extracellular space because of reduced plasma colloid oncotic pressure.

Lean body mass is the sum of skeletal muscle, plasma proteins, skin, skeleton, and visceral organs, with the skin and skeleton accounting for 50% of the total. There are no convenient markers to determine loss of nitrogen from skin or skeleton. The plasma proteins account for only 2% of the lean body mass, but measurement of plasma proteins can reflect the overall status of the lean body mass compartment. The viscera account for about 12% of the lean body mass, and decreases in size of some organs (ie, gut atrophy and cardiac atrophy) are noted in critically ill patients. Unfortunately, there is no convenient marker of loss of lean body mass from the visceral organs.

The skeletal muscles account for 35% of lean body mass and provide the major storage area for amino acids needed during illness. Urinary creatinine is related to the size of the skeletal muscle mass. A standard way to assess the size of the skeletal muscle mass is to determine the creatinine-height index by collecting a 24-hour urine and comparing the value against normal tables of creatinine excretion for age, sex, and height. A simpler way is to divide the 24-hour creatinine excretion by the patient's usual body weight obtained from the history. The normal value for an adult man is 23 mg/kg of ideal body weight; the normal value for a woman is 18 mg/kg. A creatinine-weight index 10% less than normal would be consistent with a 10% loss in muscle mass. For example, if the usual weight for a woman was 50 kg, her 24-hour urine collection should contain 900 mg creatinine. A value of 810 mg/24 hours would reflect minimal loss of muscle mass. A value of 20% less than normal would classify patients as having mild muscle loss, a 20–30% loss would classify them as having moderate loss, and a 30% or greater reduction in the 24-hour urinary creatinine would document severe muscle loss. The most accurate estimates result from measuring urinary creatinine over a 3-day period and repeating the measurements at intervals to document the loss of muscle mass over an extended period of time. Dietary creatine and creatinine intakes have only a minor influence (<20%) on urinary creatinine in the normally fed individual, and dietary influences will be very small in most critically ill patients. However, impairment of renal function reduces normal creatinine excretion and excludes the creatinine-height or creatinine-weight index as a marker of muscle mass.

Vitamins and Minerals

Many of the vitamins and minerals act as cofactors for essential processes in health and illness. The requirements for health have been well established and are published as the recommended daily requirements (Tables 6–2 and 6–3). The exact needs for the critically ill patient are not well documented.

Reduced levels of vitamin C, vitamin A, copper, manganese, and zinc are associated with poor wound healing.

Table 6–2. Adult daily nutritional requirements (RDA, 1989).

Nutrient	Oral	Intravenous	Special Requirements
Vitamin A	3300 IU	3300 IU (1 mg)	5000 + IU (serious infections)
Vitamin B ₁ , thiamine	1.5 mg	3 mg	50 mg (alcoholics, Wernicke-Korsakoff)
Vitamin B ₂ , riboflavin	1.8 mg	3.6 mg	
Vitamin B ₃ , niacin	20 mg	40 mg	
Vitamin B ₆ , pyridoxine	2 mg	4 mg	
Vitamin B ₁₂	2 µg	5 µg	
Biotin	100 µg	60 µg	
Vitamin C	60 mg	100 mg	
Vitamin D	400 IU	200 IU (5 µg)	
Vitamin E	10 mg	10 mg	
Folic acid	0.2 mg	0.4 mg	5 mg (ICU patient; thrombocytopenia)
Vitamin K	80 µg	See note 1.	
Pantothenic acid	7 mg	15 mg	

¹Vitamin K is routinely given as 10 mg subcutaneously on admission and then weekly.

Abnormally low levels of minerals are known to occur as part of the cytokine-mediated inflammatory response and also may occur secondary to poor oral intake, increased requirements, and excessive urinary and stool losses in the critically ill patient.

A. Folate—In large studies of critically ill patients, 12–52% have been noted to have a reduced folate level. Not all of these will have folate deficiency because serum levels fall rapidly, despite normal tissue stores, when folate intake is restricted. Alcohol intake has a similar effect of falsely lowering folate levels. A prospective, randomized clinical trial demonstrated that critically ill patients given only replacement doses of approximately 0.3 mg/day of folate continued to demonstrate decreased serum and red blood cell folate levels. A few of these patients developed severe hematologic disturbances that were reversed with administration of larger amounts (50 mg/week or 5 mg/day of folate).

Table 6-3. Adult daily nutritional requirement.

Nutrient	Oral	Intravenous	Special Requirements
Macronutrients			
Protein	1.5 g/kg	1.5 g/kg	2-3 g/kg (thermal injury)
Glucose	20-25 kcal/kg	20-25 kcal/kg	Fasting blood glucose >139 mg/dL, reduce to 10 kcal/kg
Lipid	4% of kcal	4% of kcal	May provide up to 60% of caloric needs as lipid
Micronutrients			
Sodium	60-150 meq	60-150 meq	Severely reduce if ascites or heart failure present
Potassium	40-80 meq	40-80 meq	
Chloride	40-100 meq	40-100 meq	
Acetate	10-40 meq	10-40 meq	
Phosphorus	10-60 mmol	10-60 mmol	Large amounts (100 mmol+) may be needed with early refeeding period, days 2-4 of refeeding
Calcium	5-20 meq	5-20 meq	
Magnesium	10-20 meq	10-20 meq	50-100 meq (cardiac arrhythmias, diarrhea)
Zinc	3 mg	2.5-4 mg	10-50 mg (diarrhea, fistula, wounds)
Copper	1.5-3 mg	1-1.5 mg	
Chromium	50-200 µg	10-15 µg	Additional amounts may be needed if diarrhea, GI losses
Molybdenum	75-250 µg	100-200 µg	
Manganese	2-5 mg	150-800 µg	
Selenium	40-120 µg	40-120 µg	120-200 µg (thermal injury, wounds)

B. Vitamin A and Vitamin C—Critically ill patients, especially those with sepsis, can have significant reductions in plasma levels of vitamins A and C. A recent study in healthy elderly patients demonstrated that approximately 20% have reduced vitamin C levels (<0.5 mg/dL), and 10% have a reduced serum vitamin A level (<33 µg/dL). The administration of multiple vitamins and minerals containing 80 mg vitamin C and 15,000 IU vitamin A daily for 1 year resulted in a significant reduction in the number of days of infection-related illnesses (48 ± 7 to 23 ± 5 days per year; mean \pm SEM). The multiple vitamin and mineral supplement improved the lymphocyte response to phytohemagglutinin and the natural killer cell activity. Providing vitamins C and E in a double-blind clinical trial of critically ill patients significantly reduced 28-day mortality (67.5% versus 45.7% mortality). In a second study, additional vitamin C and vitamin E reduced the development of end-organ failure ($p < 0.05$) but had no significant effect on 28-day mortality (2.4% versus 1.3%, vitamins versus placebo, respectively). While plasma levels of vitamin C do reflect whole body stores, plasma levels of vitamin A may not be the best marker of actual deficiency states.

Liver vitamin A measurements may be a better marker. Patients who die of infectious diseases have an 18–35% incidence of severe reduction of liver vitamin A. In other studies, serum vitamin A (retinol) levels are low in 30–92% of patients with serious infections. The mechanism for this loss may be via excessive urinary losses of vitamin A. Patients with pneumonia, sepsis, and severe injury can lose vitamin A (retinol) in the urine on a daily basis in an amount greater than the recommended dietary intake of vitamin A (5000 IU). In contrast to what is noted in serious infections, trauma patients who die within 7 days of hospitalization have only a 2% incidence of severe liver vitamin A deficiency.

Several prospective, randomized clinical trials have demonstrated that the administration of vitamin A to children who have measles or other infectious illnesses can reduce the mortality rate by up to 50%. Similar data are not available for adults. Nevertheless, because serum vitamin A levels are frequently reduced in critically ill patients who have serious infections, critically ill patients should start receiving the recommended daily allowance (RDA) of vitamin A on admission.

Vitamin A treatment of premature infants reduces the development of chronic lung disease or death from 62% to 55%. Additional vitamin A treatment of infants who were likely vitamin A deficient reduced mortality compared with placebo-treated infants (6.9% versus 5.4% mortality, $p < 0.05$).

In addition to the changes in folate, vitamin A, and vitamin C, excessive losses of several other vitamins have been observed in patients receiving medications that interfere with normal utilization or elimination (Table 6-4).

C. Magnesium—Hypomagnesemia occurs in 34–44% of patients receiving TPN. Severe depletion is associated with cardiac arrhythmias and sudden death. Alcoholics are commonly found to have poor magnesium intake and also to have excessive urinary magnesium losses. For this reason and because of recent data on the antiarrhythmic effects of magnesium, the commonly used normal values for serum magnesium levels probably should be increased from 1.7–2.3 to 2.0–2.6 mg/dL. Isolated bacteremia in otherwise healthy men

is associated with a 60-mg (5-meq) magnesium loss in the urine per day. Large losses can occur in conditions such as ulcerative colitis, where the stool can contain up to 12 meq/L and urinary losses can be as much as 25 meq/day. Large urinary losses also can be seen in patients receiving aminoglycosides, diuretics, and amphotericin B, to mention a few medications commonly used in the ICU. Furthermore, large quantities of magnesium can be found in some of the intestinal fluids (Table 6-5). The effects of magnesium depletion and hypomagnesemia are discussed in the section on hypomagnesemia in Chapter 2.

D. Phosphate—Hypophosphatemia occurs in 35–45% of patients receiving TPN. Severe hypophosphatemia results in cardiac standstill and sudden death. Recent data have demonstrated rapid and life-threatening reductions in serum phosphate associated with live-donor liver transplantation. Phosphate is an intracellular anion that must be administered in very large quantities to both the donor and the recipient. The profound hypophosphatemia is probably due to the rapid regeneration of the liver that is known to occur over the first few weeks after transplantation.

In a recent study, the mortality rate of children with severe hypophosphatemia was 33%. The refeeding syndrome (ie, severe hypophosphatemia) occurs commonly in patients who have had poor or no food intake for 2 or more days. Hypophosphatemia occurs when there is administration of glucose without adequate phosphate intake. Patients at high risk for the refeeding syndrome have a low prealbumin level (< 11 mg/dL) level. Other patients at risk include those with a history of alcoholism, diabetes, vitamin D deficiency, or chronic renal failure. In chronic renal failure, patients are frequently malnourished, and refeeding is associated with a high risk for severe hypophosphatemia. This can be due to the fact that these patients are frequently given phosphate binders, and when they are refeed, the rapid anabolism quickly reduces serum phosphorus to dangerous levels.

In addition, there are many medications that can increase urinary phosphate loss to greater than 200 mg/L. Common medications that increase urinary loss include beta-agonists, diuretics, theophylline, and glucocorticoids. The normal dietary intake of phosphorus is approximately 1000–1500 mg/day. Approximately 70% of phosphorus is absorbed per day, and stool output may represent 30% of the intake. However, in patients with malabsorption, stool phosphorus losses can be much greater.

Serum phosphorus should be monitored three times a day when beginning to refeed patients to prevent the syndrome and its 33% mortality rate. When the serum phosphorus level is less than 2.5 mg/dL (< 0.8 mmol), phosphate repletion should be given at 2 mmol/h over 6 hours to provide 24 mmol phosphate. When the phosphate level is less than 1.0 mg/dL, it is a medical emergency, and phosphate repletion should be given at 8 mmol/h for 6 hours to total 48 mmol. Renal failure patients may require a smaller dose.

Table 6-4. Drug-induced nutrient deficiencies.

Drug	Nutrients Affected
Aminoglycosides	Magnesium, zinc
Ammonium chloride	Vitamin C
Antacids	Phosphorus, phosphates
Aspirin	Vitamin C
Cholestyramine	Triglycerides, fat-soluble vitamins
Cisplatin	Magnesium, zinc
Corticosteroids	Vitamin A, potassium
Diuretics	Sodium, potassium, magnesium, zinc
Estrogen and progesterone compounds	Folic acid, vitamin B ₆
Hydralazine	Vitamin B ₆
Isoniazid	Vitamin B ₆ , niacin
Laxatives	Sodium, potassium, magnesium
Penicillamine	Vitamin B ₆
Phenobarbital	Vitamin C, vitamin D
Phenothiazines	Riboflavin
Phenytoin	Vitamin C, vitamin D, niacin
Tetracycline	Vitamin C
Tricyclic antidepressants	Riboflavin
Warfarin	Vitamin K

Table 6-5. Electrolyte and mineral content (meq/L) of body fluids.

Body Fluid	Na ⁺	K ⁺	Cl ⁻	HCO ₃ ⁻	Mg ²⁺	Zn ²⁺ (mg/L)
Saliva	10	20-30	15	50	—	—
Stomach fluids	100	10	120	0	—	—
Duodenal fluid	100-130	5-10	90	10	1-2	12
Ileal fluids	100-140	10-20	100	20-30	6-12	17
Colonic fluids	50	30-70	15-40	30	6-12	17
Diarrheal fluids	50	35	40	45	1-13	17
Pancreatic juice	140	5	75	70-115	0.5	—
Bile	145	5	100	15-60	1-2	—
Urine	60-120	30-70	60-120	—	5	0.1-0.5
Urine (post furosemide)	10 times normal	2 times normal	—	—	20 times normal	—

Rechecking serum phosphorus and adjusting the repletion rate should be done frequently, similar to management of a reduced potassium level in an ICU setting.

E. Zinc—Serum zinc levels drop as an early response to infection and injury. There are minor tissue stores of zinc in skin, bone, and intestine, but zinc is redistributed to liver, bone marrow, thymus, and the site of injury or inflammation in the critically ill patient. This redistribution is mediated by interleukin 1 (IL-1) and other cytokines secreted from macrophages. Approximately 60–70% of burn patients have a reduced serum zinc level, and in septic patients it may be 100%. Zinc administration (50 mg/day) to these patients was associated with normalization of the zinc level after 3 weeks of feeding. In elderly patients, 14 mg/day of zinc for 1 year resulted in a significant reduction in the number of days of infection-related illnesses (48 ± 7 to 23 ± 5 days per year; mean \pm SEM).

Zinc supplementation in the critically ill patient is needed for cell mitosis and cell proliferation in wound repair. It also has been demonstrated that 600 mg zinc sulfate (136 mg elemental zinc) orally daily will improve wound healing in patients who had a serum zinc level on admission of less than 100 μ g/dL. In this double-blind study, the healing rate increased more than twofold in those randomized to receive zinc supplementation. As little as 20 mg/day of zinc supplementation in very young children reduces the length of hospital stay by 25%.

Zinc supplementation is important in patients in whom there are intestinal losses, such as seen with severe diarrhea or fistula. Large losses of zinc can occur via intestinal losses (see Table 6–5) because intestinal fluids contain up to 17 mg of zinc per liter.

F. Copper—Serum copper and ceruloplasmin increase with severe injury or sepsis. Cytokines are believed to be responsible for these changes. The reasons for these increases are not known.

G. Iron—Serum iron levels fall as a result of the cytokine-mediated response to infection or injury. The iron is stored in the Kupffer cells of the liver until the inflammation wanes. This is a beneficial effect because many microbes use iron as a cofactor for energy production. Therefore, iron administration should be restricted in patients with serious infections because iron therapy in one double-blind study was associated with an increase in infectious episodes by approximately 50% compared with only 10% in placebo-treated control individuals. Lastly, iron administration has been demonstrated to cause harm in liver transplant patients. In liver transplantation, patients who receive a liver high in iron concentration have an increased incidence of fatal infections (24% versus 7%) and reduced 5-year survival rates (48% versus 77%).

NUTRITIONAL THERAPY

► Assessment of Nutritional Needs

Catabolism in Critical Illness

The best marker of catabolism is the determination of urine urea nitrogen loss. Approximately 80% of the total urine nitrogen appears as urinary urea nitrogen, and this test can be performed at the cost of a single urea determination. A classification of catabolism is based on the urine urea nitrogen loss over a 24-hour period plus approximately 2 g of nitrogen lost as creatinine, creatine, ammonia, and amino acids and approximately 2 g in skin, stool, and respiratory losses (although losses greater than 2 g can occur in thermal injury and severe diarrhea). Urinary loss of less than 6 g urea nitrogen is normal; loss of 6–12 g/day is mild, 12–18 g/day is moderate, and more than 18 g/day is severe catabolism. As mentioned earlier, 1 g urea nitrogen in the urine is equal to 6.25 g nonhydrated protein or 1 oz of lean body mass. Therefore, the loss of 16 g urea nitrogen per day is roughly equal to the loss of 1 lb of skeletal muscle per day. Although the mobilized amino acids that are broken down into urea do not all come from the skeletal muscles, those muscles are the major source of the amino acids used during the catabolic process that occurs in all critically ill patients because they represent 50% of the fat-free body weight. In a patient with mild to moderate catabolism, 12 g urinary urea nitrogen loss plus 4 g nitrogen loss from other sources calls for replacement of about 100 g nitrogen daily to maintain nitrogen balance. For a 70-kg adult, this is approximately 1.5 g/kg protein (or amino acid) per day. In severely catabolic patients, losses as much as 24 g urea nitrogen per day (28 g total) requires approximately 175 g of protein intake per day (2.5 g/kg per day) to maintain “nitrogen balance.” Nitrogen losses can be even higher in thermal injury.

Energy Expenditure in the Critically Ill Patient

Resting energy expenditure (REE) is directly linked to lean body mass. REE is difficult to determine precisely in the ICU without measuring oxygen consumption and carbon dioxide production rates and without performing appropriate calculations for estimation of energy expenditure. Various equations used to estimate REE without actual measurements are not very accurate in critically ill patients. These equations, based on REEs in healthy individuals, do, however, provide an approximation of the energy requirements. Using these estimates, several authors have suggested that energy expenditure is increased by 30–100% above REE in critically ill patients. However, recent data based on direct measurements of energy expenditure in critically ill patients do not support the need for higher estimates of energy requirements. Thus more appropriate estimates would be between 20% and 50% above predicted needs. A convenient estimate that takes REE and added energy expenditure into account is to provide

30–35 kcal/kg per day (based on ideal body weight) to patients with mild to moderately severe critical illness. In those with severe pancreatitis, closed head injury, or thermal injury, caloric requirements may be close to 40 kcal/kg per day.

Vitamins and Minerals

The recommended oral and intravenous vitamin intakes are listed in Table 6–2. The mineral and trace element requirements are listed in Table 6–3. Also included are the few exceptions to the routine intravenous amounts for both tables. These vitamin, mineral, and trace mineral recommendations are for critically ill patients who do not have oliguric renal failure or cholestatic liver disease. In acute oliguric renal failure, vitamins A and D should be reduced or eliminated from the enteral or parenteral solutions. Potassium, phosphorus, magnesium, zinc, and selenium should be reduced or eliminated. Iron and chromium are known to accumulate in renal failure and should be removed from parenteral or enteral formulations.

Copper and manganese are excreted via the biliary tree, and intake should be reduced or eliminated in patients with cholestatic liver disease to prevent toxicity. In comparison, large amounts of electrolytes and minerals can be lost in gastrointestinal fluids and in urine (see Table 6–5). It is essential to replace the estimated amounts lost on a daily basis by appropriate supplementation of the parenteral nutrition fluid.

► Enteral & Parenteral Nutrition

Choice of Enteral or Parenteral Feeding

In all clinical situations, if the gut is functional, then the gut should be used as the route of feeding. Gut atrophy predisposes to bacterial and fungal colonization and subsequent invasion associated with bacteremia. Sepsis owing to microbial translocation or endotoxin translocation from the gut into the portal system is a frequent source of fever in those who do not have an obvious source of infection. Use of the gastrointestinal tract for feeding can reduce the incidence of bacterial translocation.

A study of over 200 abdominal trauma patients compared mortality rates of parenterally and enterally fed ICU patients who had similar illness severity at admission. The group that could not tolerate enteral feeding received TPN that averaged 35 kcal/kg per day and 1.2 g/kg of protein per day. The other group tolerated enteral feedings and received 30 kcal/kg per day and 1.1 g/kg of protein per day. The overall mortality rate was significantly lower (51% versus 25%) in patients who tolerated enteral nutritional support. It appears that patients with gastrointestinal intolerance may have a poorer clinical outcome, even though they are given appropriate parenteral nutritional support.

The indications for TPN are listed in Table 6–6. Preoperative TPN should not be used routinely because most

Table 6-6. Indications for total parenteral nutrition (TPN).

Short bowel syndrome
High output gastrointestinal fistula
Hyperemesis gravidarum
Bone marrow transplantation

Note: If the gastrointestinal tract is functional, *do not use TPN*.

prospective studies have shown no benefit, and one has shown harm. However, recent evidence in malnourished cancer patients demonstrated that preoperative TPN reduces complications and may reduce mortality. Likewise, postoperative TPN should not be used routinely because most prospective trials have shown no benefit, and some have shown an increased rate of complications. This lack of benefit and increased harm may be due to failure to maintain tight glucose control (<110 mg/dL) in critically ill patients receiving TPN.

Enteral Nutrition

The feeding tube should be positioned in the small bowel up to the ligament of Treitz. This is best achieved with the aid of fluoroscopy but also can be achieved by passage of the feeding tube into the small bowel by a “corkscrew” technique after bending the distal tip of the feeding tube to about 30 degrees with the wire stylet in place. On placement in the stomach, the tube is rotated so that the tip can pass via the pylorus into the duodenum. The infusion of enteral products into the small bowel will reduce the incidence of aspiration because the infusion is below the pylorus. Patients with a cuffed endotracheal tube have a smaller risk of aspiration, so placement of a feeding tube into the small bowel is less essential.

Supine patients had a 34% incidence of aspiration pneumonia, but the risk was only 8% when patients were kept semirecumbent. The Centers for Disease Control and Prevention (CDC) recommends that ICU patients be managed in this position to reduce the risk for nosocomial infections.

A. Protein—Protein is better absorbed in the peptide form than as free amino acids because of specific transporters in the small intestines for amino acids, dipeptides, and tripeptides. Supplementation of standard enteral feeding products with increased amounts of arginine has been shown to enhance immune function, although published data in humans are very limited. It is also important to point out that arginine is a precursor of nitric oxide, a vasodilator substance that may be involved in mediating some of the effects of sepsis. Branched-chain amino acid–enriched enteral products have been shown to improve mental function and

reduce mortality rates in patients with hepatic encephalopathy and advanced cirrhosis. Albumin synthesis is nearly doubled by branched-chain-enriched amino acids. However, data to date do not demonstrate decreased morbidity or mortality rates in trauma or sepsis patients randomized to receive branched-chain-enriched amino acids as opposed to conventional feeding.

B. Lipid—The lipid composition of enteral feeding products is becoming an important consideration depending on the type of disease. The use of omega-3 (fish oil)–enriched fatty acids in the enteral product has been associated with modification of the inflammatory response. This effect may be related to increased arachidonic acid metabolism and decreased omega-6 pathway fatty acid metabolism. Because most commercially available enteral products that contain omega-3 fatty acids also have other additives such as arginine, glutamine, and nucleotides, the benefits attributed to the use of an omega-3-enriched fatty acid enteral diet await confirmation. At this time, caution with the use of so-called immunonutrition products is recommended because recently published data suggest a fourfold increase in mortality in patients with severe sepsis.

C. Enteral Feeding Products—A large number of enteral feeding products are manufactured for use in the ICU and acute medical care settings, including elemental formulas (eg, amino acids, mono- and oligosaccharides, and lipids), specialized products for certain critical care situations (eg, renal failure and liver failure), products containing fiber, and lactose-free nonelemental products containing 1–2 kcal/mL. These formulations vary in terms of the ratio of nitrogen to nonnitrogen calories, protein source, and concentration. They also vary in the amount and source of fat, electrolyte concentration, and other constituents. Most hospitals select a limited number of enteral feeding products for their formularies and have recommended products for each clinical situation.

D. Recommended Enteral Feeding Formulas—Lactose-free formulas should be used for ICU patients. The infusion rate should not exceed 30 kcal/h for the first 6–12 hours, and the rate then should be advanced as tolerated. If the patient has a serum albumin concentration of less than 2.5 g/dL, the enteral infusion rate should be increased slowly (ie, every 24 hours).

The source of carbohydrate or protein appears not to be important except in patients with hepatic encephalopathy, in whom a formula high in the branched-chain amino acids would be indicated. The addition of moderate amounts of glutamine may be helpful because only a few formulas have added glutamine. Until additional data become available, there are no specific recommendations for the source of fat calories in the enteral feeding formula, such as changing omega-3 fatty acids, omega-6 fatty acids, medium-chain triglycerides, or structured lipids.

Parenteral Nutrition

A. Central versus Peripheral Parenteral Nutrition—The route of parenteral nutrition should be secondary to the principle of meeting the individual patient's calorie and protein goals. Peripheral parenteral nutrition (ie, given through a peripheral vein) can be used in patients who can tolerate the daily 3-L fluid requirement necessary to obtain adequate calorie administration or in patients in the early phase of enteral alimentation as a supplement. Currently, the permissible concentrations of glucose, amino acids, and other nutrients delivered via peripheral vein alimentation are limited by phlebitis caused by the high osmolality of the alimentation solution. Advances in catheter technology may allow for peripheral administration of solutions of greater than 600 mOsm/L without damage to the vein. A solution of 900 mOsm/L may be well tolerated and could reduce the volume of peripheral alimentation fluid to 2 L/day. Even with this new technology, patients requiring severe fluid restriction should receive central parenteral nutrition (via a central venous catheter) using one of several fluid-restricted formulas (Table 6–7).

B. Placement of Catheters for Total Parenteral Nutrition—Central and peripheral venous catheters are composed of scarified polyvinylchloride, standard polyvinylchloride, polyethylene, silicone, hydromer-coated polyurethane, standard polyurethane, fluoroethylene,

propylene, or Teflon. The lowest rate of thrombogenicity is seen with the hydromer-coated polyurethane. The rate of thrombophlebitis is relatively low when catheters are used in a central vein owing to the rapid rate of dilution of the hyperosmolar solution. Peripheral venous access is associated with a higher rate of thrombophlebitis, which is secondary to the high-osmolality solution infused into a small vein. The size of the peripheral catheter is important, with the larger catheters having a more frequent rate of thrombophlebitis. Recent data would suggest that the use of a small silicone-coated catheter may increase the life span from 2–5 days when infusing a fluid of very high osmolality through a peripheral vein. Osmolality above 900 mOsm/kg is not recommended for peripheral infusion.

Traditional aseptic technique is required for placement of central venous catheters. The subclavian vein is the most commonly used site, followed by the internal jugular vein. Central venous access also can be obtained by the use of a long venous catheter placed in the upper arm vein and passed up near but not into the right atrium. Central catheters also can lead to thrombosis as a result of improper placement in the subclavian vein. The tip of the catheter should be positioned at the entry of the right atrium.

Heparin (1000 units/L) or hydrocortisone (5 mg/L) added to the TPN solution can reduce the occurrence of thrombophlebitis resulting from peripheral administration of hyperosmolar solutions. A nitroglycerin patch on the skin (5 mg) acts as a local vasodilator and also has been associated

Table 6–7. Some selected typical parenteral nutrition formulas.

Name ¹	Amino Acids (g/L)	Dextrose (g/L)	Calories (kcal/L)	Osmolarity (mosm/L)	BCAA ² (%)
Central A5% D15%	50	150	710	1250	19
Peripheral A3.5% D5%	35	50	310	760	19
Peripheral high BCAA 3.5% D5% L3%	35	50	310	800	41
Fluid-restricted (central) A10% D21%	100	210	1114	2108	19
Severe fluid restriction (central) A12% D15% ³	120	150	910	1950	19
High branched-chain amino acids (central) A3.5% D20%	35	200	820	1476	46
Renal failure (central) A2.7% D35%	27	350	1292	2426	39

Key: Dextrose (D) = 3.4 kcal/g, amino acids (A) = 4.0 kcal/g

Note: All formulas can have 3% lipid added to them to provide 30 g of lipid per liter; 270 additional calories.

Each 1 g amino acids = 10 mosm; each 1 g dextrose = 5 mosm

Each 1% amino acids = 100 mosm; each 1% dextrose = 50 mosm

¹Lipids are included in many of these formulas at 10–60% of total calories; these formulations are called “3 in 1;” 3% is 3 g lipid per 100 mL

²Branched-chain amino acids

³Contraindicated in renal failure and hepatic encephalopathy

with a reduction in thrombophlebitis. Subcutaneous tunneling may help to reduce the rate of catheter infection, but the best precaution is optimal nursing care and the use of chlorhexidine as an antiseptic for skin preparation.

Catheter-related infection is a major concern. The two most likely causes for catheter-related infections are migration of bacteria down the catheter sheath and trapping and growth of bacteria that accumulates on the fibrin tip at the distal end of the catheter. Replacement of the catheter involves either exchange over a guidewire or selection of a new site. If obvious infection is present at the original site, a new site must be selected. If there is no obvious infection at the catheter site, the catheter may be exchanged aseptically over a guidewire. The removed catheter tip should be sent for culture, and if bacteria grow over the next 24–72 hours, the exchanged catheter should be discontinued and a new site selected. Central line placement has a 3–5% likelihood of causing pneumothorax or some other serious complication. Changes of catheter sites reserved solely for TPN usage are not needed on a regular basis but only when there is evidence of local or systemic infection or other complication of the catheter.

The most common complication of TPN is catheter-related infection. In a pediatric setting, 15% of patients may develop bacteremia or candidemia. Patients at highest risk are those with diabetes mellitus. It has been estimated that catheter-related infections occur in 3% of nondiabetic adults and in 17% of diabetic adults. The most serious infections are due to *Candida* species, with mortality rates as high as 34% despite antifungal treatment.

C. Carbohydrate and Protein—Since the intravenous route is not the natural route for nutritional substrate administration, it is important to provide adequate but not excessive amounts of protein, carbohydrate, and fat on a daily basis. Most critically ill patients need 1.5–2.5 g/kg per day of protein. The ideal body weight value should be used in calculating the daily protein requirements. Dextrose administration to most critically ill patients should not exceed 3.0 mg/kg per minute (4.3 g/kg per day). This generally translates into about 300 g dextrose, or 2 L of 15% dextrose, in a 70-kg adult. Administration of greater amounts of dextrose can result in glucose intolerance, abnormal liver function tests, and fatty infiltration of the liver.

D. Lipid—Currently available intravenous fat emulsion products are derived from soybean or a mixture of soybean and safflower oil. The products vary slightly in the amount of linoleic, linolenic, and oleic acids. Each product is available in 10% and 20% concentrations, but the 20% product is the best choice because of its caloric density and the lack of imbalance in the phospholipid-to-lipid ratio. Intravenous lipid can be administered as a separate 20% concentration over 20–24 hours or—more commonly—as part of the TPN called “3 in 1” with dextrose and amino acids. Maximum fat administration can be estimated at 2 g/kg per day or 140 g/day (1260 kcal).

The use of intravenous fat administration in critically ill patients initially was very controversial. Some of the early studies did not demonstrate any improvement in nitrogen retention when glucose calories were exchanged for fat calories.

The septic patient has a reduced ability to use calories provided as dextrose, so any amount of dextrose in excess of 300 g/day (1020 kcal) may not be used as energy and could contribute to the development of fatty liver infiltration and mild elevations in liver function tests. Because septic patients have an approximately threefold increase in fat oxidation rate, fat calories may be readily used in these patients. As a precaution, however, and because excessive amounts of intravenous lipids in animals contribute to an increased incidence of sepsis and associated morbidity, a maximum of 60% of total calories as intravenous fat is acceptable in most critically ill patients.

There is some interest in the use of peripheral administration of lipid, amino acids, and dextrose in a single 3-L bag via a very small catheter. In theory, the catheter floats in the vein, causing less luminal damage. An option used by some is to administer the peripheral infusion of lipid emulsion for 18 of the 24 hours and to run in 5% dextrose over the 6-hour resting period. This makes physiologic sense because fasting will permit clearance of very low-density lipoprotein (VLDL) particles and allow for adaptation to the nonfed state.

Essential fatty acid requirements are estimated to be approximately 1–4% of total energy requirements and should be in the form of linoleic acid. An elevation of the eicosatrienoic acid (triene) to arachidonic acid (tetraene) ratio to 0.4 is indicative of essential fatty acid deficiency. Treatment of essential fatty acid deficiency requires approximately 10–20% of total energy to be in the form of linoleic acid.

E. Parenteral Nutrition Solutions—Some standard parenteral nutritional formulas and those containing higher amounts of branched-chain-enriched amino acid formulas are listed in Table 6–7. Most formulas provide approximately 1 kcal/mL of TPN. Standard parenteral nutrition solutions do not contain glutamine owing to the instability of this amino acid in solution. Standard parenteral formulas also do not contain large amounts of arginine. Both glutamine and arginine can be added to the parenteral formulas before administration, but there is no convincing evidence that added arginine is helpful. Recent data suggest that glutamine may be a preferred fuel for enterocytes and lymphocytes. The use of glutamine-enriched formulas can prevent postinjury expansion of the extracellular water compartment in bone marrow transplant patients. There also may be a slight reduction in the incidence of infection.

F. Recommendations for Ordering Central Parenteral Nutrition—Each hospital should have standard formulas for parenteral nutrition. Consider using a central parenteral nutrition formula with 15% dextrose, 5% amino acids, and

5% lipid containing 1160 kcal/L with osmolarity of 1250 mosm/L (see Table 6–7). Fluid-restricted formulas are often required in critically ill patients. These solutions contain more concentrated mixtures of amino acids. Special formulas may be useful in patients with hepatic and/or renal failure.

G. Recommendations for Peripheral Parenteral Nutrition—A standard solution is 3–5% amino acid and 5% dextrose for peripheral vein administration, for example, 3.5% amino acid and 5% dextrose. Each milliliter provides approximately 0.3 kcal. Therefore, 3 L of this solution provide 105 g protein (amino acids), 150 g dextrose, and about 900 kcal.

Using a microcatheter that allows for a higher-osmolarity solution to be infused safely, more calories can be given via a peripheral vein by adding 20% lipid. For ICU patients, a solution of 5% amino acid, 5% dextrose, and 5% lipid has 900 mOsm/L. Two liters of this formula provides 100 g protein and 1640 kcal (55% of calories from lipid).

NUTRITIONAL SUPPORT IN SPECIFIC DISEASES

▶ Malnutrition

Patients with a serum albumin level of less than 2.8 g/dL, a 20% weight loss over the preceding 3 months, or an ideal body weight less than 90% for height should be provided nutritional support on entry to the ICU. Other patients should be evaluated for the likelihood of being able to ingest a minimum of 1500 kcal by the fifth day in the ICU. If this seems unlikely, it would be appropriate to provide nutritional support early in the ICU stay.

▶ Cardiopulmonary Disorders

Hypoalbuminemic Pulmonary Edema

Albumin accounts for about 78% of the total oncotic pressure in the plasma compartment, and hypoalbuminemic edema can be misdiagnosed as acute respiratory distress syndrome (ARDS). In conformity with Starling's law, pulmonary edema may evolve as (1) hydrostatic edema (fluid overload), (2) increased permeability of the epithelium, (3) hypoalbuminemic edema (low plasma oncotic pressure from decreased plasma protein), and (4) lymphedema. Capillary fluid exchange is based on the balance of forces moving fluid outward (ie, hydrostatic pressure, negative interstitial pressure, and interstitial colloid pressure) and the only force moving fluid inward (ie, plasma oncotic pressure). Therefore, plasma proteins are the only force holding fluid inside the capillaries. If a patient has isolated hypoalbuminemic edema, with serum albumin level of less than 2.5 g/dL, then a 25–50-g infusion of albumin over 24 hours may resolve the edema.

Pneumonia

Both lymphopenia ($<1000/\mu\text{L}$) and hypoalbuminemia (serum albumin <2.5 g/dL) are predictors of poor prognosis in patients with pneumonia. In hospitalized patients, the use of antacids or H_2 blockers is associated with an increased incidence of nosocomial pneumonia, and use of sucralfate in place of antacids or H_2 blockers has been associated with a significantly lower rate of nosocomial infection. The reduced incidence of nosocomial infections also was associated with a significant reduction in mortality rate (from 46–24%). The decrease has been thought to be due to maintenance of gastric acidity to support the stomach's overall bactericidal activity. Although there is some controversy about increased risks of infection in patients receiving H_2 blockers in the ICU, current data also suggest that the rate of spontaneous gastritis or gastrointestinal ulceration in ICU patients actually was falling prior to the increased use of these drugs for prophylaxis against upper gastrointestinal bleeding.

Emphysema

In malnourished patients with emphysema, energy expenditure is increased by as much as 23–26% above that in weight-matched controls. Unlike the preferred fat oxidation seen in sepsis, patients with emphysema have an increase in protein and carbohydrate oxidation in the fasting and fed states. Forced vital capacity and diaphragmatic mass and strength are reduced in malnourished patients. Even though there are no prospective studies demonstrating improved survival in patients with emphysema given aggressive nutritional support, the ability to maintain respiratory muscle strength and mass during acute illness should be beneficial.

Enteral nutrition should be used with caution, however, in patients with chronic obstructive pulmonary disease (COPD) owing to increased mortality. This may be due in part to the common practice of nursing patients in the supine position (increased risk of aspiration pneumonia) instead of the safer 45-degree upright position. Another risk may be due to the elevated blood glucose level and morbidity and mortality associated with patients on mechanical ventilators. If nutritional support is provided, it must be done safely. Recent evidence suggests that weight loss during hospitalization and a low body mass index increase the risk for unplanned readmission to hospital.

Congestive Heart Failure

Many patients awaiting heart valve replacement have a combination of marasmic and hypoalbuminemic malnutrition, placing them at a higher postoperative risk for subsequent morbidity and mortality. Feeding these patients can improve cardiac function, but certain precautions are necessary. A low-sodium intake is essential owing to the association of sodium administration and fluid retention resulting in cardiac failure. Because fatty acids are used as cardiac muscle

fuel, mixed-fuel nutritional support (ie, lipid, carbohydrate, and protein) may be preferable. Ischemic cardiac muscle derives all its energy from anaerobic metabolism, so TPN with adequate glucose, potassium, phosphate, and insulin may optimize substrate delivery to areas limited to anaerobic glycolysis. Patients with severe calorie or protein malnutrition (albumin <2.5 g/dL) should be given adequate calories and protein for about 1 week before cardiac surgery to optimize the recovery period. Patients treated with diuretics (eg, furosemide) are at an increased risk for thiamine deficiency. The loss of thiamine in the urine can increase the risk for high-output congestive heart failure (ie, wet cardiac beriberi).

► Gastrointestinal Disorders

Pancreatitis

Earlier work suggested that the benefits of parenteral nutrition were especially important for patients with acute pancreatitis who were malnourished on entry into the ICU. However, nutritional status may be difficult to determine because weight history and actual weights are frequently not accurate owing to fluid accumulation in this disorder. Several studies have evaluated the benefits of parenteral nutritional support in patients with acute pancreatitis. In one study, the overall mortality rate was decreased from 21% to 3% in patients who were able to receive an average of 37 ± 1 (mean \pm SEM) versus 26 ± 4 kcal/kg per day over a 29-day period. In a second report, the mortality rate in 67 patients was reduced from 38% to 13% if patients with acute pancreatitis received parenteral nutritional support within 72 hours of admission. Other studies have not demonstrated decreased mortality rates with administration of parenteral nutrition. Septic complications are reduced in patients with acute necrotizing pancreatitis provided enteral nutritional support as compared with those given TPN (28% versus 50%). Mortality in this study was similar with TPN and enteral nutrition.

Hepatic Encephalopathy

A branched-chain amino acid–enriched formula has been shown to improve mental recovery in almost all studies to date. A meta-analysis of six large studies demonstrated that there was an improvement in overall survival if patients with liver disease were fed a parenteral formula containing increased amounts of branched-chain amino acids. The mortality rate in the branched-chain-enriched amino acid treatment group averaged 24%, and in the control group it was 43%. In a recent study, the benefits were confirmed for the use of branched-chain amino acids in patients with advanced cirrhosis. In contrast to the beneficial effects noted in hepatic encephalopathy and cirrhosis, there is no evidence

that high branched-chain-enriched nutritional regimens reduce the mortality rate in trauma or sepsis.

Alcoholic Hepatitis

One of the earliest studies of protein administration to patients with alcoholic hepatitis was performed in 1948, and this study demonstrated an improved survival rate in patients given protein and calories. One study has evaluated patients with alcoholic hepatitis who were prospectively randomized to receive parenteral nutritional support with amino acid solutions or the regular hospital diet. This small study demonstrated that morbidity and mortality rates were reduced in patients given parenteral nutrition support. A more recent study of enteral feeding versus steroid therapy demonstrated a reduced 1-year mortality in the enteral feeding group (37% versus 53%; $P < 0.05$). Survival in alcoholic hepatitis was linked to the level of protein malnutrition. Thirty-day mortality rates ranged from 2% in mild malnutrition to 15% in moderate malnutrition and up to 52% in severe malnutrition. Contrary to what is still written in most textbooks, the administration of 1.5 g/kg of protein is not associated with deterioration in mental status in patients with alcoholic hepatitis. Increased nutritional intake with calories as high as 3000 kcal/day has been associated with prolonged survival.

Gastrointestinal Dysfunction

Absolute indications for parenteral nutrition include pseudo-obstruction, radiation enteritis, massive small bowel obstruction, prolonged ileus, prolonged diarrhea, short bowel syndrome, and hyperemesis gravidarum. Parenteral or enteral nutritional support may be indicated for Crohn's disease, Whipple's disease, abetalipoproteinemia, and diarrhea associated with scleroderma. The benefits of parenteral nutrition in ulcerative colitis are no greater than the use of bowel rest and hydrocortisone. However, the potential benefit of parenteral nutrition is that the patient may be better nourished and thus better able to tolerate colectomy if needed. Dysfunctional bowel, as mentioned earlier, is predictive of a poor outcome. Methods to improve gastrointestinal function should be used when absolute contraindications to bowel utilization are not present. Osmotic diarrhea sometimes can be improved with the use of intravenous albumin supplementation when serum albumin levels are less than 2.5 g/dL.

Gastrointestinal Fistulas

Fistulas with a fluid output of at least 500 mL/day have been treated routinely with parenteral nutrition and bowel rest. A recent study suggests that enteral nutrition can be successful in patients with high-output fistulas but that these patients should be cared for in a specialized unit where optimal conditions for artificial nutrition and local management are in place.

► Renal Disorders

Acute Renal Failure

Although early studies of parenteral nutrition (amino acids and vitamins) compared with dextrose infusion alone (no vitamins or amino acids) demonstrated better recovery in patients with acute renal failure, subsequent studies have not consistently demonstrated a clear benefit. The patient who develops acute renal failure with malnutrition should receive enteral nutrition if the gut is functional and parenteral nutrition if it is not. The combination of acute renal failure and severe malnutrition is associated with a 7.2-fold increase in mortality.

Chronic Renal Failure

In chronic renal failure, the relative risk for mortality increases logarithmically as albumin decreases (see Figure 6–1). The risk increases to 12.8-fold for a serum albumin level of less than 2.5 mg/dL. In contrast, the relative risk for mortality decreases to 0.47 when the serum albumin level is greater than 4.4 g/dL. In addition to serum albumin, serum ferritin is a marker of increased morbidity. Chronic renal failure patients with serum ferritin levels of greater than 500 ng/mL have a 19-fold increase in septic episodes compared with chronic renal failure patients who do not have as high an iron load. Treatment with deferoxamine mesylate, an iron-chelating agent, reduces the sepsis rate 24-fold. Selected renal failure patients and those with iron overload should be watched carefully for a higher than expected incidence of infection. The increased use of epoetin alfa (erythropoietin) has virtually eliminated the iron-overload problem seen in patients with chronic renal failure. However, methods to remove the excess iron storage may be indicated to reduce the incidence of serious infections.

► Hematologic Disorders & Cancer

Bone Marrow Transplantation

Conventional nutritional therapy in bone marrow transplant patients in some studies can increase the engraftment rate of the donor's cells in the recipient's bone marrow but in some studies has shown no benefit. Early parenteral nutritional support rather than a hospital diet in well-nourished bone marrow recipients can increase overall survival. Recent evidence suggests that the use of glutamine-enriched parenteral nutritional support after bone marrow transplantation improves nitrogen balance, reduces the incidence of infection, and shortens the hospital stay by about 7 days.

Cancer Cachexia

A meta-analysis concluded that parenteral nutritional support does not improve survival and may in fact increase the risk for infection in nonmalnourished cancer patients.

A possible source of error in interpretation of these results is that many of the studies did not control for the severity of the malnutrition. In a few studies, the more severely ill and malnourished patients were selected to receive parenteral nutritional support. Those who were less ill or who could tolerate a hospital diet were given enteral support. Aggressive nutritional support should be provided as routine care to the cancer cachexia patient using the gastrointestinal route if available.

Iron Deficiency Anemia

Critically ill patients are often found to be anemic. This is most often found to be anemia of chronic infection (or illness). If iron deficiency anemia is diagnosed, the standard of care has been to provide the patient with iron replacement after causes of iron deficiency anemia are evaluated. Data from a prospective clinical trial have demonstrated, however, that iron replacement is associated with a significant increase in rates of infection or reactivation of malaria, brucellosis, schistosomiasis, and tuberculosis. Iron replacement therefore should be confined to those who do not have a high risk for subsequent infection and who do not have a current serious infection.

Thrombocytopenia

Sepsis and disseminated intravascular coagulation are the most common causes of thrombocytopenia in ICU patients. Folate deficiency can occur in the ICU population. Patients who are not eating should be given 5 mg/day of folate to prevent thrombocytopenia.

► Trauma & Postsurgery

Severe Head Injury and Spinal Trauma

Closed head injury is one of the most highly catabolic illnesses in ICU patients. Urinary urea nitrogen excretion can approach that seen in thermal injury. Several prospective trials have evaluated the risks and benefits of parenteral and enteral nutritional support in these patients. One early study demonstrated improved survival in parenterally fed patients compared with nonfed controls. A second trial failed to demonstrate improvement in survival over that of enterally fed patients. A clinical trial demonstrated that TPN could improve morbidity but that the improvement in mortality was not significant. Recently, patients given enteral feeding for nontraumatic coma were shown to have improved survival. Enteral diets containing glutamine reduced the incidence of pneumonia (17% versus 45%), bacteremia (7% versus 42%), and sepsis (3% versus 26%).

Abdominal Trauma

Enteral nutritional support compared with parenteral nutritional support is associated with maintenance of serum

albumin levels and a significant reduction in major infections from 20% to 3%. Patients who tolerate enteral feedings have better survival rates than those who cannot tolerate enteral feeding and therefore must receive parenteral feeding.

Abdominal Wound Dehiscence and Wound Healing

Appropriate nutrient administration is important for rapid and safe wound closure. Parenteral nutrition increases hydroxyproline levels and tensile strength in wounds. Wound dehiscence is eight times more common with decreased vitamin C levels. This is probably because vitamin C enhances capillary formation and decreases capillary fragility and is essential for hydroxylation of proline and lysine in collagen synthesis. Vitamin A enhances collagen synthesis and cross-linking of new collagen, enhances epithelialization, and antagonizes the inhibitory effects of glucocorticoids on cell membranes. Manganese is a cofactor in the glycosylation of hydroxylysine in procollagen. Copper acts as a cofactor in the polymerization of the collagen molecule and in the formation of collagen cross-links. Zinc supplementation also speeds up the wound healing rate. Vitamin, mineral, and nutritional support are essential for prompt wound repair.

Burns

Parenteral nutrition may be indicated in the early management of burn patients who develop burn-related ileus. After that time, the gut is the preferred route of feeding. In a small study of 18 burned children, providing 4.9 g/kg per day of protein versus 3.9 g/kg per day reduced the mortality rate from 44% to nil.

► Sepsis & Multiple Organ Failure Syndrome

Preoperative nutritional support of malnourished and non-malnourished patients reduces the rate of septic complications (eg, wound infections, pneumonia, intraabdominal abscess, and sepsis), but the overall mortality rate has not been consistently affected. A study of blunt abdominal trauma patients who were prospectively randomized to receive either enteral or parenteral nutritional support has demonstrated a significant reduction in the incidence of pneumonia (from 31% to 12%), intraabdominal abscesses (from 13% to 2%), and catheter sepsis (from 13% to 2%) in the group receiving enteral nutritional support.

The ability to provide adequate protein and calories to septic ICU patients has been associated with adequate IL-1 production and a significant improvement in hospital survival rates. However, early enteral nutrition during sepsis does not prevent the development of multiple organ failure. Treatment for this disorder remains supportive.

Stroke

Recent data would suggest that nutritional supplements do not reduce mortality in stroke patients. In stroke patients with dysphagia, early enteral feeding was associated with a non-significant (5.8%; $p = 0.09$) reduction in death. In fact, the use of percutaneous endoscopic gastrostomy (PEG) feeding increased the risk of death by 7.8%. Therefore, unlike what has been seen in head trauma patients, there appears little benefit for early aggressive feeding in patients with strokes.

► Endocrine & Metabolic Disorders

Diabetes Mellitus

Impaired fasting glucose (IFG) syndrome is a condition of elevated blood glucose (>109 mg/dL) in the ICU setting. The incidence of IFG ranges from 45–50% in patients receiving TPN to 99% of patients on mechanical ventilation. Patients with IFG have a 3.9-fold increase risk of death. IFG is probably not due to caloric intake alone but to elevated counter-regulatory hormones and insulin resistance. Reducing caloric intake from 1400 to 1000 kcal/day does not reduce the incidence of the syndrome. Aggressive regular insulin administration to maintain the blood glucose concentration under 110 mg/dL in 765 mechanically ventilated (mostly surgical) patients reduced mortality by 43%. In this prospective, randomized trial, patients were randomized to either intensive insulin therapy or standard therapy. The goal in the intensive therapy group was to maintain blood glucose concentrations under 110 mg/dL. This was obtained with the intravenous administration of insulin. Ninety-nine percent of patients required insulin at an average dose of 71 units/day. Both groups were equally randomized according to age, gender, body mass index, injury score, incidence of type 2 diabetes (13%), and incidence of cancer. The intensive treatment group had a significant reduction in mean early morning blood glucose (103 ± 18 mg/dL versus 173 ± 32 mg/dL; $P < 0.001$). Improved blood glucose control reduced the incidence of bacteremia by 50%, the need for hemodialysis by 42%, and the need for prolonged mechanical ventilation by 37% ($P < 0.01$). ICU mortality was reduced by 43% (from 8.1% to 4.6%), and hospital mortality was reduced by 34% (from 10.9% to 7.2%; $P < 0.01$).

Both type 1 and type 2 diabetic patients frequently have low levels of vitamin C. Type 1 diabetics also have a lower serum retinol (vitamin A) level than normal volunteers. The exact mechanisms responsible for reduced serum vitamin C and vitamin A levels in these patients are not known. In diabetic animals treated with vitamin A, abnormally low hydroxyproline levels and decreased wound breaking strength return to normal. Type 1 diabetics also have reduced serum and white blood cell zinc levels and excessive losses of zinc in the urine. Both type 1 and type 2 diabetics can have increased magnesium losses in the urine and reduced serum magnesium levels.

Diabetics also have alterations in neutrophil function, putting them at an increased risk of infection, including decreased adhesiveness, poor chemotaxis, decreased opsonization, decreased phagocytosis, and decreased intracellular killing. The lymphocyte also behaves differently in diabetics, especially if the patient is malnourished, and the lymphocyte count is decreased in proportion to the degree of malnutrition. Diabetics have decreased cell-mediated immunity with decreased lymphocyte transformation, reduced macrophage-lymphocyte interaction, and an impaired delayed-type hypersensitivity. One may be able to improve leukocyte dysfunction by maintaining excellent glucose control in the diabetic patient with a blood glucose concentration of less than 200 mg/dL at all times. A blood glucose level below 250 mg/dL improves but does not correct white blood cell phagocytic function, improves but does not correct granulocyte adherence, and improves but does not correct leukocyte bacterial killing.

Diabetic patients receiving TPN frequently have serum electrolyte and glucose levels that are difficult to control. TPN should be initiated in the diabetic patient with only 150 g of dextrose over the first 24 hours (eg, as 1 L of 15% dextrose at 40 mL/h). Approximately one-third to one-half the patient's usual total daily subcutaneous insulin dose should be added to the TPN solution. Additional subcutaneous insulin should be administered using a "sliding scale" regimen written as a standing order, with the dose of insulin based on bedside glucose measurements and serum glucose concentrations from venous blood measured every 3–4 hours. After the first 24 hours, approximately half the additional subcutaneous regular insulin administered over the 24-hour period then is added to the TPN solution prior to increasing the rate of TPN administration or the concentration of dextrose.

The optimal intravenous insulin infusion rate may take 2–3 days to determine because of the variable loss of insulin to different types of plastic and glass bottles used in hospitals. However, once the serum glucose concentration is less than 140 mg/dL over a 24-hour period, the overall rate of the TPN infusion or the dextrose concentration can be increased. If the rate of the infusion is increased, there should be no need to alter the dextrose:insulin ratio in the TPN solution. If the concentration of the dextrose is increased, the original ratio of dextrose to insulin should be maintained in the TPN solution by adding insulin to the bottle. To prevent hypoglycemia, it is advisable not to add excessive amounts of insulin to the TPN solution. Insulin must be added to the TPN solution for any patient who has a blood glucose concentration of greater than 140 mg/dL. The use of separate intravenous infusions of insulin and TPN solution has been associated with severe hypoglycemia and death.

Lastly, as mentioned earlier, new-onset diabetic patients have a fivefold increase in hospital mortality compared with hospitalized known diabetic patients. Likely the new-onset hyperglycemia is proinflammatory and contributes to more

tissue inflammation and injury. While all diabetic patients are provided insulin during their hospital stay, it is possible that the routine medications that known diabetics are given (eg, statin, angiotension-converting enzyme [ACE] inhibitor, beta-blocker, and aspirin [ASA]) are not provided in the hospital to the new-onset diabetics, and this may be a factor in the severe difference in hospital survival.

Immune-Enhancing Diet

The use of an immune-enhancing diet in severe trauma patients can reduce major infectious complications (6% versus 41%) and hospital stay (18 versus 33 days). However, in none of the surgical studies has mortality been improved.

In contrast, the use of immune-enhancing diets in a randomized clinical trial was seen to increase ICU mortality threefold (from 14% to 44%). The use of this specific form of immunonutrition was stopped because of harm to patients with septic shock and severe sepsis. Therefore, these agents should be used only in nonseptic surgical patients until safety can be established.

Acute Hepatic Porphyria

This rare cause of abdominal pain is treated with dextrose, 500 g/day (2 L of 25% dextrose at a rate of 80 mL/h).

NEW TREATMENT STRATEGIES FOR THE MALNOURISHED CRITICALLY ILL PATIENT

Insulin

There have been many recent recommendations concerning tighter glycemic control in ICU patients. Patients in the ICU should have an upper limit for glucose at 110 mg/dL. This recommendation has been established based on the clinical trials of van den Berghe and others and has increased the need for aggressive administration of insulin. Careful monitoring of the serum phosphorus level over the first 48 hours of insulin therapy is important to prevent hypophosphatemia (refeeding syndrome), which has a mortality of up to 33%. Respiratory failure and cardiac dysfunction can be seen at serum phosphorus levels below 2.5 mg/dL. A severely reduced serum phosphate concentration of less than 1 mg/dL is often lethal.

Critically ill patients without diabetes frequently have elevated blood glucose concentrations owing to metabolic stress syndrome. Some of these patients who also have insulin resistance develop new-onset diabetes, as defined by two random blood glucose values greater than 199 mg/dL on two separate days or a fasting blood glucose concentration of greater than 125 mg/dL on two separate days. The new-onset diabetes is due to insulin resistance and elevations in counterregulatory hormones. It has been demonstrated recently that the major reason why the blood glucose level is elevated

is the increased rate of hepatic glucose production and not reduced tissue uptake of glucose. This response may interfere with nutritional therapy. The metabolic abnormalities of insulin resistance include glucose intolerance, increased hepatic glucose production, increased whole body amino acid flux, and decreased whole body glucose utilization. Insulin resistance resulting in the metabolic stress syndrome is type 2 diabetic in character because patients are not insulinopenic but are insulin-resistant. The more severe the malnutrition or illness, the greater is the hepatic glucose production. Amino acid flux is also greater the more severe the malnutrition or illness. Recognizing the presence of new-onset diabetes or the milder metabolic stress syndrome in patients is important because insulin administration appears to be protein-sparing in catabolic postinjury patients and reduces mortality in ICU patients when the blood glucose level is maintained under 110 mg/dL. The use of insulin or other agents that reduce hepatic glucose production in critical illness may be helpful in reducing protein breakdown from the lean body mass for amino acid gluconeogenic precursors. A randomized study of tight glycemic control with intravenous insulin intended to keep the blood glucose level between 80 and 100 mg/dL (compared with conventional therapy with a target blood glucose level of 180–215 mg/dL) in postoperative cardiac surgery patients resulted in lower mortality (4.6% compared with 8%), fewer bloodstream infections, less need for hemodialysis, and shorter duration of mechanical ventilation. Of note is that only a small proportion of patients had a history of diabetes. Hypoglycemia (blood glucose <40 mg/dL) occurred in 5% of the intensively treated group and fewer than 1% of the conventionally treated patients. While this study was on surgical patients, these data support the beneficial effect of insulin and a target blood glucose level (<110 mg/dL) for surgical ICU patients. Similar findings have been seen in medical ICU patients and in those with stroke and myocardial infarction. While there were small differences in outcome in these studies, the overall benefit of more stringent glycemic control is generally apparent.

Growth Hormone

In a prospective, blinded study, administration of growth hormone to burned children was associated with an improved healing time. In a retrospective state, growth hormone treatment increased survival in adults with severe burns. However, the use of growth hormone also was associated with an increase in insulin resistance and the need to administer an increased insulin dose. Growth hormone probably improves wound healing by increasing protein synthesis without increasing protein oxidation, so there is a net protein deposition in the body, likely in the liver.

At present, use of growth hormone is restricted to children who are deficient in growth hormone. Growth hormone should not be used in critically ill patients because

mortality can increase 1.9- to 2.4-fold. Additional studies that support the use of growth hormone are needed prior to the use of growth hormone in patients who are seriously ill.

Anabolic Steroids

Anabolic steroids have been used in several clinical trials of malnourished patients with mixed results. Nitrogen balance has been shown to be improved in some but not all the clinical trials. The improved nitrogen balance generally was seen in patients with benign diseases (eg, hip replacement surgery, vagotomy, or pyloroplasty). In a prospective study of burns, oxandrolone 20 mg/day reduced weight loss (3 versus 8 kg), nitrogen loss (4 versus 13 g/day), and healing time (9 versus 13 days). On the other hand, oxandrolone treatment in trauma patients failed to reduce nitrogen loss, length of hospital stay (31 versus 27 days), or length of ICU stay. In fact, recent data suggest that their use is associated with a prolongation of the time on the ventilator (22 versus 16 days).

Albumin

Normal serum albumin is associated with a shorter inflammatory phase of wound healing and normal angiogenesis, collagen synthesis, and wound remodeling. Albumin levels of less than 2.5 g/dL represent a 50% loss in the normal plasma colloid oncotic pressure and may contribute to gastrointestinal mucosal edema and diarrhea. Several authors have found that close to 100% of patients with a serum albumin below 1.5 g/dL develop diarrhea when given enteral feeding.

Limited clinical trials have demonstrated some benefit from albumin administration and nutritional support in critically ill patients with noninfectious causes of diarrhea and in nontraumatic hypovolemic shock such as septic shock. Less convincing evidence exists for a beneficial effect of albumin administration in primary lung injury, such as acute respiratory distress syndrome (ARDS). A few cases of what appeared to be ARDS with low serum albumin levels have resolved following restoration of a normal colloid oncotic pressure by continuous administration of albumin until a normal level is reached. However, the use of albumin should be restricted to specific indications.

If intravenous albumin is administered, it is advisable to administer it with the TPN fluid or over a prolonged period of time. Even though the 50-mL vial of 25% human albumin can be given as a rapid intravenous infusion, one 50-mL vial of 25% albumin can rapidly expand the plasma compartment by as much as 300 mL, which may be enough to cause a sudden onset of pulmonary edema in susceptible patients.

Beta-Adrenergic Blockade

A small study showed that 2 weeks of propranolol given to children with 40% or more third-degree burns resulted in

lower heart rate, oxygen consumption, and energy expenditure by about 20%. Propranolol increased protein synthesis and prevented net whole body protein loss by approximately 10% over a 1-month period. In adults, the administration of atenolol or propranolol or atenolol resulted in a 50–80-kcal reduction in energy expenditure. Beta-adrenergic blockade may be useful in decreasing metabolic demands, but this possibility awaits confirmation in larger trials.

Imaging Procedures

Kathleen Brown, MD

7

An unprecedented array of imaging options is now available to the physician in the ICU. The choice of a particular imaging modality is occasionally difficult and should be based on recommendations in the literature, local expertise, type of equipment available, and the experience of the radiologists. Given the increasing emphasis on cost-effective practice, clinicians and radiologists must maximize the diagnostic and therapeutic yield of procedures while minimizing costs. Optimal management of critically ill patients also requires close communication between the critical care team and the diagnostic and interventional radiologist. An established practice of daily ICU radiology rounds with the participation of the radiologist facilitates this level of communication.

In a traditional model, all ICU films would be placed on a designated mechanical film alternator within either the ICU or the radiology department. With rapid advances in imaging options and telecommunications feasibility, new models for ICU imaging are being developed. In one model, films are acquired electronically and displayed in a patient archival and communications system (PACS) or on Web-based servers. The PACS unit is able to display plain radiographs, ultrasound and nuclear medicine studies, computed tomography (CT), and magnetic resonance images (MRI). Suboptimal exposures may be corrected in part by adjusting contrast and window levels. High-resolution monitors may be placed at designated sites in the ICU and throughout the hospital. An ideal system integrates PACS with the hospital information system (HIS) and the radiology information system (RIS) to display clinical and radiologic information. These systems may greatly improve the efficiency of clinicians, nurses, and support staff.

Although neurologic and musculoskeletal imaging studies play an important role in the care of the critically ill patient, this chapter will limit discussion to imaging of the chest and abdomen, with a focus on adult ICU patients.

IMAGING TECHNIQUES

Most radiographic examinations in the ICU are obtained at the bedside utilizing conventional analog or digital equipment. In most facilities, ultrasound and portable gamma cameras for planar nuclear medicine studies are useful and critical adjuncts for bedside examinations in the ICU. Other imaging methods, including high-quality ultrasound, CT, nuclear medicine techniques, and MRI, are used selectively due to cost and transport issues. Interventional procedures, either at the bedside or in the radiology suite, are also frequently performed under imaging guidance.

Plain Radiography

Digital systems are being used increasingly in the ICU for portable radiography. With these systems, images are obtained using a photo-stimulable phosphor imaging plate instead of film. The exposed imaging plate is scanned, read, and processed by computer, and the image can be transmitted to an ICU console or viewed as a hard copy on a conventional view box. Chest radiographs are the most common imaging examination, accounting for approximately 40% of the volume in a radiology department. As many as one-third of these chest radiographs may be obtained at the bedside (portable radiographs), and in the ICU almost all chest radiographs are taken using the portable technique. The utility and effectiveness of routine daily portable chest radiographs have been studied, and—despite limitations of the technique—these films play an important role in identifying and following pulmonary and cardiac disorders in ICU patients. Chest radiographs are also used to evaluate the positions of and complications from catheters and support devices used in the care of critically ill patients.

Likewise, imaging of the abdomen generally should begin with plain radiographs, which provide a readily accessible

means of diagnosing perforation, bowel obstruction, and ileus. However, because the overall sensitivity of plain radiographs remains low, further imaging with CT may be necessary to confirm suspected perforation and related complications (eg, abscess) and to inspect the features of the bowel walls and surrounding fat. Supine radiographs are most appropriate for verifying nasogastric or feeding tube placement and for investigation of renal stones and possible ileus or bowel obstruction. Additional views (ie, semiupright, left lateral decubitus, and cross-table lateral) may be helpful in cases of bowel perforation, ileus, or obstruction.

Ultrasound

Ultrasound examination at the bedside in the ICU is relatively inexpensive and does not use ionizing radiation. In the thorax, ultrasound is used most often to evaluate and localize pleural fluid collections, to determine whether such collections are free or loculated, and as a guide to thoracentesis. Ultrasound is also helpful in clarifying peridiaphragmatic processes because the diaphragm is easily visualized, allowing differentiation of supradiaphragmatic and infradiaphragmatic fluid collections. The greatest utility of ultrasound, however, is in the evaluation of abdominal disease. Ultrasound provides rapid assessment of hepatobiliary and genitourinary disease and may be used to guide percutaneous drainage of intraabdominal abscesses. It allows rapid evaluation of the hepatobiliary system, gallbladder, kidneys, pelvic organs, and scrotal disorders. Visualization of vascular perfusion and parenchymal flow is a useful feature, especially in transplanted organs. Ultrasound is also indispensable for guidance of bedside procedures such as central line placement, cholecystostomies, biopsies, and drainage of fluid collections.

Computed Tomography

By virtue of multiplanar imaging capabilities and improved contrast resolution, multidetector CT (MDCT) has been shown to be very valuable in increasing diagnostic accuracy and guiding therapeutic procedures for critically ill patients. MDCT allows for more rapid scanning of patients, with imaging of the entire chest, abdomen, and pelvis with thin sections during a single breath-hold. Such short acquisition times have facilitated the use of CT for evaluation of vascular disorders such as aortic dissection and pulmonary embolism. CT also allows for improved characterization of pulmonary diseases, particularly acute respiratory distress syndrome (ARDS), and is a critical diagnostic tool for the evaluation of an acute abdomen.

Transportation of the ICU patient to the CT scanner requires a coordinated effort from hospital personnel, including ICU physicians and nurses, respiratory therapists, radiology technologists, and radiologists. Careful monitoring during transport and during the procedure is essential and must include arrhythmia monitoring and pulse oximetry.

Nuclear Scintigraphy

Nuclear scintigraphy has a number of applications in the critically ill patient. Myocardial perfusion and infarct scanning in cardiac disease, ventilation-perfusion scanning in patients with suspected pulmonary embolism, evaluation of gastrointestinal hemorrhage and acute cholecystitis, and localization of occult infection are among the most common indications for radionuclide imaging in the ICU patient.

Magnetic Resonance Imaging

MRI has supplanted CT in the evaluation of many disorders because it does not employ ionizing radiation, because it provides excellent differentiation of vascular and nonvascular structures without the use of intravenous contrast material, and because it provides cross-sectional images in multiple planes. It is generally considered the single best imaging method for evaluation of the CNS, head and neck, liver, and musculoskeletal system. However, in many cases, MRI is not feasible in the evaluation of the critically ill patient because of interference caused by ferromagnetic monitoring devices, the difficulty of adequately ventilating and monitoring patients within the narrow MRI gantry, and long scan times. MRI may be appropriate in selected diagnostic dilemmas if MR-compatible equipment and coordinated effort among caregivers can be arranged.

IODINATED CONTRAST AGENTS

Adverse reactions to iodinated contrast agents occur at low rates but are encountered not infrequently given their widespread use. Older ionic agents, newer nonionic agents, and the newest nonionic isoosmolar agents are available, with the oldest agents having the highest incidence of adverse reactions and the newest agents having a significantly lower incidence. Idiosyncratic reactions range from benign urticaria to, very rarely, life-threatening hypotension, laryngeal edema, and bronchospasm. These events are not considered truly allergic in nature because they are not antibody-mediated and are inconsistently reproducible with subsequent administrations. Pretreatment with corticosteroids appears to be effective for mild events, but corticosteroids should not be used in patients with a history of severe reaction. In the latter situation, an alternative such as MRI with

gadolinium contrast or carbon dioxide angiography should be considered. Contrary to popular belief, allergy to shellfish is not predictive of reactions to iodinated contrast agents.

Contrast nephropathy is another important complication of intravascular iodinated contrast use and occurs in the setting of preexisting renal compromise, most often due to dehydration, surgery, nephrotoxic drugs, or long-standing diabetes. Again, the incidence is highest with the oldest agents and lowest with the isoosmolar nonionic agents. Although the serum creatinine level is a convenient measure of renal function, creatinine clearance should be calculated for a more reliable estimation—less than 25 mL/min or 25–50 mL/min with risk factors identifying high-risk patients. Potentially effective preventive strategies include adequate intravenous hydration with normal saline or sodium bicarbonate solution and administration of *N*-acetylcysteine. Metformin should be stopped until 48 hours following contrast use to avoid possible lactic acidosis in the event of contrast nephrotoxicity. Rather than using a universal creatinine level cutoff, the decision to use contrast agents should be made on a case-by-case basis, carefully weighing the need for the study in high-risk patients. In affected patients, the serum creatinine level peaks at 4–7 days and gradually normalizes. Progression to end-stage renal disease is exceptionally rare.

USE OF CENTRAL VENOUS CATHETERS FOR CONTRAST INJECTION

Peripheral veins are the preferred routes of contrast agent administration in imaging. When peripheral access is difficult, existing central venous catheters (CVCs) may be considered, with a few caveats. Intraluminal pressure limitations may result in low contrast flow rates, producing a suboptimal study, or catheter rupture may occur during rapid power injection of the relatively viscous contrast material. While most catheter manufacturers do not provide specific instructions in this regard and practice standards have not been established, the following general precautions may be useful: (1) High flow rates (>2 mL/s) should be avoided in most temporary or tunneled CVCs, (2) silicone-type peripherally inserted central catheters (PICCs) should not be used, (3) for multilumen catheters, the largest-caliber port should be used when possible, (4) Groshong-valve lines should not be used, (5) pulmonary or systemic arterial lines should not be used, and (6) catheter integrity and patency should be checked

before and after injection. Since no established guidelines are available, hospital personnel should be knowledgeable about the specific catheters used at their institution.

IMAGING OF SUPPORT & MONITORING DEVICES IN THE ICU

▶ Endotracheal & Tracheostomy Tubes

Both endotracheal intubation and tracheostomy may cause potentially serious complications. Malpositioning of the endotracheal tube into the right main stem bronchus occurs in approximately 9% of endotracheal intubations. Such malpositioning may lead to atelectasis of the left lung, hyperinflation of the right lung, and possible pneumothorax. The clinical assessment of tube location is frequently inaccurate, and a chest radiograph should be obtained immediately following intubation. Tubes currently in use are usually radiographically visible by virtue of a metallic wire or barium marker in the wall of the tube. Periodic radiographs are required to exclude inadvertent displacement of the tube by cough, suctioning, or the weight of the respiratory apparatus.

Since endotracheal tubes are typically fixed in position at the nose or mouth, flexion and extension of the neck may result in motion of the tube relative to the carina, with the tube descending during flexion and ascending during extension. With the neck in neutral position, the ideal position of the tube tip is 5–7 cm above the carina, which allows for a tolerable change in tube position during flexion and extension. In 90% of patients, the carina projects between the fifth and seventh thoracic vertebrae on the portable radiograph; when the carina cannot be clearly seen, the ideal positioning of the endotracheal tube is at the T2–T4 level. The aortic arch also may be used to estimate tube location because the carina is typically at the level of the undersurface of the aortic arch. The balloon cuff should not be greater in diameter than the trachea because cuff overinflation can cause pressure necrosis of the tracheal wall.

Inadvertent placement of the endotracheal tube into the esophagus is uncommon but may be catastrophic when it does occur. Esophageal intubation may be difficult to diagnose on the portable chest film because the esophagus frequently projects over the tracheal air column. Gastric or distal esophageal distention, location of the tube lateral to the tracheal air column, and deviation of the trachea secondary to an overinflated intraesophageal balloon cuff are radiographic signs of esophageal intubation. The right posterior oblique view with the patient's head turned to the right

allows ease of separation of the esophagus and trachea and should be obtained in equivocal cases.

Intubation may result in injury to the trachea, with tracheal stenosis developing in approximately 19% of patients following endotracheal intubation and approximately 65% of patients with tracheostomy. In patients with translaryngeal intubation, the most frequent sites of stenosis are the cuff site and the subglottic region.

Tracheostomy is typically performed in the patient who requires relatively long-term ventilatory support. Although the surgical mortality rate is less than 2%, the long-term complication rate may be as high as 60%. Pneumothorax, pneumomediastinum, subcutaneous emphysema, hemorrhage, and tube malposition may occur as early complications, whereas late complications include tracheal stenosis, tracheo-innominate artery fistula, tracheoesophageal fistula, stomal infection, aspiration, and tube occlusion. In addition, the incidence of nosocomial pneumonia is increased secondary to airway bacterial colonization.

► Central Venous Catheters

Central venous catheters are used frequently in the ICU patient for venous access, especially for purposes of parenteral alimentation, monitoring central venous pressure, and hemodialysis. Such catheters are visible on the chest radiograph, and knowledge of normal thoracic venous anatomy is required to assess catheter location. The subclavian vein, the internal jugular vein, and the femoral veins are the sites of venous access used most commonly. Central venous lines inserted via a thoracic vein are optimally positioned when the tip is past the valves in the subclavian or brachiocephalic veins within the superior vena cava.

The preferred location for hemodialysis or pheresis catheters is subject to debate, however, because some physicians believe that catheter durability and performance are improved by placement of the catheter tip within the upper right atrium.

Union of the subclavian and internal jugular veins to form the brachiocephalic vein usually occurs behind the sternal end of the corresponding clavicle. Whereas the right brachiocephalic vein has a vertical course as it forms the superior vena cava, the left brachiocephalic vein crosses the mediastinum from left to right in a retrosternal position to enter the superior vena cava. The radiographic location of the superior vena cava may be assessed relative to the tracheobronchial angle, with the upper border of the superior vena cava usually just superior to the angle of the right main stem bronchus and the trachea. The junction of the superior vena cava and right atrium is at the approximate level of the lower aspect of the bronchus intermedius. Changes in catheter location may occur with change in patient position and changes in respiration.

Approximately one-third of catheters are incorrectly positioned at the time of the initial chest radiograph. The malpositioned catheter tip may result in venous thrombosis or perforation as well as inaccurate venous pressure readings. Positioning of the catheter tip within the right atrium may result in cardiac perforation and tamponade, whereas a right ventricular location may result in arrhythmias secondary to irritation of the endocardium or interventricular septum.

Complications of central venous catheterization include pneumothorax, hemothorax, and perforation, which may result in pericardial effusion, hydrothorax, mediastinal hemorrhage, or ectopic infusion of intravenous solutions (Figure 7-1). Less common complications include air

A

B

▲ **Figure 7-1.** Mediastinal hematoma following attempted central venous catheterization. **A.** Mediastinum appears unremarkable prior to catheter placement. **B.** Following attempted central line placement, there is widening of the superior mediastinum secondary to mediastinal hemorrhage due to a lacerated subclavian artery.

embolism and catheter fracture or embolism. The incidence of pneumothorax ranges between 1% and 12% and is higher with a subclavian approach than with an internal jugular approach. Pneumothorax may be clinically occult, and a chest radiograph should be obtained to exclude a pneumothorax following line placement. A radiograph should be obtained even following an unsuccessful attempted line placement and is more critical when contralateral venous cannulation is anticipated to avoid the development of bilateral pneumothoraces. Although seldom obtained in ICU patients, the cross-table lateral view may be helpful to localize catheters malpositioned in the internal mammary or azygos vein or in extravascular positions.

Venous air embolism is an uncommon complication of central venous catheterization. Radiographically, air in the main pulmonary artery is diagnostic, but other features include focal oligemia, pulmonary edema, and atelectasis. Intracardiac air or air within the pulmonary artery is seen easily on CT.

Long-term complications of venous access devices include delayed perforation, pinch-off syndrome, thrombosis, catheter knotting, and catheter fragmentation. Left-sided catheters have a greater risk for perforation, with increased risk in catheters abutting the right lateral wall of the superior vena cava. In pinch-off syndrome, the catheter lumen is compromised by compression between the clavicle and the first rib, leading to catheter malfunction and possible catheter fracture. This is frequently first observed as subtle focal narrowing of the catheter as it crosses the intersection of clavicle and rib. As increasing numbers of chronically ill patients with long-term venous catheters—including liver and bone marrow transplant recipients—are transferred to the ICU during their hospital course, more such complications may be seen.

Access to the central venous system may be achieved through a peripherally inserted central catheter (PICC) placed via the antecubital fossa. These smaller catheters course to the superior vena cava and may be associated with fewer complications than catheters inserted via the internal jugular or subclavian approach.

► Pulmonary Artery Catheters

The pulmonary artery catheter has enhanced the management of the ICU patient, allowing monitoring of left atrial and left ventricular end-diastolic pressures and calculation of vital data such as cardiac output and vascular resistance. The catheter tip should lie within a large central pulmonary artery; the ideal position for the pulmonary artery catheter is within the right or left main pulmonary artery, below the level of the left atrium. The catheter tip when deflated should not be peripheral to the proximal interlobar arteries. Complications associated with their use include arrhythmias, pneumothorax, vascular perforation, venous air embolism, and catheter-related sepsis. Knotting, kinking, and coiling of the catheter also occur.

Pulmonary infarction, thrombosis, pulmonary artery rupture, and infection represent other major complications associated with indwelling pulmonary artery catheters. There is a 7% incidence of pulmonary ischemic lesions due to direct

injury from the use of pulmonary artery catheters. The majority of these lesions are thought to be due to vascular occlusion by the catheter itself. Continuous wedging of the catheter tip in a peripheral pulmonary artery and central pulmonary artery obstruction by the inflated balloon have been cited as precipitating causes. In a smaller number of cases, emboli arose from peripheral thrombosis around the catheter.

Pulmonary infarction secondary to a pulmonary artery catheter has a radiographic appearance like that of infarction from other causes. Typically, a wedge-shaped parenchymal opacity is seen in the distribution of the vessel distal to the catheter (Figure 7–2). The presence of a pleural effusion is variable. Management consists of removal of the catheter; anticoagulation is generally not required. Resolution of consolidation usually occurs in 2–4 weeks.

Pulmonary artery rupture is a catastrophic complication of pulmonary artery catheterization, with a reported mortality rate of 46%. The incidence is low—no more than 0.2% of catheter placements. Risk factors include pulmonary hypertension, advanced age, and improper balloon location or inflation. The mortality rate increases in anticoagulated patients. Pseudoaneurysm formation has been reported secondary to rupture or dissection by the balloon catheter tip. This appears radiographically as a well-defined nodule at the site of the aneurysm, but it may be obscured initially by extravasation of blood into the adjacent air spaces. Chest radiographic findings often precede clinical manifestations, and death due to rupture of pseudoaneurysm may occur weeks following catheterization. The CT appearance of a pulmonary artery pseudoaneurysm has been described as a sharply defined nodule with a surrounding halo of faint parenchymal density. Pulmonary artery pseudoaneurysm now may be treated in some patients with transcatheter embolization rather than surgical resection.

Location of the catheter tip should be monitored with serial radiographs. Softening of the catheter over time may result in migration of the catheter tip peripherally. Redundancy of the catheter within the right heart favors peripheral migration, and the intracardiac loop gradually becomes smaller (see Figure 7–2).

► Intraaortic Balloon Counterpulsation

Intraaortic balloon counterpulsation is used to improve cardiac function in patients with cardiogenic shock and in the perioperative period in cardiac surgery patients. The device consists of a fusiform inflatable balloon surrounding the distal portion of a catheter that is placed percutaneously from a femoral artery into the proximal descending thoracic aorta. The balloon is inflated during diastole, thereby increasing diastolic pressure in the proximal aorta and increasing coronary artery perfusion. During systole, the balloon is forcibly deflated, allowing aortic blood to move distally and decreasing the afterload against which the left ventricle must contract, thus decreasing left ventricular workload. The timing of inflation and deflation is controlled by the ECG.

A

B

C

▲ Figure 7-2. Lung infarction secondary to pulmonary artery catheterization. **A.** Initial radiograph after catheterization shows the tip of the catheter at the level of the right interlobar pulmonary artery. Mild redundancy of the catheter is present within the dilated heart. **B.** At 24 hours, the patient developed hemoptysis. Radiograph now shows migration of the catheter into a segmental arterial branch with increased density in the right lower lobe. **C.** Follow-up film demonstrates dense consolidation of the right middle and lower lobes secondary to infarction. (Reproduced, with permission, from Aberle DA, Brown K: Radiologic considerations in the adult respiratory distress syndrome. *Clin Chest Med* 1990;2:737–54. Copyright 1990 Elsevier.)

The tip of the balloon ideally should be positioned just distal to the origin of the left subclavian artery at the level of the aortic knob, maximizing the effect on the coronary arteries while reducing the possibility of occlusion of the left subclavian artery, embolization to cerebral vessels, or occlusion of the abdominal vessels by the balloon. Complications associated

with the device are most often secondary to malpositioning of the catheter and include obstruction of the subclavian artery and cerebral embolism. Aortic dissection has been described, and an indistinct aorta on chest radiographs has been suggested as an early clue to intramural location, requiring confirmation by angiography. Balloon leak or rupture also has been described.

▶ Cardiac Pacemakers and Automatic Implantable Cardioverter Defibrillators

Cardiac pacemakers can be inserted by three approaches: transvenous, epicardial, and subxiphoid. Most often the transvenous approach is used, whereby wires are introduced via the subclavian or jugular vein and fluoroscopically guided into the right atrium and ventricle.

When viewed on a chest radiograph, the pacemaker lead should curve gently throughout its course; regions of sharp angulation will have increased mechanical stress and enhance the likelihood of lead fracture. Excessive lead length may predispose to fracture secondary to sharp angulation or may perforate the myocardium, and a short lead can become dislodged and enter the right atrium. Leads also may become displaced and enter the pulmonary artery, coronary sinus, or inferior vena cava. When possible, a lateral chest radiograph is recommended to confirm pacemaker lead location, with the electrodes located at least 3 mm deep to the epicardial fat stripe. Other complications include venous thrombosis or infection, either at the pulse generator pocket or within the vein. Myocardium perforation may result in hemopericardium and cardiac tamponade.

Biventricular pacing or cardiac resynchronization therapy is a relatively new treatment for severe chronic heart failure. In patients with dilated cardiomyopathy and intraventricular conduction delay, biventricular or left ventricular pacing can synchronize contraction and increase cardiac output and exercise tolerance. Percutaneous lead placement into a coronary vein via the coronary sinus allows for left ventricular pacing. Many of

these patients also will have intravascular defibrillators because of the risk of ventricular arrhythmias. The automatic implantable cardioverter defibrillator (AICD) is used for treatment of ventricular tachyarrhythmias unresponsive to conventional antiarrhythmic drugs. Earlier devices consisted of a fine titanium mesh placed on the cardiac surface and attached to a generator source that provided an electrical output in the event of ventricular arrhythmia. Devices currently in use typically are combined with a cardiac pacemaker. Radiographs are used to assess the location of wires.

▶ Nasogastric Tubes

Nasogastric tubes are used frequently to provide nutrition and administer oral medications as well as for suctioning gastric contents. Ideally, the tip of the tube should be positioned at least 10 cm beyond the gastroesophageal junction. This ensures that all sideholes are located within the stomach and decreases the risk of aspiration. Complications of nasogastric intubation include esophagitis, stricture, and perforation.

Small-bore flexible feeding tubes have been developed to facilitate insertion and improve patient comfort. However, inadvertent passage of the nasogastric tube into the tracheobronchial tree is not uncommon, most often occurring in the sedated or neurologically impaired patient. In patients with endotracheal tubes in place, low-pressure, high-volume balloon cuffs do not prevent passage of a feeding tube into the lower airway. If sufficient feeding tube length is inserted, the tube actually may traverse the lung and penetrate the visceral pleura (Figure 7-3).

A

B

▲ **Figure 7-3.** Malpositioned feeding tube. **A.** Feeding tube courses via the right main stem bronchus with the tip (*arrow*) overlying the right costophrenic angle. An endotracheal tube is present. **B.** Following removal of the feeding tube, a pneumothorax is seen (*arrow*).

Removal of the tube from an intrapleural location may result in tension pneumothorax, and preparations should be made for potential emergent thoracostomy tube placement at the time of removal.

In addition to feeding tubes, balloon tamponade tubes occasionally are used for nasogastric intubation in the treatment of bleeding esophageal and gastric varices. The balloon can be easily recognized when distended, and correct positioning can be evaluated radiographically. Esophageal rupture complicates approximately 5% of cases in which balloon tamponade tubes are used.

▶ Chest Tubes

Thoracostomy tubes (“chest tubes”) are used for the evacuation of air or fluid from the pleural space. When chest tubes are used for relief of pneumothorax, apical location of the tip of the tube is most effective, whereas a tube inserted to drain free-flowing effusions should be placed in the dependent portion of the thorax. Chest radiographs, ultrasound, or CT should be used to guide correct placement of the tube for adequate drainage of a loculated effusion. Failure of the chest tube to decrease the pneumothorax or the effusion within several hours should arouse suspicion of a malpositioned tube. Tubes located within the pleural fissures are usually less effective in evacuating air or fluid collections. An inter-fissural location is suggested by orientation of the tube along the plane of the fissure on frontal radiographs and by lack of a gentle curvature near the site of penetration of the pleura, indicating failure of the tube to be deflected anteriorly or posteriorly in the pleural space. The lateral view may be confirmatory. Uncommonly, thoracostomy tubes may penetrate the lung, resulting in pulmonary laceration and bronchopleural fistula. Unilateral pulmonary edema may occur following rapid evacuation of a pneumothorax or pleural effusion that is of long standing or has produced significant compression atelectasis of lung.

IMAGING IN PULMONARY DISEASES

▶ Routine Daily Chest Radiographs: Technical Considerations & Utility

Portable chest radiographs are frequently obtained on a daily basis on ICU patients and as indicated by changes in their clinical situation. Several factors related to portable radiography may lead to difficulty in evaluation of radiographs in a critically ill patient. The equipment used for portable radiographs requires longer exposure time than standard radiographs obtained in the radiology department, sometimes resulting in artifacts due to respiratory, cardiac, and gross patient motion. Inadequate exposure may result from the limited power output of portable equipment. Special attention must be paid to the multiple monitoring devices required by the ICU patient, and considerable physical effort by the technologists is required to transport portable equipment.

Limitations imposed by the portable technique often complicate image interpretation. Almost all portable chest radiographs are taken with the patient supine and with the film placed behind the back of the patient (anteroposterior) rather than in the conventional upright, posteroanterior position used in the radiology department. Supine chest radiographs result in decreases in lung volume and can alter the size and appearance of the lungs, the pulmonary vasculature, and the mediastinum. Anteroposterior chest radiographs cause cardiac magnification, making evaluation of true cardiac size more difficult. Inspiratory films may be difficult to obtain because of respiratory distress, pain, sedation, or alterations in mental status. These technical limitations complicate diagnostic interpretation. Nonetheless, portable radiography continues to be a primary method of imaging critically ill patients.

The utility of daily radiographs may depend on the underlying disease process. Routine daily radiographs are of greatest utility in patients with pulmonary or complicated cardiac disease. The American College of Radiology Thoracic Expert Panel concluded that daily chest radiographs are indicated for patients with acute cardiopulmonary problems and those receiving mechanical ventilation. In patients requiring cardiac monitoring or stable patients admitted for extrathoracic disease, an initial admission film is recommended. Additional radiographs are indicated when new support devices are placed or a specific question arises regarding cardiopulmonary status.

▶ Atelectasis

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ Shift in position of a fissure or change in position of hila or mediastinum.
- ▶ Elevation of hemidiaphragm.
- ▶ Compensatory hyperexpansion of uninvolved lobes.
- ▶ Increased opacity of the atelectatic lung.
- ▶ Air bronchograms.
- ▶ Narrowing of rib interspaces.

General Considerations

Atelectasis is the most common pulmonary parenchymal abnormality seen in ICU patients. Signs and symptoms of atelectasis are nonspecific, and atelectasis may coexist with other pulmonary diseases. Multiple factors contribute to the development of atelectasis. In the bedridden patient, hypoventilation results in atelectasis of the dependent lung. Central neurogenic depression, anesthesia, or splinting may decrease alveolar volume, reducing surfactant and promoting diffuse microatelectasis. Bronchial obstruction from retained secretions and mucous plugging may lead to post-obstructive collapse of the distal lung, particularly in patients with pulmonary infection or chronic airway disorders. In the intubated or postoperative patient, other factors are contributory. A malpositioned endotracheal tube with right main stem bronchial intubation can cause atelectasis of the non-ventilated left lung. Following cardiac surgery, left lower lobe collapse occurs frequently due in part to the weight of the heart unsupported by pericardium, which compresses the left lower lobe bronchus. Phrenic nerve paresis secondary to intraoperative cold cardioplegia results in diaphragmatic elevation and is also thought to contribute to lower lobe atelectasis. Pleural processes, including pneumothorax and pleural effusion, may also result in atelectasis.

Radiographic Features

The radiographic appearance of atelectasis depends largely on the degree and cause of lung collapse. Findings noted on the chest radiograph in atelectasis range from subtle diminution in lung volume without visible opacification to complete opacification of a segment, lobe, or lung. Dependent atelectasis occurring in supine patients may be demonstrated on thoracic CT even in healthy individuals but is usually not appreciated on plain chest radiography. Linear bands of opacity may be seen in “discoid” or “platelike” atelectasis, whereas a patchy opacity is seen with atelectasis of lung subtended by a segmental or subsegmental bronchus. With more extensive volume loss such as collapse of an entire lobe or lung, radiographic signs include an

increase in opacity of the atelectatic lung; shift in the position of a fissure; change in the position of the mediastinum, hila, or diaphragm; and hyperexpansion of the uninvolved lung (Figure 7-4). In some cases, signs of volume loss may be absent because of exudation of fluid into the atelectatic lung.

Air bronchograms are linear lucencies coursing through opacified lung and represent patent bronchi and bronchioles surrounded by opacified air spaces. Air bronchograms are radiographically nonspecific and occur in any disorder in which patent air-containing bronchi are situated within consolidated lung, including atelectasis, pulmonary edema, pneumonia, and hemorrhage. The presence of air bronchograms is also variable in atelectasis and depends on the patency of the major airways and the cause of atelectasis. Air bronchograms may be useful predictors of the effectiveness of bronchoscopy in patients with lobar collapse. Patients without air bronchograms are more likely to demonstrate improvement following fiberoptic bronchoscopy than those with air bronchograms. The absence of air bronchograms in lobar collapse suggests that central

▲ **Figure 7-4.** Atelectasis in a 22-year-old man with status asthmaticus. The right upper lobe is opaque, and there is elevation of the minor fissure consistent with right upper lobe collapse. Areas of increased density in the left lung are also due to atelectasis. Lucency adjacent to the left heart border secondary to pneumomediastinum is present (*arrow*), and there is subcutaneous emphysema in the right supraclavicular region.

airways may be plugged by secretions which by virtue of their proximal location are amenable to bronchoscopic removal. In contrast, the presence of air bronchograms suggests that the collapse is more apt to be due to small airway collapse or peripheral mucous plugs that are not effectively treated by therapeutic fiberoptic bronchoscopy.

The left lower lobe is the most frequent location of lobar atelectasis, with collapse occurring two to three times more often in the left lower than in the right lower lobe. The cause is uncertain, although many of the factors cited earlier are contributory. The radiographic features of left lower lobe collapse include a triangular opacity in the retrocardiac region and loss of definition of the descending aorta and left hemidiaphragm—as well as other signs of volume loss outlined earlier (Figure 7-5). Adequate penetration and patient positioning are important in assessing left lower lobe disease. Left lower lobe collapse may be falsely diagnosed secondary to faulty radiologic technique. Cephalic angulation of the radiographic beam by 10–15 degrees (lordotic positioning) may cause projection of extrapleural fat onto the base of the left lung and result in loss of tangential imaging of the apex of the hemidiaphragm and subsequent loss of definition of the diaphragm in the absence of left lower lobe disease. In instances in which patients are examined radiographically with even a small degree of lordosis, loss of definition of the diaphragm therefore cannot be assumed to be secondary to left lower lobe collapse. Ancillary findings, including depression of the hilum, crowding of vessels, and air bronchograms, must be used to diagnose true left lower lobe disease.

▲ **Figure 7-5.** Left lower lobe collapse in a 20-year-old man with head trauma sustained in a motor vehicle accident. A triangular region of increased opacity is present in the retrocardiac region secondary to left lower lobe collapse. The major fissure is displaced inferiorly (arrow).

Unusual appearances of lobar atelectasis may occur and make diagnosis difficult. Atelectasis with marked volume loss may be caused by peripheral airway obstruction and is frequently chronic and easily missed. Atelectasis also may present as a mass and be confused with tumor. Recognition of the anatomic alterations described earlier is required for differentiation.

Many other causes of parenchymal opacification may be confused with atelectasis, including pneumonia and pulmonary infarction. In addition to other features previously discussed, temporal sequence may be helpful in distinguishing atelectasis from other causes of focal parenchymal opacification. Whereas atelectasis may appear within minutes to hours and also may clear rapidly, pneumonia and infarction typically resolve over days to weeks.

► Pneumonia

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- May present as lobar pneumonia, bronchopneumonia, or interstitial pneumonia.
- Parapneumonic effusions and cavitation may be present.
- Hilar or mediastinal densities may lead to suspicion of obstruction secondary to underlying malignancy.
- In ICU patients, development of new or worsening parenchymal pulmonary infiltrates may indicate nosocomial pneumonia, especially if accompanied by cavitation.

General Considerations

Patients with severe pneumonia complicated by sepsis, respiratory failure, hypotension, or shock are seen frequently in the ICU. Some patients will have acquired pneumonia outside of the hospital (community-acquired), but an important problem is that of *nosocomial pneumonia*, defined as lower respiratory tract infection occurring more than 72 hours after admission. Nosocomial pneumonia is the most common infection leading to death among hospitalized patients. Factors contributing to the high incidence of hospital-acquired pneumonias include endotracheal intubation or tracheostomy, aspiration, and impaired host defenses. Prior antibiotic therapy promotes colonization of the tracheobronchial tree.

Most radiologists sort the radiographic appearance of pneumonias into three categories that may aid in differentiation: lobar (alveolar or air space) pneumonia, lobular

pneumonia (bronchopneumonia), and interstitial pneumonia. Lobar pneumonia is characterized on x-ray by relatively homogeneous regions of increased lung opacity and air bronchograms. The entire lobe need not be involved, and in fact, with early therapy, consolidation does not usually affect the entire lobe. Pathologically, the infecting organism reaches the distal air spaces, resulting in edema filling the alveoli. The infected edema fluid spreads centripetally throughout the lobe via communicating channels to adjacent segments. Air bronchograms are common. *Streptococcus pneumoniae* (pneumococcal) pneumonia is the classic lobar pneumonia, although other organisms, including *Klebsiella pneumoniae* and *Legionella pneumophila*, may produce an identical pattern. Since the airways are not primarily involved, volume loss is not conspicuous. Indeed, expansion of the lobe may occur in *Klebsiella* or pneumococcal pneumonia.

Bronchopneumonia (lobular pneumonia) results from inflammation involving the terminal and respiratory bronchioles rather than the distal air spaces. Since the process focuses in the airways, the distribution is more segmental and patchy, affecting some lobules while sparing others. Pathologically, there is less edema fluid and more inflammation of the mucosa of bronchi and bronchioles. Patchy consolidation is seen radiographically. Mild associated volume loss may also be present. Air bronchograms are not as common a feature in bronchopneumonia as in lobar pneumonia. The most common organisms producing classic bronchopneumonia are *Staphylococcus aureus* and *Pseudomonas* species.

Interstitial pneumonia is typically caused by viruses or *Mycoplasma pneumoniae*. In the immunocompromised patient, *Pneumocystis carinii* (now known as *Pneumocystis jirovecii*) is an important cause of interstitial pneumonia. The pathologic process is located primarily in the interstitium, and the classic radiograph reflects the interstitial process and demonstrates an increase in linear or reticular markings in the lung parenchyma with peribronchial thickening and occasionally septal lines (Kerley A and B lines). Although the pathologic process is primarily located in the interstitium, proteinaceous fluid is exuded into the air spaces and consequently may progress to a pneumonia that radiographically appears alveolar.

Radiographic Features

A. Plain Films—Although plain films cannot provide a specific microbial diagnosis in a patient with pneumonia, radiology has a central role in both initial evaluation and treatment. The chest radiograph documents the presence and extent of disease. Associated parapneumonic effusions, mediastinal or hilar adenopathy, cavitation, and abscess formation—as well as predisposing conditions such as central bronchogenic carcinoma—may be identified. Such information can guide the clinician to a high-yield diagnostic procedure such as thoracentesis or bronchoscopy, which may be necessary in a patient who cannot produce adequate sputum for bacteriologic culture. The chest radiograph is

also critical in evaluating the patient's response to therapy. Antibiotic therapy is frequently empirical, and the chest radiograph may be the first indicator of failure of antibiotics and a need for change in management. A pneumonia that does not clear despite antibiotic therapy should raise the suspicion of central airway obstruction by a mass or foreign body or may represent a bronchoalveolar carcinoma mimicking pneumonia.

Localization of the consolidation to a specific lobe is important not only to correlate with the physical examination but also to guide the bronchoscopist when necessary. In addition, different types of pneumonia may be more likely to occur in specific regions. For example, reactivation tuberculosis occurs most commonly in the apical and posterior segments of the upper lobes and the superior segment of the lower lobes. The silhouette sign is useful in determining the site of pneumonia. When consolidation is adjacent to a structure of soft tissue density (eg, the heart or the diaphragm), the margin of the soft tissue structure will be obliterated by the opaque lung. For example, right middle lobe consolidation may cause loss of the margin of the right heart border, lingular consolidation may cause loss of the left heart border, and lower lobe pneumonia may obliterate the diaphragmatic contour.

Intrathoracic nodal enlargement may be a useful diagnostic feature. Enlargement of the hilar or mediastinal lymph nodes is uncommon in bacterial pneumonia and most viral pneumonias. Tuberculosis, atypical mycobacterial infections, fungal infections such as coccidioidomycosis and histoplasmosis, and viral infections such as measles and Epstein-Barr virus may be associated with adenopathy.

Pleural effusions occur in up to 40% of patients with bacterial pneumonia. A parapneumonic effusion consists of intrapleural fluid in association with pneumonia or lung abscess. *Empyema* is defined as pus in the pleural space. Thoracentesis is required for differentiation between a simple parapneumonic effusion and an empyema, and the decision to place a chest tube depends on the characteristics and the quantity of the effusion. A pleural effusion usually is identified radiographically on a plain film, although ultrasound or CT may be necessary in some cases.

1. LUNG ABSCESS AND CAVITATION—Cavitation of pneumonia results from destruction of lung tissue by the inflammatory process, leading to lung abscess formation (Figure 7-6). Although often seen in pneumonias due to gram-negative organisms such as *Pseudomonas* and *Klebsiella*, cavitation is rare in pneumococcal pneumonia. Pneumonias due to *Mycobacterium tuberculosis*, atypical mycobacteria, and fungi and those due to anaerobes and staphylococci also frequently cavitate. Cavitory lung abscesses must be distinguished from bullae, pneumatoceles, cavitory lung cancers, and other lucent lesions. Most abscesses have a wall thickness between 5 and 15 mm, allowing differentiation from bullae and pneumatoceles, which usually have thin, smooth walls. A lung abscess is usually surrounded by adjacent parenchymal consolidation, which may serve to differentiate an abscess from a

▲ Figure 7-6. Cavitary pneumonia. Posteroanterior (**A**) and lateral (**B**) chest radiographs demonstrate consolidation with cavitation (*arrows*) in the superior segment of the left lower lobe secondary to *Pseudomonas aeruginosa*. A small left pleural effusion is present, best seen on the lateral view (*arrowhead*). Changes of chronic obstructive pulmonary disease are also present.

cavitary bronchogenic carcinoma. Complications of lung abscess include sepsis, cerebral abscess, hemorrhage, and spillage of contents of the cavity into uninfected lung or pleural space.

In one review, 18% of lung abscesses were radiographically occult, with only nonspecific lung opacities or nodules identified. In these patients, the diagnosis was made at surgery or at postmortem examination. One reason lung abscesses were not identified was probably failure to use a horizontal beam in obtaining the chest radiographs. With semierect or supine positioning, air-fluid levels within the cavity were obscured. In cases where erect chest films are unobtainable, decubitus or cross-table lateral views can be obtained with a horizontal beam and may be diagnostic.

2. NOSOCOMIAL PNEUMONIA—Definitive diagnosis of nosocomial pneumonia is difficult because both the clinical features and the chest radiographic findings may be present in other disease processes and because abnormalities on chest radiographs are often present prior to development of nosocomial pneumonia. Clinical suspicion in patients with underlying heart and lung disease is important. For example, the incidence of nosocomial pneumonia is increased in patients with ARDS as well as in other patients with respiratory failure.

Radiographically, nosocomial pneumonia is heralded by the development of new or worsening parenchymal opacities, usually multifocal. Since nosocomial pneumonias

are most often due to aerobic gram-negative organisms or staphylococci, abscesses and pleural effusions may develop. Development of cavitation helps to distinguish nosocomial pneumonia from other causes of parenchymal opacification such as atelectasis, lung contusion, or pulmonary edema.

B. Computed Tomography—The cross-sectional imaging plane and superior contrast resolution make CT useful in the evaluation of complicated inflammatory diseases. Cavitation, which may be obscured on plain films, is easily identified on CT. Localization of parenchymal diseases facilitates the direction of invasive studies such as bronchoscopy or open lung biopsy. Superimposed pleural and parenchymal processes are more easily differentiated on CT than on plain films ([Figure 7-7](#)). Loculated pleural effusion or empyema associated with pneumonia may be difficult to evacuate, and CT may serve to guide thoracentesis, chest tube placement, or percutaneous drainage of large lung abscesses.

Empyema and lung abscess are more easily distinguished on CT than on conventional radiographs. Separation of thickened visceral and parietal pleural surfaces (“split pleura sign”) may be seen in empyema. Other useful findings included wall characteristics, with smooth, uniform walls seen in empyema and thick, irregular walls more commonly seen in lung abscess. The size and shape of the lesion are less helpful; lung abscesses generally tend to be round—as opposed to lenticular in empyemas. The administration of

A

B

▲ **Figure 7-7.** Pneumonia with loculated empyema. **A.** CT shows a loculated pleural effusion in the left hemithorax (arrows). **B.** More caudally, dense consolidation with air bronchograms secondary to pneumonia is present in the left lower lobe. The consolidated lung enhances with contrast and is easily distinguished from the surrounding pleural effusion.

intravenous contrast material facilitates differentiation of pleural and parenchymal disease because the lung parenchyma will enhance with contrast, whereas the pleural effusion will retain its low attenuation.

▶ Aspiration Pneumonia

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ Consolidation in dependent regions of the lung, varying with position of patient at time of aspiration, but may be multilobar and bilateral.
- ▶ Cavitation and abscess formation may be seen, but pleural effusions are infrequent.
- ▶ May lead to necrotizing pneumonia and lung abscess.
- ▶ Aspiration of gastric contents may result in noncardiogenic pulmonary edema, cavitation, and atelectasis.

General Considerations

Aspiration pneumonia results from endotracheal aspiration of oropharyngeal or gastric secretions. Aspiration is thought to be a common occurrence in the healthy adult, with the incidence during sleep estimated to be as high as 45%. Small-volume aspirates are cleared by physical entrapment and coughing along with the mucociliary elevator action of the respiratory epithelium. Inactivation by IgA antibodies and opsonization and ingestion of bacteria by phagocytic cells play a role as well. Although organisms are present in pathogenic numbers even in small-volume aspirates, normal individuals are able to clear these organisms without sequelae.

Several clinical conditions predispose patients to aspiration. Depressed levels of consciousness secondary to medications, alcohol intoxication, seizures, anesthesia, or neurologic disease result in impaired upper airway reflexes. Endotracheal intubation increases the rate of aspiration, with both high-volume, low-pressure cuffs and uncuffed or low-volume, high-pressure tubes implicated. The incidence of aspiration is even higher in patients with tracheostomies as compared with endotracheal tubes. Nasogastric and feeding tubes, gastric distention, gastroesophageal reflux, hiatal hernia, decreased esophageal mobility, and vomiting have all been cited as predisposing factors for aspiration. Severe periodontal disease is also a risk factor for aspiration pneumonia. Bacterial colonization of gastric secretions also plays a role in the development of aspiration pneumonia. Although gastric acidity prevents significant bacterial colonization, antacid therapy for prophylaxis for stress ulcers may change gastric pH, resulting in increased bacterial colonization of gastric contents.

Aspiration pneumonia occurs when a normal host aspirates a large amount of contaminated matter, overwhelming host defenses, or when smaller amounts are aspirated in a patient with impaired defenses. Aspiration pneumonia is caused by mixed anaerobic and aerobic organisms, with up to 80% of cases caused by multiple strains of bacteria. The

organisms responsible for the pneumonia vary with the clinical setting—community-acquired, nursing home, or hospitalized patients—and reflect colonization of the upper airway. Aerobic bacteria associated with community-acquired aspiration pneumonia are mostly streptococci, whereas gram-negative organisms, particularly *Klebsiella* and *Escherichia coli*, are seen more often in nosocomial infection. The major anaerobic organisms include *Fusobacterium nucleatum*, *Peptostreptococcus*, *Bacteroides melaninogenicus*, and *Bacteroides intermedius*.

There are three general clinical patterns that may be seen following aspiration: (1) respiratory compromise followed by rapid clinical and radiographic improvement, (2) rapid clinical and radiographic progression, and (3) transient stabilization followed by protracted worsening of clinical and radiographic status, with bacterial superinfection or ARDS.

Aspiration of acidic gastric contents resulting in an acute pulmonary reaction with pulmonary edema is sometimes referred to as *Mendelson's syndrome*. Manifestations depend on the volume, pH, and distribution of the aspirate. The absorption of acid by the pulmonary vasculature and subsequent pulmonary injury are almost immediate and lead to consolidation, alveolar hemorrhage, and collapse with transudation of fibrin and plasma into the alveoli. Aspiration of a combination of acid and gastric particulate material produces a more severe injury pattern than either acid or gastric particulate matter alone.

Radiographic Features

Aspiration pneumonia results in consolidation in dependent regions of the lung. The location of the consolidation will vary according to the patient's position at the time of aspiration. In the supine patient, the superior segments of the lower lobes, the posterior segment of the right upper lobe, and the posterior subsegment of the left upper lobe are involved—whereas in the upright patient, the basal segments of the lower lobes are more often affected, particularly on the right. The more obtuse angle between the trachea and the right main stem bronchus compared with the angle of the trachea and the left main stem bronchus results in a higher percentage of right-sided abnormalities in the supine patient. Consolidation is usually multilobar and bilateral (Figure 7–8). Because of frequent infection with anaerobes, cavitation and abscess formation may be seen. Effusions are infrequent.

CT is useful in the evaluation of aspiration disease and to differentiate aspiration from other parenchymal diseases. CT is also more sensitive than chest radiographs for the detection of aspirated foreign bodies.

Complications of simple aspiration pneumonia include necrotizing pneumonitis and lung abscess. Necrotizing pneumonia results in multiple small cavities within the involved lung and may extend into the pleural space, leading to empyema formation. Lung abscess radiographically appears as a cavitary lesion within a focus of consolidation, usually solitary. Empyema is less likely in lung abscess since extension

▲ **Figure 7–8.** Aspiration pneumonia. Multiple areas of pulmonary opacification are present bilaterally—secondary to aspiration pneumonia following drug overdose.

of infection into the pleural space is usually impeded by the barrier effect of the fibrous wall of the abscess cavity.

Patients who aspirate gastric contents may develop a chemical pneumonitis that shows characteristics consistent with noncardiogenic pulmonary edema. ARDS and features of secondary bacterial infection may follow, including lung necrosis and cavitation. Atelectasis may be a feature of airway obstruction with food particles.

Franquet T et al: Aspiration diseases: Findings, pitfalls, and differential diagnosis. *Radiographics* 2000;20:673–85. [PMID: 10835120]

▶ Chronic Obstructive Pulmonary Disease

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ Hyperinflation.
- ▶ Bullae or blebs.
- ▶ Pulmonary arterial deficiency pattern (areas of decreased pulmonary vasculature).
- ▶ Features of pulmonary hypertension.

General Considerations

Chronic obstructive pulmonary disease (COPD) is any pulmonary disorder characterized by airflow obstruction. Emphysema and chronic bronchitis are the most common examples. Emphysema is defined as a lung condition characterized by enlargement of the air spaces distal to the

terminal bronchiole, accompanied by destruction of the walls without obvious fibrosis. Four principal types of emphysema are described: centrilobular, panlobular, paraseptal, and paracicatricial. Chronic bronchitis is usually defined in clinical terms, manifested by chronic productive cough for at least 3 months for a minimum of 2 consecutive years and characterized by excessive secretion of mucus in the bronchi. Emphysema and chronic bronchitis frequently coexist.

Radiographic Features

There is considerable controversy regarding the utility of the chest radiograph in the evaluation of emphysema. Although moderate to severe emphysema is usually apparent on the chest radiograph, mild disease is difficult to appreciate. Hyperinflation results from obstruction of small airways, resulting in air trapping. Radiographic features include an increase in size of the retrosternal clear space, flattening of the hemidiaphragms, increased height of the lung, and increased radiolucency (Figure 7–9). Measurements obtained from chest x-rays have shown that the height of the lung and the height of the arc of the right hemidiaphragm correlate best with spirometric measures such as the forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC). A lung height of 29.9 cm or greater, as measured from the tubercle of the first rib to the dome of the right hemidiaphragm, will identify 70% of patients with abnormal pulmonary function tests. A height of the right hemidiaphragm of less than 2.6 cm on the lateral projection identifies 68% of patients with abnormal pulmonary function tests.

Bullae and blebs appear as focal regions of hyperlucency. Although good indicators of emphysema, they also may be seen in patients without COPD. Bullae are recognized as hyperlucent or avascular regions and occasionally are demarcated peripherally by a fine curvilinear wall. The lung adjacent to large bullae may be compressed, and redistribution of pulmonary blood flow away from areas of extensive bullous disease may occur. The arterial deficiency pattern refers to regions of radiolucent, hypovascular pulmonary parenchyma characterized by a decrease in the size and number of vessels. This appearance may be due to multiple bullae. Emphysema eventually can lead to pulmonary arterial hypertension, manifested radiographically by disproportionate enlargement of the central pulmonary arteries and right heart chambers.

The radiographic appearance of the lungs in chronic bronchitis is even less specific. Unlike that of emphysema, the diagnosis of chronic bronchitis is based on clinical symptoms and not morphologic appearance. In addition, chronic bronchitis and emphysema frequently coexist, making pure chronic bronchitis difficult to characterize. Radiographic findings suggesting chronic bronchitis include thickening of bronchial walls and increased linear markings (“dirty lungs”). Hyperinflation and hypovascularity have been described but are probably due to concomitant emphysema.

A

B

▲ **Figure 7–9.** Chronic obstructive pulmonary disease. Posteroanterior (A) and lateral (B) chest radiographs show hyperinflated lungs with increased anteroposterior diameters, flattening of the diaphragm, and increased retrosternal clear space.

High-resolution CT (HRCT) is more sensitive than plain radiographs in the detection of emphysema. On HRCT, emphysema appears as regions of low attenuation, lung destruction, or simplification of the pulmonary vasculature. The type of emphysema can often be defined by its pattern and distribution on CT, with centrilobular CT predominantly upper zone in distribution and panlobular emphysema more diffuse or more severe within the lower lobes. The CT appearance of chronic bronchitis may be overshadowed by coexisting emphysema. Bronchial wall thickening and centrilobular abnormalities have been described.

▶ Asthma

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ Hyperinflation.
- ▶ Peribronchial thickening.
- ▶ Increased lung markings centrally.
- ▶ Subsegmental atelectasis.

General Considerations

Asthma is a disease characterized by widespread narrowing of the airways that fluctuates in severity over short periods of time either spontaneously or following therapy. Hyperactivity of airways may be induced by a variety of stimuli, and asthma is usually divided into two types: intrinsic and extrinsic. Pathologic changes include smooth muscle hypertrophy, mucosal edema, mucous hypersecretion, and plugging of airways by thick, viscid mucus. The result is narrowing of the airway diameter.

Radiographic Features

The radiographic manifestations of asthma vary from a normal radiograph to hyperinflation, atelectasis, or barotrauma. Radiographic findings may be categorized as (1) those common features of asthma that do not affect management and are therefore not unanimously considered abnormalities and (2) findings that influence patient management. The incidence of radiographic abnormalities depends on the age of the patient and the definition of *abnormal* by the investigator.

A. Uncomplicated Asthma—Hyperinflation, bronchial wall thickening, and prominent perihilar vascular markings are all features commonly seen in uncomplicated asthma that do not alter patient management. Hyperinflation, characterized by flattening of the hemidiaphragms and an increase in the retrosternal clear space, results from air trapping. Bowing of the sternum, another sign of hyperinflation, is seen more frequently in the pediatric population, probably secondary to more pliable osseous structures. Hyperinflation is not specific for asthma and occurs in other pulmonary diseases associated with air trapping, including emphysema and cystic fibrosis.

Bronchial wall thickening results from edema of the bronchial wall and can be diagnosed when the walls of secondary bronchi peripheral to the central bronchi appear abnormally thickened. Identification of bronchial wall thickening may be difficult and is best made when serial films are compared. Mucous plugs may be identified as tubular or branching soft tissue densities; plugging of large airways may result in atelectasis. Prominent perihilar vascular shadows and prominence of the main pulmonary artery segment are probably due to transient pulmonary arterial hypertension and are more often seen in children.

B. Complications of Asthma—Radiographic findings that alter medical management and therefore are considered manifestations of complicated asthma consist of pneumonia, segmental or lobar atelectasis, and barotrauma, including pneumomediastinum and pneumothorax. Exacerbation of asthma secondary to pneumonia is usually secondary to viral infection. Although subsegmental atelectasis from mucous plugging is common in uncomplicated asthma, plugging of large airways may result in lobar collapse (see Figure 7–4). Lobar atelectasis occurs more often in children, with an incidence between 5% and 10%.

Pneumomediastinum complicating asthma is uncommon but has been reported in 1–5% of cases of acute asthma. This complication occurs primarily in children; the presumed mechanism is an increase in intraalveolar pressure and subsequent alveolar rupture secondary to mucous plugging, giving rise to pulmonary interstitial emphysema. Central dissection of air along the perivascular sheaths results in pneumomediastinum and may eventuate in subcutaneous emphysema and pneumothorax. In aerated lung, pulmonary interstitial emphysema is usually not identifiable, but the sequelae of pneumomediastinum and pneumothorax may be recognized.

C. Assessment of Asthma Severity—Several studies have addressed the usefulness of chest radiography in acute asthma. Although the findings of hyperinflation, increased perihilar markings, bronchial wall thickening, and subsegmental atelectasis are seen frequently, identification of these abnormalities does not change medical management. Most investigators agree that a chest radiograph should be obtained when asthma is diagnosed initially to rule out other causes of wheezing such as airway obstruction by tumor or foreign body, congestive heart failure, bronchiectasis, or pulmonary embolism.

D. High-Resolution CT—HRCT is rarely used to evaluate patients with asthma. Bronchial wall thickening with narrowing of the bronchial lumen is identified. Mild bronchiectasis also may be seen with mucous plugging of small centrilobular bronchioles, resulting in a tree-in-bud appearance. Air trapping may be identified with focal or diffuse hyperlucency, accentuated on expiratory images.

▶ Epiglottitis

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ Enlargement of the epiglottis and thickening of the aryepiglottic folds on lateral radiographs of the neck.
- ▶ Ballooned hypopharynx, narrowed tracheal air column, prevertebral soft tissue swelling, and obliteration of the vallecula and piriform sinuses.

General Considerations

Epiglottitis is a potentially lethal infection of the epiglottis and larynx resulting in supraglottic airway obstruction. Although usually a disorder of children aged 3–6 years, epiglottitis can occur in adults as well. In the pediatric patient, the causative organism is usually *Haemophilus influenzae*, whereas in adults the etiologic agents also include *H. parainfluenzae*, pneumococci, group A streptococci, and *S. aureus*. Epiglottitis results in edema of the epiglottis, aryepiglottic folds, false cords, and subglottic region and may involve the entire pharyngeal wall. The clinical presentation differs somewhat in children and adults, with fever more common in the pediatric patient.

Radiographic Features

The radiologic examination may be diagnostic. However, sudden death from airway obstruction is known to occur, and patients should be accompanied by a physician during the examination in the event that emergency endotracheal intubation or tracheostomy is necessary. Films should be obtained in

the erect position to minimize respiratory distress; manipulation of the neck should be avoided. A single lateral radiograph of the neck should be confirmatory. In the patient with obvious (classic) epiglottitis, roentgenographic diagnosis is not necessary, and airway management is started immediately.

In acute epiglottitis, enlargement of the epiglottis and thickening of the aryepiglottic folds are noted in 80–100% of patients. The normal epiglottis has a shape like a little finger, whereas the enlarged epiglottis has been likened to a thumb (“thumb sign”). Other radiographic features of acute epiglottitis include a ballooned hypopharynx, narrowed tracheal air column, prevertebral soft tissue swelling, and obliteration of the vallecula and the piriform sinuses. In one report of an affected adult, CT examination demonstrated enlargement of the epiglottis and aryepiglottic folds as well as induration of preepiglottic fat. CT is not appropriate in children with suspected epiglottitis and is rarely required in an adult.

Radiography may be useful in distinguishing epiglottitis from other causes of upper airway obstruction in the pediatric patient such as croup, retropharyngeal abscess, or foreign body aspiration.

▶ Pulmonary Embolism

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ Chest radiograph usually abnormal but nonspecific, showing atelectasis. Useful to exclude other causes of symptoms such as pneumonia, pneumothorax, and pulmonary edema.
- ▶ In pulmonary embolism, chest radiograph may show focal oligemia and radiolucency. In pulmonary infarction, may show peripheral parenchymal opacities.
- ▶ Pleural effusions occur frequently.
- ▶ Ventilation-perfusion lung scan can be used to assess probability of pulmonary embolism in a given patient.
- ▶ Spiral or multidetector CT allows for direct visualization of thrombus and parenchymal and pleural changes secondary to pulmonary embolism.
- ▶ Pulmonary angiography considered the “gold standard” for the diagnosis of pulmonary embolism, but is rarely performed. If clinical suspicion of pulmonary embolism is high but the patient has an indeterminate, intermediate, or low-probability ventilation-perfusion scan or an indeterminate CT angiogram, pulmonary angiography is necessary for diagnosis.

General Considerations

Pulmonary embolism is a common life-threatening disorder that results from venous thrombosis, usually arising in the deep veins of the lower extremities. In situ pulmonary arterial

thrombosis is exceedingly rare. The signs and symptoms of pulmonary embolism are nonspecific, and can be seen in a variety of pulmonary and cardiovascular diseases. The clinician must stay alert to the possibility of pulmonary embolism in any patient at risk for Virchow's triad of venous stasis, intimal injury, and hypercoagulable state. The high morbidity and mortality rates of pulmonary embolism and the not inconsequential risk of anticoagulant therapy make accurate diagnosis of venous thromboembolism crucial. A variety of imaging resources, including chest radiography, ventilation-perfusion scans, pulmonary angiography, and spiral or helical CT, play a role in the diagnosis of pulmonary embolism.

Radiographic Features

A. Chest Radiograph—Although the chest x-ray is abnormal in 80–90% of cases, findings are nonspecific. Despite its low sensitivity and specificity, the chest radiograph may exclude other diseases that can mimic pulmonary embolism, such as pneumonia, pneumothorax, or pulmonary edema. In addition, the chest radiograph is necessary for proper interpretation of the ventilation-perfusion radionuclide scan.

Radiographic findings include atelectasis, pleural effusion, alterations in the pulmonary vasculature, or consolidation. Linear opacities (discoid or plate atelectasis) occur commonly in pulmonary embolism as well as in several other disorders in which ventilation is impaired. These linear shadows are most prevalent in the lung bases and are presumed to be secondary to regions of peripheral atelectasis from small mucous plugs. Some investigators have suggested that these linear opacities are caused by infolding of subpleural lung in low-volume states with hypoventilation, distal airway closure, and decreased surfactant production. Linear shadows also may occur secondary to regions of fibrosis due to pulmonary infarction or prior inflammatory disease. Pleural effusions are a frequent finding, occurring in up to 50% of patients. The effusions are usually small and unilateral. Effusions may be present with or without pulmonary infarction, although patients with lung infarction tend to have larger, more slowly resolving effusions that are often hemorrhagic. Alterations in the pulmonary vasculature are manifested radiographically by focal oligemia and radiolucency (Westermark's sign). These findings result from obstruction of pulmonary vessels either by thrombus or by reflex vasoconstriction. Focal oligemia usually requires occlusion of a large portion of the vascular bed and is uncommonly observed. Associated enlargement of the central pulmonary artery may be seen secondary to a large central embolus or acute pulmonary hypertension.

It is estimated that approximately 10–15% of pulmonary thromboemboli cause pulmonary infarction. By virtue of dual blood supply via the pulmonary and bronchial arterial circulations, infarcts are relatively uncommon, occurring more often peripherally, where collateral flow via bronchial arteries is reduced. The incidence of pulmonary infarction is also greater in patients with left ventricular failure, in whom there is compromise of the bronchial circulation. Infarcts are more common in the lower lobes and vary in size from less

than 1 cm to an entire lobe. Radiographically, they appear as regions of parenchymal opacity adjacent to the pleura, typically developing 12–24 hours following the onset of symptoms. Initially ill-defined, the lesion becomes more discrete and well-demarcated over several days. Air bronchograms are uncommon, presumably because the bronchi are filled with blood. Hampton and Castleman described the classic appearance of a pulmonary infarct as a wedge-shaped, well-defined opacity abutting the pleura (Hampton's hump), but this is observed in a minority of cases.

Infarcts may resolve entirely or may clear with residual linear scars or pleural thickening. The appearance of a resolving infarct has been likened to a melting ice cube in that the infarct shrinks in size while maintaining its basic configuration. This is in contrast to infectious processes, which show gradual resolution or fading of the entire involved area.

B. Ventilation-Perfusion Lung Scan—The ventilation-perfusion (\dot{V}/\dot{Q}) scintigraphic lung scan was previously frequently performed in the patient with suspected pulmonary embolism before the advent of CT pulmonary angiography and still has a role in the diagnosis of this disease today. A normal perfusion scan virtually excludes pulmonary embolism. Interpretation of \dot{V}/\dot{Q} scans is complex, and an abnormal \dot{V}/\dot{Q} scan does not make a definitive diagnosis of pulmonary embolism. Instead, the \dot{V}/\dot{Q} scan in conjunction with the chest radiograph may be used to determine the probability of pulmonary embolism in a given patient. The results of a \dot{V}/\dot{Q} scan in an individual patient then must be evaluated in conjunction with the clinical data to determine the course of action for that specific patient. Based on these combined data, the decision to treat the patient or not or to perform additional diagnostic procedures is made.

Ventilation-perfusion scans are based on the premise that pulmonary thromboembolism results in a region of lung that is ventilated but not perfused. The study consists of two scans—the perfusion scan and the ventilation scan—that are compared for interpretation. The perfusion scan involves injection of an agent such as macroaggregated albumin labeled with technetium-99m (^{99m}Tc). This agent is trapped via the precapillary arterioles and identifies areas of normal lung perfusion. Following injection, the patient is immediately scanned in multiple projections. Regions of the lung with absent perfusion will appear photon-deficient. The ventilation scan is performed by having the patient inhale a radionuclide, usually xenon (^{133}Xe), krypton (^{81m}Kr), or ^{99m}Tc . Images are obtained during an initial breath-hold of approximately 15 seconds while breathing in a closed system (equilibrium) and during a “washout” phase. Most images are obtained in a posterior projection, allowing for evaluation of the largest lung volume. Ventilation scans can also be performed using a radionuclide aerosol. This has the advantage of allowing multiple images to be acquired with the patient in the same positions as during the perfusion scan.

Although the concept behind \dot{V}/\dot{Q} scanning is simple, image interpretation is quite complex. Perfusion scans are

quite sensitive in the detection of perfusion abnormalities. However, several disorders other than pulmonary thromboembolism may cause perfusion defects, including COPD, pulmonary edema, lung cancer, pneumonia, atelectasis, and vasculitis. In an attempt to increase the specificity of radionuclide lung scans, ventilation scans were added to perfusion scans. Whereas pulmonary embolism results in a region of nonperfused lung, ventilation to this region is maintained, resulting in a perfusion defect without an associated ventilation defect (mismatch). In obstructive pulmonary disease, both perfusion and ventilation are impaired, resulting in a matched perfusion and ventilation defect.

There has been considerable controversy regarding the efficacy, reliability, and interpretation of \dot{V}/\dot{Q} scans. The majority of these studies were retrospective, resulting in bias secondary to patient selection. Standardized criteria have been established that are used most often in the interpretation of the \dot{V}/\dot{Q} scan. The chest radiograph, the size and number of perfusion defects, and the match or mismatch of ventilation defects are all taken into consideration in assigning probability categories for pulmonary embolism. There are four probability categories: normal, low, indeterminate or intermediate, and high. Fewer than 8% of patients in the low-probability category had pulmonary embolism documented by angiography, whereas those in the high-probability category had pulmonary embolism documented in approximately 90% of cases. Of the intermediate-probability group, 20–33% had pulmonary embolism documented angiographically. In a multicenter prospective study (PIOPED) of the value of the ventilation-perfusion study in acute pulmonary embolism, 88% of patients with high-probability scans had pulmonary embolism, whereas 33% of those with intermediate-probability scans and 12% of those with low-probability scans had pulmonary embolism. However, only a minority of patients with pulmonary embolism had high-probability scans. Angiography was required for a substantial number of patients to make a definitive diagnosis of pulmonary embolism in this study.

C. CT Pulmonary Angiography—The search for a noninvasive study that can detect thrombus rather than the secondary effects of thrombi has led to the use of CT scanning for the evaluation of pulmonary embolism. Contrast-enhanced helical (spiral) or electron beam CT has sensitivities and specificities of approximately 90% in the diagnosis of pulmonary embolism involving segmental or larger pulmonary arteries. Although subsegmental thrombi may be missed, the clinical significance as well as the incidence of an isolated subsegmental clot remains uncertain. Multidetector CT (MDCT) demonstrates subsegmental pulmonary artery embolism with greater frequency. Given the relatively noninvasive nature of the technique and its high sensitivity and specificity for central clot, many institutions have chosen to perform CT pulmonary angiography as the initial study in the investigation of suspected pulmonary embolism, bypassing the ventilation-perfusion scan. Using CT venography, the deep veins of the pelvis and lower extremities also may be evaluated. Scanning of the lower extremities may be performed

3–4 minutes after scanning the pulmonary arteries, without additional contrast material.

CT findings of pulmonary embolism include partial or complete filling defects within the pulmonary artery due to nonocclusive or occlusive thrombi, contrast material streaming around a central thrombus, complete cutoff of vascular enhancement, enlargement of an occluded vessel, and mural defects (Figure 7–10). Parenchymal and pleural changes that occur with pulmonary emboli are also easily detected on CT. Oligemia of lung parenchyma distal to the occluded vessel may be present. Pulmonary embolism may result in hemorrhage that is visible as ground-glass opacification or consolidation on CT. An infarct may appear as a peripheral region of consolidation, typically wedge-shaped with a central region of lower attenuation due to uninfarcted lobules. Pleural effusions are seen commonly. Acute right-sided heart failure may occur secondary to pulmonary embolism and is suggested on CT by right ventricular dilatation and deviation of the interventricular septum toward the left ventricle. On non-contrast-enhanced CT, a region of increased attenuation within the pulmonary artery may suggest acute central pulmonary embolism. CT also may provide an alternative diagnosis in patients with suspected pulmonary embolism and may demonstrate pulmonary edema, pneumonia, pericardial disease, aortic dissection, or pneumothorax.

Pitfalls in the interpretation of CT pulmonary angiography include breathing artifacts in patients unable to breathold, inadequate contrast opacification of the pulmonary arteries, and suboptimal visualization of vessels that are obliquely oriented relative to the transverse imaging plane (eg, the segmental branches of the right middle lobe and lingula). Partially opacified veins may be confused with thrombosed arteries, and hilar lymph nodes and mucus-filled bronchi may be misinterpreted as thrombi.

▲ **Figure 7–10.** Acute pulmonary embolism. CT pulmonary angiogram demonstrates low-attenuation filling defects within the right pulmonary artery and within the left lower lobe pulmonary artery. There is distention of the left lower lobe pulmonary artery.

D. Pulmonary Angiography—Pulmonary angiography is generally considered the most sensitive and specific imaging method for the diagnosis of pulmonary embolism. Angiography is indicated when there is disagreement between the results of the CT angiogram or \dot{V}/\dot{Q} scan and the clinical suspicion of pulmonary embolism; when the CT angiography is indeterminate or the \dot{V}/\dot{Q} scan is indeterminate or is of intermediate probability, when there is a contraindication to anticoagulant therapy, or when other studies are indeterminate, therapy involves more complicated treatment such as an inferior vena cava filter, surgical embolectomy, or thrombolytic therapy. Complications of pulmonary angiography are related to the catheter and its manipulation through the heart and to reactions to intravenous contrast material. Dysrhythmias, heart block, cardiac perforation, cor pulmonale, and cardiac arrest may occur. Relative contraindications to pulmonary angiography include elevated right ventricular and pulmonary arterial pressures, bleeding diathesis, renal insufficiency or failure, left-sided heart block, and a history of contrast material allergy. Pulmonary angiography can be performed in all these settings if appropriate measures are taken to reduce the risk of the procedure.

At angiography, the diagnosis of pulmonary embolus is made when an intraluminal filling defect or an occluded pulmonary artery is identified. Secondary findings include decreased perfusion, delayed venous return, abnormal parenchymal stain, and crowded vessels, which, though suggestive, may be seen in other pulmonary disorders.

E. MRI—The role of MRI and MR angiography (MRA) in the diagnosis of pulmonary embolism remains unclear. Although central and peripheral emboli have been detected on MRA, and physiologic information on ventilation and perfusion may be provided, CT is more readily accessible and suitable for imaging of the critically ill patient.

F. Imaging Techniques in Chronic Pulmonary Embolism—Chronic pulmonary embolism may lead to right ventricular failure and pulmonary arterial hypertension. Radiographic findings include enlargement of the right side of the heart and of the main and proximal pulmonary arteries and decreased peripheral vascularity. Bronchial arteries distal to the occluded pulmonary artery may become dilated. As in patients with acute pulmonary embolism, evaluation of the patient with suspected chronic pulmonary embolism includes \dot{V}/\dot{Q} scanning, CT pulmonary angiography, and pulmonary angiography. In addition to direct visualization of clot, other signs of chronic pulmonary embolism seen on CT angiography include abrupt narrowing of the vessel diameter, cutoff of distal lobar or segmental arterial branches, webs and bands, and an irregular or nodular arterial wall. Calcification within the vessel is uncommon but may be present. Recanalization and eccentric location of thrombi also suggest chronicity. Direct pulmonary angiography may demonstrate similar findings. Findings indicative of pulmonary arterial hypertension, such as enlargement of the main pulmonary artery, pericardial fluid, and right ventricular enlargement, also may be seen on CT. Abnormalities of the lung

parenchyma may include local regions of decreased lung attenuation and perfusion.

▶ Septic Pulmonary Emboli

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ Wedge-shaped or rounded peripheral opacities of varying size, usually multiple and more numerous in the lower lobes.
- ▶ Thin-walled cavities, sometimes with necrotic debris, are common.
- ▶ On CT scan, peripheral nodules, wedge-shaped peripheral opacities, and cavitation.

General Considerations

Infections of the right side of the heart or of the peripheral veins may give rise to septic pulmonary emboli. Risk factors include intravenous drug use, indwelling catheters, pelvic inflammatory disease, organ transplantation, and immunologic deficiencies such as lymphoma or AIDS. Infectious thrombophlebitis also may result from infection of the pharynx extending to the parapharyngeal space and internal jugular venous system (Lemierre's syndrome or postanginal sepsis). Tricuspid valve endocarditis is the most common source of septic emboli in the intravenous drug user. *S. aureus* is the most commonly isolated organism, followed by streptococci.

Radiographic Features

Septic pulmonary emboli appear radiographically as wedge-shaped or rounded peripheral opacities. Septic emboli are usually multiple and are more numerous in the lower lobes, reflecting increased blood flow to the dependent lung. The lesions may vary in size by virtue of variations in the timing of embolization. Cavitation, typically thin-walled, is common, and necrotic debris may be identified within the cavity. Hilar and mediastinal adenopathy can occur, and empyema may occur.

The CT features of septic emboli have been described. Peripheral nodules with identifiable feeding vessels, wedge-shaped peripheral opacities, and cavitation are the most diagnostic features. Peripheral enhancement along the margins of the wedge-shaped densities has been reported following administration of intravenous contrast material (Figure 7-11). It has been suggested that CT can detect disease earlier than the plain radiograph and that it better characterizes the extent of disease. Moreover, the cross-sectional perspective of CT affords better identification of embolic lesions that may be obscured on chest radiographs by edema or other diffuse consolidations.

► Pulmonary Edema

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

Interstitial edema:

- Kerley B (most common), A, and C lines.
- Peribronchial cuffing.
- Indistinct pulmonary vessels.
- Hilar haze.

Alveolar edema:

- Poorly margined, coalescent opacities.
- Air bronchograms.
- "Butterfly" pattern.

General Considerations

Pulmonary edema—an excess of water in the extravascular space of the lung—is a frequent cause of respiratory distress in the critically ill patient. The three main categories of pulmonary edema are cardiac edema secondary to myocardial or endocardial disease, volume overloaded state due to renal failure or excess

▲ **Figure 7-11.** Young woman with septic emboli secondary to intravenous drug abuse. Blood cultures were positive for *Staphylococcus aureus*. **A.** Peripheral nodular opacities are present with evidence of cavitation (arrow). A feeding vessel is identified leading to a pulmonary nodule, consistent with hematogenous dissemination (arrowhead). **B.** Wedge-shaped subpleural lesion is noted with peripheral enhancement after administration of intravenous contrast material.

administration of fluid, and increased capillary permeability, which may result from a variety of insults to the microvasculature of the lung. In the ICU patient, more than one mechanism may contribute to the formation of edema, increasing the difficulty of diagnostic interpretation on radiographs.

There are four principal mechanisms that result in the development of edema: elevated capillary hydrostatic pressure, decreased plasma oncotic pressure, increased capillary permeability, and obstruction of lymphatic drainage. Decreased plasma oncotic pressure and obstruction to lymphatic drainage only rarely lead to pulmonary edema but may be contributing factors in the setting of increased hydrostatic pressure. The

most common cause of pulmonary edema is hydrostatic pressure elevation due to cardiac disease. Acute myocardial infarction, acute volume overload of the left ventricle, and mitral stenosis are common causes of cardiogenic edema.

Radiographic Features

The chest radiograph is the most commonly used noninvasive test in the evaluation of a patient with pulmonary edema. Interstitial edema may be present radiographically in the absence of clinical signs and symptoms, and the chest radiograph may be the first indication of pulmonary edema.

A. Cardiogenic Pulmonary Edema—In the patient with heart failure, pulmonary edema is preceded by pulmonary venous hypertension. In patients with left ventricular failure, elevated left ventricular end-diastolic pressure (pulmonary venous hypertension) is reflected in the pulmonary vasculature by dilation and redistribution of pulmonary blood flow to the upper lobes. In the normal erect patient, the upper zone vessels are smaller than the lower zone vessels, and a significant fraction of the pulmonary circulation, particularly to the upper lobes, is not perfused. In conditions of increased pulmonary blood volume or left ventricular failure, there is recruitment of these nonperfused reserve vessels in the upper lobes, while reflex hypoxic vasoconstriction of lower lobe vessels occurs. These and other pathophysiologic factors contribute to the phenomenon of upper lobe arterial and venous redistribution. Vascular redistribution is often difficult to observe on radiographs, particularly in critically ill patients imaged in the semierect or supine position. As the pulmonary venous pressure continues to increase, pulmonary edema develops.

Pulmonary edema may be present within the pulmonary interstitium, the alveoli, or both. Radiographic evidence of interstitial edema includes Kerley A, B, and C lines; peribronchial cuffing; hilar haze; indistinct vascular markings; and subpleural edema. Kerley lines represent thickened interlobular septa, with Kerley B lines being the most easily and most frequently seen. These lines are horizontal linear densities measuring 1–2 cm in length and 1–2 mm in width. They are located peripherally, extend to the pleural surface, and are best seen at the lung bases on the frontal film (Figure 7–12). Kerley A lines are longer and more randomly oriented and are best seen in the upper lobes, directed toward the hila. Kerley C lines are presumably a superimposition of many thickened interlobular septa and appear as a fine reticular pattern. Other signs of interstitial edema, including peribronchial cuffing, hilar haze, and indistinct vascular markings, result from accumulation of fluid in the perivascular and peribronchial interstitium. Accumulation of fluid in the subpleural interstitium is best demonstrated along the pleural fissures.

Alveolar edema occurs as fluid fills the air spaces of the lungs (Figure 7–13). Although interstitial edema precedes alveolar edema and continues to be present in the alveolar filling stage, the interstitial component is frequently obscured by concomitant air space edema. With filling of the air spaces, the lung becomes opaque, with poorly defined confluent opacity. Air bronchograms are identified as tubular lucencies representing normal patent bronchi surrounded by fluid-filled air spaces. The butterfly pattern, appearing as a dense perihilar

▲ **Figure 7–12.** Interstitial edema. Kerley B lines are identified at the lung bases (*arrows*).

opacification, has been described in volume overloaded states and cardiogenic edema.

In general, cardiogenic pulmonary edema is bilateral and symmetric. Atypical edema patterns may be seen in patients with underlying acute or chronic lung disease or as a consequence of gravitational forces related to patient positioning. Destruction of the lung due to emphysema may cause a patchy, asymmetric distribution of edema that spares regions of bullous disease. Gravitational forces also affect the distribution of edema, with increased edema in the dependent lung. Shifting the patient's position can change the appearance of

▲ **Figure 7–13.** Alveolar edema. Air space opacities with vascular redistribution, perihilar haze, cardiomegaly, and bilateral pleural effusions are secondary to cardiogenic edema. A pulmonary artery catheter and nasogastric tube are present.

edema. Such maneuvers may help to distinguish atypical edema from other air space processes such as pneumonia. The temporal sequence of parenchymal opacification is also crucial because the onset and resolution of hydrostatic edema may be rapid, whereas in other conditions such as pneumonia and ARDS, changes are more gradual.

The CT findings in heart failure have been studied and, as predicted by the chest radiograph, include “ground glass” opacities, interstitial and alveolar edema, and pleural effusions. Small pulmonary nodules also have been described and likely represent pulmonary vessels and regions of edema. Mediastinal adenopathy may be present, with 35% of patients with chronic heart failure demonstrating nodal enlargement on CT.

B. Distinguishing Cardiogenic from Noncardiogenic Pulmonary Edema

Three principal features have been proposed to distinguish cardiogenic from noncardiogenic pulmonary edema radiographically: distribution of pulmonary flow, distribution of pulmonary edema, and width of the vascular pedicle. Ancillary features include pulmonary blood volume, peribronchial cuffing, septal lines, pleural effusions, air bronchograms, lung volume, and cardiac size. The vascular pedicle width is defined as the width of the mediastinum just above the aortic arch, with normal width ranging from 43 to 53 mm in an erect patient. The vascular pedicle is enlarged in 60% of patients with cardiac failure and in 85% of patients with renal failure or volume overload. This is in contrast to patients with noncardiogenic capillary permeability edema,

who have a normal or narrowed vascular pedicle in 70% of cases. The distribution of flow is also a discriminating feature in that patients with hydrostatic edema more typically have balanced flow or vascular redistribution. In contrast, patients with capillary permeability edema usually demonstrate a normal or balanced distribution of flow. Finally, the distribution of edema is symmetric and perihilar or basilar in patients with cardiogenic edema or volume overloaded states, whereas capillary permeability edema appears patchy and peripheral.

Heart size and the presence or absence of septal lines also may be useful criteria for differentiating cardiogenic from permeability edema with an accuracy of 83%. Thus, if the heart is enlarged or of normal size and septal lines are present, cardiogenic edema is likely, but if the heart size is of normal and septal lines are absent, permeability edema is more likely. There may be considerable overlap. In one study, a classic hydrostatic pattern occurred in 90% of patients with hydrostatic edema, but 40% of patients with increased permeability edema had radiographic features consistent with hydrostatic edema. A peripheral or patchy air space pattern was relatively specific for capillary permeability edema. Overlapping features may arise from differences in patient populations, including differences in the severity of edema, underlying heart or lung disease, and radiologic technique and patient positioning.

The radiographic diagnosis of edema may be complicated by several factors. However, general guidelines can be suggested. In general, noncardiogenic edema typically demonstrates normal cardiac size with air space opacities (Figure 7–14) and

A

B

▲ **Figure 7–14.** Noncardiogenic pulmonary edema secondary to near-drowning. **A.** Anteroposterior chest radiograph demonstrates asymmetric air space opacities bilaterally. Heart size is normal, and there are no pleural effusions. Endotracheal tube is high in position, and a nasogastric tube is present. **B.** Radiograph 48 hours after admission shows heterogeneous parenchymal opacification with worsening at the lung bases. A left thoracostomy tube and pulmonary artery catheter are now present, and the endotracheal tube is in satisfactory position. There is evidence of barotrauma with pneumomediastinum (*arrow*).

infrequent Kerley lines, peribronchial cuffing, or pleural effusions. In contrast, hydrostatic edema is associated with cardiac enlargement, septal lines, and frequent pleural effusions. The accuracy of chest radiographic diagnosis depends on the integration of all available clinical and physiologic data.

▶ Acute Respiratory Distress Syndrome

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ **Early ARDS:** Decrease in lung volumes, but lungs are generally clear. If ARDS is caused by aspiration or pneumonia, parenchymal opacifications may be present.
- ▶ **Later:** Air space opacification is usually bilateral but may be asymmetric and patchy and may progress later to more uniform consolidation. Air bronchograms are usually present.
- ▶ **Late ARDS associated with collagen deposition** shows less dense parenchymal consolidations with interstitial or “ground glass” opacities.
- ▶ **Complications include pulmonary interstitial emphysema, pneumomediastinum, and pneumothorax.**

General Considerations

ARDS is a catastrophic consequence of acute lung injury, with damage to the alveolar epithelium and pulmonary vasculature resulting in increased capillary permeability edema. Despite numerous attempts at clarification in the literature, there is still disagreement about the best way to describe this disorder. It is usually characterized clinically by refractory hypoxemia, decreased lung compliance, severe acute respiratory distress, and pulmonary parenchymal consolidations on chest radiographs. A number of disorders are associated

with ARDS, including both direct insults to the lungs and nonpulmonary systemic conditions.

Radiographic Features

A. Chest Radiographs—The radiographic manifestations correlate with the pathologic changes seen in the lungs and vary with the stage of lung injury. Three stages have been described in ARDS. Stage I (also known as the acute exudative phase) is the earliest and most transient stage of lung injury and occurs during the first hours after the insult. Pathologically, this stage is characterized by pulmonary capillary congestion, endothelial cell swelling, and extensive microatelectasis. Fluid leakage is confined to the interstitium and is limited. Clinically, respiratory distress with tachypnea and hypoxemia is present. In patients with ARDS secondary to systemic insults, diffuse microatelectasis and diminished lung compliance may result in a decrease in lung volumes, but the lungs are generally clear. Interstitial fluid is usually too mild to be radiographically apparent (Figure 7–15). In primary pulmonary insults causing ARDS, such as aspiration or pneumonia, parenchymal opacifications may be present (Figure 7–16). Physiologic changes due to therapy are also reflected on the radiograph, including volume overload and barotrauma. The use of positive end-expiratory pressure (PEEP) may cause improvement in aeration on the chest radiograph without physiologic or clinical improvement. In fact, occasionally there is paradoxical worsening of oxygenation from alveolar overdistention with subsequent diversion of pulmonary flow to poorly ventilated regions.

In stage II (also referred to as the fibroproliferative phase), the pathologic features of hemorrhagic fluid leakage, fibrin deposition, and hyaline membrane formation result in radiographic consolidation. Air space opacification is usually bilateral but may be asymmetric and patchy and may progress later to more uniform consolidation. Air bronchograms are usually present and become more conspicuous with severe consolidation. The transition to stage II may occur 1–5 days following the pulmonary insult depending on its type and severity. More severe injuries result in a more rapid transition. Pleural effusions are uncommon and, when present, are small.

Stage III (also referred to as the fibrotic or recovery phase) is characterized by hyperplasia of type II alveolar epithelial cells and collagen deposition. Decreased lung compliance, ventilation-perfusion imbalance, diffusion impairment, and destruction of the microvascular bed result in abnormal gas exchange and lung mechanics. Radiographically, parenchymal consolidations become less dense and confluent. Interstitial or “ground glass” opacities develop as fluid is replaced by the deposition of collagen. Subpleural lucencies may develop in regions of peripheral ischemia and ischemic necrosis. The treatment of ARDS, including positive-pressure ventilation, sometimes results in barotrauma that is manifested as pulmonary interstitial emphysema, pneumomediastinum, and pneumothorax (Figure 7–17).

Long-term sequelae of ARDS are variable. The overall mortality rate is approximately 50%. Although long-term survivors

Lung volumes are slightly decreased. **B.** Stage II ARDS. Within 24 hours, the chest radiograph shows diffuse parenchymal opacification consistent with ARDS.

may have complete recovery of pulmonary function, respiratory impairment may result from pulmonary fibrosis and microvascular damage. Improvement in lung function is relatively rapid during the first 3–6 months, reaching maximum recovery within 6–12 months following the onset of ARDS. The chest radiograph may continue to show hyperinflation and some residual lung opacities, but most often it returns to normal.

B. CT Scans—The CT appearance of ARDS has been described by numerous investigators. In general, CT demonstrates a variable and patchy distribution, with most marked involvement in the dependent lung regions. These opacities probably represent severe diffuse microatelectasis as well as edema fluid and have been observed to migrate under the influence of gravity. Air bronchograms are frequent, and pleural effusions, typically small, occur in approximately one-half of patients. The distribution of consolidation may depend on the stage of ARDS. Early changes may show patchy areas of “ground glass” opacity or consolidation diffusely but not uniformly, without central or gravity dependence. Later changes show more homogeneity as the lung becomes more edematous, and gravity-dependent atelectasis increases. On CT, barotraumatic lung cysts and infectious complications such as cavitation or empyema are better identified than on projectional radiographs (Figure 7–18).

IMAGING IN PLEURAL DISORDERS

► Pleural Effusions

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- Blunting of the lateral costophrenic angle (meniscus sign).
- Elevation of the apparent level of the diaphragm. Increased separation between the lung and the stomach bubble.
- Homogeneous increased density of the involved hemithorax.
- Fluid capping the lung apex.
- Decreased visibility of pulmonary vessels below the diaphragm.
- Increased density within the pleural fissures (“pseudotumor”).

General Considerations

Pleural fluid is primarily formed on the parietal pleural surface and absorbed on the visceral pleural surface, with approximately 25 mL of fluid present normally in the pleural space. Pleural effusion is an excess accumulation of intrapleural fluid. A wide variety of disorders result in excess pleural fluid. Although the chest radiograph is useful for detecting and estimating the amount of pleural effusion, the differentiation between transudate, exudate, empyema, and hemorrhagic pleural effusion requires a thoracentesis. Congestive heart failure is the most common cause of pleural effusion in the ICU population.

▲ Figure 7-16. ARDS secondary to pneumococcal pneumonia in a patient with a history of Hodgkin's disease and splenectomy several years earlier. **A.** Initial chest radiograph demonstrates patchy bilateral consolidation. **B.** Within 12 hours of admission, dense air space consolidation is present, necessitating intubation. Clinical course was consistent with ARDS. **C.** Follow-up radiograph 5 weeks after admission to the ICU shows a coarse reticular pattern bilaterally. Lung volumes are slightly decreased in comparison with the admission radiograph.

Radiographic Features

The distribution of fluid within the pleural space is greatly affected by lung elastic recoil and gravity. On erect frontal and lateral radiographs, free pleural effusions typically have a concave, upward-sloping contour (the meniscus appearance). Since the posterior costophrenic angles are usually deeper than the

lateral costophrenic angles, small pleural effusions are typically best seen on the lateral view. Blunting of the lateral costophrenic angle—detectable on an erect posteroanterior chest radiograph—may occur with as little as 175 mL of fluid, although in some cases as much as 525 mL will be present before blunting is noted. Pleural effusion also may accumulate in a subpulmonary location between the lung base and diaphragm without causing

A

B

C

▲ Figure 7-17. Barotrauma in ARDS. **A.** Chest radiograph demonstrates diffuse lung consolidation secondary to ARDS. Parenchymal stippling is present with lucent perivascular halos secondary to pulmonary interstitial emphysema. **B.** On chest radiograph 4 days later, pneumomediastinum is now identified with extensive subcutaneous emphysema. **C.** In another patient with ARDS, subpleural cysts (*arrow*) and parenchymal stippling due to pulmonary interstitial emphysema are present.

blunting of the lateral costophrenic sulcus. These subpulmonary collections simulate elevation of the diaphragm; on the left, the distance between the gastric air bubble and the “pseudodiaphragm” will be increased. The pulmonary vessels are not seen through the basilar pulmonary parenchyma. The pseudodiaphragm is elevated and flattened, with the dome appearing more lateral than normal.

Pleural effusions may extend into the fissures, with the radiographic appearance depending on the shape and orientation

of the fissure, the location of the fluid, and the direction of the radiographic beam. Collections of fluid in the fissures may mimic a mass, resulting in a “pseudotumor” appearance.

Although the preceding radiographic appearances of pleural effusion are well known and easily recognized on posteroanterior and lateral chest radiographs, these projections are infrequently obtained in the ICU patient, and recognition of pleural effusion in the supine patient may be difficult. In supine patients, the most dependent regions of the pleural

▲ **Figure 7-18.** Adult respiratory distress syndrome. CT shows heterogeneous consolidation with subpleural air cyst secondary to barotrauma.

space are the posterior aspects of the bases and the lung apex. Free pleural effusions layer posteriorly, resulting in a homogeneous increased density of the lower involved hemithorax. Fluid also may accumulate at the apex of the thorax, resulting in apical capping. These findings, however, are seen frequently only in moderate or large pleural effusions, and small effusions may not be detected on supine radiographs. Although very small accumulations of pleural effusion can be detected on lateral decubitus views, this projection is logistically difficult to obtain in the ICU patient.

Atelectasis and lung consolidation may be difficult to distinguish from a pleural effusion because they too may result in elevation of the hemidiaphragm and decreased visibility of lower lobe vessels. Cross-sectional imaging using ultrasound or CT is very helpful in detecting small amounts of pleural effusion and in distinguishing complicated pleural and parenchymal processes. These imaging methods are also used frequently to guide interventional procedures, including diagnostic thoracentesis, drainage of empyema or malignant pleural effusions, intracavitary fibrinolytic therapy, and sclerotherapy. Ultrasound can be performed at the bedside and can easily detect both free pleural effusions and loculated collections (Figure 7-19). In most situations, ultrasound is the imaging method of choice for guiding thoracentesis and may decrease the incidence of iatrogenic pneumothorax. The percutaneous drainage of pleural fluid collections with small catheters instead of large-bore thoracostomy tubes has been shown to be effective in treating both sterile and infected effusions. Intracavitary fibrinolytic therapy, the installation of fibrinolytic enzymes into the pleural space, has greatly improved the effectiveness of pleural fluid drainage with smaller catheters.

CT is extremely sensitive in detecting even small amounts of free pleural effusion, demonstrating loculations, and evaluating the underlying lung parenchyma. The excellent contrast

▲ **Figure 7-19.** Pleural effusion on ultrasound. Right pleural effusion is seen as a region of low echogenicity (*asterisk*) above the hyperechoic diaphragm (*arrow*).

resolution of CT allows demonstrations of regions of high attenuation secondary to blood or proteinaceous collections and shows calcifications that are not apparent on chest radiographs. By virtue of the cross-sectional perspective, air-fluid levels are easily identified. In complicated cases, intravenous contrast administration will help to differentiate pulmonary and pleural processes in that perfused, consolidated lung will be enhanced, whereas pleural processes will not (see Figure 7-7). The disadvantages of CT are its relatively high cost and the need for transporting the critically ill patient to the radiology department.

► Pneumothorax

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- Identification of a visceral pleural line.
- Absence of pulmonary vessels peripheral to visceral pleural line.
- Basilar hyperlucency in the supine patient.
- Deep sulcus sign (supine patient).

General Considerations

Pneumothorax is a frequent and serious complication in the ICU. Iatrogenic pneumothorax may develop as a sequela of invasive diagnostic or therapeutic procedures, including central venous catheterization, endotracheal intubation, tracheostomy, thoracentesis, pleural biopsy, percutaneous lung biopsy, bronchoscopy, cardiothoracic or abdominal surgery, and interventional abdominal procedures to the liver and upper abdominal viscera. Pneumothorax also may result from blunt chest trauma or underlying lung diseases such as COPD, asthma, cystic fibrosis, and interstitial lung disease. Pneumothorax can complicate the course of cavitary pneumonias due to infections with *M. tuberculosis*, staphylococci, *Klebsiella* and other gram-negative organisms, or fungi; similarly, there is an increased incidence of pneumothorax in patients with AIDS who develop *Pneumocystis* pneumonia. Finally, in patients receiving positive-pressure mechanical ventilation, pneumothorax may result from pulmonary interstitial emphysema due to barotrauma.

In a recent study of pneumothorax in ICU patients, 35 of 60 patients (58%) who developed a pneumothorax during the study period had procedure-related pneumothoraces. Patients with pneumothoraces due to barotrauma or who had concurrent septic shock or a tension pneumothorax had a higher risk of mortality than patients with postprocedural pneumothoraces.

Radiographic Features

A. Simple Pneumothorax—As with fluid in the pleural space, the distribution of a pneumothorax is influenced by gravity, lung elastic recoil, potential adhesions in the pleural space, and the anatomy of the pleural recesses. In the upright patient, air accumulates in the nondependent region of the pleural space, the apex. Radiographically, a pneumothorax is identified by separation of the visceral pleural surface from the chest wall and the absence of pulmonary vessels peripheral to the pleural line. A pneumothorax typically is better seen on expiratory images because of a relative decrease in lung volumes compared with the air in the pleural space.

Imaging in the supine position alters the radiographic appearance of pneumothorax. In this position, the least dependent regions of the pleural space are the anteromedial and subpulmonary regions. Pleural air in the anteromedial space results in sharp delineation of mediastinal contours, including the superior vena cava, the azygos vein, the heart border, the inferior vena cava, and the left subclavian artery. The accumulation of air in the subpulmonary region is seen as a hyperlucent upper quadrant of the abdomen; a deep, hyperlucent lateral costophrenic sulcus (“deep sulcus sign”); sharp delineation of the ipsilateral diaphragm; and visualization of the inferior surface of the lung (Figure 7–20). Air can accumulate in the apicolateral pleural space in the supine patient just as in the erect patient, especially when a large pneumothorax is present. In the presence of lower lobe collapse, air can

▲ **Figure 7–20.** Pneumothorax in a supine patient with ARDS. Chest radiograph demonstrates a large right pneumothorax with intrapleural air adjacent to the diaphragm and evidence of a deep sulcus (arrow). The margin of the right hemidiaphragm is obliterated by adjacent adhesions.

accumulate in the posteromedial pleural recess. This results in a sharp delineation of the posterior mediastinal structures, including the descending aorta and the costovertebral sulcus.

Subtle pneumothoraces may require other projections for detection, such as decubitus or cross-table lateral views. CT is an excellent method for diagnosing a pneumothorax not demonstrated on plain chest radiographs.

Several conditions may be confused with a pneumothorax. Pneumoperitoneum may result in a hyperlucent upper abdomen, mimicking pneumothorax. Skin folds can be confused with apicolateral pneumothorax but should be recognized when they extend outside the bony thorax or are traced bilaterally. Pneumomediastinum may simulate medial pneumothorax, but pneumomediastinum may cross the midline and extend into the retroperitoneum.

B. Tension Pneumothorax—Recognition of even small pneumothoraces is crucial to prevention of progressive accumulation of pleural air collections, particularly in patients being maintained on mechanical ventilation. Tension pneumothorax occurs when the pressure of air in the pleural space exceeds ambient pressure during the respiratory cycle. With this pressure gradient, air enters the pleural space on inspiration but is prevented from exiting the pleural space during expiration due to a check-valve mechanism. A tension

▲ **Figure 7-21.** Spontaneous tension pneumothorax. The left lung is completely collapsed, with visualization of a visceral pleural line and hyperlucency of the thorax. The mediastinum is shifted to the right, and there is depression of the left hemidiaphragm consistent with tension pneumothorax.

pneumothorax may result in acute respiratory distress and, if untreated, cardiopulmonary arrest and death. The diagnosis of tension pneumothorax is made clinically, reflecting the hemodynamic sequelae of impaired venous return to the right side of the heart. Radiographic signs include displacement of the mediastinum toward the contralateral thorax, inferior displacement or inversion of the diaphragm, and total lung collapse (Figure 7-21). However, significant hemodynamic compromise can exist in the absence of these findings. Adhesions may prevent mediastinal shift, and lung collapse may not occur in patients with stiff lungs such as those with ARDS. A small pneumothorax may convert to a tension pneumothorax, particularly in patients receiving mechanical ventilatory support. In patients with ARDS, poorly compliant lungs and pleural adhesions may result in difficulty identifying a pneumothorax on portable chest radiographs, and CT may be particularly useful in the diagnosis of loculated pneumothorax and in guiding appropriate chest tube placement.

► Pulmonary Interstitial Emphysema & Pneumomediastinum

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- **Pulmonary interstitial emphysema:** Perivascular “halo” (air surrounding pulmonary vessels seen on end), linear radiolucencies radiating toward the hila, irregular radiolucent mottling, parenchymal cysts, or collections of air along visceral pleural surface.
- **Pneumomediastinum:** Linear lucencies adjacent to the heart and aortic arch, descending aorta, and great vessels. May have subcutaneous emphysema with linear radiolucencies extending along tissue planes in the chest wall and neck.

General Considerations

Barotrauma is a serious and frequent complication in the ICU patient. Defined as damage secondary to the presence of extraalveolar or extraluminal air, the incidence is highest in patients being supported by mechanical ventilation. Alveolar overdistention and an increased intraalveolar pressure gradient from alveolus to vascular sheath allow rupture of air into the interstitial space along the perivascular sheaths, resulting in pulmonary interstitial emphysema. Reduction in the caliber of pulmonary vessels—as well as general and local alveolar overinflation—contributes to the pressure gradient, causing alveolar rupture. Although commonly associated with mechanical ventilation, barotrauma may also result from coughing, straining, trauma, pneumonia, a Valsalva maneuver, anesthesia or resuscitation, parturition, positive-pressure breathing, and asthma. Other manifestations of barotraumas develop because air from ruptured alveoli follows the path of least resistance. Air dissects centrally to cause pneumomediastinum and dissects via the cervical fascial planes, resulting in subcutaneous emphysema in the neck and chest wall. Air also can dissect through the mediastinum into the abdomen, leading to retroperitoneal air and pneumoperitoneum or into the pleural space resulting in a pneumothorax.

Barotrauma has a high incidence in patients with ARDS. In one study of 15 patients with ARDS—all requiring positive-pressure ventilation—radiographic evidence of pulmonary interstitial emphysema was found in 87%. Although there was no correlation with positive end-expiratory pressure or mean airway

pressure, in all but one of the patients barotrauma was noted when peak airway pressure was greater than 40 cm H₂O. Other studies report an incidence of about 50% and suggest that PEEP does contribute to the development of barotrauma. Decreased compliance of the lungs in patients with ARDS necessitates higher ventilatory pressures to maintain adequate oxygenation, which results in an increased risk of barotrauma. Pulmonary diseases that increase lung compliance also may promote barotrauma because there is greater overdistention of the lung.

Radiographic Features

Radiographic findings of pulmonary interstitial emphysema include visualization of perivascular air along pulmonary vessels seen on end (producing a perivascular “halo”), linear radiolucencies radiating toward the hila, irregular radiolucent mottling, parenchymal cysts (pneumatocoles), and linear or rounded collections of air along the visceral pleural surface (subpleural air cysts). Pulmonary interstitial emphysema may be difficult to detect and to distinguish from air bronchograms. Moreover, pulmonary interstitial emphysema is usually not apparent radiographically unless present in conjunction with pulmonary opacification.

Pneumomediastinum may be recognized radiographically by linear lucencies adjacent to the heart and aortic arch, descending aorta, and great vessels. Visibility of the wall of a main bronchus, air outlining the thymus, and air between the parietal pleura and diaphragm also have been described. Pneumomediastinum is usually easier to identify than pulmonary interstitial emphysema and is often the first evidence of barotrauma. Subsequent dissection of air from the mediastinum along fascial planes may result in subcutaneous emphysema, with linear radiolucencies extending along tissue planes in the chest wall and neck (see Figure 7–17). Less often, dissection of air along the descending aorta into the retroperitoneum will occur, with rare rupture into the abdomen giving rise to pneumoperitoneum. In such instances, clinical correlation is essential to exclude a perforated abdominal viscus. Early diagnosis of pulmonary interstitial emphysema may alert clinicians to pneumothorax, a potentially catastrophic consequence of barotrauma. Although other manifestations of barotrauma are usually self-limited, even a small pneumothorax may progress to tension pneumothorax in critically ill patients, particularly in patients being maintained with mechanical ventilators. As previously discussed, pneumothorax in the supine patient may be difficult to diagnose and must be considered or it will be missed. Occasionally, tension pneumomediastinum may occur, although this is usually of greater clinical likelihood in pediatric patients. Concomitant pulmonary interstitial emphysema will result in further respiratory embarrassment secondary to compression of lung parenchyma by interstitial air and decreases in both ventilation and perfusion. Pneumopericardium arises infrequently secondary to

barotrauma but may progress to tension, in which there is increased intrapericardial pressure and impairment in venous return and cardiac function.

IMAGING OF THE ABDOMEN & PELVIS

General Principles

Imaging of the gastrointestinal tract generally should begin with plain radiographs because these are readily obtained and provide useful information regarding perforation, bowel obstruction, and ileus. However, because the overall sensitivity of plain radiographs remains low, further imaging with CT may be necessary to confirm suspected pneumoperitoneum or intraabdominal abscess and to inspect the features of the small and large bowel walls and surrounding fat. Imaging of abdominal and pelvic solid organs, including the gallbladder and urinary bladder, should begin with ultrasound because it is nonionizing and portable to the ICU.

▶ Gastrointestinal Perforation

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ Lucency over the liver or abdomen.
- ▶ Lucency under a hemidiaphragm on upright views.
- ▶ “Double-wall sign.”
- ▶ Visualization of the falciform ligament.
- ▶ “Football sign.”
- ▶ “Inverted-V sign.”
- ▶ “Triangle sign.”

General Considerations

In the ICU, bowel perforation usually results from an upper abdominal source, such as a penetrating gastric or duodenal ulcer; a lower gastrointestinal tract source, such as diverticulitis or toxic megacolon; or from complications of upper and lower endoscopic procedures. Other causes of perforation include severe intestinal inflammation, bowel obstruction, bowel infarction, or neoplasm.

Radiographic Features

An experienced abdominal radiologist may identify even small amounts of free air on a supine abdominal radiograph, finding small bubbles or generalized increased lucency over the abdomen, right upper quadrant, or subhepatic space. Other signs include the “double-wall sign” of Rigler, the “triangle sign,” the “football sign,” or the falciform ligament sign (Figure 7–22). For less experienced readers, a second view must be added to the supine radiograph to increase sensitivity. Most commonly, this is an upright abdominal film in which air rises to outline the thin curvilinear hemidiaphragm. However, to obtain this view properly is nearly impossible in the ICU. Useful alternatives include the left lateral decubitus view (where the patient maintained in the left-side-down position for at least 5–10 minutes), allowing free air to rise toward the right subphrenic space. A right lateral decubitus view is usually nondiagnostic because of confusion arising from the adjacent stomach bubble. In immobile patients, a cross-table lateral view may be obtained, in which the patient remains supine, but the x-ray beam is tangential to the anterior abdominal wall. However, small amounts of free air may be missed on this view. If plain films are equivocal and perforation is suspected, an abdominal CT (Figure 7–23) offers an excellent means of detecting even tiny amounts of free air and possibly localizing a source.

Differential Diagnosis

Pneumoperitoneum has a variety of causes and is not synonymous with bowel perforation, its most serious and surgically urgent cause. In the ICU, the most common reason for pneumoperitoneum is probably the postoperative state. Pneumoperitoneum may persist for up to 14 days after surgery, the amount of air decreasing progressively and never increasing over time. Other forms of pneumoperitoneum requiring urgent attention include peritonitis caused by gas forming microorganisms. Benign causes include dissection of gas from the thoracic cavity in patients with COPD receiving mechanical ventilation.

▲ **Figure 7-23.** **A.** Pneumoperitoneum and pneumoretroperitoneum in a 76-year-old man after biliary stent placement because of obstruction from pancreatic cancer. A supine radiograph shows characteristic air under the diaphragm and surrounding liver. The psoas muscles and kidneys are also outlined by gas, confirming the presence of pneumoretroperitoneum. **B.** Abdominal CT demonstrates ectopic gas and confirms the diagnosis of pneumoperitoneum in the patient in Figure 7-21.

▶ Bowel Obstruction

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ Asymmetric dilation of proximal bowel loops.
- ▶ Normal or collapsed distal bowel loops.
- ▶ Small bowel obstruction: Dilated U-shaped loops with air-fluid levels (upright or decubitus films) or a single loop with air-fluid levels at different heights.
- ▶ Large bowel obstruction: Cecal distention, absence of rectal gas, or “triple flexure” and “coffee bean” signs of sigmoid volvulus.
- ▶ CT scan: Excellent for detecting bowel obstruction and confirming the cause.

General Considerations

Mechanical obstruction of the bowel is a relatively common occurrence in hospitalized patients. In the general population, bowel obstructions account for approximately 20% of acute abdominal conditions. Obstruction usually results from extrinsic compression but can occur from luminal obstruction. Without prompt attention, bowel obstruction may progress to bowel infarction because of disruption of venous outflow and subsequent arterial blood supply. Bowel infarction may progress to mucosal ulceration, necrosis, and perforation. Mortality rates for untreated obstruction have been as high as 60%.

Approximately three-fourths of bowel obstructions are related to the small bowel (enteric) and one-fourth to the colon. Small bowel obstructions are most commonly due to adhesions from prior abdominal surgery. Adhesions can form rapidly, sometimes within 4–10 days after surgery, or may develop manifestations many years later. Other causes of small bowel obstruction include hernias (external and internal), primary and metastatic tumors, intussusception, inflammatory bowel disease, abscesses, and trauma.

Large bowel obstructions are most often (60%) caused by primary carcinomas of the distal (left) colon. Metastatic tumor or invasion from cancers of surrounding organs, diverticulitis, sigmoid volvulus, and fecal impaction also may cause a distal colonic obstruction.

Radiographic Features

A. Plain Abdominal Radiographs—An abdominal series that includes supine plus upright or decubitus views of the abdomen is only 50–60% sensitive for small bowel obstruction. Objective evidence of small bowel obstruction includes asymmetric dilation (luminal diameter >3 cm) of small bowel proximal to the site of obstruction, with normal or decompressed

small bowel loops distally and normal to absent colonic gas. However, these findings may not be seen in all patients who present with a small bowel obstruction. More valuable is the relative change in distention over time, and for this reason, comparison of a series of studies is prudent. Other radiographic signs include an inverted U-shaped loop of dilated small bowel with air-fluid levels, multiple air-fluid levels, and dynamic loops (air-fluid levels at varying heights in different limbs of a loop). In some cases, a “string of pearls sign” can be seen (Figure 7–24).

On a single supine film of the abdomen, dilated small bowel loops may be mostly fluid-filled, with a minimal amount of gas, or may be completely devoid of gas. In this case, the film will be nonspecific, and additional views or CT may be required. Diagnosis of small bowel obstruction may be difficult because the presence of radiographic signs will depend on the site, duration, and degree of obstruction. Bowel distal to a complete obstruction takes 12–48 hours to evacuate all its gas. Serial plain films sometimes are required to capture these changes because films may be nonspecific if imaging is performed too early.

Because of the limited utility of plain radiographs, helical CT is now the preferred method for evaluating suspected small bowel obstruction (Figure 7–25). In patients who cannot undergo CT or if CT is unavailable, serial radiographs may be taken after ingestion of enteric contrast material. Although water-soluble contrast agents are preferred, especially for patients who are surgical candidates, they are hypertonic and become progressively more dilute, limiting the ability of the study to accurately identify the site of obstruction. Barium is preferred in nonsurgical patients because progressive dilution does not occur, and the site of obstruction is more easily identified. However, in high-grade obstructions, barium may thicken and become difficult to evacuate. The high density of retained barium also degrades CT images because of a beam-hardening artifact that results in a nondiagnostic CT examination. Given these problems, CT is the initial imaging procedure of choice if small bowel obstruction is suspected.

In general, colonic obstruction (Figure 7–26) tends to occur distally because most obstructing colon cancers occur in the distal large bowel. A single supine radiograph often fails to identify the site of obstruction, and supplementary views—an upright view, a right lateral decubitus view, or a prone view—may be necessary to work up a possible obstruction and distinguish it from an ileus. In large bowel obstruction, the cecum distends to a greater degree than does the remainder of the colon regardless of the site of obstruction. This follows from Laplace’s law, which states that the pressure required to distend the walls of a hollow structure is inversely proportional to its radius. The cecum has the largest radius of any part of the large bowel. Generally, the upper limits of normal for the transverse diameter of a large bowel loop is 6 cm; for the cecum, it is 9 cm. However, these are rough estimates only and may not hold true for a given patient. Again, one must interpret, if possible, the relative change in distention with comparison studies over time. Perforation is a

dreaded complication of obstruction. The overall risk of cecal perforation is low—approximately 1.5%—but may increase to 14% with delay in diagnosis. There is an increased risk of cecal perforation if the luminal diameter exceeds 9 cm and persists for more than 2–3 days.

B. Computed Tomography—Over the last 10 years, several investigators have emphasized the value of CT scanning in detecting bowel obstruction. Helical and multidetector CT can produce multiplanar images to help determine whether obstruction is present, the severity and level of obstruction, the cause of obstruction, and whether strangulation or ischemia is present. Current helical and multidetector technology permits evaluation of the abdomen and pelvis in 20 seconds to 2 minutes. Oral and intravenous contrast material may not be required if experienced radiologists interpret the scans. In most cases of small bowel obstruction, a transition point between dilated and nondilated bowel can be demonstrated. Identification of the transition zone and the cause of obstruction, when not apparent on axial images, may be aided by the multiplanar reformatting possible on current CT scanners and image-processing workstations. Although adhesions themselves are too thin to be imaged, most other common causes of small bowel obstruction—including hernia, tumor, intussusception, postradiation fibrosis, and gallstone ileus—may be identified. The accuracy of CT is 90–95% in high-grade bowel obstruction but somewhat less in low-grade obstruction.

► Ileus

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- Diffuse symmetric dilation of small and large bowel.
- May be focal when adjacent to an inflammatory source.
- Colonic ileus (Ogilvie’s syndrome) may be seen alone or in conjunction with small bowel ileus.

A

B

C

▲ **Figure 7-24.** **A.** Small bowel obstruction. Because of their widespread availability, conventional upright and supine radiographs are a good first step in suspected small bowel obstruction, although sensitivity and specificity are low. A supine radiograph demonstrates asymmetric dilation of the proximal small bowel (note plicae circulares) without significant gas in the colon. **B.** In the same patient, an upright abdominal radiograph demonstrates a prominent air-fluid level from proximal small bowel obstruction. **C.** The “string of pearls sign” in small bowel obstruction; an upright radiograph demonstrates numerous air-fluid levels.

A

B

▲ **Figure 7-25.** **A.** CT is excellent for diagnosing small bowel obstruction and for detecting a cause (eg, mass, intussusception, or hernia). In this patient, a large leiomyosarcoma caused a high-grade small bowel obstruction. **B.** In certain situations, following luminal contrast material through the small bowel (small bowel follow-through) may be helpful for detecting small bowel obstruction. This study from the same patient demonstrates an abrupt tapering of the bowel lumen with dilated proximal bowel due to the mass.

General Considerations

Ileus is generalized dysfunction of bowel related to an underlying disorder, usually most severe in the 2–4 days following abdominal surgery with extensive bowel manipulation. Dysfunction due to humoral, metabolic, and neural factors contributes to the overall process. Other common causes include abdominal infections, peritonitis, active inflammatory bowel disease, opioid or chemotherapy use, electrolyte imbalances, visceral pain syndrome (biliary or ureteral colic, ovarian torsion), and myocardial infarction.

Radiographic Features

In the generalized form of ileus, the small and large bowel are dilated but generally to a lesser degree than seen in moderate to severe bowel obstruction (Figure 7-27). In many cases, there is a significant overlap with clinical and radiologic features of small bowel obstruction, and differentiation on the basis of a single study may not be possible. Serial radiographs, contrast studies with water-soluble contrast agents or barium, or CT may be required.

An intraabdominal inflammatory event (acute pancreatitis) or trauma may produce a focal form of ileus. The dysfunctional segment of bowel may lose peristaltic activity and enlarge. This is known as a *sentinel loop*.

Colonic ileus—also known as *intestinal pseudo-obstruction* or *Ogilvie's syndrome*—usually presents in elderly, debilitated, or bedridden patients with major underlying systemic abnormalities, severe infection, cardiac disease, or recent surgery. Progressive large bowel distention is variably accompanied by small bowel distention. Massive cecal distention compromises blood flow and may be complicated by perforation, with a mortality rate of 30–45%. As in the small bowel, colonic ileus is not always diffuse and may be segmental, typically in the cecum. In cecal ileus, there is massive dilation of the cecum. If the cecum is mobile, this condition may be difficult to distinguish from cecal volvulus, and a contrast examination may be necessary to make the differentiation.

Conservative treatment, consisting of nasogastric tube, rectal tube, or colonoscopic decompression, is successful in 78% of patients. Alternatively, surgical cecostomy may be necessary. Percutaneous cecostomy may be offered to high-risk patients.

A

B

C

D

▲ **Figure 7-26.** Large bowel obstruction. **A.** Most large bowel obstructions occur distally and are due to tumors or diverticulitis. In this patient, the large bowel is diffusely dilated and filled with stool. **B.** A single-contrast barium enema depicts a short segment annular carcinoma causing sigmoid colon obstruction. **C.** Sigmoid volvulus. On plain radiograph, the dilated sigmoid colon may project over the right upper quadrant with a "coffee bean" appearance. The remainder of the colon is dilated. **D.** Cecal volvulus. On plain radiographs, the dilated cecum is filled with stool and projects over the midabdomen or sometimes the left upper quadrant. The small bowel is diffusely dilated.

▲ **Figure 7-27.** Ileus. Plain abdominal radiograph demonstrates mild diffuse gaseous dilation of both the small and the large bowel. No transition point is present.

▶ Intestinal Ischemia

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ Plain films: Early: normal or nonspecific dilation of bowel; later: focal, edematous, thick-walled bowel loops, gas in the superior mesenteric and portal veins, pneumatosis intestinalis, ileus, and gasless abdomen.
- ▶ Abdominal CT: bowel wall thickening, pneumatosis; portal venous gas usually sign of infarction.
- ▶ CT or MRA provides excellent evaluation of the larger mesenteric arteries and veins.
- ▶ Conventional angiography is infrequently needed but may be confirmatory in some situations.

General Considerations

Early diagnosis of bowel ischemia and infarction remains difficult because of limited clinical and radiologic sensitivity. Vascular insufficiency must be considered in elderly patients or for any patient with atherosclerotic vascular disease, hypotension, cardiac failure, or arteritis. In young patients, vasculitis, a hypercoagulable state, pregnancy, illicit use of cocaine, or embolic sources (eg, patent foramen ovale) must be suspected. Morbidity and mortality rates remain high (30–80%).

Ischemia has a variety of underlying causes, including mesenteric arterial occlusion (ie, thrombus, embolus, or dissection), venous occlusion (ie, hypercoagulable states or malignancy), nonocclusive mesenteric ischemia (ie, vasospasm, myocardial infarction, or shock), and mechanical obstruction, including colonic pseudo-obstruction. Any portion of the small bowel may be affected; the cecum and distal left colon are the large bowel segments affected most commonly. Rectal ischemia is infrequent because of the rectum's dual blood supply, but it may be seen in patients who have had prior radiation therapy to that area.

Clinical symptoms are variable. Generally, abdominal pain out of proportion to physical findings, and bloody diarrhea may be suggestive of ischemic colitis. Segmental ischemia often resolves spontaneously, but fibrotic strictures may develop. Infarcted bowel must be surgically resected. In selected patients, clots identified on IV contrast-enhanced CT may be treated with angiographic interventional techniques, including thrombolysis or stent placement.

Radiographic Features

A. Plain Radiographs—Edematous, thick-walled bowel, pneumatosis intestinalis, and portal venous gas are the most specific signs of ischemia and infarction but are insensitive. More commonly, plain films are normal, show lack of abdominal gas, or suggest focal ileus or small bowel obstruction (Figure 7-28).

B. Computed Tomography—Helical CT is important for detecting early changes of ischemia. A high-quality helical CT is usually performed with oral contrast material to opacify and distend the small bowel along with rapid IV contrast material injection (3 mL/s) to optimize opacification of the superior mesenteric artery and vein. The CT features of intestinal ischemia vary with its cause, chronicity, and severity. Bowel wall thickening is a sensitive but nonspecific early finding and may be accompanied by a “target sign” appearance of bowel caused by submucosal edema. Indirect signs of ischemia include focal ascites, bowel distention, and mesenteric edema. In more advanced stages of bowel ischemia, the presence of gas within the bowel wall or within the superior mesenteric or portal vein makes the prognosis more grave. Colonic ischemia generally results from hypoperfusion or hypotension, and mesenteric thrombosis is rare. CT angiography using newer-generation multidetector helical scanners

A

B

▲ **Figure 7-28.** Colonic ischemia. **A.** Plain radiograph demonstrates mottled lucency of the wall of the ascending colon consistent with pneumatosis. **B.** Abdominal CT is excellent for confirmation of pneumatosis.

allows excellent vascular and intestinal wall assessment, aided by three-dimensional image processing (eg, multiplanar, volume-rendered, and maximum-intensity projection views). Thrombus in the major mesenteric vessels may be detected. However, a normal CT does not exclude ischemia, and if a

strong clinical suspicion is present—especially in patients with vasculitis—angiography or surgery may be required.

C. Catheter Angiography—Angiography may be both diagnostic and therapeutic. Vasodilators may be used in conjunction with thrombolytic agents in certain patients. While angiography remains the diagnostic standard in patients with vasculitides given its unparalleled spatial resolution, multidetector CT and modern MR scanners have narrowed the resolution gap. Angiography has a limited role in colonic ischemia because low-blood-flow states rather than occlusion of the vasculature are most often the cause.

▶ Colitis

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ Colonic wall thickening and nodularity associated with paralytic ileus.
- ▶ Infiltration of pericolonic fat, often seen on CT.
- ▶ Plaque-like filling defects are suggestive of pseudomembranous colitis.

General Considerations

Inflammatory bowel disease, ischemia, and infections are the most common causes of colitis. Patients present with pain, bloody diarrhea, cramping, fever, and leukocytosis. Infectious colitis may be bacterial, viral, fungal, or parasitic. Stool cultures, serologic tests, or colonic biopsy may be required.

Pseudomembranous colitis—the most common cause of colitis in hospitalized populations—is a complication of antibiotic therapy. *Clostridium difficile* produces an enterotoxin that causes mucosal ulceration and edema and the development of pseudomembranes. The process may be focal or diffuse.

Neutropenic colitis is typically seen in patients undergoing chemotherapy or bone marrow transplantation with myelosuppression. Although involvement can be diffuse, it typically affects the ascending colon, cecum, appendix, and terminal ileum. If cecal inflammation is present, then the term *typhlitis* (or necrotizing enterocolitis) is used.

Radiographic Features

Although usually normal or nonspecific, plain radiographs may reveal colonic fold thickening and nodularity. Features of paralytic ileus may be present. Contrast studies such as a barium enema should be avoided but can be performed carefully with water-soluble agents only if absolutely necessary (Figure 7–29). Although abdominal CT is an excellent test, it may be normal in early infectious colitis. In more advanced cases of infectious colitis and in pseudomembranous colitis, mural thickening is more severe, averaging 15–20 mm, with a target or halo pattern. An accordion-like pattern reflecting haustral thickening may be produced in addition to pericolic inflammatory changes and lymphadenopathy. In neutropenic colitis (typhlitis), similar features are present, but most commonly in the right colon. Occasionally in advanced cases, pneumatosis intestinalis and frank perforation may develop.

▶ Toxic Megacolon

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ Gaseous colonic distention, which may be diffuse or segmental.
- ▶ Effacement of haustra, edematous folds (thumbprinting), relative paucity of feces.
- ▶ Common complication of a number of inflammatory conditions, notably ulcerative colitis.

A

B

▲ **Figure 7–29.** **A.** Colitis. Plain radiograph demonstrates mild dilation and severe fold thickening (thumbprinting) of transverse colon in this case of pseudomembranous colitis. **B.** Abdominal CT also demonstrates mural colonic thickening with associated infiltration of the pericolic fat.

General Considerations

Toxic megacolon is a complication of many different types of ischemic, inflammatory, or infectious conditions of the colon but is most closely associated with ulcerative colitis. Patients are usually in extremis, complaining of fever and bloody diarrhea. Tachycardia and abdominal pain may be present. Clinical features are accompanied by thickened colonic haustra on plain radiographs. Due to the transmural nature of the inflammation, the neuromuscular and neurohumoral tone of the colon is disrupted. Without treatment, the mortality rate is nearly 20%.

Radiographic Features

Generally, plain radiographs will reveal varying degrees of colonic dilation (generally >6.5 cm) with or without associated fold thickening. Thickened or effaced haustra are present, with edematous or inflamed folds, and there is a paucity of feces. An enema is contraindicated if toxic megacolon is suspected (Figure 7-30). These features are more clearly seen on abdominal CT imaging, and complications such as perforation and gas within the colonic wall are easier to detect. The pericolonic fat is usually infiltrated, and both colon and fat are sometimes hyperemic.

▶ Intraabdominal Abscess

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ **Plain film:** Usually invisible except when abscess is gas-filled or produces a mass effect.
- ▶ **Ultrasound:** Well-circumscribed collection of variably echogenic fluid.
- ▶ **Abdominal CT:** Well-circumscribed fluid-filled mass, which may contain gas. Wall is of variable thickness and enhancement.
- ▶ **Radionuclide scintigraphy:** Radionuclide-tagged white blood cell scan may be useful in search of occult abscess or other sources of infection.

General Considerations

Over the past 25 years, imaging has revolutionized the diagnosis and management of abdominal and pelvic abscesses, often precluding the need for laparotomy and for incision and drainage in the vast majority of patients.

Intraabdominal abscesses typically are caused by perforated appendicitis in the young and diverticulitis in the

▲ **Figure 7-30.** Toxic megacolon. Plain radiograph demonstrates diffuse dilation and severe thickening of mucosal folds (thumbprinting) of the colon. There is no stool. The patient was in extremis with a severe flare of ulcerative colitis.

elderly. Overall, most cases are iatrogenic, occurring after intraabdominal surgery. Hematogenous seeding of bacteria may be responsible for liver and, especially, splenic abscesses. The mortality remains high, ranging from 80% to 100% without treatment and up to 30% in patients receiving appropriate therapy.

Radiographic Features

A. Plain Radiographs—These may be helpful in evaluating the gastrointestinal tract but are not generally able to localize an abscess. On occasion, the abscess will appear as a gasless fluid collection mimicking a mass with defined radiodense contours that displaces bowel or bladder.

B. Ultrasound—Ultrasound is an excellent means for bedside evaluation of defined areas such as the upper quadrants,

the paracolic gutters, and the pelvis. Features that suggest an infected fluid accumulation on sonography include rounded or ovoid collections with thick walls, with variable internal echoes and without evidence of central vascularity, as demonstrated by color, power, or spectral Doppler signals. Focal bright echoes with variable shadowing within collections may suggest the presence of gas. However, these signs are not specific for infected fluid; a hematoma or seroma may appear identical. On the other hand, noninfected collections generally have angular margins, conform to anatomic spaces, and tend to lack significant internal echogenicity.

Ultrasound is especially valuable for evaluating the subdiaphragmatic regions or the low pelvis. However, one should bear in mind its limitations. Ultrasound will not reliably evaluate the retroperitoneum and retroperitoneal organs such as the pancreatic body and tail. Evaluation of complex collections in postoperative patients or in patients with open abdominal incisions or surgical dressings is likely to be suboptimal. Imaging of abscesses within organs may be difficult.

C. Computed Tomography—CT is the method of choice for evaluation of an intraabdominal abscess (Figure 7-31). Although preparation with oral and IV contrast agents is preferred for optimal diagnosis in most patients, contrast material is not always required when using the latest-generation equipment. This is especially true in obese patients because of inherent contrast provided by intraabdominal fat. Actual scanning time with a multidetector helical scanner is typically on the order of 20–40 seconds.

Abscesses generally appear as round or ovoid collections with thick surrounding rims. Intraluminal gas due to anaerobic bacterial infection may be present in up to 50% of collections. If IV contrast material is given, enhancement of the surrounding rim may be noted in up to 50% of abscesses. Abscesses under the diaphragm and surrounding the liver or kidney may have crescentic margins. However, in many cases, the CT signs of an abscess are nonspecific. Necrotic tumors may have an identical appearance, and percutaneous aspiration may be required to distinguish between them.

D. Radionuclide Scintigraphy—Although unnecessary in the vast majority of patients, nuclear medicine studies with indium (^{111}In)-labeled or gallium citrate (^{67}Ga)-labeled white blood cells are useful for the detection of occult abscesses, especially in patients with fever of unknown origin. Both indium oxine-labeled and gallium citrate-labeled cells are injected intravenously, and scans are typically obtained 48–72 hours later. Although gallium is highly sensitive for the detection of intraabdominal abscess (80–90%), specificity is limited by intestinal secretion at 48–72 hours.

A

B

▲ Figure 7-31. Psoas abscess. Young woman with pain and fever 1 month after renal and pancreas transplantation. **A.** CT demonstrates a multiloculated right psoas abscess with air and gas tracking into the right psoas sheath. **B.** Air in the right abdominal wall is from a recent biopsy.

Overall, indium-labeled white blood cell scans are more accurate for abdominal applications.

E. Algorithm for Imaging the Patient with Suspected Abdominal Abscess—In patients without localizing signs or symptoms and varying degrees of suspicion of abdominal abscess, the test of choice is helical or multidetector CT with IV and oral contrast. This study helps to exclude potential peritoneal and retroperitoneal sources of infection. CT is necessary for adequate visualization of the pancreas, psoas muscles, other retroperitoneal structures and complex collections. CT is superior to other imaging methods in patients

with ileus, open incisions, dressings, indwelling catheters, and drains. If symptoms are localized to the upper abdominal quadrants or to the pelvis, ultrasound is an excellent choice for diagnosis and can be performed quickly at the bedside. Furthermore, bedside percutaneous incision and drainage may be performed with sonographic guidance. Scintigraphy has a limited role in diagnosing abscess in an acutely ill patient.

F. Percutaneous Image-Guided Drainage—Percutaneous drainage has revolutionized the management of infected fluid collections. Expanded criteria render only a small minority of collections unsuitable for such drainage. General criteria include a fluid collection at least 2–3 cm in diameter and safe access to the collection without intervening blood vessels, pleura, bladder, or bowel. One should confirm with CT or sonographic Doppler that the collection in question is not a pseudoaneurysm. Fluid collections may be multiloculated or communicate with the gastrointestinal, biliary, or genitourinary tracts. Solid organ and tubo-ovarian abscesses may be drained safely, although the latter frequently respond to antibiotics and needle aspiration alone.

A number of catheter types and sizes are available. Noninfected serous collections usually can be drained with 6–8F catheters, whereas infected, thick purulent collections may be drained with 10–14F catheters. Multiple catheters or larger catheters (16–18F) occasionally may be needed for multiloculated noncommunicating thick-walled collections. Guidance for drainage procedures includes ultrasound, fluoroscopy, or CT. Ultrasound is especially versatile because cavity probes (endovaginal or endorectal) can help diagnose deep pelvic abscesses and guide transrectal or transvaginal drainage. Catheters should be left to gravity drainage and flushed gently with 5 mL of normal saline at 8-hour intervals to ensure patency. Drainage output should be recorded on the nursing flow sheet.

Catheter position may be confirmed by fluoroscopic injection of contrast material or by ultrasound or CT. General criteria for catheter removal include resolution of symptoms and signs, decrease in net catheter output to under 10 mL/day, and closure of the cavity as determined by follow-up imaging studies.

▶ Acute Pancreatitis

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ **Plain radiographs:** Gallstones, ileus of regional bowel (sentinel loop), transverse colon ileus (colon cutoff), pancreatic calcifications (chronic pancreatitis), and pleural effusion.
- ▶ **Ultrasound:** Peripancreatic fluid, enlarged pancreas with variable echogenicity, localized fluid collections, cholelithiasis, choledocholithiasis, biliary tract obstruction.
- ▶ **Helical CT:** Pancreatic enlargement, necrosis, or hemorrhage; thoracic and intraabdominal fluid or fluid collections; cholelithiasis; choledocholithiasis.

General Considerations

Imaging studies in acute pancreatitis help to confirm the diagnosis, suggest possible causes (eg, choledocholithiasis or pancreas divisum), detect features suggesting chronicity, and demonstrate the extent of complications, such as abscess, pseudocyst, hemorrhage, and necrosis. Imaging findings may add to prognostic information derived from clinical and serum laboratory parameters.

Acute pancreatitis is caused mainly by alcohol abuse or choledocholithiasis. In the ICU, iatrogenic causes such as postoperative state, medications (eg, antiretrovirals, chemotherapeutic agents), or endoscopic retrograde cholangiopancreatography may cause acute pancreatitis. Other causes include trauma, hypercalcemia, hypertriglyceridemia, peptic ulcer disease, and structural congenital anomalies.

By imaging criteria, acute pancreatitis may be subdivided broadly into acute interstitial (edematous) pancreatitis and acute necrotizing or hemorrhagic pancreatitis. While acute interstitial pancreatitis is usually self-limited and requires supportive care, acute necrotizing pancreatitis is difficult to manage and carries a significant risk of high morbidity and mortality. In up to 60% of patients, peripancreatic and pancreatic fluid collections are present. Pseudocysts, which are collections of pancreatic juice and debris, are lined by a fibrous capsule and by definition have been present for at least 4 weeks. In the acute phase, the behavior of a phlegmon or nonliquefied inflammatory pancreatic tissue is difficult to predict, although most resolve. If a pancreatic abscess is detected, prompt percutaneous or surgical debridement must be performed because it is associated with a high mortality.

Radiographic Features

A. Plain Abdominal Radiographs—Several indirect signs in a patient with acute back or epigastric pain suggest acute pancreatitis (Figure 7–32). However, none of the following are

A

B

▲ **Figure 7-32.** Acute pancreatitis. **A.** Plain film demonstrates focal dilated “sentinel loops” resulting from localized ileus. **B.** Abdominal CT in the same patient shows peripancreatic stranding and a fatty liver from recent ethanol abuse.

specific for pancreatitis: (1) duodenal ileus—gas in the second portion of the duodenum—reported in up to 50% of patients, (2) jejunal ileus—focal gaseous distention of a jejunal loop (“sentinel-loop sign”), (3) transverse colon ileus—gaseous distention of the transverse colon with a paucity of gas in the descending colon—compatible with the “colon cutoff sign,” and (4) left-sided pleural effusion, reported in 10–15% of patients.

B. Fluoroscopic Contrast Studies—Upper gastrointestinal studies may be indicated to look for peptic ulcer disease. Although they are not indicated for the diagnosis of acute pancreatitis, one sometimes may observe a widening of the C-loop with thickening of the duodenal folds due to edema.

C. Ultrasound—An ultrasound examination may be necessary to confirm or exclude the presence of gallstones within the gallbladder or common duct. Sonographic imaging of the pancreas may reveal diffuse edema.

D. Abdominal CT—Current CT techniques allow detailed pancreatic imaging tailored to the particular clinical situation. In the setting of acute pancreatitis, a single or multidetector helical CT may be performed, imaging the pancreas with a minimum of 3-mm collimation with IV contrast enhancement in the “pancreatic phase,” approximately 40 seconds after bolus contrast material injection in patients with normal cardiac output. In addition to highly detailed pancreatic images, the remainder of the abdomen and pelvis should be imaged to exclude distant complications, including fluid collections and phlebitis. CT is the single best imaging method for pancreatic evaluation because it provides excellent evaluation and the ability to treat complications percutaneously.

Uncomplicated acute pancreatitis has an extremely variable presentation. The pancreas may be normal or edematous, increasing the attenuation of the intrapancreatic fat. The peripancreatic fat planes may become infiltrated by edema and products of the nonspecific inflammatory response. In patients with severe pancreatitis, sections of the gland undergo necrosis and may become hemorrhagic or infected. On CT, lack of diffuse and homogeneous pancreatic enhancement with IV contrast material reflects poor parenchymal perfusion and is typical of necrotizing pancreatitis. In areas of necrosis, the pancreas becomes ill-defined, with a severe peripancreatic inflammatory response and local and distant free and contained fluid. Splenic vein thrombosis may be present, and other complications such as pseudoaneurysm formation and pseudocyst formation may be seen at local and distant sites (Figure 7-33). A proposed CT grading system is used in some centers to estimate the amount of pancreatic injury and to predict outcome. Hemorrhagic complications are well seen because recent hemorrhage (<1 week) is usually of high attenuation compared with surrounding tissue. Over time as the hematoma ages, its attenuation gradually decreases.

A pancreatic abscess, which may complicate acute pancreatitis in up to 9% of patients, implies a poor prognosis, with reported mortality rates of 40–70% in the pre-CT era. Prompt CT diagnosis and treatment have reduced the mortality rate to 20%. CT appearance of a pancreatic abscess can be variable and can range from a contained fluid collection to a more typical rim-enhancing lesion with central low attenuation and gas collection. The latter findings are present in only 20–30% of all pancreatic abscesses, and percutaneous aspiration is usually necessary for confirmation. The presence of gas bubbles also may suggest a fistulous communication with bowel.

▲ **Figure 7-33.** Complicated pancreatitis. CT demonstrates a large pseudocyst in the head of the pancreas.

Treatment

Acute pancreatitis complicated by necrosis or infection often can be treated successfully by aggressive percutaneous catheter drainage with large-bore catheters. In more complex or severe cases, percutaneous management may help to temporize a critically ill patient until surgical debridement is possible.

The management of pseudocysts is complex. Generally, pseudocysts may be managed expectantly because most will regress over time. By definition, a true pseudocyst has a mature fibrous wall developed over at least 4 weeks. Indications for percutaneous drainage or internal drainage into the stomach are the following: infection; enlargement; pain; bowel, bile, or urinary obstruction; and diameter greater than 5 cm. For noninfected pseudocysts, success rates for internal or external drainage are high. For the 20–30% of pseudocysts communicating with the pancreatic duct, external drainage will be difficult, and a cyst gastrostomy performed percutaneously, surgically, or laparoscopically may be better.

Superinfection of a previously sterile pseudocyst occurs in less than 5% of cases. As with most fluid collections, identification of infection within a pseudocyst requires clinical suspicion and confirmation by percutaneous aspiration. Successful drainage of an infected pseudocyst uses the same principles of drain placement and management as for most intraabdominal abscesses.

IMAGING OF ACUTE GALLBLADDER & BILIARY TRACT DISORDERS

▶ Acute Calculous Cholecystitis

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ **Plain films:** 15–20% of gallstones are radiopaque; distended gallbladder may be present in the right abdomen and produce a rounded radiodensity; gas may be present in the lumen or wall in emphysematous cholecystitis.
- ▶ **Ultrasound:** Thickening of gallbladder wall (>3 mm), intraluminal gallstones and sludge, pericholecystic fluid and focal tenderness over gallbladder (sonographic Murphy's sign).
- ▶ **CT:** Nearly 100% of gallstones visualized. Distended gallbladder with thickened wall, rim enhancement, pericholecystic fat stranding, gas in lumen or wall in emphysematous cholecystitis.
- ▶ **Hepatobiliary scintigraphy:** Uptake of iminodiacetic acid analogues into liver but nonvisualization of gallbladder within 60 minutes of injection.

General Considerations

In acute calculous cholecystitis, cystic duct obstruction results from a lodged gallstone in almost 95% of cases. The gallbladder distends, with resulting mucosal inflammation and edema from bile stasis. Both distention and mural edema may lead to venous obstruction and subsequent mural ischemia and possible perforation.

Clinical parameters are of limited utility in the critical care setting. There is a significant clinical overlap among a variety of conditions, such as acute pancreatitis, perforated peptic ulcer, pyelonephritis, and thoracic abnormalities such as pneumonia and myocardial infarction.

Radiographic Features

A. Plain Abdominal Radiographs—Plain radiographs can detect the 15% of gallstones that are radiopaque. In emphysematous cholecystitis, typically seen in diabetics, gas within the gallbladder wall and lumen may be seen. Plain films also may be useful to distinguish other causes of right upper quadrant pain, such as a perforated viscus or pneumonia.

B. Ultrasound—Ultrasound should be the test of choice for rapid diagnosis of acute cholecystitis at the bedside. Features highly suggestive of acute calculous cholecystitis include a thick-walled, distended gallbladder with gallstones, pericholecystic fluid, and focal tenderness overlying the gallbladder (sonographic Murphy's sign)(Figure 7-34). However, in

B
▲ Figure 7-34. Acute cholecystitis. **A.** Ultrasound demonstrates a stone at the gallbladder neck with thickening of the gallbladder wall, pericholecystic fluid, and tenderness on compression (sonographic Murphy's sign). In combination, these features are highly specific for acute cholecystitis. **B.** In another patient, abdominal CT shows distended gallbladder with gallstones and surrounding infiltration of the fat.

patients who have been in the ICU for a few days or longer, the gallbladder tends to look abnormal on sonography, usually having a thickened wall and internal echoes. In these patients, a reliable sonographic Murphy's sign should be absent. Sonography also may be limited by body habitus, overlying bowel gas, gangrenous cholecystitis, or overlying dressings. Pericholecystic fluid is an unreliable sign in patients with ascites. Gallbladder wall thickening alone in the absence of other findings may have many causes, including acute hepatitis, HIV cholangiopathy, IL-2 therapy, and anasarca.

C. Scintigraphy—In patients with equivocal signs and sonography, scintigraphy may provide complementary information in acute calculous cholecystitis. Technetium (^{99m}Tc) iminodiacetic acid–derived agents have been shown to have high sensitivity and specificity for the diagnosis of acute cholecystitis. These agents are injected intravenously, and sequential imaging is performed over the liver with a SPECT camera. Sequential liver uptake and excretion into the biliary tree and intestine are imaged for up to 1 hour after injection. Normally, the gallbladder should fill with the radiotracer within 1 hour. Lack of filling confirms the diagnosis of acute calculous cholecystitis. However, lack of filling is also seen with intrinsic gallbladder dysfunction.

Although scintigraphy is an excellent test, it is cumbersome to perform at the bedside in the ICU compared with sonography. An accurate test requires that the patient fast for at least 2–4 hours prior to the procedure, and delayed images up to 4 hours may be needed. Scintigraphy has high negative predictive value; filling of the gallbladder within 1 hour excludes the diagnosis of acute calculous cholecystitis. However, many causes can prevent radiotracer flow into the cystic duct, and false-positive examinations have been reported in up to 40% of severely ill or debilitated patients. The most common causes of false-positive tests are bile stasis, bile hyperviscosity, and gallbladder distention. Specific causes include chronic cholecystitis, hyperalimentation, severe jaundice, hepatic dysfunction, pancreatitis, prolonged fasting, and recent nonfasting state. Causes of false-negative tests include pancreatitis and poor hepatic function. Hepatobiliary scintigraphic agents also may be used to confirm complications such as total common duct obstruction or bile leak.

▶ Acalculous Cholecystitis

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- ▶ **Ultrasound:** Gallbladder wall is thickened; no intraluminal stones; sonographic Murphy's sign usually present.
- ▶ **CT:** Mural thickening and inflammatory infiltration of the pericholecystic fat.

General Considerations

Acalculous cholecystitis is associated with a variety of clinical conditions, including chronic debilitation, prolonged intubation, nasogastric suction and hyperalimentation, burns, and pancreatitis. Although comprising 10–15% of all cases of cholecystitis, acalculous cholecystitis predominates in the postoperative and posttraumatic patient population, accounting for up to 90% of all cholecystitis cases seen in that group. Mechanisms are poorly understood and probably multifactorial. Bile stasis, bile hyperconcentration, and edema with pressure in the gallbladder wall leading to progressive ischemia have been linked to the pathogenesis of this disorder. In addition, reflux of pancreatic juices through biliary enteric anastomoses and pancreatitis have been suggested. The clinical presentation of acalculous cholecystitis is similar to that of calculous cholecystitis. However, typical symptoms may be masked by concomitant problems.

Radiographic Features

As with the clinical diagnosis, the radiologic diagnosis is also difficult. In the patient population most prone to acalculous cholecystitis, intrinsic functional and morphologic abnormalities of the gallbladder limit the specificity of both scintigraphy and sonography (Figure 7–35). Scintigraphy relies on technetium (^{99m}Tc) iminodiacetic acid to fill the gallbladder, and scans often are done with pharmacologic intervention to improve accuracy. Morphine may cause contraction of the sphincter of Oddi, resulting in increased back pressure; cholecystikinin can be used to first empty the gallbladder. Although the sensitivity of scintigraphy has been reported to be as high as 95%, specificity is significantly lower than in calculous cholecystitis. This is so because of the high number of false negatives resulting from coexisting conditions such as prolonged intubation, nasogastric suction, and hyperalimentation.

Sonographic features suggesting cholecystitis are similarly compromised in these patients. They may have mild wall thickening from edema and mild contraction. Often, right upper quadrant tenderness mimicking a sonographic Murphy sign is present in these patients in the absence of acalculous cholecystitis. Although the sensitivity of sonography is high, specificity is poor.

If results are equivocal, both scintigraphy and ultrasound may be necessary, or a CT scan may be performed. Using IV contrast-enhanced CT, mural thickening, mucosal enhancement, and subtle pericholecystic inflammatory changes may improve specificity.

Treatment

In patients with uncomplicated acute cholecystitis, IV antibiotics contain the inflammatory response and suppress further inflammation, allowing patients to undergo less invasive surgery with fewer complications. Although percutaneous aspiration usually can be performed in patients with acute cholecystitis, its role is debated because there is a high incidence of false-negative sterile aspirates resulting from effective antibiotic treatment.

A

B

▲ Figure 7–35. Acalculous cholecystitis. **A.** Ultrasound demonstrates diffuse echoes throughout the gallbladder, a marginally thickened wall, and positive sonographic Murphy's sign. **B.** HIDA (hepatobiliary iminodiacetic acid) scan. The gallbladder does not fill with tracer by 60 minutes despite provocative maneuvers.

Temporary gallbladder decompression by percutaneous cholecystostomy is beneficial in patients with acute cholecystitis who are at high surgical risk. The procedure is performed with sonographic and fluoroscopic guidance in most institutions, but it may be performed with CT guidance. It also can be performed with sonographic guidance alone at the bedside. Complications, including bile leak, hemobilia, and vagal reaction, have been reported in 5–10% of patients—less than the complication rate associated with surgery (24%). Other

indications for percutaneous drainage include decompression of the biliary tract in cases of distal common duct obstruction with only mild dilation of the intrahepatic ducts. Some have advocated performing percutaneous cholecystostomy in critically ill patients as a means of diagnosing and treating acute cholecystitis. With this approach, in one study, 58% of critically ill patients improved.

IMAGING IN EMERGENT & URGENT GENITOURINARY CONDITIONS

▶ Acute Renal Failure

- ▶ **Ultrasound:** In obstructive uropathy, dilation of the calices and renal pelvis with visualization of echogenic calculi; in intrinsic renal disease, increased cortical echogenicity correlates with chronic medical renal disease.
- ▶ **CT:** In obstructive uropathy, signs of acute obstruction on CT include dilation of the collecting system, a source of obstruction such as stone, swollen kidney with increased stranding in the perinephric space; CT urography (noncontrast helical CT) provides a rapid method of detecting renal calculi and obstructive nephropathy from a passing stone.
- ▶ **MR urography:** Rapid assessment of cause and level of obstruction; with gadolinium enhancement, differential rates of enhancement permit assessment of renal perfusion.
- ▶ **Renal scintigraphy:** Technetium-99m MAG 3 scan permits rapid assessment of differential renal function, including flow, uptake, and excretion. Especially valuable in transplanted kidneys to assess for a vascular occlusion from intrinsic renal abnormality.

General Considerations

The workup of acute renal failure traditionally has been focused on identifying prerenal, intrinsic renal, and postrenal causes. Prerenal causes (eg, cardiac or liver failure) and systemic hypotension account for 75% of all causes of renal failure. Intrinsic causes such as acute tubular necrosis and glomerulonephritis account for 20%, and postrenal causes such as obstructive nephropathy account for less than 5% of cases. Imaging is used mainly to exclude an obstructive cause of acute renal failure. These causes include obstruction from a lower urinary tract source such as bladder tumor, prostatic enlargement, or urethral stricture. Concomitant reflux also may decrease renal function. Ureteral causes of obstruction include luminal stones, tumors, blood clots, fungus balls, and sloughed papillae, as well as extraluminal causes such as mural strictures or extramural causes such as retroperitoneal fibrosis, lymphadenopathy, or inadvertent ureteral ligation.

Radiographic Features

Azotemia due to obstruction is usually easily and rapidly treatable. Cross-sectional imaging allows rapid identification of hydronephrosis and its causes, as well as clues to evaluate pyonephrosis, pyelonephritis, or abscess.

Sonography is the imaging method of choice to evaluate hydronephrosis in the critically ill patient. It may be performed at the bedside. Since it detects the presence of a dilated collecting system, pitfalls in interpretation may be present. In acute hydronephrosis, sonography may be normal in 50% of patients because dilation is suboptimal, especially in the first 72 hours. In subacute situations, a ruptured calix may decompress the collecting system, leading to a false-negative diagnosis if perinephric fluid is minimal or absent. A volume-depleted patient may also have poor distention of the collecting system due to low urine output. Patients with retroperitoneal fibrosis or neoplastic encasement of the ureters may have only minimally distended collecting systems. Conversely, patients with vesicoureteral reflux, parapelvic cysts, or prior episodes of inflammation may receive a false-positive diagnosis of hydronephrosis. Sonography may suggest the diagnosis of pyonephrosis or renal bleeding by the presence of echoes in the collecting system.

In a large series of patients with azotemia undergoing renal sonography, hydronephrosis was detected in 29% of those known to be at high risk (ie, pelvic malignancy, palpable abdominal or pelvic mass, renal colic, known nephrolithiasis, bladder outlet obstruction, recent pelvic surgery, or sepsis). However, in patients without these risk factors, hydronephrosis was detected in only 1%. Sixty-five percent of patients in the low-risk group had medical renal disease compared with 36% of high-risk patients. The simplicity and relatively low cost of a sonogram must be weighed against a typically negative result in the vast majority of patients and the risk of missing an obstructive cause of renal failure.

Helical noncontrast CT has emerged over the past few years as the imaging procedure of choice for the evaluation of renal colic (Figure 7-36). Helical CT detects over 99% of all types of calculi—with the exception of the stones caused by crystallization of the antiretroviral protease inhibitor indinavir. Helical CT images stones not only in the renal collecting system but also in the ureters, bladder, and posterior urethra. CT also images the retroperitoneum and pelvis, allowing detection of processes such as retroperitoneal fibrosis and lymphadenopathy. CT is excellent for the detection of perirenal abscesses and abscesses in other areas of the abdomen and pelvis.

When a potentially obstructing stone is found in the urinary tract, the specific signs of obstruction include hydronephrosis and hydroureter to the level of obstruction, unilateral infiltration of perirenal and periureteral fat, and a swollen kidney. Hydronephrosis may not be distinguishable from pyonephrosis. However, high-density debris or, especially, gas within the collecting system suggests pyonephrosis.

MRI is emerging as a tool for evaluating urinary tract disease. However, it is currently impractical in critically ill patients.

► Urinary Tract Infection

ESSENTIALS OF RADIOLOGIC DIAGNOSIS

- **Ultrasound:** Usually normal in uncomplicated pyelonephritis. However, the kidneys may be enlarged, with variable echogenicity. Focal nephritis may appear as a solid renal mass. A renal abscess appears as a complex cystic or hypoechoic mass.
- **CT:** Pyelonephritis is typically associated with nonspecific findings. Kidneys may be enlarged, with perinephric stranding. With IV contrast material, a striated nephrogram may be seen with delayed function in infected areas. Focal nephritis appears as an ill-defined region of low attenuation in a lobar distribution. Renal abscesses are well-defined masses, often with an enhancing rim, increased attenuation of the adjacent perirenal fat, and thickening of the renal fascia.

General Considerations

Pyelonephritis is typically a clinical diagnosis. Imaging is helpful to detect complications of pyelonephritis or urosepsis or in patients who have failed to respond to standard medical therapy. Complications of pyelonephritis include pyonephrosis, renal or perirenal abscess, or other conditions requiring surgical or percutaneous intervention.

A

B

C

▲ **Figure 7-36.** Obstructive uropathy. **A.** Ultrasound shows moderate hydronephrosis of the left kidney. **B.** CT scan demonstrates moderate left hydronephrosis with hydroureter. **C.** There is a tiny calculus obstructing the left ureterovesical junction.

Radiographic Features

Sonography is relatively insensitive and nonspecific in diagnosing acute pyelonephritis. It is useful to exclude hydronephrosis and possibly pyonephrosis, as well as renal or perirenal abscess. However, sonography cannot diagnose changes in the perinephric fat or inflammatory thickening of the perirenal fascia.

Intensive Care Monitoring

Kenneth Waxman, MD
Frederic S. Bongard, MD
Darryl Y. Sue, MD

8

Physiologic monitoring is available for appropriate indications in the ICU. Monitoring should be selected and applied to detect pathophysiologic abnormalities in patients at high risk of developing them and to aid in the titration of therapy to appropriate physiologic end points.

► Electrocardiography

Continuous electrocardiography permits monitoring of heart rate, detection of arrhythmias, and evaluation of pacemaker function. It also may help detect myocardial ischemia or electrolyte abnormalities. Continuous electrocardiographic monitoring is indicated for patients with potential for developing arrhythmias—particularly those with acute myocardial infarction, traumatic cardiac contusion, following cardiac surgical procedures, and those with a prior history of arrhythmia. It is also useful for those in whom heart rate monitoring is indicated, such as patients at risk of hemorrhage or those undergoing fluid resuscitation. Monitoring of the ST segments is indicated for patients at risk of myocardial ischemia, such as those with coronary artery disease who have an injury, illness, or operation. Monitoring of the ECG also may be useful to detect certain electrolyte abnormalities such as hypokalemia during treatment of diabetic ketoacidosis.

The cardiac electrical potential available for skin surface monitoring is between 0.5 and 2.0 mV. Because of this low signal level, electrocardiographic systems must have good sensing, amplifying, and display capabilities. The electrodes used for electrocardiographic monitoring are usually composed of silver–silver chloride gel (Ag/AgCl) inside an adhesive pad. Prior to placement, the skin should be clean and dry. The stratum granulosum has an electrical resistance of $50,000 \Omega/\text{cm}^3$, which can be reduced to $10,000 \Omega/\text{cm}^3$ simply by cleansing, which removes oils and dead cells. Difficulties with a low signal are often remedied by reapplying the electrode after cleaning the skin.

Optimal electrode placement (Figure 8–1) allows proper detection of the electrocardiographic signals with a minimum

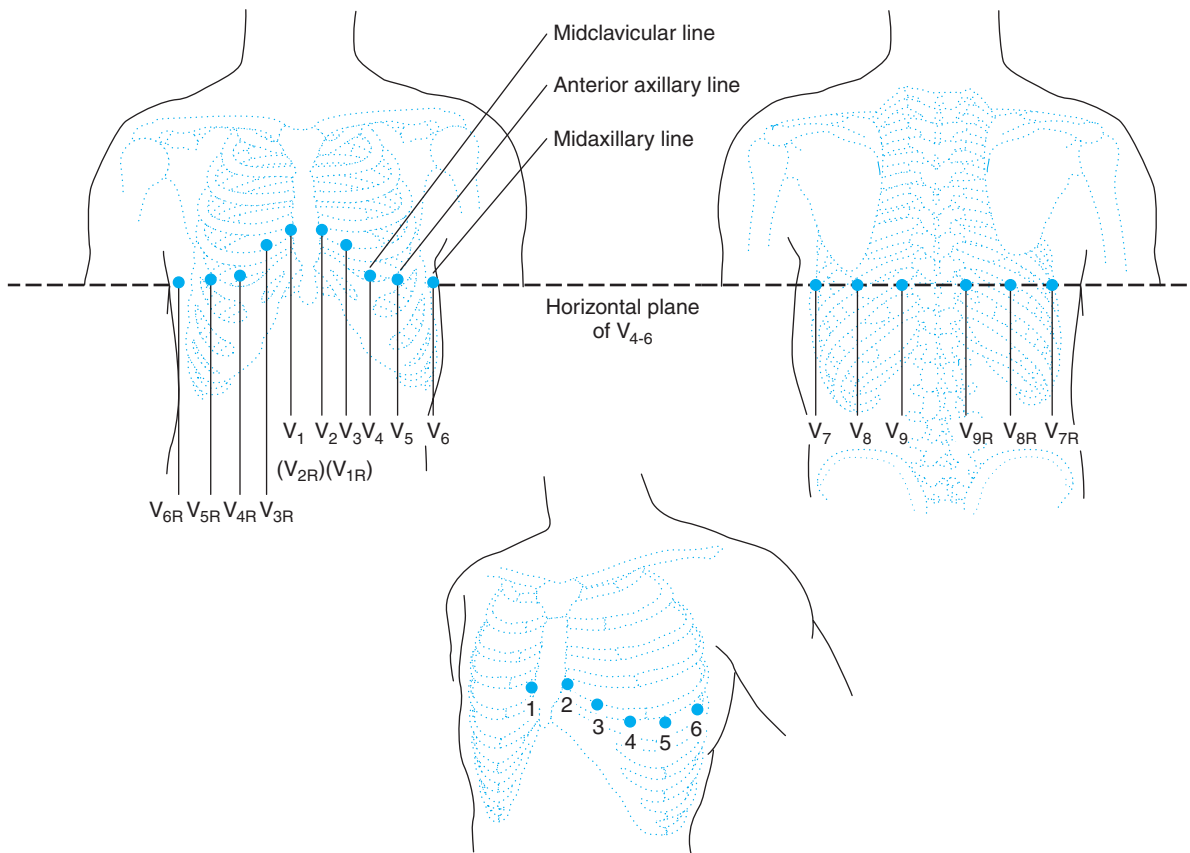

of extraneous noise. A “modified lead II” configuration is appropriate for routine monitoring, with limb leads extended proximally to lie over the shoulders. Placing them over bony prominences reduces electrical noise from muscle contractions.

Most electrocardiographic amplifiers and display modules can be used for both diagnostic and monitoring applications. The diagnostic setting permits greater amplifier bandwidth (0.05–100 Hz) when compared with the monitor setting (0.5–50 Hz). For routine rate and arrhythmia detection, the monitor setting is preferred because it decreases baseline wander, reduces unwanted interference, and improves overall trace quality. However, because it may falsely elevate or depress ST segments, the diagnostic mode should be selected when myocardial ischemia is the primary concern.

Clinical Applications

A. Electrocardiographic Monitoring—Lead placement at the shoulders and in the lead II position parallels the atria and results in the greatest P-wave voltage of any surface lead configuration. This facilitates recognition of arrhythmias and inferior wall ischemia. When placed in the V_5 position along the anterior axillary line, both anterior and lateral wall ischemia can be detected. Because patient positioning may make a true lead V_5 position difficult, a modified arrangement (CS_5), in which the left arm lead is placed just lateral to the left nipple and the lower limb lead is placed over the iliac crest, is a good alternative. When possible, leads II and V_5 should be monitored simultaneously. Esophageal leads are better than lead II for the detection of arrhythmias, but their use is difficult in patients who are not paralyzed and sedated, and they are rarely used in the ICU setting.

B. Complications—Difficulties associated with electrocardiography are usually due to technical error or equipment malfunction. Electrodes may not function properly when they are old and dry or if they are not attached securely. Electrical noise

▲ **Figure 8-1.** Locations of the unipolar precordial leads on the body surface. (Reproduced, with permission, from Goldschlager N, Goldman MJ: *Principles of Clinical Electrocardiography*, 13th ed. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

accompanying the displayed electrocardiogram is usually due to loose electrodes, broken wires, or poorly fitting contacts or problems with associated electrical equipment. Proximity of the patient to electrical lines (ie, power cords, etc.) produces a potential difference through capacitive coupling known as *common-mode voltage*. Typically as low as a few millivolts, coupling can cause voltages as high as 20 V. Common-mode voltage interference usually presents as 60-Hz interference and often can be reduced by using properly placed shielded wires, good skin preparation, and an electrocardiographic amplifier that offers common-mode rejection.

Proper sensitivity setting of the amplifier and recorder is essential to make certain that large T waves are not “double-counted” in the rate determination. Additional filtering is occasionally required for patients who have pacemakers—in whom the pacer spike is interpreted as a QRS complex.

► Blood Pressure Monitoring

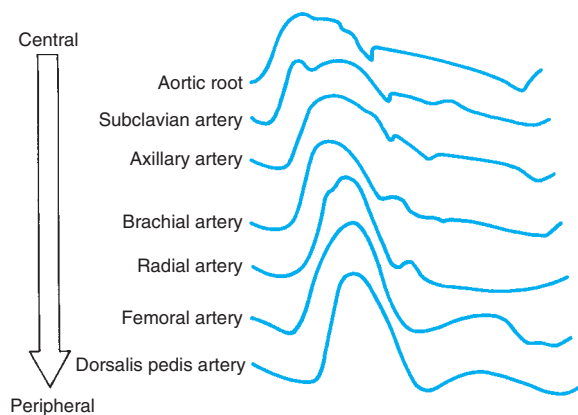

Because systemic blood pressure is related to both cardiac function and the peripheral circulation, blood pressure monitoring provides information related to the overall circulatory condition. While blood pressure monitoring is standard and universal for critically ill patients, the type of blood pressure monitoring and its frequency should be chosen based on the individual patient’s diagnosis and condition.

Blood pressure represents lateral force exerted on the vasculature by flowing blood. Pressure is maximal shortly after ventricular systole (SBP). The diastolic pressure (DBP) follows cardiac diastole and is the lowest pressure in the cycle. The mean arterial pressure (MAP) represents the standing pressure in the arterial circuit and is calculated as follows:

$$\text{MAP} = \frac{(\text{SBP} + 2 \times \text{DBP})}{3}$$

Pulse pressure is the arithmetic difference between the systolic and diastolic pressures. Pulse pressures vary with stroke volume or vascular compliance. Pulse pressures less than 30 mm Hg are common with hypovolemia, tachycardia, aortic stenosis, constrictive pericarditis, pleural effusions, and ascites. Widened pulse pressures may be due to aortic regurgitation, thyrotoxicosis, patent ductus arteriosus, arteriovenous fistula, and coarctation of the aorta. Variability of pulse pressure and systolic pressure during the respiratory cycle has been correlated with response to intravascular fluid repletion.

The initial upstroke and peak of the arterial waveform are produced by left ventricular ejection. The end of systole is marked by a brief decline in pressure until the aortic valve closes and redirects backflowing blood into the aorta. The “dicrotic notch” so created may be detected on recordings obtained from aortic or proximal arterial sites. The waveform becomes more peaked and of higher amplitude as it progresses distally. The initial upstroke is prolonged, producing a higher systolic and a lower diastolic pressure (Figure 8–2).

▲ **Figure 8–2.** The shape of the arterial pressure wave front changes as it progresses distally. The systolic peak becomes more pronounced, as does the dicrotic notch. (Reproduced, with permission, from Morgan GE, Mikhail MS: *Clinical Anesthesiology*. Originally published by Appleton & Lange. Copyright © 1992 by The McGraw-Hill Companies, Inc.)

The velocity of blood flow is slowest in the largest arteries because they are distensible and absorb energy from the pressure wave front. The pulse wave travels at a rate of 7–10 m/s in large arteries such as the subclavian artery and increases to 15–30 m/s in smaller distal arteries.

When a pressure wave front enters a small, nondistensible artery, part of the wave may be reflected back proximally. If a reflected wave strikes an oncoming wave, the two summate, causing a higher pressure than would occur otherwise. This phenomenon produces pressures in the distal peripheral arteries that paradoxically may be more than 20–30 mm Hg above those recorded in the aorta.

Arterial pressure depends on cardiac output (CO) and systemic vascular resistance (SVR). The latter is calculated as follows:

$$\text{SVR} = \frac{(\text{MAP} - \text{CVP})}{\text{CO}} \times 80$$

When MAP and CVP (central venous pressure) are in millimeters of mercury and CO is in liters per minute, SVR is expressed in dynes \times seconds \times cm⁻⁵. Evaluation of the equation indicates that an increase in either SVR or CO will increase mean arterial pressure.

Clinical Applications

Arterial blood pressure can be assessed either by direct instrumentation of the vascular tree or by indirect means. The indirect technique usually involves inflating a cuff to occlude an artery. As the cuff is deflated and inflow resumes, arterial pressure can be determined.

A. Noninvasive Arterial Pressure Monitoring—

1. PALPATION—A blood pressure cuff is placed above an easily palpated artery and inflated until pulsation ceases. On cuff deflation, systolic pressure is estimated as that pressure at which pulsation resumes. This method is limited because it underestimates true arterial pressure and does not provide a diastolic pressure.

2. AUSCULTATION (RIVA-ROCCI METHOD)—When an occluding proximal cuff is deflated below systolic pressure, flow begins through the compressed artery. The turbulent flow thus created strikes the walls of the vessel, causing them to reverberate (Korotkoff sounds). As long as the cuff pressure is higher than diastolic pressure, no flow will occur during diastole. The sound thus produced is rhythmic in nature. Once the pressure in the cuff is below diastolic pressure, flow occurs throughout the cardiac cycle, and the sounds disappear. A cuff 20% wider than the diameter of the limb must be used to obtain correct sphygmomanometric pressures. If the cuff is too narrow, the systolic and diastolic pressures will be artificially increased, and vice versa. Other sources of error include too-tight or too-loose cuff application and too-rapid or too-slow cuff deflation.

Unduly slow deflation produces venous congestion, which decreases the amplitude of the Korotkoff sounds as the cuff pressure nears the diastolic pressure.

When compared with intraarterial pressure measurements, those obtained by auscultation differ by 1–8 mm Hg systolic and 8–10 mm Hg diastolic. At intraarterial pressures below 120 mm Hg systolic, auscultation tends to overestimate pressure, whereas above 120 mm Hg, auscultation underestimates arterial pressure.

3. OSCILLOMETRY—The oscillometer uses two cuffs in series; one occludes the artery proximally, whereas the other detects the onset of pulsations. Slow deflation of the proximal cuff produces aneroid needle oscillation or mercury column variation at systolic pressure. Oscillometry is the only noninvasive technique capable of indicating mean arterial pressure, which coincides with maximum deflection of the manometer. Although diastolic pressure is defined as that point at which oscillation ceases, measurement of diastolic pressure is in fact inaccurate. Oscillometry requires several cardiac cycles to measure blood pressure accurately.

Automated oscillometry devices generally use single-bladder cuffs that are alternately inflated and deflated. On deflation, alterations in cuff pressure are sensed by a transducer inside the instrument. Pairs of oscillations and corresponding cuff pressures are stored electronically to permit measurement of the systolic and diastolic pressures. Use of these automated devices is limited in those with irregular rhythms or when motion cannot be minimized. In addition, measurements tend to be unreliable in low-flow states.

4. PLETHYSMOGRAPHY—Arterial pulsations produce minute changes in the volume of an extremity. Such alterations in finger volume can be detected photometrically with a plethysmograph. These devices tend to be less accurate than alternative pressure monitoring techniques, particularly during low-flow and stress conditions.

5. DOPPLER—The Doppler principle states that any moving object in the path of a sound beam will alter the frequency of the transmitted signal. The sound beam used to “insonate” tissue is created by applying an electrical potential to a crystal that causes it to oscillate in the radiofrequency spectrum. This sound is coupled to the tissue of interest through an acoustic gel.

When the beam strikes moving blood cells, the frequency of the reflected beam is altered in a manner proportionate to the velocity of the reflecting surface. Continuous- and pulsed-wave Doppler equipment is currently available. Continuous-wave transducers have two crystals mounted together in a single probe. One is continuously transmitting, and the other is continuously receiving. Only the velocity of flow and its direction can be determined by a continuous-wave device. Because a Doppler shift occurs only when blood moves relative to the transducer, an angle correction must be applied:

$$\Delta f = \frac{2 f_e v (\cos \theta)}{C}$$

where Δf is the frequency shift, f_e is the frequency of the insonating beam, V is blood velocity, θ is the incident angle of insonation, and C is the velocity of sound in tissue.

The depth of tissue penetration by the sound beam is inversely proportional to the frequency of insonation. Because arteries of interest are typically superficial, a 10-MHz probe can be used. As can be seen from the equation, the largest frequency shift is obtained when the probe is held parallel to the artery. Perpendicular positioning decreases the frequency shift ($\cos \theta \rightarrow 0$). Doppler blood pressure measurements are obtained by placing an ultrasonic probe on an artery distal to a compressing cuff.

Doppler sounds become apparent when cuff pressure falls below arterial pressure. Arterial pressures obtained using a Doppler probe usually are higher than those obtained by palpation and lower than those obtained by direct measurement, although the overall correlation is excellent. An automated device (Arteriosonde) is available for Doppler measurements. It uses a 2-MHz insonation frequency directed at the brachial artery. Overall accuracy is very good—especially at low pressures, when ultrasonic and palpatory techniques are more accurate than auscultation. Disadvantages include motion sensitivity, requirement for accurate placement, and the need to use a sonic transmission gel.

B. Invasive Pressure Monitoring—Insertion of a catheter into an artery is the most accurate technique for pressure monitoring. Such catheters are connected by tubing to pressure transducers that convert pressure into electrical signals. Because arterial pressure waves are themselves too weak to generate electrical impulses, most transducers actually measure the displacement of an internal diaphragm. This diaphragm is connected to a resistance bridge such that motion of the diaphragm modulates an applied current. The transducer’s sensitivity is the change in applied current for a given pressure change.

Because transducers are ultimately mechanical, they absorb energy from the systems they monitor. If absorbed energy in the transducer’s diaphragm is suddenly released, it will begin to vibrate at its natural (resonant) frequency. The tendency for this oscillation to stop depends on the damping of the system. Oscillating frequency increases as damping decreases. The resonant frequency is a function of the natural frequency and the damping coefficient. Classically, a system’s damping coefficient is determined by applying and releasing a square pressure wave (Figure 8–3).

Damping increases when compliance increases. Soft (compliant) connecting tubing absorbs transmitted pressure waves and damps the system. Other factors that increase damping include air in the transducer dome or tubing, excessively long or coiled tubing, connectors containing diaphragms, and the use of stopcocks. Because air is more compressible than water, even small bubbles increase the system damping. Excessive damping results in underestimation of systolic pressure and overestimation of diastolic pressure. There is little effect on mean pressure. Underdamped systems produce the opposite effects. Additionally, systems with

DAMPING:

$$\text{Amplitude ratio} = \frac{D_2 \text{ (mm)}}{D_1 \text{ (mm)}} = \frac{13}{22.5} = 0.58$$

$$\text{Damping coefficient} = \beta = \sqrt{\frac{\left(\ln \frac{D_2}{D_1}\right)^2}{\pi^2 + \left(\ln \frac{D_2}{D_1}\right)^2}} = 0.17$$

Amplitude ratio (D ₂ /D ₁)	Damping coefficient

NATURAL FREQUENCY:

$$\begin{aligned} \text{Natural frequency} = fn &= \frac{1}{2\pi} \sqrt{\frac{\pi D^2 \Delta P}{4\rho L \Delta V}} = \frac{\text{Paper speed (mm/sec)}}{\text{Length of 1 cycle (mm)}} \\ &= \frac{25 \text{ mm/sec}}{2 \text{ mm}} = 12.5 \text{ HZ} \end{aligned}$$

D = Internal diameter of tubing

ρ = Density of blood

L = Length of tubing

$\frac{\Delta P}{\Delta V}$ = Compliance ("stiffness") of system

▲ **Figure 8-3.** The amplitude ratio obtained by measuring the amplitude of oscillations after pressure release. Either the listed formula or the tables then can be used to calculate the damping coefficient. (Reproduced, with permission, from Morgan GE, Mikhail MS: *Clinical Anesthesiology*. Originally published by Appleton & Lange. Copyright © 1992 by The McGraw-Hill Companies, Inc.)

insufficient compliance tend to “ring” when rapid pressure changes cause oscillations within the system. Conversely, overdamping decreases the frequency response to the point that rapid changes in pressure may not occur. The effect of damping on the natural frequency of the system is illustrated in Figure 8–4. The optimal damping coefficient is near 0.7 because there is essentially no effect on amplitude until the measured frequency approaches the natural frequency of the measuring system.

Clinical Applications

The arteries commonly used for invasive blood pressure monitoring, in order of usual preference, are the radial, ulnar, dorsalis pedis, posterior tibial, femoral, and axillary arteries. The radial artery is preferred because of its ease of cannulation and relatively low incidence of serious complications. The ulnar artery is the dominant artery to the hand in 90% of patients. It connects with the radial artery through the palmar arches in 95% of patients. Because vascular

insufficiency may result from occlusion of the dominant artery, all patients should undergo an Allen test prior to catheter insertion, and the results should be entered into the medical record. However, one prospective study has demonstrated that vascular complications were not reliably related to results of the Allen test. Overall, there is a 10% incidence of arterial occlusion in adults cannulated with 20-gauge Teflon catheters for a period of 1–3 days. The use of 22-gauge catheters seems to reduce this incidence.

For unknown reasons, women have a lower incidence of arterial thrombosis than men. When thromboses do occur in women, occlusions are usually temporary. Distal occlusion of the radial artery may cause overestimation of systolic pressure because of increased wave reflection, whereas proximal occlusion usually causes reduction in pressure owing to overdamping. Another complication of arterial catheters is infection, most commonly limited to the skin but sometimes involving the artery as well; distal septic emboli rarely occur. The incidence and severity of such infections can be minimized by strict adherence to policies of daily catheter

▲ **Figure 8–4.** The amplitude ratio depends on the natural frequency of the system and the damping ratio (h). A system that operates below its natural frequency and with a damping ratio near 0.7 is desirable. (Reproduced, with permission, from Fry DL: Physiologic recording by modern instruments with particular reference to pressure recording. *Physiol Rev* 1960;40.)

▲ **Figure 8-5.** The height of the transducer must be adjusted to the phlebostatic axis to ensure accuracy of the pressure measurements.

inspection, sterile dressing changes, and limiting catheterization to 5 days or less at any single site. Pseudoaneurysm formation may be a late complication of arterial catheters. The incidence of pseudoaneurysms may be minimized by using smaller catheters, minimizing the duration of catheterization, and preventing catheter infections.

Physiologic pressures are measured with reference to the tricuspid valve, where intravascular pressure is defined as zero. This phlebostatic axis is independent of changes in body habitus. Postural changes affect the reference pressure by less than 1 mm Hg. The phlebostatic point is identified as (1) 61% of the way from the back to the front, (2) exactly in the midline, and (3) one-quarter of the distance above the inferior tip of the xiphoid process. A convenient method of system calibration is to move an open stopcock attached by fluid-filled connecting tubing to the transducer up against the patient's midaxillary line. The digital display on the monitor indicates whether the midaxillary line is above (positive pressure) or below (negative pressure) the transducer. The bed is then moved up or down until the pressure reads zero (Figure 8-5).

Calibration of the monitor for nonzero pressure can be done internally or externally. External calibration can be done with a mercury manometer for systemic arterial pressures. A convenient method adequate for the lower pressure range required for a pulmonary artery catheter (up to 60 cm H₂O) takes advantage of the fluid-filled connecting tubing. After establishing the zero reference, move an open stopcock connected to the transducer above the transducer a measured amount. The height above the transducer in *centimeters* (cm H₂O pressure) should be read by the monitor system in *millimeters of mercury* as height in centimeters divided

by 1.36. Therefore, if the system is calibrated accurately, the pressure reading should be about 14.8 mm Hg when the stopcock is raised 20 cm above the transducer.

An additional use of arterial catheterization is to provide access for arterial blood sampling. This is often indicated in patients who require frequent sampling of blood for arterial blood gases or other blood tests.

▶ Central Venous Catheters

Central venous (CV) catheters are inserted via the subclavian, internal jugular, or a peripheral vein in the arm. Femoral venous catheters are not long enough to reach "central" veins but provide similar access for intravenous

infusions. For monitoring purposes, CV catheters provide estimates of central venous pressure (CVP) and measurement of central venous oxygen saturation ($ScvO_2$). Central venous pressure (CVP) reflects the balance between systemic venous return and cardiac output. In the normal heart, the right ventricle is more compliant than the left. This difference in compliance accounts for the slope of their corresponding Frank-Starling curves. The use of CVP to assess left-sided preload causes difficulty because CVP primarily reflects changes in right ventricular end-diastolic pressure and only secondarily reflects changes in pulmonary venous and left-sided pressures. The relationship between CVP and venous return is shown in **Figure 8–6A**. Decreasing right atrial pressure below zero does not significantly increase CVP because of collapse of the vasculature leading to the chest. The figure also demonstrates that changes in mean systemic pressure cause a parallel change in venous return. Alterations in vascular resistance (decreased by anemia, arteriovenous fistulas, pregnancy, or thyrotoxicosis) change the slope of the respective curves (**Figure 8–6B**).

A water manometer may be used to measure CVP. The normal range of CVP is between -4 and $+10$ mm Hg (-5.4 and $+13.6$ cm H_2O).

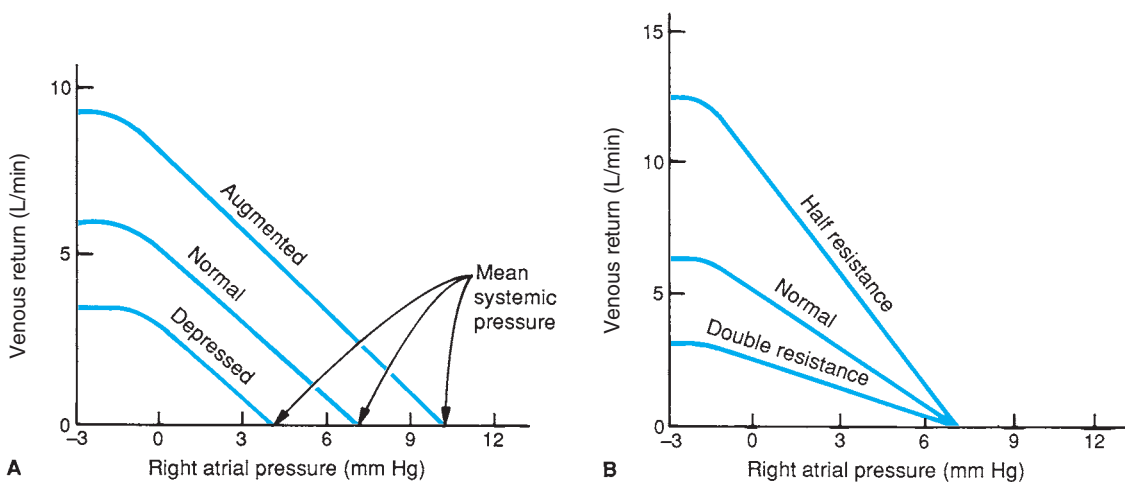

An electronic transducer also displays the pressure waveform. The bandwidth of a catheter-transducer system used to monitor CVP can be significantly narrower than that used for arterial pressure.

A typical CVP waveform has three positive deflections (a , c , and v) and two descents (x and y) (**Figure 8–7**). The increase in venous pressure caused by atrial contraction produces the a wave. The c wave is created when the tricuspid valve is displaced into the right atrium during initial ventricular

contraction. The x descent corresponds to the period of ventricular ejection, when blood empties from the heart; it is inscribed when the ventricle draws down on the floor of the atrium and decreases the CVP. The v wave is produced by the increase in atrial pressure that takes place as venous return continues while the tricuspid valve is closed. The y descent occurs when the tricuspid valve opens at the conclusion of ventricular contraction, and blood enters the right ventricle. The a wave is absent during atrial fibrillation and is magnified by tricuspid stenosis (cannon wave). The x descent also may be absent with atrial fibrillation. The x and y descents are both exaggerated by constrictive pericarditis. Cardiac tamponade magnifies the x descent while abolishing the y descent. When tricuspid regurgitation occurs, the c wave and the x descent are replaced by a large single regurgitant wave. Pulmonary hypertension decreases right ventricular compliance and accentuates the v wave.

Clinical Applications

A. CVP Monitoring—CVP monitoring is best used for patients without preexisting cardiac disease as one indicator of the adequacy of venous return and cardiac filling. An intravenous fluid challenge is employed to aid in determining whether decreased blood pressure is due to hypovolemia or to cardiogenic failure. Measurements of CVP are affected by ventilation because transthoracic pressure is transmitted through the pericardium and the thin-walled venae cavae. During spontaneous ventilation, inspiration lowers CVP, and exhalation increases it. The situation is reversed in patients being mechanically ventilated, in whom inspiration increases intrathoracic pressure and elevates CVP.

▲ **Figure 8–6.** **A.** Effect of mean systemic pressure on venous return. **B.** Effect of systemic vascular resistance on venous return. (Reproduced, with permission, from Otto CW: Central venous pressure monitoring. In: Blitt CD (ed), *Monitoring in Anesthesia and Critical Care*. New York: Churchill Livingstone, 1985. Copyright 1985 Elsevier.)

▲ **Figure 8-7.** Effect of mechanical ventilation on central venous pressure. The *a*, *c*, and *v* waves along with the *x* and *y* descents are shown. (Reproduced, with permission, from Otto CW: Central venous pressure monitoring. In: Blitt CD (ed), *Monitoring in Anesthesia and Critical Care*. New York: Churchill Livingstone, 1985. Copyright 1985 Elsevier.)

The degree of this elevation depends on the compliance of the lungs and intravascular volume and will vary among patients. For this reason, CVP measurements are best made and compared at end expiration. When positive end-expiratory pressure (PEEP) is applied, the positive pressure is transmitted through to the right atrium, causing a decrease in venous return and a rise in CVP. Again, the magnitude of this effect of PEEP on CVP varies with pulmonary compliance and blood volume. Some argue that the patient should be temporarily removed from PEEP while the measurement is taken. This is both impractical and potentially dangerous. In critical situations, an esophageal probe can be inserted to estimate transthoracic pressure. Subtracting the transthoracic pressure from the CVP provides transmural pressure, which is a better estimate of right atrial pressure in the presence of elevated transthoracic pressure.

B. Central Venous O₂ Saturation—Mixed venous oxygen saturation ($S\bar{V}O_2$) reflects the relative delivery of O₂ to the tissues compared with consumption. If lower than normal, concern should be raised about tissue hypoxia. True $S\bar{V}O_2$ must be measured in the pulmonary artery. Central venous O₂ saturation ($ScvO_2$) does not require a pulmonary artery catheter, but theoretically, the value will differ from $S\bar{V}O_2$ because $ScvO_2$ obtained from a subclavian or internal jugular vein does not reflect venous blood returning via the inferior vena cava or coronary sinus. Generally, $ScvO_2$ is about 5% higher than $S\bar{V}O_2$.

In practice, however, $ScvO_2$ appears to have similar predictive value for end-organ hypoxia as $S\bar{V}O_2$. Recent studies emphasizing early goal-directed therapy in sepsis have emphasized a target $ScvO_2$ of greater than 70% by giving blood transfusion and cardiac inotropic drugs. $ScvO_2$ can be obtained from a small sample of blood drawn back through the catheter or by using an oximeter-tipped CVP catheter.

C. Complications—Inadvertent arterial insertion occurs about 2% of the time; such insertion is particularly dangerous if large, rigid “introducer” catheters are inserted. Perforation of the superior vena cava is associated with a 67% mortality rate, whereas the rate associated with laceration of the right

ventricle approaches 100%. Such perforations may occur either from guidewires or from catheter erosion—again, particularly with introducer catheters. Other structures that may be injured on insertion include the brachial plexus, the stellate ganglion, and the phrenic nerve. Air emboli are uncommon at insertion but more often during use or at the time of removal when the patient is not positioned properly. Late complications are due to catheter migration, embolization, and infection. The incidence of cannula-related thrombosis of the axillary and subclavian veins varies between 16.5% and 46%. Central venous catheter infections occur in approximately 5% of insertions. The organisms most commonly involved are *Staphylococcus epidermidis*, 30%; *Staphylococcus aureus*, 8%; streptococci, 3%; gram-negative rods, 18%; diphtheroids, 2%; *Candida* species, 24%; and other pathogens, 15%. Both colonization of central venous catheters and systemic sepsis are reduced by routine catheter care and periodic removal and reinsertion.

► Pulmonary Artery Catheterization

Catheterization of the pulmonary artery is a useful addition to CVP monitoring. It provides information related to left heart filling pressures and allows sampling of pulmonary artery blood for determination of mixed venous oxygen saturation. Thermodilution cardiac output measurements are made using a thermistor-tipped catheter.

As the balloon flotation catheter is advanced through the heart, characteristic pressure waveforms are obtained that indicate the position of the catheter's distal port (Figure 8–8). Simultaneous electrocardiographic monitoring ensures that ventricular tachyarrhythmias will be detected as the catheter traverses the right ventricle. After a pulmonary artery capillary wedge tracing is obtained, the catheter should be deflated and withdrawn until only 1 mL of inflation is required to advance from a pulmonary artery to a capillary wedge tracing. Insertion of excessive catheter length contributes to intracardiac knotting. If subsequent pressure tracings are not obtained within 15 cm of additional insertion, looping should be suspected. When the catheter is placed through either the subclavian or the jugular vein, the typical distances required are as follows: right atrium, 10–15 cm; right ventricle, 20–30 cm; pulmonary artery, 45–50 cm; and pulmonary capillary wedge, 50–55 cm. As the catheter

passes through the right ventricle, a wedgelike pressure tracing may be obtained. This “pseudowedge” is due to engagement of the catheter tip beneath the pulmonary valve or within trabeculations. Withdrawal of 10 cm of the catheter will solve the problem. Overinflation of the balloon, causing it to herniate over the tip of the catheter, results in a pressure tracing that continues to rise to high levels. The balloon should be deflated and a short length of catheter withdrawn before further advancement is attempted.

The final position of the catheter tip within the pulmonary artery is critical. This may be described with reference to three lung zones that depend on the relationship of airway and vascular pressures (Figure 8–9). In zones I and II, mean airway pressure is intermittently greater than pulmonary venous pressure, which results in collapse of the vasculature between the catheter tip and the left atrium. In this position, observed pressures will be more indicative of airway pressure than of left atrial pressure. Only in zone III is there an uninterrupted column of blood between the catheter and the left atrium. In the supine position, zone III assumes a more dependent position, caudal to the atrium. Decreased airway pressures change the ventilation-perfusion relationship, producing a relative increase in zone III. Hypovolemia decreases vascular pressures and decreases zone III.

Correct catheter position should be ensured by chest x-ray. Although most catheters migrate caudally and to the right, an occasional catheter will become wedged anterior to the vena cava. In this position, true pulmonary capillary pressures may be less than alveolar pressures, resulting in spuriously elevated measurements. A lateral chest x-ray will

▲ **Figure 8–8.** Normal pressures and waveforms obtained as a pulmonary artery flotation catheter is advanced from the right atrium to a pulmonary artery wedge position. ▲ **Figure 8-9.** The effect of airway pressure on the pulmonary vasculature is divided into three zones. A pulmonary artery flotation catheter should wedge in zone III, where there is a continuous column of blood between the pulmonary capillary and the left atrium. (Reproduced, with permission, from West JB, Dollery CT, Naimark A: Distribution of blood flow in isolated lung: Relation to vascular and alveolar pressures. *J Appl Physiol* 1964;19:713.)

demonstrate when the catheter has assumed this position. Indicators of proper tip placement include (1) a decline in pressure as the catheter moves from the pulmonary artery into the “wedged” position, (2) ability to aspirate blood from the distal port (eliminating the possibility of overwedging), and (3) a decline in end-tidal CO_2 concentration with inflation of the balloon (produced by a rise in alveolar dead space). In a patient receiving positive end-expiratory pressure (PEEP), another indicator of correct positioning is an increase pulmonary capillary wedge pressure less than 50% of any increase in PEEP. This is so because normal lung and chest wall compliances are approximately equal at end expiration. Therefore, intrathoracic pressure will increase by 50% of PEEP, and pulmonary capillary wedge pressure also will increase by at most 50%. Lung disease (decreased lung compliance generally) will distort this relationship, but almost always to less than 50%. If the pulmonary capillary wedge pressure rises more than 50% of the PEEP, repositioning must be considered.

The pulmonary capillary wedge (pulmonary capillary occlusion) pressure (PCWP) estimates left ventricular end-diastolic pressure and thus serves as an estimate of left ventricular preload. Because the pulmonary vasculature is a low-resistance circuit, the pulmonary artery end-diastolic pressure in normals is usually only 1–3 mm Hg higher than

the mean pulmonary capillary wedge pressure and has been used to estimate left ventricular pressure when the pulmonary capillary wedge pressure is not available—but this is unreliable and inconsistent in the case of lung disease, pulmonary hypertension, or tachycardia. Normal values for pulmonary artery catheter pressures are shown in Figure 8-8.

Pulmonary capillary filtration pressure (P_{cap}) is a measure of the potential difference that drives fluid from the pulmonary vasculature into the perivascular interstitial and alveolar spaces. The contribution of hydrostatic and osmotic pressure differences to fluid filtration is described by Starling’s law. The equation relating mean PA pressure, PCWP, and P_{cap} is

$$P_{\text{cap}} = \text{PCWP} + 0.4 \times (\text{PA} - \text{PCWP})$$

Adult respiratory distress syndrome (ARDS) widens the PA-to-PCWP gradient and increases P_{cap} , contributing to pulmonary edema.

Clinical Applications

A. Pressure Measurements—In most instances, PCWP is an accurate indicator of left ventricular end-diastolic pressure. Correlation between CVP and PCWP may be poor in critically ill patients with cardiopulmonary disease because

of differences between right and left ventricular function. In this group, both absolute values and relative changes in CVP are unreliable because alterations in the pulmonary vascular bed affecting the right side of the heart do not equally affect the left ventricle. This is of particular importance following pulmonary embolization, which increases right ventricular afterload without affecting left ventricular end-diastolic pressure. CVP and pulmonary systolic and diastolic pressures are all elevated, whereas PCWP is decreased because of the decline in forward flow.

PCWP correlates best with left atrial pressure (LAP) when the latter is less than 25 mm Hg. However, PCWP will be lower than LAP in hypovolemic patients, whose pulmonary vasculature collapses during peak inspiration. When LAP increases to more than 25 mm Hg—which may occur after acute myocardial infarction with decreased left ventricular compliance—PCWP tends to underestimate left-ventricular end-diastolic pressure (LVEDP). As left ventricular function deteriorates, the contribution that atrial contraction makes to left ventricular filling is increased, and LVEDP can be significantly higher than PCWP. Several conditions affect the accuracy of PCWP as an indicator of LVEDP. In mitral stenosis, left atrial pressure at end diastole may be significantly higher than left ventricular pressure. This is diagnosed by the presence of large *v* waves on a PCWP tracing. Large left atrial myxomas also elevate PCWP. Aortic regurgitation produces an underestimation of LVEDP by PCWP because the mitral valve closes early despite increasing left ventricular pressure. Mitral regurgitation results in accentuation of LVEDP because of backward flow during systole. Pericardial tamponade restricts filling of all four cardiac chambers and results in an equalization of CVP and PCWP because all such pressures are under the restrictive influence of the tamponade. Positive end-expiratory pressure (PEEP) adversely affects the ability of PCWP to monitor left ventricular preload. High positive airway pressures (PEEP >15 mm Hg) can result in pulmonary vascular collapse, causing PCWP to reflect airway pressure instead of left atrial pressure (conversion from zone III to zone I). As with CVP, an esophageal pressure transducer permits calculation of transmural rather than transthoracic pressures. However, because pulmonary compliance is not disturbed uniformly, the pressure obtained through the esophageal probe may not correctly reflect the pressure that surrounds the pericardium.

While PCWP often closely estimates LVEDP, these values may not accurately reflect true LV preload, which is a function of LV end-diastolic volume and stretch of myocardium. Patients with LV hypertrophy, diastolic heart failure, and LV ischemia have distorted relationships between LVEDP and ventricular preload. Consequently, a single PCWP measurement may be less helpful than therapeutic trials of volume loading or diuretics with serial measurements.

B. Mixed Venous Oxygen Saturation—Mixed venous oxygen saturation ($S\bar{v}O_2$) is obtained from blood from the pulmonary artery drawn out of the distal port of the catheter.

Pulmonary artery blood should be withdrawn slowly to avoid inadvertently pulling “pulmonary capillarized” blood with a misleadingly higher O_2 saturation.

Mixed venous oxygen saturation is an indicator of systemic oxygen utilization. Normally, peripheral oxygen consumption ($\dot{V}O_2$) is independent of oxygen delivery (DO_2). Therefore, as cardiac output and oxygen delivery decline, peripheral oxygen extraction increases to keep consumption constant. This results in decreased mixed venous oxygen saturation. Conversely, sepsis may cause a reduction in peripheral oxygen consumption, thereby increasing mixed venous oxygen saturation.

The partial pressure of oxygen in mixed venous blood is normally about 40 mm Hg, resulting in a hemoglobin saturation of 75%. Oxygen content can be calculated for both arterial and venous hemoglobin saturations (%Sat Hb) using the following formula:

$$C_{xO_2} = 1.34 \times Hb \times \%Sat + (0.0031 \times P_{xO_2})$$

If hemoglobin concentration is in grams per deciliter, oxygen content is expressed in milliliters per deciliter. Dissolved oxygen ($0.0031 \times P_{O_2}$) contributes minimally to oxygen content but may become significant in patients who are profoundly anemic. The normal arteriovenous oxygen content difference— $C(a-v)O_2$ —is 5 mL/dL. Hypovolemia and cardiogenic shock both increase the difference (>7 mL/dL), whereas sepsis decreases it (<3 mL/dL). Left-to-right intracardiac shunts produce a significant step-up in hemoglobin saturation in the right ventricle and therefore decrease the $C(a-v)O_2$ gradient.

Mixed venous saturation can be obtained continuously from pulmonary artery catheters with integral fiberoptic oximetry capabilities. Dual oximetry combines mixed venous and arterial pulse oximetry ($SpaO_2$) to provide continuous estimates of oxygen extraction and intrapulmonary shunting. From continuous oximetry data, the ventilation-perfusion index ($\dot{V}/\dot{Q}I$) can be calculated by the following equation:

$$\frac{\dot{V}}{\dot{Q}I} = \frac{1.32 + Hb \times (1 - SpaO_2) + (0.0031 \times PAO_2)}{1.32 \times Hb \times (1 - S\bar{v}O_2) + (0.0031 \times PAO_2)}$$

where PAO_2 is alveolar oxygen tension, calculated from the alveolar gas equation. $\dot{V}/\dot{Q}I$ correlates well with shunt (\dot{Q}_s/\dot{Q}_t) over a wide range of parameters and clinical conditions.

C. Complications—Complications of pulmonary arterial catheterization may occur both on insertion and subsequently. The incidence of a pneumothorax with either the subclavian or internal jugular approach is 2–3%. Catheter knotting is related to the size of the catheter and the insertion length. Smaller catheters knot more frequently, as do those with excessive redundancy in the ventricle. The incidence of catheter-induced transient right bundle branch block is

between 0.1% and 0.6% and is thought to be caused by direct trauma to the bundle of His. The incidence increases to as high as 23% in patients with preexisting left bundle branch block. Ventricular arrhythmias also may occur, although they are usually transient and do not require treatment. Other complications that may occur during insertion include tracheal laceration, innominate artery injury, and bleeding.

Pulmonary artery rupture may occur at the time of placement, as a result of laceration by the catheter tip, or subsequently, from overinflation of the balloon in the distal pulmonary artery. The overall incidence of rupture is substantially less than 1%. Contributory factors include distal position of the catheter, decreased vessel diameter (primary pulmonary hypertension), systemic anticoagulation, and prolonged balloon inflation. Hemoptysis is usually the presenting sign. The need for complete removal of the catheter is debatable because the requirements for monitoring are compounded by the complication. The catheter should be withdrawn to a more proximal site and the patient positioned with the affected side down to optimize ventilation-perfusion relationships. Emergency thoracotomy is required in rare cases when uncontrolled bleeding occurs.

Air embolism occurs most commonly with tubing changes and transducer calibrations. Approximately 20 mL/s of air is required in adults before symptoms appear, with 75 mL/s required to produce hemodynamic collapse and death. The precipitating cause is mechanical obstruction of right ventricular outflow by the air embolus. Patients should be placed in the left decubitus and steep Trendelenburg position. This puts the outflow tract in a dependent location and allows the air to rise in the ventricle. Aspiration of air through the pulmonary artery catheter has been reported with varying results. Obstruction of the pulmonary vasculature by the embolus results in hypoxemia, increased pulmonary artery pressure, and right ventricular dysfunction. Passage of air through a patent foramen ovale may cause cerebral embolization and stroke.

Thromboemboli may originate from the tip or body of the catheter and can result in pulmonary emboli. Catheters left in place for long periods may cause subclavian or jugular venous thrombosis. Other complications include infective endocarditis, sepsis, aseptic thrombotic endocarditis, and rupture of the chordae tendineae.

The avoidance of sepsis from pulmonary arterial catheters is identical to the protocols for central venous catheters. Daily sterile catheter care, dressing changes, and regular rotation of insertion sites are critical to minimize catheter-related infections.

► Cardiac Output

The bedside technique of measuring cardiac output by thermal dilution added a new dimension to ICU monitoring. When a known quantity of hot (or cold) solution (indicator) is injected into the circulation, a time-temperature curve may be produced that allows calculation of flow. The area under the time-temperature curve is inversely proportional to cardiac output. This is calculated using the Stewart-Hamilton indicator dilution equation:

$$\text{Cardiac output} = \frac{V_i \times (T_b - T_i) \times S_i \times C_i \times 60}{S_b \times C_b}$$

where V_i is the volume of injectate (mL) and T_b , T_i , S_i , S_b , C_b , and C_i are temperature, specific gravity, and specific heat of blood (B) and indicator (I), respectively.

$$\frac{S_i \times C_i}{S_b \times C_b} = 1.08 \text{ for } D_5W$$

Either iced or room-temperature thermal boluses can be used, although the use of iced fluid slightly improves the signal-to-noise ratio. Room-temperature boluses generally are adequate except when cardiac output is very low. For best results, the difference between the blood's temperature and that of the injectate should be at least 12°C, which is easily achieved with room-temperature injectate. Bolus injection speed and warming of the indicator as it passes through the catheter have only minimal effects ($\pm 3\%$). When technique is optimal, measurement repeatability is within 10%. Severe cardiac arrhythmias may reduce repeatability and yield results that may not accurately reflect average cardiac output. Timing of injection with a particular phase of respiration (end expiration) improves consistency of measurements. Excessive patient movement also may produce erratic results.

Continuous thermodilution cardiac output measurements can be obtained using special pulmonary artery catheters. In one type, the right ventricular segment of the catheter warms the blood by a small amount above body temperature. A sensitive downstream thermistor records the change in temperature. In another type, blood flow is estimated by how much electric current is needed to maintain a segment of the catheter at a temperature slightly above body temperature. Blood flow is directly related, but in a complex manner, to the amount of energy needed for a constant temperature. These methods correlate well with conventional bolus thermodilution but may differ in systematic or nonsystematic fashion.

Other Methods to Measure Cardiac Output

A. Indicator Dilution Cardiac Output—This technique relies on dilution of a colored dye. A bolus of dye is injected intravenously through a central venous catheter while peripheral arterial blood is withdrawn. The arterial sample is continuously passed through a densitometer. The area under the dye curve is calculated, and a modification of the Stewart-Hamilton equation is applied. This technique is rarely used in the ICU.

$$\text{Cardiac output} = \frac{60 \times \text{indicator dose (mg)}}{\text{average concentration} \times \text{time}}$$

B. Doppler Ultrasound—Doppler devices measure ascending aortic flow and calculate cardiac output. A continuous-wave Doppler probe is placed in the sternal notch to measure the velocity of aortic blood flow. A separate A-mode pulsed Doppler probe is centered in the third or fourth anterior intercostal space to measure the cross-sectional diameter of the aortic root. The stroke volume is the product of the cross-sectional area and the average blood velocity. Cardiac output is calculated by multiplying the heart rate and the stroke volume. Potential sources of error include (1) misalignment of the Doppler beam, which produces errors in measurement of blood velocity, (2) the assumption that the aorta is circular, and (3) the assumption that aortic blood flow is laminar. Each of these factors accounts for a cardiac output error that approaches 15% when compared with determinations obtained by other means. The difference between suprasternal Doppler ultrasound cardiac output and standard thermodilution has been reported to range from -4.9 to $+5.8$ L/min. An esophageal probe is now available that measures descending aortic flow. An insertion depth of about 30 cm is required to reach the esophageal “window.” The aortic root is sized using an A-mode pulsed Doppler, and a single measurement of ascending aortic flow is performed with a continuous-mode suprasternal probe. The esophageal probe is then calibrated against the cardiac output obtained by the suprasternal technique. This method

yields results as good as those obtained with the suprasternal technique and offers the added advantage of providing data continuously. A recently developed transtracheal probe uses a pulsed Doppler probe attached to the distal end of an endotracheal tube. Controlled studies have shown good accuracy, but extensive clinical experience is wanting.

C. Thoracic Bioimpedance—This noninvasive technique measures stroke volume by passing a small alternating current (2.5–4.0 mA) through the chest at radiofrequency 70–100 kHz. Four pairs of electrodes (one transmitter and one sensor) are required. Two pairs are placed at the base of the neck and two at the level of the xiphoid process in the midcoronal plane. The change in thoracic impedance is due to blood flow, ventilation, and body movement. Respiratory variations occur much more slowly than those associated with blood flow and can be eliminated by the computer algorithm. Similarly, motion artifacts can be rejected by special circuitry. The majority of systolic blood flow is due to pulsatile blood flow in the descending thoracic aorta. Stroke volume is obtained by analyzing the impedance change over a cardiac cycle. Heart rate is determined at the same time and multiplied by stroke volume to yield cardiac output. Other parameters obtained include ejection velocity index, thoracic fluid index, and ventricular ejection time. The thoracic fluid index is thought to correlate with extravascular lung water, whereas ejection time has been used as a parameter of cardiac function.

Because bioimpedance cardiac output measurements are noninvasive, they can be repeated frequently. The volume of electrically participating tissue (VEPT) is critical in determination of the stroke volume. Although changes in body habitus are included in the nomogram used to calculate VEPT, small changes can produce significant error. Similarly, electrode placement is important. A 2-cm change in the distance between the sensing electrodes will produce a 20% variation in recorded cardiac output. Overall correlation with thermodilution in adults has been only fair. The method is further limited by inaccuracies caused by dysrhythmias. Furthermore, readings are difficult during patient movement, including shivering. Cardiac output is overestimated when preload is reduced; in low-flow states, when inotropes are required; and with aortic insufficiency. Underestimation is produced by hyperdynamic sepsis, hypertension, and intracardiac shunts.

D. Fick Method—Cardiac output may be calculated by relating oxygen consumption to arterial and mixed venous oxygen saturation using Fick's equation:

$$\text{Cardiac output} = \frac{\dot{V}O_2}{C(a-v)O_2 \times 10}$$

Calculation of cardiac output using Fick's equation is the reference with which all other techniques are compared. The

arteriovenous oxygen content difference requires that a pulmonary artery catheter be placed to obtain mixed venous blood. Oxygen consumption is calculated by measuring the oxygen content difference between inspired and exhaled gas. A modification of this technique substitutes mixed venous CO₂ (rebreathing), arterial PCO₂, and expired volume of CO₂ for the corresponding oxygen values in the Fick equation.

E. Pulse Waveform Analysis—A noninvasive method that shows some promise despite varying reported accuracy uses algorithmic analysis of the arterial pulse waveform. The waveform bears a certain relationship with stroke volume but is modified a great deal by the capacitance, impedance, and other characteristics of upstream and downstream arterial beds. The aortic impedance plays a major role in this relationship and is likely to differ between patients. Thus “calibration” of a noninvasive system (or one using an arterial catheter) using the arterial waveform with thermodilution cardiac output has been necessary. Recently, several commercially available systems have been reported to have adequate agreement with conventional measurements.

Sources of Error

Use of correct temperatures and volumes is the most important factor contributing to accurate thermodilution cardiac output results. If the amount of indicator injected is less than the amount used in calculation, the fall in indicator temperature will be less than anticipated, and the cardiac output will be falsely elevated. Cardiac output also will be falsely elevated if the injectate is warmer than that used in the calculation. The latter problem has been largely overcome with

the introduction of new cardiac output computers that measure the injectate’s temperature and automatically enter the value into the calculation.

Right-to-left intracardiac shunt will result in loss of the indicator, causing a falsely elevated cardiac output. Left-to-right shunts permit recirculation of indicator that has already passed through the lungs. This produces multiple peaks in the time-temperature curve that cannot be interpreted by the cardiac output computer, resulting in a bad curve alert. When tricuspid regurgitation occurs, blood and indicator mix, resulting in prolongation of transit time. The curve produced has a slow upstroke and decay, thereby increasing the area underneath it. This causes sporadic readings and underestimation of the true cardiac output.

Derived Parameters

Cardiac output measurements may be combined with systemic arterial, venous, and pulmonary artery pressure determinations to calculate a number of hemodynamic variables useful in assessing the overall hemodynamic status of the patient (Table 8–1). Oxygen transport parameters also may be calculated (see below).

Cholley BP, Payen D: Noninvasive techniques for measurements of cardiac output. *Curr Opin Crit Care* 2005;11:424–9. [PMID: 16175028]

► Pulse Oximetry

Pulse oximetry affords a noninvasive estimate of arterial oxygen saturation using the change in light absorption across a

Table 8–1. Hemodynamic calculations and normal ranges.

	Formula	Normal Range
Stroke volume, mL	$\frac{1000 \times \text{CO (L/min)}}{\text{HR (beats/min)}}$	60–90 mL
Stroke volume index, mL/m ²	$\frac{\text{Stroke volume (mL/beat)}}{\text{BSA (m}^2\text{)}}$	30–65 mL
Cardiac index, L/min/m ²	$\frac{\text{CO (L/min)}}{\text{BSA (m}^2\text{)}}$	2.8–4.2 L/min/m ²
Systemic vascular resistance, dyne-s/cm ⁵	$\frac{[\text{Mean BP (mm Hg)} - \text{CVP (mm Hg)}]}{\text{CO (L/min)}} \times 80$	1200–1500 dyn-s/cm ⁵
Pulmonary vascular resistance, dyne-s/cm ⁵	$\frac{[\text{Mean PAP (mm Hg)} - \text{PAWP (mm Hg)}]}{\text{CO (L/min)}} \times 80$	100–300 dyn-s/cm ⁵

CO = cardiac output; BSA = body surface area; BP = systemic blood pressure; CVP = central venous pressure; PAP = pulmonary artery pressure; PAWP = pulmonary artery wedge pressure.

vascular bed during the arterial pulse. In the ICU, pulse oximetry has important uses and has become a standard of care in many institutions. There are, however, a number of issues that should be understood and considered with this monitoring technique. In particular, the reliability of this method may be limited in patients with severe hypoxemia, abnormal arterial pulsations, and hypoperfusion of the site of measurement.

When light of a particular wavelength is transmitted through a clear solvent containing solute that absorbs light at that wavelength, the amount of light absorbed is the product of solute concentration, path length, and the extinction coefficient (determined by the solute and the wavelength). For a hemoglobin solution, the relative concentrations of oxy- and deoxyhemoglobin can be determined in a spectrophotometer because the extinction coefficients are different for these two hemoglobin species at certain wavelengths.

Pulse oximetry uses the beat-to-beat changes in light absorption through a vascular bed to estimate arterial O_2 saturation, discarding any nonvariable light absorption by considering only the difference between peak and nadir light intensities. The method determines O_2 saturation by a complex calculation that includes several important assumptions. With the use of two light-emitting diodes (LEDs) producing light in the red and infrared ranges, pulse oximetry is able to estimate oxyhemoglobin as a proportion of the sum of oxyhemoglobin plus deoxyhemoglobin—the so-called functional oxyhemoglobin saturation. Pulse oximeters are “calibrated” by comparison of arterial blood oxygen saturation in volunteers to calculated values; the devices use a “look-up table” to translate the measured proportion to the displayed saturation. Pulse oximetry is subject to artifact-caused errors. Movement of the oximeter probe, extraneous incident light (especially if pulsatile), variations in arterial pulsation, dependent position, venous pulsations, and other factors may result in incorrect O_2 saturation readings. Pulse oximeters are most commonly transmission pulse oximeters, in which light is passed through tissue (ear or fingertip) to a sensor on the opposite side, but they may be reflectance pulse oximeters, in which light passes through tissue but is reflected back to a sensor on the same side as the light source.

Validity

The accuracy of pulse oximetry is generally considered good in the range of normoxia to mild hypoxemia. However, accuracy may be suspect during more severe hypoxemia, such as when arterial O_2 saturation is below 75%. In this range, differences between measured O_2 saturation and pulse oximetry saturation range from 5–12%.

A. Patient Factors—Patients in the ICU frequently have hypotension, poor distal extremity perfusion, and impaired oxygen delivery—or are being given pharmacologic vasopressors or vasodilators. These factors affect blood flow to the site of pulse oximetry and vary the contour and intensity of the beat-to-beat pulse used to calculate O_2 saturation. Most

devices are programmed to avoid reporting O_2 saturation when low perfusion or a poor pulse signal is being measured. In some of the few studies considering these issues in the ICU, failure of the pulse oximeter to measure O_2 saturation was not infrequent in patients with hemodynamic instability (12–15%). However, other studies have demonstrated that some pulse oximeters continue to measure and report O_2 saturation despite very poor blood flow and severe hypotension. These results may not be reliable, and there is concern that pulse oximeter O_2 saturation under these conditions may be misleadingly high. Pulse oximeter technology continues to evolve. The latest-generation devices have improved resistance to motion artifact and low perfusion. These are expected to be more reliable and accurate in the ICU setting.

B. Abnormal Hemoglobins—The pulse oximeter cannot measure carboxyhemoglobin nor accurately measure oxyhemoglobin in the presence of carboxyhemoglobin. The oxygen saturation displayed is essentially equal to the difference between total hemoglobin and deoxygenated hemoglobin (100% – the percentage of deoxyhemoglobin), but the relative concentrations of oxy- and carboxyhemoglobin are unknown. Other substances in the blood may or may not affect pulse oximetry. Bilirubin has little effect on pulse oximetry; methemoglobin, generated in the presence of oxidizing agents such as nitrites and sulfonamides, usually increases the difference between functional O_2 saturation and oxyhemoglobin, but a sufficiently high methemoglobin concentration also may have the peculiar effect of causing the pulse oximeter to read 85% regardless of other conditions. A number of dyes such as indocyanine green and methylene blue also have effects on the accuracy of measurement.

Clinical Applications

Pulse oximetry has widespread usefulness in the ICU, especially in adjusting inspired oxygen, during weaning from mechanical ventilation, and in testing different levels of PEEP, inverse I:E ratio, or other mechanical ventilator adjustments. Other uses include monitoring during procedures such as bronchoscopy, gastrointestinal endoscopy, cardioversion, hemodialysis, and radiography. Pulse oximetry is particularly accurate in following O_2 saturation in patients who have mild to moderate hypoxemia (O_2 saturation >75%) but without severe hypoperfusion or hypotension. It cannot be regarded as a complete substitute for arterial blood gas determinations partly because of the lack of PO_2 and pH determinations but also because of the relationship between PO_2 and O_2 saturation when the latter is above 90–95%. Results of pulse oximetry should be interpreted cautiously in patients with carboxyhemoglobinemia or methemoglobinemia.

Airway CO₂ Monitoring

A disposable colorimetric device that detects CO₂ can confirm endotracheal tube placement and position. When the device tests positively for CO₂, this confirms that the endotracheal tube is in the trachea. However, a negative result is not as reliable, and alternative means for checking tube placement must be used.

Continuous airway CO₂ monitoring uses a rapidly responding infrared CO₂ analyzer. *Capnography* is a continuous display or recording of CO₂ concentration during each breath. Other devices may display the end-tidal CO₂ fraction or partial pressure (PETCO₂).

The infrared analyzer uses an appropriate wavelength of infrared light for which the CO₂ concentration is proportionate to the absorption of the light. It has the advantage of relatively low cost, real-time sampling, reliability, ease of calibration, and acceptable response time.

Capnography shows a continuous display of expired and, if desired, inspired CO₂ concentration or partial pressure. The expired CO₂ waveform can give a qualitative assessment of the degree of ventilation-perfusion mismatching. For example, the steepness of the slope of the “alveolar plateau” indicates more severe \dot{V}/\dot{Q} mismatching because it demonstrates emptying of progressively less well ventilated lung units compared with a waveform showing a flatter alveolar plateau in a patient with less severe \dot{V}/\dot{Q} mismatching. The inspiratory segment also should be inspected to confirm that the inspired gas is free of CO₂ as a result of malfunction of the ventilator’s expiratory valve or some other component.

End-Tidal and Mixed Expired Pco₂

In normal subjects at rest and breathing at a normal tidal volume and respiratory rate, PETCO₂ is close numerically to arterial PCO₂, with the usual difference between PaCO₂ and PETCO₂ 0–4 mm Hg (P[a–ET]CO₂). In patients with respiratory failure, contribution to expired gas from dead space and high \dot{V}/\dot{Q} lung units decreases CO₂ concentration during expiration and at end expiration. The P(a–ET)CO₂ becomes increasingly large, with a strong correlation between P(a–ET)CO₂ and the dead space–tidal volume ratio. The PETCO₂ should not be used as a substitute for PaCO₂ in patients with lung disease. Furthermore, P(a–ET)CO₂ cannot be assumed to remain constant in the face of lung disease and mechanical ventilation.

The mixed expired CO₂ fraction or partial pressure (P \bar{E} CO₂) is usually determined from collection of expired gas for several minutes. This should be distinguished from PETCO₂ sampled at the end of a single breath. The mixed expired CO₂ fraction can be used with PaCO₂ to calculate the dead space–tidal volume ratio (V_D/V_T) using the modified Bohr equation:

$$\frac{V_D}{V_T} = \frac{P_{aCO_2} - P_{\bar{E}CO_2}}{P_{aCO_2}}$$

In addition, if minute ventilation is measured,

$$\dot{V}_{CO_2} (\text{L/min, STPD}) = 0.826 \times V_E (\text{L/min, BTPS}) \times \frac{P_{\bar{E}CO_2}}{P_B}$$

where P_B is barometric pressure.

Volumetric Capnography

Capnography records CO₂ concentration against time during expiration. If CO₂ is plotted against expired volume, then a semiquantitative estimate of dead space:tidal volume ratio is obtained. Equipment for doing volumetric capnography can be built into mechanical ventilators. Volumetric capnography has been used to help diagnose pulmonary embolism and theoretically should be applicable to other situations where dead space:tidal volume ratio is useful (eg, weaning, ARDS, and asthma).

Validity

As described earlier, end-tidal PCO₂ should not be used as an accurate estimate of PaCO₂. Patients with either worsening of gas exchange function (increased PaCO₂) or improvement in function (decreased PaCO₂) can have a fall in PETCO₂. The former occurs because of an increase in P(a–ET)CO₂; the latter represents a parallel fall in both PETCO₂ and PaCO₂.

However, among the relatively few reports involving ICU patients—most of whom were receiving mechanical ventilation—some indicate that PaCO₂ and PETCO₂ track together relatively well, with mean differences less than 5 mm Hg and no change in difference during weaning or extubation. In COPD patients, the difference was considerably higher (as much as 9 mm Hg) but, again, relatively constant. In contrast, other studies have found that P(a–ET)CO₂ varies considerably, and while there was correlation with V_D/V_T, there was a lack of a constant value for P(a–ET)CO₂ that would allow “tracking” of PaCO₂ from PETCO₂ alone. In particular, one study demonstrated that both increases and decreases in P(a–ET)CO₂ may result from mechanical ventilator adjustments.

Clinical Applications

Airway CO₂ monitoring has the advantage of being noninvasive, and studies are available that indicate a decrease in the number of arterial blood gases obtained when this modality is used. However, it is clear that the critically ill patient with respiratory failure will have the largest and most unpredictable difference between PaCO₂ and PETCO₂; in these patients, PETCO₂ is an unreliable estimate of PaCO₂. On the other hand, the difference between PaCO₂ and PETCO₂ can be used as a measure of dead space:tidal volume ratio and therefore as a measure of the severity of gas exchange derangement.

Although studies are lacking on the benefit of routine monitoring of airway CO₂, capnography and PETCO₂ monitoring

have been used in several clinical situations. First, airway CO_2 monitoring can provide rapid noninvasive assurance of correct endotracheal tube placement. The capnogram should show increasing CO_2 concentration during expiration, and PETCO_2 should be a plausible value. Second, PETCO_2 has been used during cardiopulmonary resuscitation as a measure of the effectiveness of artificial circulatory assistance; a very low PETCO_2 suggests that venous blood is not adequately returning to the central circulation. Third, the combination of arterial and end-tidal PCO_2 provides an estimate of the inefficiency of ventilation (V_D/V_T). Some researchers have suggested that $P(a-ET)\text{CO}_2$ can be used to titrate the optimal amount of PEEP. While the smallest difference in $P(a-ET)\text{CO}_2$ has correlated with the highest degree of tissue oxygen delivery, this measurement has not proved ideal in all studies. Finally, it has been suggested that capnography can help in weaning patients from mechanical ventilation, but the predictive value of airway CO_2 monitoring in this clinical situation is unclear.

▶ Transcutaneous Blood Gases

Using transcutaneous blood gas monitors, partial pressures of oxygen and carbon dioxide may be measured in the tissue beneath heated skin electrodes. This monitoring technique has value because it reflects tissue levels, but it cannot yet be employed as a substitute for blood gas monitoring.

Principle

The Clark electrode, similar to that used in blood gas analyzers, has been modified to be used on the skin surface. The skin in the area of the electrode is heated to 43–45°C. This heating is necessary to make the skin permeable to oxygen, but it has the additional effect of increasing perfusion in the tissues beneath the probe. Since transcutaneous PO_2 (PtCO_2) reflects the oxygen tension level of the tissue beneath the probe, values may be affected either by arterial oxygenation or by systemic and regional perfusion. At relatively normal cardiac output and with normal regional blood flow, PtCO_2 values reflect arterial PO_2 values. In adults, the ratio of transcutaneous-to-arterial PO_2 is normally about 0.8,

whereas in children it tends to be higher. (Values in neonates may be very close to equal.) However, when either cardiac output or regional perfusion is decreased, the ratio of transcutaneous-to-arterial PO_2 is decreased in proportion to the level of decreased perfusion. Hence transcutaneous oxygen monitoring may be used as a monitor of both oxygenation and perfusion. A low PtCO_2 value is an indicator that the patient is either hypoxicemic or in a low-flow state (or has reduced regional perfusion).

Transcutaneous PCO_2 (PtCCO_2) has been measured using a modified PCO_2 electrode attached to the skin surface. In contrast to PtCO_2 , however, CO_2 is more soluble than O_2 , so tissue stores of CO_2 act as a buffer, reducing the dependence of PtCCO_2 on blood flow and metabolism. In theory, PtCCO_2 should mirror PaCO_2 more closely than PtCO_2 reflects PaO_2 , and there is no need to heat the skin at the monitoring site. Newly designed sensors with heaters have been studied recently. Results have been variable.

Both PtCO_2 and PtCCO_2 devices should be calibrated against known PO_2 and PCO_2 . Because of the heating of the PtCO_2 electrode site, the location must be changed every 4–6 hours to minimize the risk of thermal injury.

Clinical Applications

Many neonatal ICUs routinely employ PtCO_2 monitoring and have found good correlation with arterial blood gases except in patients with severe cardiac compromise. In adults, PtCO_2 measurement is best used as a measure of tissue *hypoperfusion*. A reduction of PtCO_2 may be an early indicator of low flow, particularly if pulse oximetry does not indicate severe hypoxemia.

▶ Respiratory Mechanics

Measured parameters are tidal volume, vital capacity, airway pressure, and intrathoracic pressure. From these, respiratory system and lung compliance, airway resistance, and work of breathing can be estimated. Modern mechanical ventilators often are equipped to measure airway pressure, tidal volume, inspiratory flow, and other derived values. They may be able to display in real time flow-volume or pressure-volume loops. A discussion of respiratory compliance and resistance is found in Chapter 12.

Tidal Volume

In the ICU, tidal volume is measured most commonly in patients who have endotracheal tubes and require mechanical ventilation. Respiratory inductive plethysmography provides

a noninvasive estimate of tidal volume. Tidal volume should be monitored frequently in patients receiving mechanical ventilation. When volume-preset modes are used, a difference in expired volume compared with preset volume indicates that there is a leak in the ventilator circuit, that inspiratory flow demand is extremely high, or that inspiratory peak pressure exceeds the preset limit. In pressure-controlled ventilation, tidal volume is used to adjust the level of set airway pressure, and any change in expired tidal volume indicates a change in lung or chest wall compliance or airway resistance. During spontaneous respiration, tidal volume monitoring using noninvasive measurement can be employed to help identify patients with obstructive sleep apnea or abnormal breathing patterns (Cheyne-Stokes respiration).

Maximum Inspiratory and Expiratory Airway Pressure

Inspiratory and expiratory maximum pressures are determined by a manometer connected either to a mouthpiece or to tubing adapted to fit onto the endotracheal tube. These pressures are measured correctly starting at functional residual volume so that lung and chest wall elastic recoils are neutralized, and the pressures reflect only respiratory muscle strength. In practice, this detail is often omitted. Normal maximum inspiratory pressure is more than -80 to -100 cm H_2O ; maximum expiratory pressure in normal individuals exceeds 120 – 150 cm H_2O . Maximum negative inspiratory and positive expiratory pressures are useful in assessment of respiratory failure in patients with neuromuscular disorders. Studies support the use either of the average of maximum inspiratory and expiratory pressures or of vital capacity in roughly predicting the onset of hypercapnia in these patients when pressures fall by about 70% or when vital capacity is less than about 55% of predicted. These direct measures are notably better than extrapolations of respiratory muscle strength from measurements of the strength of the extremities.

Intrathoracic (Intraesophageal) Pressure

Intrathoracic pressure requires a pressure sensor within the chest—almost always a balloon placed in the lower third of the esophagus and connected to a suitable manometer. The balloon must be filled carefully with a small amount of air so that the changes in intrathoracic pressure are faithfully recorded without the confounding effects of the balloon's compliance. Care must be taken to position the balloon within the chest and not in the stomach. Systems for measuring esophageal pressure are available commercially. Esophageal pressure is used most often to determine lung or chest wall compliance or work of breathing, but it also can be helpful in identifying auto-PEEP. A potential use is to “correct” pulmonary artery or pulmonary artery wedge pressures for large swings in intrathoracic pressure during the respiratory cycle.

Lung and Chest Wall Compliance

Calculation of compliance of the respiratory system (chest wall and lungs together) is reviewed in Chapter 12. The components of respiratory system compliance can be subdivided into chest wall and lung compliances. Lung compliance (CL) is calculated as the ratio of change in volume (ΔV) to change in pressure (ΔP), where ΔV is usually the tidal volume and ΔP is the difference between end-inspiratory and end-expiratory transpulmonary pressure. Transpulmonary pressure is the pressure difference between the pressure in the airway and the esophageal pressure. Normal lung compliance is about 200 mL/cm H_2O at end-expiratory volume. If chest wall compliance (CCW) is desired, the formula $1/CRS = 1/CL + 1/CCW$ can be used, where RS is the respiratory system). Decreased lung compliance has been used as a criterion of ARDS in some clinical studies but is not usually required for its clinical diagnosis. Low lung or chest wall compliance suggests increased work of breathing and could suggest that weaning would be difficult or inappropriate. On occasion, abnormal chest wall compliance as a cause of respiratory failure is not identified unless measured. If low chest wall compliance is found to contribute to respiratory failure, a very different approach to treatment may be warranted.

Work of Breathing

The work required for breathing is derived from the formula for mechanical work: $W = \text{force} \times \text{distance}$. For breathing in which the force is applied over a predetermined volume, substitute pressure for work, and for distance, substitute change in volume. Thus work of breathing is the product of $\Delta P \times \Delta V$. Work of breathing can be calculated for the patient-ventilator system, with the result indicating the work being done by the *mechanical ventilator* for a particular tidal volume. The same work, of course, would be done by the patient breathing spontaneously, but this is usually not relevant because the patient is unlikely to breathe at the same rate, tidal volume, and I:E ratio. For spontaneous breathing, tidal volume should be measured noninvasively, and the pressure difference between end expiration and end inspiration is measured inside the thorax (esophageal pressure). Thus a setup for measuring mechanical work of breathing generally measures tidal volume (noninvasive or through the endotracheal tube) and esophageal pressure.

Work of breathing calculated from tidal volume and esophageal pressure may underestimate actual work being performed by a significant amount. Some of the difference arises from nonuniform expansion of the lung or chest wall or compression of intrathoracic gas, and the calculation does not consider the expiratory work of breathing. In practice, work of breathing is rarely measured for clinical purposes. Theoretically, increased work of breathing should be a good predictor of the success of weaning from mechanical ventilation and could provide a guide to maximizing respiratory

muscle strength, maximizing lung and chest wall compliance, and minimizing airway resistance. In the area of research in critically ill patients, work of breathing has been used to characterize an excessive burden on the respiratory muscles from high resistance in the ventilator circuit, poorly functioning expiratory and inspiratory valves, development of auto-PEEP, and other factors.

► Respired Gas Analysis

Measurement of respired gases includes determination of CO₂ output (\dot{V}_{CO_2}) and O₂ uptake (\dot{V}_{O_2}). In the steady state, these are considered equivalent to CO₂ production and O₂ consumption. The ratio $\dot{V}_{CO_2}/\dot{V}_{O_2}$ is the respiratory gas exchange ratio, which is equal to the respiratory quotient (RQ) in the steady state.

\dot{V}_{CO_2} and \dot{V}_{O_2} are measured by comparing inspired and expired gas concentrations of O₂ and CO₂ and knowing the inspired or expired minute ventilation. Gas concentrations are measured using O₂ and CO₂ analyzers. Oxygen analyzers measure PO₂ using an electrochemical method to generate current proportionate to PO₂. Infrared CO₂ analyzers are highly reliable and accurate. Both inspired and expired gas concentrations are needed.

The product of mixed expired CO₂ fraction ($F_{\bar{E}CO_2}$) and expired minute ventilation is \dot{V}_{CO_2} (L/min) expressed at standard temperature and pressure, dry (STPD). For \dot{V}_{O_2} (L/min), the calculation is more complex, having to take into account the inspired oxygen fraction and the small but significant difference between inspired and expired minute ventilation owing to the gas exchange ratio.

Automated instruments allow for continuous measurement of \dot{V}_{CO_2} and \dot{V}_{O_2} and often report these results in tables or graphs. Indirect calorimetry uses \dot{V}_{O_2} and an estimate of the substrate mix being used for energy production (RQ) to estimate the energy expenditure or caloric requirement of the patient:

$$\begin{aligned} \text{kcal/day} &= \dot{V}_{O_2} \text{ (L/min)} \times 1440 \text{ min/day} \\ &\times (3.82 + 1.23 \times \text{RQ}) \text{ kcal/L } \dot{V}_{O_2} \end{aligned}$$

\dot{V}_{O_2} and \dot{V}_{CO_2} also can be measured using the Fick equation with knowledge of arterial and mixed venous O₂ and CO₂ contents (mL/dL or mL/L of blood) and cardiac output (thermodilution or other technique). For critically ill patients, this requires a pulmonary artery catheter, and most commonly it has been an intermittent calculation. However, with continuous cardiac output technology, continuous mixed venous oximetry, and arterial pulse oximetry, a continuously calculated oxygen consumption is now possible.

Validity

Carbon dioxide output (\dot{V}_{CO_2}) determination is generally satisfactory in the ICU, including patients receiving mechanical ventilation. With high inspired O₂, CO₂ analyzers require adjustment according to the manufacturer's instructions, but this does not detract from accuracy.

On the other hand, \dot{V}_{O_2} is calculated most often using the difference between inspired and expired fraction of O₂ and an adjustment that accounts for the small difference between inspired and expired minute ventilation. This formula is very sensitive to inspired O₂ concentration, especially when FiO₂ > 0.50. In fact, some investigators are suspicious of \dot{V}_{O_2} determinations from expired gas when FiO₂ exceeds 0.21, and many commercial systems are not reliable when FiO₂ is greater than 0.30–0.40.

Calculation of oxygen consumption by the Fick equation also has significant inherent inexactness. Intermittent thermodilution measurements of cardiac output have significant variance, as do measurements of arterial and venous saturation, as well as hemoglobin. Any errors in these measurements are increased geometrically during calculation of oxygen consumption—so-called mathematical coupling. However, the importance of this limitation to the accuracy of this methodology in clinical practice is a matter of controversy.

► Clinical Applications

Monitoring of oxygen delivery and oxygen consumption allows titration of ICU interventions to specific physiologic end points for individual patients. However, it is not clear that providing “supranormal” oxygen delivery improves outcome for critically ill patients with shock, sepsis, trauma, or hemorrhage. One important exception is during the early phase of sepsis and septic shock, in which attention to oxygen delivery (assessed using central venous oxygen saturation) increases survival.

Oxygen uptake by indirect calorimetry in the ICU also may be used to determine metabolic requirements so that appropriate caloric requirements as well as substrate

utilization may be monitored. There are insufficient outcome data supporting routine use of indirect calorimetry, but numerous studies have pointed out that, without direct measurements, patients are often under- or overfed in comparison with their actual needs.

As indicated earlier, precise determination of dead space:tidal volume ratio requires measurement of expired CO₂ rather than estimation. Respired gas measurements therefore may be useful in predicting weaning from mechanical ventilation or for estimating prognosis in ARDS or COPD exacerbations.

Transport

Samuel J. Stratton, MD, MPH

This chapter will describe and discuss *interfacility transport* of the critically ill. As technology advances and as fiscal realities increase the incentive to control health care spending, increased regionalization will result in transport of the critically ill to the hospital that can best manage the patient. Lessening the need for duplicate resources by regionalization of specialized health care services may achieve optimal patient outcomes at minimal costs. Repatriation of health plan participants with their primary care providers has led to a dramatic increase in interfacility transport of persons requiring hospitalization or extended emergency evaluation.

Management of resource-intensive critical illness in specialized regional centers has been shown to improve medical outcomes and cost-effectiveness. Most studies support the concept that patient volume in tertiary care centers (Table 9–1) leads to better patient outcomes because staffs of these centers maintain high experience and proficiency levels. With medical evidence strongly supporting regionalized medical specialty centers, methods for transport of patients to these centers must be developed using practices based on the best scientific and management evidence.

► Interhospital Transport

Composition of the Transport Team

Once the referring physician decides that a patient needs a higher level of care, the mode of transport must be chosen as well as the composition of the transporting crew.

For interfacility transfers, there are no standard guidelines regarding which patients may be transferred solely with paramedics, which require a nurse in attendance, and which require a physician in attendance. Local regulations may restrict the role of paramedics, who should not, for example, give medications or manipulate unfamiliar equipment such as ventilators unless they have documented evidence of training and competence. The scope of such training may be limited by the paramedic licensing or certification board.

There are no national data on overall transport volumes or team composition within transport systems. Published guidelines recommend that a minimum of two medically qualified people in addition to vehicle operators accompany a critically ill patient. The two medical attendant teams usually consist of combinations of ambulance attendants, emergency medical technicians (EMTs) who receive 100–300 hours of initial education, paramedics who receive 1000–3000 hours of initial education, respiratory therapists, critical care technicians, licensed registered nurses, and physicians. In urban areas, ground transport is most common; in rural areas, air transport is more often required because of the distances and the difficulties of road travel. In most settings, the EMT is the highest-level care provider on the interfacility transport team, but for critical care transports, a physician, nurse, or paramedic is most often the highest-level provider. EMTs, paramedics, respiratory therapists, critical care technicians, and nurses usually have defined scopes of practice in the jurisdiction where they are licensed. This scope of practice limits what the individual may or may not do during the transport process. Many critical care transport programs that have physicians on board transport vehicles are using physicians who are still in training—there is little information about whether the level of experience of the physicians is a factor in outcome. Many programs ascribe considerable value to the presence of physicians; this despite the fact that only 11% of programs fly with physicians on board.

Table 9-1. Medical services most effectively delivered in specialized referral centers.

Burn injuries
Trauma
High-risk blunt and penetrating injuries
Neurologic injuries
Vascular injuries
Complex orthopedic injuries
Pediatric-age trauma
Oro-maxillary-facial injuries
Obstetric, high-risk
Neonatal care
Pediatric critical care
Cardiac
Invasive coronary revascularization
High-risk cardiac care
Cerebrovascular (“stroke”) management
Rehabilitation, intensive

Appropriately educated and monitored nonphysicians can use paralytic pharmacologic agents and perform intubation, cricothyrotomy, and tube thoracostomy safely; nurses or respiratory therapists may be more familiar with ventilators than a physician.

Current standards for interfacility transport dictate that the decision on transport mode and team composition is based on individual patient requirements for minimization of transport time and monitoring and anticipated treatment requirements during transport. For example, a patient who requires advanced airway monitoring and skills should be transported in a vehicle with airway monitoring equipment, accompanied by an individual trained and qualified in advanced airway management.

Mode of Transport

Current options for mode of transport are the ground ambulance, either a helicopter or a fixed-wing aircraft, and watercraft. In many urban centers, all options are available, and in rural areas—Alaska, for example—the airplane is essential. Decisions that will influence the mode of transport (if all options are available) include the distance and thus the duration of transport, the diagnosis and thus the complications that may arise during transport, the level of training and techniques the transporting personnel can provide, the urgency of access to tertiary care, and local weather conditions and geography. In general terms, ground ambulances are more available than air vehicles; ground ambulances may be dispatched from a local facility, although an outreach team from the tertiary care center may be requested; mobilization time of such a team and their arrival will have to be taken into consideration (Table 9-2).

Table 9-2. Factors that favor a specific mode of critical care transport.

Favoring ground ambulance
Ambulance staffed by critical care team
Ambulance equipped appropriately
Patient location accessible to ground transport
Ambulance can be spared for use within the local system
Geography allows ground transport
Favoring helicopter transport
Transport distance 30–180 miles
Important to minimize transport time
Helicopter staffed by critical care team
Helicopter equipped appropriately
Patient location and receiving location accessible to helicopter landing and takeoff
Allowable weather conditions
Patient/equipment weight allows use of available helicopter
Favoring fixed-wing aircraft
Transport distance over 100–150 miles
Important to minimize transport time
Aircraft staffed by critical care team
Aircraft equipped appropriately
Patient location and receiving location accessible to an airport
Allowable weather conditions
Patient/equipment weight allows use of available aircraft
Critical care transport available for moving patient to and from landing sites

A. Ground Ambulance—Ground ambulance vehicles are usually the most readily available and may be categorized as vehicles for basic life support (BLS) or advanced life support (ALS). BLS ambulances are most often staffed with two EMTs and can provide basic first aid, monitoring of vital signs, basic airway management and intervention, automatic external defibrillation, monitoring of maintenance intravenous fluid infusions, and oxygen without cardiac monitoring. ALS ambulances are staffed with a paramedic, nurse, or physician as the highest-level provider. ALS ambulance personnel can provide cardiac monitoring and advanced airway management and can deliver the drugs and intravenous fluids commonly used for resuscitation and stabilization of medical and trauma patients. ALS ambulances must have the necessary outlets for managing ventilators or balloon pumps for interfacility critical transfers. However, if the ambulance belongs to the local Emergency Medical Services (EMS) jurisdiction, the administrators may not allow the vehicle to be out of service for a long trip to a tertiary center. In many urban areas, ambulance companies maintain some ALS ambulances for interfacility transports so that the primary EMS system is not affected. Ground ambulances are limited by surface conditions or traffic congestion. Equipment used to support patients during transport should have a backup supply (ie, batteries or extra oxygen tanks) in case of need. The U.S.

Department of Transportation (DOT) has published standards that have been adopted by most states that relate to minimum ambulance configuration and equipment requirements. Communication between the ground ambulance and the receiving facility or designated medical control center can be a consideration during transport. The ground ambulance is the most widely used and least expensive mode of interfacility transfer. This method should be considered for transport distances of 30 miles or less.

B. Helicopter—Helicopters should be considered for transports over distances of 30–150 miles. They travel at ground speeds of 120–180 miles per hour and often are dispatched from the receiving tertiary facility or urban area emergency service providers. The physical location of the helicopter at the time of dispatch is important to consider because an in-flight round trip to transport a patient may not offer advantages over a one-way trip by an available ground vehicle. Helicopters usually require a warmup time of 2–3 minutes before liftoff and—allowing for communication time—can be launched within 5–6 minutes after the flight request is received. Medical transport helicopters are usually staffed by critical care (ALS) crews. Under normal weather conditions, helicopters can fly point to point and land at accident scenes or sending facilities; the liftoff capability depends on the type of helicopter used. Helicopter transports are limited by adverse weather conditions and available landing sites (often a problem in densely populated areas). Helicopters are expensive—the capital cost is between \$ 2.5 million and \$ 15 million depending on whether a single- or dual-engine model is selected; likewise, the number of patients that can be transported is determined by aircraft selection and configuration.

Helicopters can fly from point to point under visual flight rules (VFR). In inclement weather, several helicopter programs can fly under instrument flight rules (IFR). This, however, requires that they take off and land at an airport with appropriate instrumentation. Helicopters cannot fly in freezing rain or dense fog.

C. Fixed-Wing Aircraft—Fixed-wing aircraft should be considered for transport over distances exceeding 100–150 miles. Fixed-wing aircraft will have IFR capability and can fly from airport to airport, with ground transportation required at both ends. Fixed-wing aircraft are less susceptible to adverse weather in comparison with helicopters. Aircraft cabins normally are pressurized between 6000 and 8000 feet, and this may have effects not only on the patient's clinical condition but also on apparatus such as endotracheal tubes or Swan-Ganz catheters; in addition, ventilators may need to be recalibrated. Some patients—for example, those being transferred to hyperbaric facilities for treatment of decompression sickness—may require pressurization at ground level. Fixed-wing aircraft are being used more often as long distant transports across states and regions occur. Fixed-wing aircraft are used commonly for international transports. When national borders are crossed by transport craft, international rules and national immigration and visa requirements must be met.

D. Watercraft—Watercraft are used rarely for interfacility critical care transport. In special environments, such as offshore islands and oil platforms, watercraft do play a role in medical transport. The use of watercraft for critical care transport is usually in a situation where inclement weather does not allow for helicopter transport. Because of problems with water damage to electrical equipment and dangers of staff electrical shock from defibrillators, the monitoring and ALS activities that can be supported on watercraft are limited.

Liability and Legal Issues

A. Interfacility Transfer—Interfacility transport of patients received increased legal visibility by the passage in 1986 of COBRA 1985, Section 9121, Amendments to the Social Security Law, and Section 1867, Special Responsibilities for Hospitals in Emergency Cases. These rules have undergone repeated emendation, and the regulations have been renamed the Emergency Treatment and Active Labor Act (EMTALA), further amending Section 1867. Briefly, these laws refer to emergency transfers of unstable patients and were drafted to address the problem of transfers of uninsured patients. Indeed, the EMTALA regulations are often referred to as “antidumping legislation.” EMTALA provides a framework of legal liability under which the sending facility is responsible for initiating the transfer and selecting the mode of transportation (including the level of expertise of transferring personnel) and thus indirectly the equipment on the transporting vehicle. The sending facility is responsible for ensuring that the receiving facility has space and personnel available for care of the patient, and the sending physician is responsible for the risks of transfer and for deciding that the benefits to the patient following successful transfer outweigh the risks. A receiving facility that has specialized units such as burn units, shock trauma units, cardiac catheterization units, and neonatal ICUs shall not refuse to accept an appropriate transfer if that hospital has the capability to treat the individual. This is a nondiscrimination clause and is an attempt to prevent receiving facilities from accepting only funded patients. All emergency critical care and transferring personnel should understand the implications of these statutes.

B. Confidentiality—All ambulance and transport providers who engage in transactions that transmit protected health information in electronic form are required to comply with the U.S. Health Insurance Portability and Accountability Act (HIPAA). Protected health information includes any information identifiable to a specific person that relates to that individual's past, present, or future physical or mental health. HIPAA provides criminal and civil penalties for the improper use of protected health information, requiring that consent be given to obtain health information and that safeguards are in place to protect such information. Records pertaining to the use and disclosure of protected health information must be maintained for inspection by appropriate parties.

In addition to the legal requirements of transfer, the transferring personnel have certain liability concerns—

particularly if they perform air medical transport. The high degree of acuteness of these patients and the potential for adverse outcomes mandate medical malpractice coverage for the transferring personnel; the premiums will vary according to the staffing pattern selected. Medical directors also may need to make certain that they are appropriately covered for giving offline medical direction and may find that although some of their responsibilities are covered by medical malpractice insurance, directors' and officers' insurance may be needed to cover their management decisions.

Outcome

The data that support the validity of transfer of the critically ill emphasize five recurring themes:

1. Outcomes of the critically ill in tertiary centers are better than outcomes in other facilities (matched for severity).
2. Transport of the critically ill does not adversely affect the patient during transport—and therefore, by implication, the patient receives the benefit of theme 1.
3. Transport of critically ill patients improves outcome when compared with national norms.
4. Established systems of care (encompassing critical transport as a component) have societal outcomes better than those of comparable communities without such a system and better than those in the same community before the system was in place.
5. Regionalization of specialized care is cost-effective and improves utilization of community resources.

An outcome study of all critically injured children with respiratory failure and head trauma in Oregon for 6 months compared mortality in 71 nontertiary and 3 tertiary facilities. Using the pediatric risk of mortality score, the study found that outcomes in the nontertiary facilities were lower than those in tertiary facilities—and further, that the difference in outcome was more pronounced the higher the expected mortality. For the most critical group (mortality risk >30%), the odds ratio of dying in a nontertiary versus a tertiary facility was 8:1. The study concluded that “pediatric survival from a broad range of disorders might be improved by regional organization of pediatric care.”

Improved outcome of the critically ill has been related to the volume of patients. This has been shown for coronary artery bypass surgery, trauma management, acute cardiac disease, abdominal aortic aneurysm, and stroke. For example, using the Trauma and Injury Severity Score (TRISS) methodology, it has been shown that rapid transport or transfer by helicopter of trauma patients to a specialized trauma center resulted in a 13% reduction in mortality when compared with the outcome expected from the benchmark Multiple Trauma Outcome Study database. Studies demonstrating improved outcomes of the critically ill in regionalized specialty centers are in strong support of critical patient transport systems that facilitate movement of patients to these centers.

Transfer of the critically ill has been shown to be safe in cardiac patients, patients with respiratory distress, and pediatric patients. Transfer of patients sustaining acute myocardial infarction by air does not appear to be detrimental to patient outcome. Currently, critical care regionalization is becoming more common in developed countries throughout the world, and interfacility critical care transport is an essential component of this move to regionalization.

► Equipment & Monitoring

Interfacility critical care transport requires continuous monitoring and clinical management of the patient throughout the transport environment. The transporting vehicle should have the necessary power converters for all equipment that could be needed during a transfer; in addition, much of the equipment needs battery backup in case of electrical failure and backup oxygen supply in case of vehicle breakdown. In cold climates, provision must be made for maintenance of a warm environment in case of vehicle failure. In 2004, the American College of Critical Care Medicine, the Society of Critical Care Medicine, and the American Association of Critical Care Nurses published a consensus document that details minimum equipment and medications recommended for critical care transport units.

Airway Management

Critical care transport often involves patients who require advanced airway management. Often patients have had an endotracheal tube placed prior to transport, but transport team members always must be prepared to reintubate or establish an advanced airway should the need arise. In addition to standard endotracheal intubation equipment, a backup system such as the laryngeal mask or pharyngotracheal lumen tube should be available for those in whom intubation cannot be accomplished. Emergency transtracheal jet ventilation by means of needle cricothyrotomy and airway tube placement by cricothyrotomy have been successful in establishing a temporary airway during transport when

performed by properly trained personnel. The effectiveness of transtracheal jet ventilation at the higher altitudes encountered in fixed-wing aircraft is not established. In addition to advanced airway management, ALS transport crews should have equipment available for decompression of tension pneumothorax (ie, either needle or chest tube thoracostomy).

Medications

Medication lists have been published for the management of the obstetric patient, the neonatal patient, the pediatric patient, and the adult patient during transport. Additional medications may be required that depend on patient profiles, and protocols should be prepared for the use of these medications. Care must be taken to ensure that expiration dates on medications are recognized, and guidelines should be in place beforehand for authorization to use them. Use of critical care transport under these circumstances allows a higher level of pharmacologic intervention—for example, many flight programs routinely use paralytic agents to facilitate endotracheal intubation.

The use of thrombolytic agents for acute cardiac and stroke patients during interfacility transport is controversial. Observational studies have shown that thrombolytic use during transport of acute myocardial infarction patients has acceptable risk profiles, but with cardiac catheterization becoming a primary reason for transport, interest in transport thrombolytics has decreased.

Blood Utilization

Blood product transfusion during interfacility transport is controversial. It has been shown that in rotor-wing programs using flight nurses, the transfusion of blood can be performed safely and is feasible during transport. Use of blood product transfusions is limited to lengthy transports during which crystalloid infusion alone will not stabilize a patient. Use of blood products during transport requires adherence to strict standard blood transfusion protocols, with blood administered by properly trained transport personnel.

Ventilators

Several types of ventilators are available for the transport environment. The choice of ventilator will depend on the mission profile, compatibility with sponsoring ICUs, and the preferences of the medical director. Mechanical ventilation of intubated patients during transport has been shown to be optimal in comparison with manual ventilation. Food and Drug Administration (FDA)-approved transport ventilators have performance indexes comparable with those of ICU ventilators. Transport ventilators must be monitored continuously during transport and, because of the unique transport environment, are subject to problems such as power failure and disconnection. Pressure-controlled ventilators are used most commonly during transport and in aircraft must be adjusted to for altitude changes. Most critical care transport

programs monitor their patients continuously by oximetry and continuous end-tidal carbon dioxide monitoring; in one study, continuous oximetry monitoring identified clinically unrecognized hypoxia.

Monitoring

The ECG, blood pressure, oxygen saturation, and, if necessary, end-tidal carbon dioxide level, pulmonary artery pressure, intraarterial pressure, and intracranial pressure should be monitored during transport. Successful defibrillation has been performed during flight, and use of this equipment does not interfere with other systems on helicopters and fixed-wing aircraft. If the patient does not have an intraarterial line, occlusion oscillometry or Doppler measurement will give a satisfactory indication of blood pressure; normal auscultation of the blood pressure using a sphygmomanometer cuff is difficult in the transport environment because ambient noise may exceed 110 dB.

Medications should be administered by infusion pump throughout transport to ensure smooth and accurate dosing. Many small, rugged infusion pumps are available and can be reprogrammed rapidly to manage unstable patients. In addition, portable intraaortic balloon pumps and left ventricular assist devices are now available commercially that weigh less than 150 lb and can be transported on most ambulances, helicopters, and airplanes.

► Education & Training

Crew Composition Decisions

Once the mission profile of the transport program has been specified, decisions must be made concerning the qualifications of the personnel. The mission profile also may dictate the qualifications of the medical director.

Physicians: On- and Offline

In addition to their duties in off-line medical control (eg, supervising training, development of medical protocols and standing orders, and quality assurance), physicians must be available online 24 hours a day (by cellular phone or radio) to help manage critical situations. Most online medical control is provided by emergency physicians. These individuals have experience conveying instruction by radio to paramedics, are immediately available 24 hours a day, and are

familiar with radio equipment and the rules and regulations covering their use. Occasionally, online medical direction may be obtained through an ICU or from a neonatologist at a tertiary care facility.

Crew Qualifications

Training modules for all transporting personnel should be developed in such a way that it is consistent with the policies and practices of the local emergency medical services and critical care community. The facilities and the crew should be subjected to ongoing curriculum development and quality assurance by the medical director.

A. The Emergency Medical Technician—Emergency medical technicians (EMTs) have completed a course of training outlined by the DOT and are required to recertify every 2–4 years, usually by means of taking a nationally standardized skills and knowledge test. EMTs are taught first aid and basic rescue skills in programs composed of 100–300 contact hours. EMTs receive training in the basic management of trauma and medical, pediatric, obstetric, and psychiatric emergencies. Many EMTs are proficient in the use of automatic external defibrillators. EMTs know basic noninvasive airway techniques and are often certified to monitor continuous maintenance intravenous infusions. Generally, EMTs do not have training in cardiac rhythm recognition, intravenous access, or invasive procedures.

B. The Paramedic—Paramedics have completed a course curriculum outlined by the DOT and usually are required to pass a state licensing examination and to seek recertification every 2 or 4 years. Most U.S. paramedics obtain initial certification by participating in a nationally recognized testing program. In the United States, paramedic training programs vary from 1000–3000 contact hours. Paramedics have knowledge of all emergency situations, including the acute management of trauma and of cardiac arrhythmias. Under state or regional guidelines, they usually can perform defibrillation and are able to recognize and treat lethal dysrhythmias. They are trained in endotracheal intubation and cricothyrotomy, interosseous lines, needle thoracostomy, and transthoracic cardiac pacing, although not all of these skills are sanctioned for performance by paramedics in all states. Paramedic training corresponds to what is required for Aeromedical Crew Level 2 personnel by the American College of Surgeons.

C. The Critical Care Transport RN—A standard curriculum and certification program for critical care nurses has been developed by the American Association of Critical Care Nurses. Schools for flight nursing have been developed, along with a generally recognized curriculum. In addition to other nursing skills, transport nurses should be trained to perform endotracheal intubation, needle thoracostomy, and cricothyrotomy and to insert and maintain interosseous lines and central venous lines. They are also expected to be

familiar with the operation of transport ventilators and, if the mission profile includes intraaortic balloon pumping, the management of a balloon pumps (although many programs use pump technicians for this function). They should have knowledge of the critical care management of obstetric, neonatal, pediatric, and burn patients as well as cardiac, CNS, and psychiatric patient management. Transport teams involved in aerospace medicine should have knowledge about altitude physiology, aircraft safety, aviation communications, and emergency aeromedical procedures such as crash response and survival. Training guidelines have been developed and are in concert with the suggestions outlined in the ACS publication cited below.

► Reimbursement Standards & Costs

Standards

Any medical interfacility aeroground transport vehicle will have to be licensed by the designating agency as a transferring ambulance. Ambulance licensing varies considerably from state to state but may depend on minimal equipment requirements, staffing availability, staff licensing, and record keeping. Non-public-sector aeromedical programs also are required to comply with Federal Aviation Administration regulations with respect to equipment, qualifications, and hours of pilot duty. If transport vehicles cross state lines, licensing of both staff and vehicles in neighboring states may be required unless an interstate agreement has been reached covering medical practice and emergency response contingencies. Voluntary standards have been developed by the Society of Aeromedical Systems, the Commission on Accreditation of Medical Transport Systems, and the Commission on Accreditation of Ambulance Services, and accreditation tracks are available.

Reimbursement

For hospital-based transport teams involving ground ambulances, the sponsoring facilities often support the medical crew and contract with an ambulance company for the ambulances, drivers, and in some cases the services of paramedical personnel. Ground ambulance services may be covered by third-party insurers. A medical necessity form is usually required justifying the transfer before payment is made.

Helicopter programs often lease the helicopter together with pilots, support mechanics, and a backup for service during scheduled or unscheduled maintenance procedures. Hospital support is provided by the medical crew.

Most programs bill third-party payers for the transport service. Both fixed-wing and helicopter rates and reimbursement vary widely nationally, and most continue to require support by sponsoring institutions in order to maintain financial viability. Charges and reimbursements are variable—and indeed, charge structure may vary from one program to another because the medical costs such as crew salaries and equipment may be part of the hospital's or the flight program's cost base. Third-party payer reimbursement also varies nationally and usually requires utilization review. Medicare traditionally reimburses for transport only to the closest medical facility capable of managing the patient, and this policy may not be congruent with the emergency medical services plan for the state or region. Medicare reimbursement is made by a prospective payment system similar to what is used for hospital ambulatory care billing.

Cummings G: Scene disposition and mode of transport following rural trauma prospective cohort study comparing patient costs. *J Emerg Med* 2000;18:349–54.

► Current Controversies & Unresolved Issues

The beneficial and cost-effective use of air transport has been and remains controversial. Studies now question the use of more expensive air transport modalities in rural areas. Air transport is a strong consideration for long-range (>50–60 miles [80.5–96 km]) transport. With regard to intermediate transport distances of about 50 miles (80.5 km), data are conflicting with regard to the benefit of air transport versus ground transport. Recent evidence has shown no advantage to air transport of trauma or burn patients when there is an intermediate (80 km) or less transport distance. In urban areas, a large number of variables determine the risks and

benefits of a particular mode of transport, and because of population density with resulting loss of landing sites and safety, ground transport is often preferred.

Chemical restraint for combative or agitated patients has been reported to be appropriate, particularly during air transport. Benzodiazepines are used most commonly. As with opioid analgesic use, patients must be closely monitored when chemical restraint is used.

Although critical care transport is a common practice, truly comparative studies that address controversial practices are not yet available. Because of the nature of transport and the large number of variables to consider in transport research, most of the published literature is qualitative and descriptive. Qualitative research methods are appropriate for addressing many of the issues of critical care transport and should be done in conformity with proper research design techniques.

The role of physician staffing of air transport units has been questioned in recent literature. While physicians have a broad skill set that may be an advantage during a long transport, the opportunity and means to fully apply the physician skill set during transport are severely limited. Further, with advanced telemetry and telecommunications, physician input and backup can be readily available.

Ethical, Legal, & Palliative/ End-of-Life Care Considerations

Paul A. Selecky, MD

10

Advances in modern medicine have increased the ability of the physician and the health care team to prolong life by using a wide variety of life support modalities, including medications, mechanical devices, and the transplantation of vital organs. Despite their scientific success, these treatments can prolong life of a quality that in many cases is not meaningful or rewarding to the patient. The result has been that the physician and the health care team sometimes must help their patients make decisions about whether to withhold or withdraw life support medications or mechanical devices—and sometimes whether even to withhold basic life support measures such as nutrition and hydration.

Life support decision making in the ICU often presents ethical or legal dilemmas that must be resolved by staff and patients and the patients' families or surrogates. This chapter will attempt to review the basic principles that form the ethical framework of the modern practice of medicine. The purpose of this discussion will not be to erect standards of practice or to give legal advice but to offer a system for applying ethical principles in an effort to avoid or resolve conflicts. These principles are also applied in the light of the health care worker's personal and professional values, institutional policies and statutory mandates, and the published statements of professional bodies.

► Ethical Principles

The principles of medical ethics are rooted in religious and philosophical traditions, which include the absolute values of good and evil, right and wrong, and that human life is of infinite worth and sanctity. Ethics is the system of principles by which these beliefs govern our behavior and our interaction with others. The application of these beliefs may therefore change over time to adapt to the needs of society, but the boundaries of the absolute values are maintained.

Four basic ethical principles flowing from these absolute values strongly influence the practice of medicine, particularly in critical care medicine. The first is *beneficence*, which directs

the physician and health care worker to do good, specifically by restoring health and relieving suffering. This has been a fundamental goal of medical practice since the time of Hippocrates in the fourth century BC, but it is not the only goal.

The ethical companion of beneficence is *nonmaleficence*, compelling health care workers *first of all to do no harm* (*primum non nocere*). Nonmaleficence is not merely a corollary of beneficence because these two principles must sometimes be in conflict. For example, it is considered ethically justified to administer morphine to relieve pain (beneficence) in the terminally ill patient even though the morphine might increase the risk of death, an act that may violate the principle of nonmaleficence. This has been described as the *principle of double effect*, one act having two opposing effects.

The third ethical principle is *autonomy*, which dictates that any competent adult patient who has been appropriately informed has the right to accept or refuse medical treatment, including life-sustaining measures—that is, the right of self-determination. This does not include the right to commit suicide or to require a physician to assist in suicide or perform euthanasia. Although Oregon legalized physician-assisted suicide under limited circumstances in 1997, physicians' participation remains voluntary. The physician and the health care team have a mandate to preserve patient autonomy, however, by being honest and truthful in providing clinical information to the patient in order to obtain informed consent to treatment. [Table 10–1](#) lists the patient's rights adopted by the American Hospital Association. The Joint Commission has drawn up a similar list of patient rights.

The fourth ethical principle is *justice*, dictating that individuals be treated fairly in relation to other patients and the overall distribution of medical resources. When medical resources are limited, this principle states that treatment should be administered to patients who are most likely to benefit from them. The overriding consideration for the physician is an obligation to care for the individual patient at hand. Thus ethicists have argued that physicians involve themselves in the process of providing medical care to society

Table 10-1. A patient's bill of rights.¹

The patient has a right to—
Considerate and respectful care
Information about diagnosis, treatment, and prognosis
Make decisions about treatment
Have an advance directive
Consideration of privacy
Expect confidentiality
Review medical records
Request medical services
Be informed about health care business practices
Consent or decline to participate in research
Expect reasonable continuity of care
Be informed of hospital policies on patient care, including resources for conflict resolution

¹With permission from the American Hospital Association.

in general but not use arguments about limited resources in making decisions about an individual patient.

► Conflicts Between Ethical Principles

The practice of medicine often generates conflicts among these fundamental principles. Efforts have been made to prioritize them, often putting autonomy first as the most important ethical guideline, but the matter is controversial. Nonetheless, the physician and health care team are required to address any conflicts among these principles in the light of the circumstances presented in each individual case.

Patient autonomy must be preserved, but the physician sometimes may find that the patient's wishes are in conflict with the physician's own professional, personal, or religious values. In these situations, the patient's wishes take precedence while the physician attempts to transfer the responsibility for the patient's care to another physician.

Medical Futility

A conflict also may arise if the physician feels that the therapy requested by the patient is medically futile—particularly if it is a life support measure. A method of treatment is judged to be futile if reason and experience indicate that it would be highly unlikely to result in meaningful survival. One need not conclude that success of the treatment is impossible—it is enough to decide that a good result would be highly unlikely; for example, one proposed working definition of futility is no successful outcomes in the last 100 reported or observed attempts of that treatment. The physician is best qualified to judge whether the treatment is medically futile, but only the patient can decide whether continued survival would be personally acceptable. An example might be the decision whether or not to initiate

ventilatory support for a patient with severe progressive chronic lung disease. Ideally, the treatment goals of the physician and the patient should be identical and consensually derived.

The current consensus among ethicists holds that the physician has no ethical obligation to provide life-sustaining treatment he or she considers to be futile but does have the responsibility to inform the patient of the reasons for that opinion. If the patient requests the treatment nonetheless, the physician is required to take measures necessary to transfer the patient's care to another physician or institution that would follow the patient's wishes. At the same time, all other care that is both medically indicated and agreed to by the patient must be continued.

► Ethical Decision Making

Assessing Decision-Making Capacity

Medical decisions made in the ICU are governed by the principle of patient autonomy, but the patient's illness may have significantly diminished his or her decision-making capacity. This capacity is generally defined as the patient's ability to (1) receive and understand pertinent information, (2) reflect on this information in an appropriate way, and (3) communicate decisions and desires to the caregivers.

Surrogate Decision Makers

When this decision-making capacity is diminished or lost, a surrogate decision maker can be sought. Ideally, this will be an individual previously so designated by the patient in a written advance directive. Alternatively, it may be an appropriate family member in an order of authority and responsibility identified by local institutional or legal guidelines. A common hierarchy progresses from the patient's spouse to an adult child, then to a parent, then to an adult sibling, and then to a grandparent. Rarely, a court-appointed individual (conservator) undertakes this role.

In the absence of specific decisions about health care previously made by the patient, the surrogate is obliged to act in the patient's best interests, weighing the potential benefits and burdens of treatment—that is, applying the concept of *proportionality*. The surrogate ideally therefore should be someone who (1) is willing to accept these duties, (2) understands and accepts the personal values of the patient, (3) has no major emotional opposition to fulfilling the role, and (4) has no conflict of interest.

For circumstances when an appropriate surrogate decision maker cannot be identified (eg, "patient John Doe"), the health care institution should have a mechanism in place for naming someone to act in the patient's best interests. Such a mechanism should be governed by factors such as local medical practice, legal precedents, and institutional policies. Consultation might be sought from an appropriate resource, such as a bioethicist or a hospital health care ethics committee.

Although rarely necessary, a legal decision can be sought from the courts, such as in situations in which (1) the state of the patient's decision-making capacity is in doubt, or (2) the surrogate decision maker cannot make or refuses to make the decision, or (3) the health care team feels that the surrogate's decision is not in the patient's best interests, or (4) the surrogate's decision is contrary to the patient's advance directive.

Shared Decision Making

Decision making in the ICU should be a shared responsibility between the physician and the patient or surrogate decision maker. The physician should avoid making independent paternalistic medical decisions for the patient involving life support measures even though doing so might seem to be in the patient's best interests. The physician is singularly qualified to determine the medical futility of a specific treatment, but only the patient or surrogate decision maker can decide quality-of-life issues, that is, whether prolongation of life would be meaningful and valuable to the patient. The physician should seek input from other members of the patient's health care team, including nurses and other care providers.

► Advance Care Planning

In an attempt to support the fundamental ethical principle of patient autonomy, legislation has been enacted to facilitate the process by which the patient's wishes may be carried out when he or she is no longer able to make decisions. That is, a legal declaration by the patient gives the physician and health care team advance notice of what he or she wants to be done or not done under various future circumstances. Federal legislation requires hospitals and skilled nursing facilities that receive Medicare or Medicaid funding to inform all patients of their right to complete such an advance directive. These documents exist in most states, but the legal requirements and implications vary in different jurisdictions.

The *living will* is the most common document by which the patient may request or refuse life-sustaining treatment if he or she becomes terminally ill and no longer able to make medical decisions or becomes permanently unconscious. Such documents are not legally binding in all states but serve as guides for the physician and surrogate decision maker. A legally binding natural advance death declaration health care directive can include the decision to forego basic life support measures of artificially administered nutrition and hydration.

The *advance health care directive* appoints a health care agent ("attorney-in-fact") to act in the patient's best interests when the patient can no longer do so. Such an advance directive is most helpful when the patient has expressed his or her wishes in writing in some detail rather than merely using general terms such as "no heroic measures." Ideally, individuals executing these directives should discuss their intentions,

beliefs, and value systems with their health care agent, family, and physician, in addition to completing the advance directive document. It is also important that these wishes and the directive be reviewed on a regular basis, particularly each time the patient is hospitalized.

► Medicolegal Aspects of Decision Making

Critical care practices have been influenced by court actions that were pursued to resolve ethical conflicts regarding individual patients. While the actions are not legally binding outside those jurisdictions, they are used as legal precedents to guide behavior and to aid in arriving at future court decisions.

A number of cases have strengthened the ethical principle of patient autonomy and have helped to clarify the role of the surrogate decision maker in exercising the process of "substituted judgment" when acting for the patient. For example, in 1976, the New Jersey Supreme Court allowed the family of Karen Quinlan to withdraw her from mechanical ventilation because it agreed with her parents that this treatment would not allow her to return to a cognitive and sapient life but would merely keep her in a persistent vegetative state. Similarly, legal decisions surrounding the care of Nancy Cruzan in Missouri in 1990 ultimately acknowledged that her parents as surrogate decision makers, based on past comments the patient had made, could refuse life-sustaining treatment, including nutrition and hydration.

Patient autonomy was further strengthened by the legal determination in 1991 concerning the care of Helga Wanglie, who was in a persistent vegetative state on a ventilator in Minneapolis. The hospital had requested permission from her husband to discontinue life support treatment based on the medical decision that Ms Wanglie had no chance for recovery, that is, that the treatment was futile. Her husband refused, deciding that based on her religious beliefs, Ms Wanglie would have wished to continue living. The court affirmed Mr. Wanglie's decision and refused to appoint an independent conservator to replace him as decision maker.

More recently, the decision to withdraw nutrition and hydration from Terri Schiavo, a woman in a persistent vegetative state following a cardiac arrest, was marked by protracted conflict between the patient's husband and her parents that went on for 15 years. The decision to withdraw treatment was contested in the local, state, and federal judicial systems, and even by Congress, before the treatment was finally withdrawn, allowing the patient to die according to her wishes shared in the past with her husband. This case illustrates the value of advance care planning for everyone and making one's wishes in end-of-life care known to the family rather than debating them later in the courts.

These precedents reaffirm the principle of patient autonomy, but ethical conflicts nonetheless remain, particularly for individuals who stress the principle of justice and the fair allocation of medical resources.

▶ Withholding & Withdrawing Life Support

Based on the ethical principles discussed in the preceding paragraphs, the patient or the surrogate decision maker can request that life support treatments be withheld or withdrawn. Current judgment does not distinguish an ethical or legal difference between the act of withholding and the act of withdrawing life support measures. Nevertheless, the patient, the family, and the health care team may find it more difficult to withdraw life support than to withhold it. In addition, Orthodox Jewish tradition does not permit the withdrawing of life support measures, including nutrition or hydration, feeling that this would be equivalent to suicide. There is usually less concern about the more passive act of withholding treatment.

Decisions to withhold or withdraw treatment are best made in advance of a life-threatening situation, allowing the patient and family to consider the potential outcome of life support measures. This is particularly important in patients who are terminally ill or who have an illness that is severe and irreversible.

“Do Not (Attempt) Resuscitate (Resuscitation)” (DNR/DNAR) Orders

In the event of cardiac or respiratory arrest in a hospitalized patient, cardiopulmonary resuscitation (CPR) is initiated automatically. In some cases, it may be desired to forgo CPR, in which case a “do not resuscitate” order is written. This decision is made jointly by the patient (or surrogate) and the physician, but either party may initiate discussion about the decision. In general, physicians should initiate discussions about CPR and DNR/DNAR—ideally, before the patient becomes critically ill and before the disease progresses to a life-threatening stage despite optimal therapy. Some writers have advocated use of the term “allow natural death” (AND) as more descriptive of the intent of this order.

The physician should choose an appropriate setting for this discussion with the patient and family, allowing ample time for discussion. The DNR/DNAR order should be presented in a positive light, emphasizing the continuation of supportive treatment, relief of physical suffering such as pain and dyspnea, and support for emotional suffering. It should be made clear that such a decision does not mean that the health care team is “giving up” but that the focus of therapy is altered, emphasizing comfort while avoiding futile or unnecessary treatment.

When the outcome is bleak, the discussion should focus not only on whether CPR should be initiated but also on whether life support measures should be withheld or withdrawn. The “do not resuscitate” decision does not, by itself, imply any decisions about other medical treatment, including ICU admission, surgery, or other treatment. Thus, if the patient’s outcome is likely to be poor, offering CPR may give the patient and family false hope about the likelihood of a good outcome. A better approach is to discuss whether to

withhold or withdraw life support measures when a crisis develops if such measures are judged to be futile. The treatment plan thus should be presented in an atmosphere that will allow the patient, family, and health care team to “hope for the best, but prepare for the worst.”

There may be situations in which a physician recommends that a DNR order be written, but the patient or family disagrees and wishes CPR to be initiated at the time of cardiac or respiratory arrest. In this situation, several steps can be taken. First, the physician and patient (or surrogate) should continue the discussion, with clarification about the reasons for each person’s decision, misconceptions about CPR, and the continuation or discontinuation of other medical care. Second, the American Medical Association (AMA) Council on Ethical and Judicial Affairs has decided that a physician who determines that CPR may be futile may initiate a DNR order against the patient’s wishes. In this situation, the patient must be informed of the decision and its reasons. Third, in the event of disagreement, the patient should be transferred to the care of another physician able to reconcile the wishes of the patient with his or her own medical judgment.

Once the decision for a DNR order is made by the patient or physician, institutional policies and procedures should govern how such an order should be written in order to avoid miscommunication. Major points of the discussion with the patient and family should be documented in the medical record, including who participated, the decision-making capacity of the patient, the medical diagnosis and prognosis, and the reasons for the DNR decision.

Withholding or Withdrawing Treatment

A. A Stepwise Approach—Decisions to withhold or withdraw life support treatment must not be made hastily. Several steps are recommended: (1) The physician should have a clear understanding of the patient’s diagnosis, physiologic and functional status, and any coexisting morbid states. (2) The physician should seek unanimity among the health care team for the decision to withhold or withdraw life support measures. (3) The next step is to seek informed consent from a legally competent patient. If the patient is not legally competent, the surrogate decision maker must be contacted. It is wise to include the family and the patient’s referring or primary care physician in the process, although the patient or the surrogate decision maker holds responsibility for the ultimate decision. (4) If a decision cannot be made in a timely fashion and life support measures are imminently required, the physician might consider recommending a limited trial of the life support measure—for example, ventilatory support for the next 72 hours, with reassessment at that time. In the absence of a firm decision, life support measures should be initiated or continued.

Physicians and other health care workers may fear that their actions in withholding or withdrawing life support may subject them to litigation or even criminal prosecution.

While no one is immune from criticism or challenge, health care workers who act thoughtfully and rationally, with concern for the patient and in the open company of their peers, should not fear legal retribution.

B. Establish a Treatment Plan—Once a decision has been made to withhold life support measures, a specific treatment plan should be formulated with emphasis on providing comfort and support and continually adjusting the plan to meet the changing needs of the patient. A DNR order should not automatically preclude care for a patient in the ICU. All efforts should be made to avoid giving the patient and family a feeling of abandonment. Forgoing treatment does not mean forgoing care. It may be helpful to involve the services of a medical social worker or chaplain to make certain that the patient and family receive appropriate emotional and spiritual support and attention to their physical comfort.

C. Withdraw Life Support—When a decision to withdraw life support measures has been made, the order should be executed in a timely manner, paying close attention to the emotional needs of the patient and family.

After the life support measure is discontinued—for example, disconnecting the patient from mechanical ventilation—the family should be allowed access to the patient to the extent possible, and attention should be given to their emotional and physical needs. If the dying process is prolonged, the patient may be transferred to a separate room for more privacy. Medications appropriate to control pain, dyspnea, and other symptoms should be administered liberally. Nursing care and physician attention should be as diligent as before the decision was made. The primary training and practice of critical care clinicians are to prevent and treat life-threatening medical crises, but they also must be prepared to provide palliative care, administering to the dying patient and his or her family. A large body of educational resources is available to assist the health care team in providing palliative care in the critical care setting.

► Organ Donation

Organ transplantation has progressed rapidly in recent years and now offers hope to patients who otherwise would die because of failure of a vital organ. One of the limiting factors, however, is the short supply of donor organs from individuals who have suffered irreversible cessation of brain stem function.

In order to establish the diagnosis of death by neurologic criteria, that is, “brain death,” a physician who has no conflict of interest must verify by appropriate clinical evaluation that the patient has suffered irreversible cessation of all brain function. Such a diagnosis must be made in the absence of hypothermia, drug effect, or metabolic intoxication that can temporarily suppress the CNS. It also must be made with caution in patients in shock because reduced brain perfusion may make the examination unreliable. Guidelines have been published by the American Academy of Neurology.

Because of the possibility that some patients may become candidates for organ donation, physicians and health care professionals in the ICU should be aware of the processes by which donations can be made. Some patients already may have disclosed in an advance directive that they wish to donate body organs or tissues under these circumstances. Otherwise, authorization for such organ donation must be obtained from the surrogate decision maker or appropriate family member unless the religious beliefs of the patient preclude such donation (eg, Christian Science, Orthodox Judaism, or Jehovah’s Witnesses).

Organ donation is a sensitive issue that health care providers are often reluctant to raise, particularly at a time when the potential donor patient’s family is suffering the impending loss of their loved one. It is therefore necessary to discuss these issues in a sensitive and timely manner once the family has accepted the irreversibility of the brain damage. Legislation in some states requires that such a discussion take place. In the absence of any known family members or other appropriate surrogate decision maker, the institution may be permitted to arrange a donation in accordance with statutory guidelines. It is important that all health care personnel be familiar with the policies and procedures for organ donation in order to identify potential transplant donors.

► Role of the Health Care Professional

Education

All health care professionals who work in the critical care setting should be intimately familiar with the ethical and legal principles that influence their medical decision making. A number of professional bodies have published position statements on the ethical implications of critical care, and some of these resources are listed in the references at the end of this chapter and in the appendix of Web sites. Copies of these statements should be readily available to critical care personnel. Skilled legal resources also should be available.

Discussions with patients concerning life support measures are potentially within the purview of all health care workers, so this education should be offered to the entire medical staff and all hospital medical personnel. The patient’s primary physician ideally should initiate discussion about advance directives and decisions concerning treatment long before a crisis occurs. Such discussions can be encouraged through public education and by taking advantage of opportunities to document decisions such as when preparing wills and other estate planning instruments.

Communication Skills

In addition to possessing knowledge about the ethics of critical care medicine, health care workers should be skilled in communicating these principles and their conflicts to patients and families as well as among the health care team. The physician traditionally assumes the role of the leader of

that team, but critical care nurses and respiratory care practitioners often develop close relationships with patients and their families as well and can aid in the process.

Communication is aided by allowing ample time for discussing these issues in an appropriate setting—ideally, long before a critical decision must be made. This would allow general discussion of such sensitive issues as whether to initiate or withhold CPR or other life support measures and other decisions about which the patient may wish to express a preference.

Medical institutions should establish mechanisms by which ethical conflicts can be resolved satisfactorily. This might include the availability of ethics and/or palliative care consultations, patient care conferences, and resources such as patient advocates, medical social workers, and the hospital's retained legal advisers or others who are knowledgeable about critical care and ethical issues.

Compassion Fatigue

Critical care professionals, by the nature of their work, are subject to significant emotional distress in the care of critically ill and/or dying patients. This can result in *compassion fatigue*, by which the emotional strain on the professional caregivers begins to affect their decision making, care delivery, and sometimes their personal lives. Signs and symptoms of compassion fatigue can include feelings of anger toward the patient and family resulting in avoiding them and thus stifling communication and empathy. This is best addressed and/or avoided by providing an open and collegial atmosphere within the health care team, allowing members to discuss their feelings about caring for the patient and family.

Development of Institutional Policies

Institutional policies and procedures should be drafted to aid the health care worker in responding to ethical issues in the critical care arena and other areas of the hospital. A number of such policies are listed in [Table 10-2](#). They are designed as much to prevent ethical conflicts as to aid in resolving them.

Table 10-2. Institutional policies to help prevent or resolve ethical conflicts in critical care.

Intensive care unit admission and discharge criteria
Methods for resolving ethical conflicts
Do not resuscitate orders
Guidelines for withholding and withdrawing life support
Care of the dying patient
Definition of and procedure for determining brain death
Requesting organ or tissue donation
Organizational ethics

Guidelines for formulating these policies may be found in the references listed below. Some state hospital associations are also a resource for such policies.

Shock & Resuscitation

Frederic S. Bongard, MD

The diagnosis and management of shock are among the most common challenges the intensivist must deal with. Shock may be broadly grouped into three pathophysiologic categories: (1) hypovolemic, (2) distributive, and (3) cardiac. Failure of end-organ cellular metabolism is a feature of all three. Hemodynamic patterns vary greatly and constitute the diagnostic features of the three types of shock.

HYPOVOLEMIC SHOCK

ESSENTIALS OF DIAGNOSIS

- ▶ Tachycardia and hypotension.
- ▶ Cool and frequently cyanotic extremities.
- ▶ Collapsed neck veins.
- ▶ Oliguria or anuria.
- ▶ Rapid correction of signs with volume infusion.

General Considerations

Hypovolemic shock occurs as a result of decreased circulating blood volume. The most common cause is trauma resulting in either external hemorrhage or concealed hemorrhage from blunt or penetrating injury. Hypovolemic shock also may occur as a result of sequestration of fluid within the abdominal viscera or peritoneal cavity.

The severity of hypovolemic shock depends not only on the volume deficit but also on the age and premorbid status of the patient. The rate at which the volume was lost is a critical factor in the compensatory response. Volume loss over extended periods, even in older, more severely compromised patients, is better tolerated than rapid loss. Clinically, hypovolemic shock is classified as mild, moderate, or severe depending on the blood volume lost (Table 11-1). While

these classifications are useful generalizations, the severity of preexisting disease may create a critical situation in a patient with only minimal hypovolemia.

Hypovolemic shock produces compensatory responses in virtually all organ systems.

A. Cardiovascular Effects—The cardiovascular system responds to volume loss through homeostatic mechanisms for maintenance of cardiac output and blood pressure. The two primary responses are increased heart rate and peripheral vasoconstriction, both mediated by the sympathetic nervous system. The neuroendocrine response, which produces high levels of angiotensin and vasopressin, enhances the sympathetic effects. Adrenergic discharge results in constriction of large capacitance venules and small veins, which reduces the capacitance of the venous circuit. Because up to 60% of the circulating blood volume resides in the venous reservoir, this action displaces blood toward the heart to increase diastolic filling and stroke volume. It is probable that venular constriction is the single most important circulatory compensatory mechanism in hypovolemic shock.

Precapillary sphincter and arteriolar vasoconstriction results in redirection of blood flow. The greatest decrease occurs in the visceral and splanchnic circuits. Flow to bowel and liver decreases early in experimental shock. Intestinal perfusion is depressed out of proportion to reductions in cardiac output. Reduction in flow to the kidneys accounts for the decline in glomerular filtration and urine output, whereas decreased skin flow is responsible for the cutaneous coolness associated with hypovolemia. The cutaneous vasoconstrictive response diverts flow to critical organs and has the further effect of reducing heat loss through the skin. The reduced diameter of the small, high-resistance vessels increases the velocity of flow and decreases the viscosity of blood as it reaches the ischemic vascular beds, thus permitting more efficient microcirculatory flow.

Increased flow velocity in the microcirculation may have the additional benefit of improving oxygen delivery

Table 11-1. Pathophysiology and clinical features of hypovolemia.

	Pathophysiology	Clinical Features
Mild (<20% of blood volume)	Decreased perfusion of organs that are able to tolerate ischemia (skin, fat, skeletal muscle, bone). Redistribution of blood flow to critical organs.	Subjective complaints of feeling cold. Postural changes in blood pressure and pulse. Pale, cool, clammy skin. Flat neck veins. Concentrated urine.
Moderate (deficit = 20–40% of blood volume)	Decreased perfusion of organs that withstand ischemia poorly (pancreas, spleen, kidneys).	Subjective complaint of thirst. Blood pressure is lower than normal in the supine position. Oliguria.
Severe (deficit > 40% of blood volume)	Decreased perfusion of brain and heart.	Patient is restless, agitated, confused, and often obtunded. Low blood pressure with a weak and often thready pulse. Tachypnea may be present. If allowed to progress, cardiac arrest results.

From Holcroft JW, Wisner DH: Shock and acute pulmonary failure in surgical patients. In: *Current Surgical Diagnosis and Treatment*, 9th ed. Way LW (editor). Originally published by Appleton & Lange. Copyright © 1991 by the McGraw-Hill Companies, Inc.

while reducing tissue acidosis. A countercurrent exchange mechanism has been postulated in which oxygen diffuses from arterioles into adjacent venules. Normally, the amount of arterial oxygen lost by this mechanism is small. However, as flow decreases through dilated arterioles, more oxygen can leave the slowly flowing arterial blood and diffuse to the venous circuit. Arteriolar constriction increases flow velocity and decreases blood residence time. This effectively reduces the peripheral oxygen shunt. In a similar fashion, CO₂ diffuses from the post-capillary venules into the arterioles. In the absence of arteriolar vasoconstriction, such diffusion could increase the volume of CO₂ reaching the tissues and result in worsening of tissue acidosis.

The balance of fluid shifts between the intravascular and extravascular spaces is governed by Starling's law, which relates net transvascular flux to differences in hydrostatic and osmotic pressure:

$$\dot{Q} = K[(P_c - P_i) - \sigma(\Pi_c - \Pi_i)]$$

where Q is fluid flux, (P_c - P_i) is the hydrostatic pressure gradient, (Π_c - Π_i) is the osmotic pressure gradient, K is the permeability coefficient, and σ is the reflection coefficient.

Under normal circumstances, intravascular hydrostatic pressure (P_c) is greater than interstitial hydrostatic pressure (P_i), and fluid tends to move from the capillaries into the interstitium. Interstitial osmotic pressure (Π_i) is usually less than the intravascular osmotic pressure (Π_c), favoring the movement of fluid back into the capillary. This results in a small net movement of water, Na⁺, and K⁺ out of the capillaries. When hypovolemia occurs, intravascular pressure falls, facilitating the movement of fluid and electrolytes from the interstitium back into the vascular space. The degree of this translocation is limited because as fluid moves back into the capillaries, the albumin remaining in the interstitium exerts an increased extravascular osmotic pressure. Compensatory vasoconstriction facilitates this process because fluid can be recovered more easily if the vascular space is collapsed than if it is dilated. The degree of such translocation is probably limited to a total of 1–2 L. This vascular refill accounts not only for the decrease in intravascular osmotic pressure, but it is also primarily responsible for the decline in hematocrit observed in hypovolemic patients before resuscitation is started.

Increased heart rate and contractility are important homeostatic responses to hypovolemia. Both the direct adrenergic response and the epinephrine secreted by the adrenal medulla are responsible for these reflexes. Cardiac output is the product of heart rate and stroke volume. It is supported both by tachycardia and by translocated fluid. Because blood pressure is the product of systemic vascular resistance and cardiac output, peripheral vasoconstriction is an essential factor in supporting blood pressure.

B. Metabolic Effects—Tissue metabolic pathways require ATP as an energy source. Normally, ATP is produced through the Krebs cycle via the aerobic metabolism of glucose. Six molecules of oxygen are consumed when six molecules of glucose are used to convert six molecules of ADP into six molecules of ATP, CO₂, and water. When oxygen is not available, ATP is generated through anaerobic glycolysis, which not only yields smaller quantities of ATP for the amount of glucose consumed but also produces lactic acid. This latter product is largely responsible for the acidosis of ischemia. The point at which tissues change from aerobic to anaerobic metabolism is defined as the *anaerobic threshold*. This theoretic point varies between tissues and clinical situations. The most important factor influencing the conversion to anaerobic glycolysis is oxygen availability.

The delivery of oxygen depends on the quantity of oxygen present in the blood and the cardiac output. The former, defined as the oxygen content, is calculated as follows:

$$CaO_2 = 1.34 \times Hb \times SaO_2 + (0.0031 \times PaO_2)$$

where CaO_2 is arterial oxygen content (in milliliters per deciliter), Hb is hemoglobin concentration (in grams per deciliter), SaO_2 is hemoglobin saturation of arterial blood (in percent), and PaO_2 is partial pressure of dissolved oxygen in arterial blood (in millimeters of mercury).

The principal determinants of oxygen content are the concentration of hemoglobin and its saturation. Although PaO_2 is the most commonly used indicator of oxygenation, the dissolved oxygen component contributes only minimally to oxygen content in patients with normal hemoglobin concentration and saturation. When anemia is profound, the relative contribution of dissolved oxygen increases. Systemic oxygen delivery is defined as follows:

$$\text{Do}_2 = \text{CaO}_2 \times \text{CO} \times 10$$

where Do_2 is systemic oxygen delivery (in milliliters per minute), CaO_2 is arterial oxygen content (in milliliters per deciliter), and CO is cardiac output (in liters per minute).

Normally, Do_2 is in excess of 1000 mL/min. When cardiac output falls with hypovolemic shock, Do_2 declines as well. The extent depends not only on the cardiac output but also on the fall in hemoglobin concentration. As oxygen delivery declines, most organs increase their extraction of oxygen from the blood they receive and return relatively desaturated blood to the venous circuit. Systemic oxygen consumption is calculated by rearranging Fick's equation:

$$\dot{V}\text{O}_2 = (a - v)\text{Do}_2 \times \text{CO} \times 10$$

Systemic oxygen consumption is typically 200–260 mL O_2 per minute for a 70-kg patient under baseline conditions. The arteriovenous oxygen content difference— $(a - v)\text{Do}_2$ —is approximately 5 ± 1 mL/dL under these conditions. With hypovolemia, oxygen consumption remains remarkably constant, although peripheral oxygen extraction increases, resulting in an increase in $(a - v)\text{Do}_2$ to values typically greater than 7 mL/dL. The oxygen extraction ratio (O_2ER), which is defined as $\dot{V}\text{O}_2/\text{Do}_2$, is also augmented. Increased $(a - v)\text{Do}_2$ and O_2ER are metabolic hallmarks of hypovolemic shock.

Tissues vary greatly in their ability to increase oxygen extraction. The normal extraction ratio is near 0.3 and may increase to as much as 0.8 in conditioned athletes. The heart and brain maximally extract oxygen under normal circumstances, making them extremely flow-dependent. Peripheral oxygen consumption ($\dot{V}\text{O}_2$) remains essentially constant during hypovolemia until a critical threshold is reached, at which point increased extraction can no longer keep pace with delivery. There is conflicting evidence about whether oxygen consumption decreases in the face of reduced oxygen delivery in humans. This so-called pathologic supply dependence may, however, occur in patients with distributive shock and with acute respiratory distress syndrome (ARDS). When circulating blood volume falls sufficiently, oxygen delivery declines, and death occurs below a critical Do_2 of less than 8–10 mL O_2 per minute.

Compensated shock occurs when system oxygen delivery falls below $\text{Do}_{2,\text{crit}}$, and anaerobic metabolism becomes more prevalent. Cell function is maintained as long as the combination of aerobic and anaerobic metabolism provides adequate ATP. Tissues vary greatly in their resistance to hypoxia. While the brain may tolerate only brief intervals, skeletal histiocytes may withstand up to 2.5 hours of ischemia. Significantly, the gut appears to be very sensitive to decreased perfusion. Uncompensated shock, which results in tissue damage, occurs when combined aerobic and anaerobic metabolism is not adequate to sustain cellular function. Loss of cellular membrane integrity results in cell swelling and ultimate cell death.

C. Neuroendocrine Effects—Adrenergic discharge and the secretion of vasopressin and angiotensin are neuroendocrine compensatory mechanisms that together produce vasoconstriction, translocation of fluid from the interstitium into the vascular space, and maintenance of cardiac output.

1. SECRETION OF ALDOSTERONE AND VASOPRESSIN—Together these hormones increase renal retention of salt and water to assist in maintaining circulating blood volume.

2. SECRETION OF EPINEPHRINE, CORTISOL, AND GLUCAGON—These hormones increase the extracellular concentration of glucose and make energy stores available for cellular metabolism. Fat mobilization is increased. Serum insulin levels are decreased.

3. ENDORPHINS—Although their exact role is unclear, these endogenously occurring opioids are known to decrease pain. They promote deep breathing, which might increase venous return by decreasing intrathoracic vascular resistance. Endorphins have a vasodilatory effect and actually may counteract the sympathetic influence.

D. Cellular and Immunologic Effects—Although separation of shock and resuscitation into cellular and immunologic effects is somewhat artificial, the distinction provides a useful framework for the subsequent discussion of resuscitation.

1. CELLULAR EFFECTS—Injured cells die by either apoptosis or necrosis. Apoptosis requires energy and is a more controlled than simple necrosis. Although apoptosis is required for homeostasis, an increase in apoptosis may indicate cellular injury and organ dysfunction. Recent research has shown that the type of resuscitation fluid used may have a significant effect on the extent of apoptosis. Additionally, the extent of apoptosis varies between cell types and may be particularly significant in the CNS and brain.

Recent research has shown that the fluid used for resuscitation also has an effect on cellular function. Some of the factors thought to exert an influence include (1) the electrolyte composition of the fluid used, (2) tonicity, (3) duration of resuscitation, (4) type of cells exposed, (5) concurrent inflammation or infection, (6) presence of additional periods of shock or infection/contamination (“second hit”), and (7) timing of resuscitation.

2. IMMUNOLOGIC EFFECTS—Hypovolemic shock initiates a series of inflammatory responses that may have deleterious effects. Stimulation of circulating and fixed macrophages induces the production and release of tumor necrosis factor (TNF), which, in turn, leads to production of neutrophils, inflammation, and activation of the clotting cascade. Neutrophils are known to release free oxygen radicals, lysosomal enzymes, and leukotrienes C₄ and D₄. These mediators may disrupt the integrity of the vascular endothelium and result in vascular leaks into the interstitial space. Activated complement and products of the arachidonic acid pathway serve to augment these responses.

Adhesion molecules are glycoproteins that cause leukocyte recruitment and migration after hemorrhagic shock. The most frequently involved cell adhesion molecules are the selectins, integrins, and immunoglobulins. Although the roles of the adhesion molecules are still under investigation, some authorities have reported a correlation between the severity of injury and the release of soluble cell adhesion molecules (SCAMs). Others also have noted a relationship between the development of multiple-organ failure and the expression of SCAMs. The feasibility of using monoclonal antibodies to SCAMs—as well as pathway blockade—is under study. Isotonic crystalloid resuscitation fluids, as well as some artificial colloids, have been demonstrated to produce an oxidative burst and the expression of adhesion molecules on neutrophils in a dose-dependent manner. Natural colloids, such as albumin, did not create such a burst, and the use of hypertonic saline has been shown to suppress some neutrophil functions.

Oxygen metabolites, including superoxide anions, hydrogen peroxide, and hydroxyl-free radicals, are produced when oxygen is incompletely reduced to water. These radical intermediates are extremely toxic because of their effects on lipid bilayers, intracellular enzymes, structural proteins, nucleic acids, and carbohydrates. Phagocytes normally generate oxygen radicals to assist in killing ingested material. Antioxidants protect surrounding tissue if these compounds leak from the phagocytes. Ischemia, followed by reperfusion, has been shown to accelerate the production of toxic oxygen metabolites independently of the activity of inflammatory cells. This ischemia-reperfusion syndrome may lead to extensive destruction of surrounding tissue and may play a significant role in determining the ultimate outcome of an episode of hypovolemic shock.

Animal experiments have identified a number of other potentially important immunologic responses to hypovolemia, including failure of antigen presentation by Kupffer cells in the liver and translocation of bacteria from the gut into the systemic circulation. This latter mechanism may explain the occurrence of sepsis after hypotension without other sources of infection.

E. Renal Effects—Blood flow to the kidneys decreases quickly with hypovolemic shock. The decline in afferent flow causes glomerular filtration pressure to fall below the critical

level required for filtration into Bowman's capsule. The kidney has a high metabolic rate and requires substantial blood flow to maintain its metabolism. Therefore, sustained hypotension may result in tubular necrosis.

F. Hematologic and Thrombotic Effects—When hypovolemia is due to loss of fluid volume without loss of red blood cells, which occurs with emesis, diarrhea, or burns, the intravascular space becomes concentrated, with increased viscosity. This sludging may lead to microvascular thrombosis with ischemia of the distal bed.

G. Neurologic Effects—Sympathetic stimulation does not cause significant vasoconstriction of the cerebral vessels. Autoregulation of the brain's blood supply keeps flow constant as long as arterial pressure does not decrease to less than 70 mm Hg. Below this level, consciousness may be lost rapidly, followed by decline in autonomic function.

H. Gastrointestinal Effects—Hypotension causes a decrease in splanchnic blood flow. Animal models have shown a rapid decrease in gut tissue oxygen tension, which may lead to the ischemia-reperfusion syndrome or to translocation of intestinal bacteria. Increased concentrations of xanthine oxidase occur within the mucosa and also may be responsible for bacterial translocation. Pentoxifylline has aroused recent interest as a potential agent for increasing intestinal microvascular blood flow after periods of ischemia.

Clinical Features

A. Symptoms and Signs—The findings associated with hypovolemic shock vary with the age of the patient, the pre-morbid condition, the extent of volume loss, and the time period over which such losses occur. The physical findings associated with different degrees of volume loss are summarized in Table 11-1. Heart rate and blood pressure measurements are not always reliable indicators of the extent of hypovolemia. Younger patients can easily compensate for moderate volume loss by vasoconstriction and only minimal increases in heart rate. Furthermore, severe hypovolemia can result in bradycardia as a preterminal event. Orthostatic blood pressure testing is often helpful. Normally, transition from the supine to the sitting position will decrease blood pressure by less than 10 mm Hg in a healthy person. When hypovolemia is present, the decline is greater than 10 mm Hg, and the pressure does not return to normal within several minutes. Older patients who present with apparently normal blood pressures while supine often become hypotensive when brought to an upright position. Such testing must be used with caution in patients who have sustained multiple injuries because potentially unstable vertebral injuries may be present.

Decreased capillary refilling, coolness of the skin, pallor, and collapse of cutaneous veins are all associated with decreased perfusion. The extent of each depends on the severity of the underlying shock. These findings are not specific to hypovolemic shock and may occur with cardiac shock

or shock from pericardial tamponade or tension pneumothorax. Collapsed jugular veins are commonly found in hypovolemic shock, although they also may occur with cardiac compression in a patient who is not adequately fluid-resuscitated. Examination of the jugular veins is best performed with the patient's head elevated to 30 degrees. A normal right atrial pressure will distend the neck veins approximately 4 cm above the manubrium.

Urine output is usually markedly decreased in patients with hypovolemic shock. *Oliguria* in adults is defined as urine output of less than 0.5 mL/kg per hour. If oliguria is not present in the face of clinical shock, the urine should be examined for the presence of osmotically active substances such as glucose and radiographic dyes.

B. Laboratory Findings—Laboratory studies may be useful in determining the cause of hypotension. However, resuscitation of a patient in shock should never be withheld pending the results of laboratory determinations.

The hematocrit of a patient in hypovolemic shock may be low, normal, or high depending on the cause and duration of shock. When blood loss has occurred, evaluation prior to capillary refill by interstitial fluid will yield a normal hematocrit. On the other hand, if the patient has bled slowly, if recognition is delayed, or if fluid resuscitation has been instituted, the hematocrit will be low. When hypovolemia results from loss of nonsanguineous fluid (eg, emesis, diarrhea, or fistulas), the hematocrit is usually high. A crude way to estimate the extent of blood loss is to assume that the intravascular space is a single compartment and that the change in hemoglobin concentration is proportional to the extent of blood loss and fluid replacement with nonsanguineous fluids. Where H_i is the (presumed) initial hematocrit, H_f is the final hematocrit, and EBV is the approximate circulating blood volume (approximately 70% of the body weight in an adult), the estimated blood loss (EBL) may be calculated as $EBL = EBV \times \ln(H_i/H_f)$.

Lactic acid accumulates in patients with shock that is severe enough to cause anaerobic metabolism. Both the extent of elevation of arterial lactic acid and the rate at which it is cleared with volume resuscitation and control of bleeding are useful markers of the presence of ischemia and its resolution. Failure to clear elevated arterial lactic acid is an indication of inadequate resuscitation. If arterial lactic acid concentration remains elevated despite seemingly appropriate fluid resuscitation, other causes of hypoperfusion should be sought.

Other nonspecific findings include decreased serum bicarbonate and a minimally increased white blood cell count. Base excess, calculated from an arterial blood gas determination, indicates that portion on an acidosis that is metabolic in nature. Some laboratories use the term *base deficit*, which is simply the negative absolute value of the base excess. Like lactic acid, base deficit should resolve with adequate resuscitation.

C. Hemodynamic Monitoring—Assessment of central venous pressure is seldom required to make the diagnosis of

hypovolemic shock. Because the decreased volume allows venous collapse, insertion of central venous monitoring catheters can be particularly hazardous. If the patient's blood pressure and mental status do not respond to fluid administration, a continued source of bleeding should be suspected. Central venous pressure monitoring may be useful in older patients with a known or suspected history of congestive heart failure because excessive fluid administration may rapidly result in pulmonary edema. In extreme cases, a pulmonary artery flotation catheter may be required to optimize fluid status.

Capnographic monitoring will reflect a decrease in end-tidal CO_2 . This is produced by a decrease in blood flow to the lungs. When compared with arterial blood gases, a widening of the arterial–end-tidal CO_2 gradient is apparent. If pulmonary function is normal, only minimal changes in arterial hemoglobin saturation will be present. Hence pulse oximetry indicates normal saturation. The introduction of noninvasive transcutaneous tissue oxygen probes, which use near-infrared spectroscopy to measure subcutaneous tissue oxygen tension (StO_2), holds promise as a simple bedside method for determining the adequacy of resuscitation. A pilot study showed that trauma patients who maintained StO_2 above 75% within the first hour of ED arrival had an 88% chance of surviving without multiple-organ dysfunction.

Differential Diagnosis

Shock owing to hypovolemia may be confused with shock from other causes (Table 11–2). Cardiac shock produces signs similar to those found with hypovolemia, with the exception that neck veins are usually distended. Absence of such distention may be due to inadequate fluid resuscitation. Central venous pressure monitoring will help to make the differentiation. Following trauma, peripheral vasodilation owing to spinal cord injury may produce shock that is relatively resistant to fluid administration. Hypovolemia is the primary cause of shock in trauma victims, and it should never be assumed that other causes are responsible until fluid in adequate amounts has been administered.

Alcoholic intoxication may make the diagnosis of hypovolemia difficult. Serum ethanol elevation causes the skin to be warm, flushed, and dry. The patient usually makes dilute urine. These patients may be hypotensive when supine, with exaggerated postural blood pressure changes. Hypoglycemic shock owing to excessive insulin administration is not uncommon in the ICU. The patients are cold, clammy, oliguric, and tachycardiac. A history of recent insulin administration should arouse suspicion of hypoglycemic shock. After samples have been taken for blood glucose determinations, intravenous administration of 50 mL 50% glucose should improve the situation.

Treatment

A. General Principles—Unlike acute posttraumatic situations, resuscitation of patients with hypovolemic shock in

Table 11-2. Clinical findings associated with shock.

	Cardiogenic Shock	Cardiac Compressive Shock	Hypovolemic or Traumatic Shock			Low-Output Septic Shock	High-Output Septic Shock	Neurogenic Shock
			Mild	Moderate	Severe			
Skin perfusion	Pale	Pale	Pale	Pale	Pale	Pale	Pink	Pink
Urine output	Low	Low	Normal	Low	Low	Low	Low	Low
Pulse rate	High	High	Normal	Normal	High	High	High	Low
Mental status	Anxious	Anxious	Normal	Thirsty	Anxious	Anxious	Anxious	Anxious
Neck veins	Distended	Distended	Flat	Flat	Flat	Flat	Flat	Flat
Oxygen consumption	Low	Low	Low	Low	Low	Low	Low	Low
Cardiac index	Low	Low	Low	Low	Low	Low	High	Low
Cardiac filling pressures	High	High	Low	Low	Low	Low	Low	Low
Systemic vascular resistance	High	High	High	High	High	High	Low	Low

From Holcroft J, Robinson MK: Shock: Identification and management of shock states. In: *Care of the Surgical Patient*. Scientific American, 1992.

the ICU typically proceeds from a more controlled baseline. As in any emergent situation, the priorities of airway, breathing, and circulation must be addressed sequentially. Although many ICU patients will already have an established airway, attention to this area of concern is always the first priority. Techniques to control the airway and reestablish adequate breathing are discussed in Chapter 11.

Intravenous access through at least two large-bore (16-gauge) catheters is mandatory. The relatively small ports on pulmonary artery and triple-lumen catheters are inadequate for rapid fluid resuscitation and should be used only until larger catheters can be placed. Central venous catheters inserted in the internal jugular or subclavian vein generally should not be inserted in hypovolemic patients for emergent resuscitation because of the risk of a pneumothorax associated with attempts to place a catheter into a collapsed overlying vein. A quick search should be made for sources of blood and fluid loss. Potential sources include gastrointestinal bleeding, accelerated fluid loss through fistulas, disconnection of intravenous access lines with retrograde bleeding, and disruption of vascular suture lines. When external bleeding is present, direct pressure over the site should be applied until definitive surgical control can be secured. Blind probing of a bleeding wound with clamps almost invariably fails to control the bleeding and may cause further injury.

B. Fluid Resuscitation—Rapid fluid resuscitation is the cornerstone of therapy for hypovolemic shock. Fluid should be infused at a rate sufficient to rapidly correct the deficit. In younger patients, infusion is typically at the maximum rate

sustainable by the delivery equipment and the access vein. In older patients or those with prior cardiac disease, infusion should be slowed once a response is detected to prevent complications associated with hypervolemia.

Parenteral solutions for the intravenous resuscitation of hypovolemic shock generally are classified as crystalloids or colloids depending on the highest molecular weight of the species they contain.

1. CRYSTALLOIDS—Crystalloid solutions have no species with a molecular weight greater than 6000. Although a large number of crystalloids are available, only those isotonic with human plasma that have sodium as their principal osmotically active particle should be used for resuscitation. Commonly available solutions are listed in Table 11-3. Because they have low viscosity, crystalloids can be administered rapidly through peripheral veins.

Because isotonic fluids have the same osmolality as body fluids, there are no net osmotic forces tending to move water into or out of the intracellular compartment. Therefore, the electrolytes and water partition themselves in a manner similar to the body's extracellular water content: 75% extravascular and 25% intravascular. When isotonic crystalloids are used for resuscitation, administration of approximately three to four times the vascular deficit is required to account for the distribution between the intra- and extravascular spaces. This partitioning typically occurs within 30 minutes after the fluid is given. Within 2 hours, less than 20% of the infused fluid remains within the intravascular space.

Table 11-3. Composition of balanced salt solutions.

Solutions fluid	Glucose (g/L)	N ⁺	Cl ⁻	HCO ₃ ⁻	K ⁺ (meq/L)	Ca ²⁺	Mg ²⁺	HPO ₄ ⁻	NH ₄ ⁺
	Extracellular fluid	1000	140	102	27	4.2	5	3	3
5% dextrose and water	50								
10% dextrose and water	100								
0.9% sodium chloride (normal saline)		154	154						
0.45% sodium chloride (0.5 normal saline)		77	77						
0.21% sodium chloride (0.25 normal saline)		34	34						
3% sodium chloride (hypertonic saline)		513	513						
Lactated Ringer's solution		130	109	28*	4	2.7			
0.9% ammonium chloride		168							168

*Present in solution as lactate but is metabolized to bicarbonate.

Crystalloid solutions are safe and effective for resuscitation of patients in hypovolemic shock. The major complications associated with their use are undertreatment and overtreatment. Clinical parameters such as restoration of urine output, decreased heart rate, and increased blood pressure should be used to determine when a sufficient quantity of fluid has been given. Restoration of mental status, skin turgor, and capillary refill are also useful parameters. Central venous or pulmonary artery pressure monitoring is useful in patients with preexisting cardiopulmonary disease.

Excessive administration of crystalloids is associated with generalized edema. Unless quantities sufficient to increase the pulmonary hydrostatic pressure to very high levels are given (typically >25–30 mm Hg), pulmonary edema does not occur. Subcutaneous edema may be a significant problem because it limits patient mobility, increases the potential for decubitus ulcers, and potentially restricts respiratory excursions.

It has been shown recently that the type of crystalloid used may exert an important effect on the cellular injury caused by hemorrhagic shock. Investigation of this “resuscitation injury” has shown that the D-isomer found in traditional lactated Ringer's solution (a racemic mixture along with the L-isomer) may have adverse immunoinflammatory properties. Additional work has shown that both pulmonary and hepatic apoptosis may be reduced if lactate in the solution is replaced with either sodium pyruvate, ethylpyruvate, or β-hydroxybutyrate. It is believed that the modified Ringer's

solutions exert their protective effect through posttranslational modification of important regulatory proteins and by selective acetylation of histones. Presently, however, the choice of the specific crystalloid for resuscitation remains largely a matter of individual preference. Normal saline has the advantages of being universally available and being the only crystalloid that can be mixed with blood. Because its chloride concentration is significantly higher than that of plasma, patients resuscitated with normal saline often develop a fixed hyperchloremic metabolic acidosis that requires renal chloride excretion for correction. Lactated Ringer's solution has the advantage of a more physiologic electrolyte composition. The added lactate is converted to bicarbonate in the liver. Such conversion occurs readily in all but the sickest of patients.

Hypertonic saline solutions are crystalloids that contain sodium in suprphysiologic concentrations. They expand the extracellular space by exerting an osmotic effect that displaces water from the intracellular compartment. They also may exert a mild positive inotropic effect as well as producing systemic and pulmonary vasodilation. In comparison with isotonic crystalloids, hypertonic saline decreases wound and peripheral edema. Recent studies have indicated, however, that hypertonic saline resuscitation may increase the incidence of bleeding. Animal models indicate that this may be due to decreased ADP-mediated platelet aggregation.

Hypertonic saline solutions have received recent attention, particularly with regard to resuscitation of battlefield casualties,

because small volumes may produce large effects. Additionally, hypertonic saline may suppress neutrophil function through the modulation of chemoattractant receptor signaling pathways. Recent clinical work has found no increase in the incidence of hypernatremic seizures, increased bleeding or blood transfusion requirement, coagulopathies, renal failure, cardiac arrhythmias, or central pontine myelinosis. Hypertonic saline also has been shown to be advantageous when mixed with artificial colloids such as dextran.

2. COLLOIDS—As a group, colloids are solutions that rely on high-molecular-weight species for their osmotic effect. Because the barrier between the intra- and extravascular spaces is only partially permeable to the passage of these molecules, colloids tend to remain in the intravascular space for longer periods than do crystalloids. Smaller quantities of colloids are required to restore circulating blood volume. Because of their oncotic pressure, colloids tend to draw fluid from the extravascular to the intravascular space. They are significantly more expensive to use than crystalloids, even though smaller absolute volumes are required. The use of albumin solutions in the initial resuscitation stages of hypovolemic shock has not been shown to be more effective than the use of crystalloid. Rather, a meta-analysis of 26 prospective, randomized trials found an increased absolute risk for death of 4% when colloids were used for resuscitation.

a. Albumin—Albumin (normal serum albumin) is the most commonly used colloid. It has a molecular weight of 66,000–69,000 and is available as a 5% or 25% solution. Normal serum albumin is approximately 96% albumin, whereas plasma protein fraction is 83% albumin. Each gram of albumin can hold 18 mL of fluid in the intravascular space. The serum half-life of exogenous albumin is less than 8 hours although less than 10% leaves the vascular space within 2 hours after administration. When 25% albumin is administered, it results in increased intravascular volume approaching five times the administered quantity.

Like crystalloid infusion, the endpoints for the administration of colloid to patients in hypovolemic shock are largely subjective. Because albumin has been implicated as a cause of decreased pulmonary function, strict attention to resuscitation endpoints is required. Other reported complications include depressed myocardial function, decreased serum calcium concentration, and coagulation abnormalities. The latter two may be due simply to volume effects.

b. Hetastarch—Hetastarch (hydroxyethyl starch) is a synthetic product available as a 6% solution dissolved in normal saline. It has an average molecular weight of 69,000. Forty-six percent of an administered dose is excreted by the kidneys within 2 days, and 64% is eliminated within 8 days. Detectable starch concentrations may be found 42 days after infusion. Hetastarch is an effective volume expander, with effects that typically last between 3 and 24 hours. Intravascular volume increases by more than the volume infused. Most patients respond to between 500 and 1000 mL. Renal, hepatic, and pulmonary complications may occur when dosing exceeds 20 mL/kg per day.

Hetastarch may cause a decreased platelet count and prolongation of the partial thromboplastin time owing to its anti-factor VIII effect. Anaphylaxis is rare. A combination product containing 6% hetastarch in a balanced salt solution is now available. Because it may cause inhibition of factor VIII, its use for large-volume resuscitation requires further review. When used, it is typically administered at doses of 500–1000 mL.

A similar five-carbon preparation (pentastarch) is currently available only for leukapheresis but is also a useful volume expander. It may have fewer effects on the coagulation cascade than does hetastarch.

c. Dextrans—Two forms of dextran are generally available: dextran 70 (90% of molecules have MW 25,000–125,000) and dextran 40 (90% of molecules have MW 10,000–80,000). Both may be used as volume expanders. The extent and duration of expansion are related to the type of dextran used, the quantity infused, the rate of administration, and the rate of clearance from the plasma. The lower-molecular-weight molecules are filtered by the kidney and produce diuresis; the heavier ones are metabolized to CO₂ and water. The higher-molecular-weight dextrans remain in the intravascular space longer than do the lighter compounds. Dextran 70 is preferred for volume expansion because it has a half-life of several days. A 10% solution of dextran 40 has a greater colloid oncotic pressure than the 70% solution but is cleared from the plasma rapidly.

Several complications are associated with dextran administration, including renal failure, anaphylaxis, and bleeding. Dextran 40 is filtered by the kidney and may result in an osmotic diuresis that actually decreases plasma volume. It should be avoided in patients with known renal dysfunction. Dextran 70 infrequently has been associated with renal failure. Anaphylactic reactions occur in patients with high anti-dextran antibody titers. The incidence of reactions is between 0.03% and 5%.

Both dextrans inhibit platelet adhesion and aggregation probably via factor VIII:Rag activity. The clinical effect is similar to von Willebrand's disease. The effect is greater with dextran 70 than with dextran 40. Both preparations may interfere with serum glucose determinations and blood cross-matching.

d. Other colloids—Modified fluid gelatin (MFG) and urea-bridged gelatins are prepared as 3.5% and 4% solutions in normal saline, respectively. Both are effective plasma volume expanders. Their low molecular weight leads to rapid renal excretion. Anaphylactoid reactions (0.15%) are the most common complication. Rapid infusion of the urea-bridged formulation causes histamine release from mast cells and basophils. The incidence of allergic reactions is less for MFG. Gelatins may cause depression of serum fibronectin. They are not associated with renal failure and do not interfere with blood banking techniques. These preparations are used widely in Europe and in the military for mass casualties. They are currently unavailable in the United States.

Oxygen-carrying solutions such as stroma-free hemoglobin and perfluorocarbons are the subjects of active research. At present, however, they are available only for limited use and in clinical trials.

3. BLOOD—The hemoglobin concentration at which blood should be transfused is still hotly debated. The so-called transfusion trigger depends on a number of factors, including age, comorbid factors, presence of ongoing bleeding, etc. In healthy human volunteers, isovolemic hemodilution is tolerated at concentrations as low as 5 g/dL, whereas the National Institutes of Health recommend a concentration of greater than 7 g/dL. Traditionally, the transfusion trigger was set at 10 g/dL, but epidemiologic studies have shown that early transfusion is a strong independent risk factor for multiple-organ failure. While the exact mechanism is not known, neutrophil priming may play a role. This occurs when passenger leukocytes accompanying stored red blood cells generate proinflammatory agents. Such agents increase at between 14 and 42 days of blood storage. Additional factors such as decreased red cell deformability and cytokine production also have been cited.

Current Controversies and Unresolved Issues

A. Crystalloids versus Colloids—The crystalloid versus colloid debate has emerged anew, fueled by the findings that the traditional lactated Ringer's solution may be proinflammatory and that hypertonic saline may suppress disadvantageous immune responses. Presently, there is no clear indication that the current use of lactated Ringer's or normal saline as the resuscitation fluid of choice should be changed. Additional studies on the use of single-isomer solutions and hypertonic saline will be required. A meta-analysis of colloid use found an increase in the absolute number of deaths when compared with crystalloid, thus discouraging the use of high-molecular-weight solutions.

B. Ischemia-Reperfusion—Ischemia-reperfusion is an area of critical investigation. Clarification of the mechanism of oxygen radical tissue destruction with tissue reperfusion may help to prevent some of the complications of ischemia. A number of compounds, including diltiazem, amiloride, and pentoxifylline, have been explored in an effort to improve cardiac, peripheral vascular, and renal function after reperfusion.

C. Endpoints—The endpoints of resuscitation are parameters such as blood pressure, heart rate, and urine output. Tissue-specific monitors such as tissue oxygen tension (TPO_2) and intramucosal pH (pH_i) have received recent attention as objective indices. Because of the time required for pHi sample collection, it is unlikely to become a clinically useful tool for resuscitation. It may, however, be valuable for monitoring patients after they have stabilized. Tissue oxygen measurements use several modalities, including electrodes and fluorescence-quenching optodes. The latter has proved to be a reliable indicator of oxygen tension in the subcutaneous and visceral tissues during shock and resuscitation. Its clinical usefulness remains to be demonstrated.

D. Bacterial Translocation—The anomalous appearance of sepsis in patients who develop hypovolemic shock has raised the question of intestinal bacterial translocation. This theory proposes that ischemia of the intestinal mucosa allows

luminal bacteria to pass through or between cells and into the portal venous system. The mechanism has been clearly demonstrated in animals, but definitive evidence in humans is lacking. Elucidation of this mechanism may provide information on the prevention of sepsis in this setting.

DISTRIBUTIVE SHOCK

Distributive shock is so named because of the redistribution of blood flow to the viscera. The three types of distributive shock commonly treated in ICUs are septic, anaphylactic, and neurogenic shock.

▶ Septic Shock

ESSENTIALS OF DIAGNOSIS

- ▶ Increased cardiac output in the face of decreased blood pressure.
- ▶ Decreased peripheral oxygen consumption.
- ▶ Decreased systemic vascular resistance.
- ▶ Decreased ventricular ejection fraction.
- ▶ Associated multiple organ system failure.

General Considerations

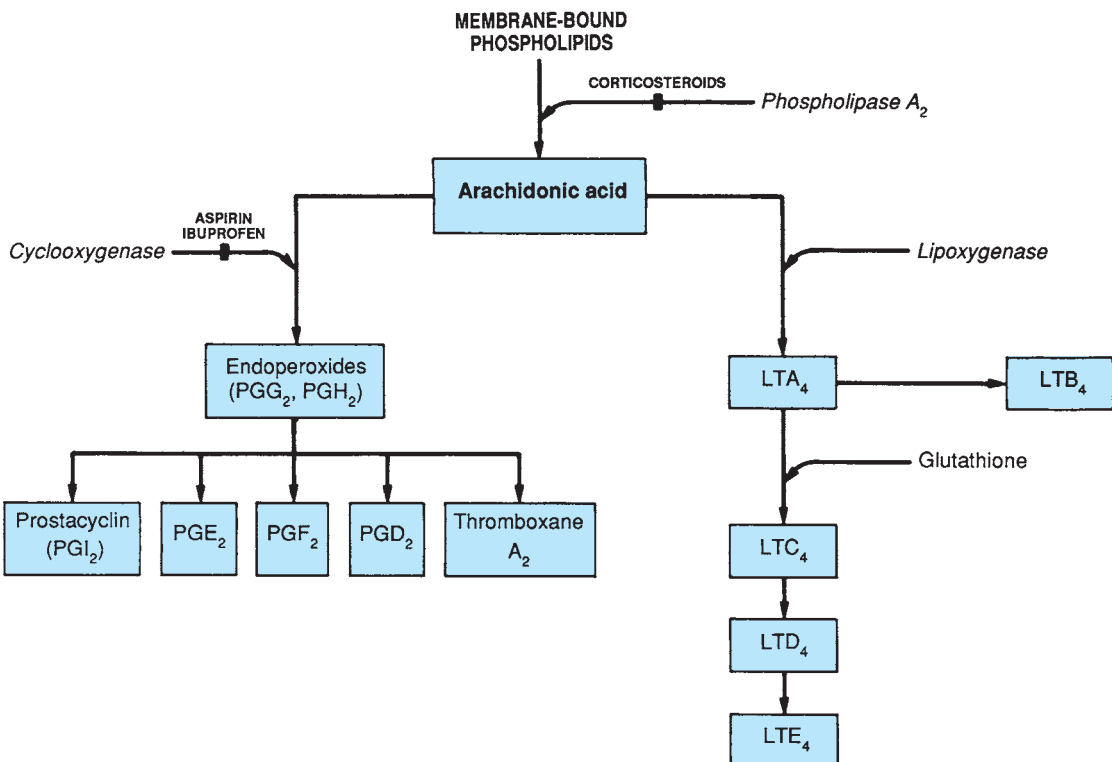

The incidence of septic shock has been increasing in the United States over the past several years. Approximately 100,000–300,000 people develop bacteremia each year, and one-half of these patients progress to septic shock. The overall

mortality rate from septic shock is between 40% and 60%. Higher death rates occur in the aged and in those with compromised immune status as a result of trauma, diabetes, malignancy, burns, cirrhosis, or treatment with antitumor chemotherapeutic agents. Aerobic gram-negative bacillary infections are the most common cause. The predominant organisms are *Escherichia coli* and *Klebsiella*. Gram-positive organisms such as staphylococci and fungi also may cause septic shock.

A. Pathogenesis—It is unlikely that bacteria per se are responsible for septic shock. Rather, interactions between their products and normal host defenses probably elicit the usual reactions. Gram-negative organisms have complex walls composed of lipopolysaccharides and proteins. Endotoxin is a lipopolysaccharide component of the outer membrane. It is composed of oligosaccharide side chains, a core polysaccharide, and lipid A. The chemical and physical structure of the latter is highly conserved between different bacterial species and is highly antigenic. In both animal and human studies it has been shown that infusion of lipid A causes many of the same effects observed in clinical sepsis. Endotoxin has effects on multiple regulatory systems, including complement, kinins, coagulation, plasma phospholipases, cytokines, β -endorphins, leukotrienes, platelet-activating factor (PAF), and prostaglandins.

Cytokines are a group of proteins produced by white blood cells in response to a number of stimulating factors. Although multiple cytokines have been identified, those known to be involved in the human septic response are TNF and interleukin-1 (IL-1), IL-2, and IL-6. These agents are likely to have both beneficial and deleterious effects. Increased levels of TNF, IL-1, and IL-6 have been correlated with a poor outcome. TNF produces hypotension and decreased ventricular function in animal studies. The cytokines are known to induce the release of counterregulatory hormones such as glucagon, epinephrine, and cortisol, which are necessary to support the response to sepsis. Cytokines responsible for modulation of the immune response include IL-4, IL-6, IL-10, IL-11, IL-13, and IL-1Ra (receptor antagonist). Compounds responsible for amplification of the immune response include IL-8, IL-12, IL-18, PAF, serotonin, and the eicosanoids.

Circulating endotoxin induces the production of a number of white blood cell products that arise from the release of arachidonic acid from leukocyte cell membranes mediated by phospholipase A_2 . The mobilized arachidonic acid then can follow one of two pathways: conversion to leukotrienes via the lipoxygenase pathway or creation of prostaglandins and thromboxanes via the cyclooxygenase pathway (Figure 11-1). The lipoxygenase and cyclooxygenase

▲ **Figure 11-1.** Pathways of arachidonic acid. (Adapted from Holcroft J, Robinson MK: Shock: Identification and management of shock states. In: *Care of the Surgical Patient*. Scientific American, 1992.)

compounds have distinct actions (Table 11–4). Phospholipase A₂ also releases membrane-bound alkyl phospholipids that may be converted into PAF, the most potent lipid mediator known. The actions of PAF include activation of phagocytes as well as of platelets, production of oxygen-free radicals, increase of vascular permeability, and decrease of cardiac output and blood pressure. Cells known to produce PAF include neutrophils, basophils, endothelial cells, and platelets.

Several plasma proteases are activated in septic shock. These include the kinin system, the clotting cascade, and the complement system. Endotoxin and gram-positive bacteria both activate the complement cascade via the extrinsic pathway. The effects of complement activation include (1) increased vascular permeability, (2) release of toxic oxygen metabolites by activated phagocytes, and (3) increased opsonization and phagocytosis by neutrophils and macrophages. It is likely that the increased vascular permeability so produced plays an important role in the hemodynamic picture characteristic of septic shock. A correlation has been demonstrated between increased concentration of activated complement and mortality rates. Concomitant activation of Hageman factor (XIIIa) may be responsible for

the disseminated intravascular coagulopathy associated with sepsis. Factor XIIIa also may lead to the conversion of prekallikrein to kallikrein and ultimately to the release of bradykinin, which causes severe hypotension.

Recent interest has focused on the roles of toxic oxygen metabolites and nitric oxide. Activated phagocytes produce oxygen radicals that kill ingested bacteria. When these products leak from the cell, they may cause severe tissue damage. Endothelium-derived relaxing factor (EDRF) is another toxic-free radical species. Chemically, it is nitric oxide (NO). While small quantities of NO may improve blood flow in the microcirculation, higher concentrations produce vasodilation and hypotension. NO may arise from several cell lines, including neutrophils, the vascular endothelium, and Kupffer cells. NO synthetase is induced by both endotoxin and TNF. It produces NO from L-arginine.

B. Hemodynamic Effects—The distinguishing hemodynamic features of septic shock are elevated cardiac output, decreased systemic vascular resistance, and decreased blood pressure. Tachycardia is partially responsible for maintaining the blood pressure. Earlier investigators described hyperdynamic and hypodynamic phases of septic shock. More recent investigations have shown, however, that cardiac output remains elevated until decreased output develops as a preterminal event. It is likely that the earlier observations were made in patients who were inadequately fluid-resuscitated.

Right and left ventricular ejection fractions are decreased in septic shock, as is left ventricular stroke work. In contrast to hypovolemic shock, increasing preload by administering volume only minimally increases left ventricular stroke work. This may be due to altered compliance characteristics of the ventricles. Pulmonary artery hypertension, which frequently develops early, also may be partially responsible for right ventricular dysfunction. Cardiac adrenergic downregulation also occurs. The number of receptors and their affinities are reduced. Patients who recover from septic shock increase their left ventricular stroke work index, whereas those who succumb do not. Radionuclide scans have shown that left ventricular dilation occurs within 1–2 days of the onset of shock. This increased end-diastolic volume permits a greater stroke volume in the face of decreased ejection fraction. Left ventricular dilation improves as patients recover. Despite the ventricular abnormalities, the coronary circulation exhibits above-normal flow, normal myocardial oxygen consumption, and net myocardial lactate extraction.

The myocardial depressant factor (MDF) of sepsis has been characterized as a low-molecular-weight protein (<1000). Patients with cardiac disease and sepsis without shock fail to exhibit such activity. MDF may originate from the intestinal tract in patients with hypovolemic shock. The cytokines and endotoxin have been suspected as the origin of MDF. However, TNF has a molecular weight of 17,000. Lipopolysaccharide, IL-1, and IL-2 in high concentrations

Table 11–4. Actions of arachidonic acid mediators.

Mediator	Actions
Prostacyclin (PGI ₂)	Vasodilation Decreased platelet aggregation
PGE ₂	Vasodilation Immunomodulation Platelet aggregation
PGF ₂	Vasodilation
PGD ₂	Vasodilation
Thromboxane A ₂	Vasoconstriction Increased platelet aggregation
LTB ₄	Chemotaxis Leukocyte–endothelial cell adhesion
LTC ₄	Immunomodulation Vasoconstriction Bronchoconstriction Increased vascular permeability
LTD ₄	Vasoconstriction Bronchoconstriction Increased vascular permeability
LTE ₄	Vasoconstriction Bronchoconstriction Increased vascular permeability

fail to duplicate the effect of MDE. The decrease in circulating plasma volume owing to increased capillary permeability is a major influence in the hemodynamic pathophysiology of sepsis. In addition to actual transudation of fluid from the intravascular into the interstitial space, peripheral pooling, hepatosplanchnic venous pooling, and gastrointestinal and wound losses—along with idiopathic polyuria—also reduce cardiac preload.

Changes in the pattern of blood flow distribution are characteristic of septic shock. It was once thought that shunting of blood through cutaneous arteriovenous pathways was responsible for decreased peripheral oxygen extraction, but the anatomic presence of such shunts has not been demonstrated. Rather, it is likely that a mismatching of blood flow and metabolic demand occurs. Thus some organs receive supranormal oxygen delivery, whereas others are rendered ischemic. This is of particular importance in the splanchnic circulation, where hepatic venous desaturation has been reported in septic patients. Oxygen extraction is also affected, resulting in flow-dependent oxygen consumption. A normal or elevated mixed venous oxygen saturation and decreased arterial-venous oxygen content difference is present. Lactic acidosis may indicate the presence of pathologic oxygen delivery-dependent consumption. It is unlikely that oxygen utilization is limited by mitochondrial dysfunction.

C. Metabolic Abnormalities—The extent of the metabolic response to sepsis depends not only on the duration and severity of the illness but also on the premorbid nutritional and immunologic status. Even though systemic oxygen consumption is decreased, the metabolic rate in sepsis is markedly elevated. Mixed fuels serve as the energy source, with an increase in the respiratory quotient (RQ) to between 0.78 and 0.82. Hepatic glucose production is markedly increased, with lactate and alanine serving as the major gluconeogenic precursors. Hyperglycemia is common, as is insulin resistance. The elaboration of catechols in response to the cytokines induces lipolysis, although ketosis is reduced as a result of decreased hepatic production. Hypertriglyceridemia may occur as a result of increased hepatic synthesis and decreased lipoprotein lipase activity. Protein turnover is greatly increased as a result of the breakdown of skeletal muscle, connective tissue, and visceral proteins as acid sources. Branched-chain amino acids serve as the preferred fuel source for skeletal muscle. Production of acute-phase reactants is increased, whereas production of albumin and transferrin is decreased.

D. Multiple-Organ Failure—Septic shock affects virtually all organ systems (Table 11–5). Although the exact mechanism responsible is not clear, this may result from microvascular injury and local inflammatory responses. Ischemia results from tissue hypoperfusion as blood flow is redistributed away from tissues with high metabolic demands.

The usual progression of organ system failures is pulmonary, hepatic, and renal. The mortality rate is proportionate to the number of organ systems that fail and reaches

80–100% when three or more systems are involved. Respiratory failure occurs in 30–80% of patients with septic shock and usually is in the form of ARDS. Hypoxemia refractory to increasing levels of support is characteristic. An elevated intrapulmonary shunt (\dot{Q}_s/\dot{Q}_t) makes the hypoxia resistant to increased concentrations of inspired oxygen. Pulmonary hypertension, increased extravascular lung water, and decreased pulmonary compliance accompany the syndrome. Respiratory muscle fatigue and depressed diaphragmatic contractility further complicate the situation.

Liver failure is manifested as hyperbilirubinemia and elevation of the aminotransferase and alkaline phosphatase concentrations. Decreased hepatic amino acid clearance and an elevation of serum amino acid concentrations are preterminal events. Histologic examination reveals intrahepatic cholestasis with minimal necrosis.

Renal failure may occur as a consequence of hypotension, from nephrotoxic drug administration (eg, aminoglycosides and amphotericin B), or from intrarenal corticomedullary shunting.

Clinical Features

A. Symptoms and Signs—Septic shock is classically defined as a mean blood pressure of less than 60 mm Hg (systolic pressure <90 mm Hg)—or a decrease in systolic blood pressure of more than 40 mm Hg from baseline—in a patient with clinical evidence of infection. Accompanying findings include fever or hypothermia, tachycardia, and tachypnea. Patients are frequently obtunded. The skin may be warm if hypovolemia is not present.

If a pulmonary artery catheter is placed for monitoring, an elevated cardiac output in the face of decreased systemic vascular resistance will be found. When decreased cardiac output is noted, hypovolemia should be suspected. Increased pulmonary artery pressures are common as a result of vascular reactivity and increased pulmonary vascular resistance. A pulmonary artery catheter capable of ejection fraction measurement will indicate a decrease in right ventricular ejection fraction and stroke volume. The left ventricular stroke work index is similarly depressed. Pulmonary capillary wedge pressure (PCWP) is usually low or normal. Volume infusion to increase the PCWP generally produces only minimal increases in cardiac output.

B. Laboratory Findings—Leukocytosis with an increased percentage of juvenile band forms is the usual finding. Neutropenia occurs in a small percentage of patients and portends a poor outcome. Disseminated intravascular coagulation (DIC) with increased prothrombin time, elevated fibrin split products, and decreased fibrinogen concentration are also common. Thrombocytopenia occurs in 50% of patients and may be due to endothelial adherence of platelets to reactive vascular endothelium. Overt bleeding is noted in less than 5% of patients.

Table 11-5. Recognition and assessment of organ system dysfunction.

	Indicators of Dysfunction	Degree of Dysfunction		
		Mild	Moderate	Severe
Respiratory tract	Pao ₂ , Fio ₂ , Pao ₂ /Fio ₂ , PEEP number of days on ventilator; peaks airway pressure; use of high-frequency ventilation or extra-corporeal membrane oxygenation	Pao ₂ /Fio ₂ >250	Pao ₂ /Fio ₂ 150-250	Pao ₂ /Fio ₂ <150
Kidneys	Creatinine level, creatinine clearance, BUN, need for dialysis to regulate serum potassium and bicarbonate	Creatinine <1.5 mg/dL	Creatinine 1.5-3.0 mg/dL	Creatinine >3.0 mg/dL; need for dialysis
Liver	Bilirubin, albumin, cholesterol, ALT, AST, γ -glutamyltransferase, alkaline phosphatase, ammonia	Bilirubin <3 mg/dL	Bilirubin 3-8 mg/dL; elevation of transaminases or alkaline phosphatase to twice normal values	Bilirubin >8.0 mg/dL; elevation of serum ammonia
Gastrointestinal tract	Stress-related mucosal ulceration and bleeding, mucosal acidosis, failure of pH regulation, volume of nasogastric drainage, ileus, diarrhea, intolerance of enteral feeding, acalculous cholecystitis, pancreatitis	Nasogastric drainage <300 mL/24 h, diarrhea in response to enteral feeding	Nasogastric drainage 300-1000 mL/24 h, visible blood in drainage fluid	Nasogastric drainage >1000 mL/24 h, upper GI bleeding necessitating transfusion, acalculous cholecystitis, pancreatitis
Heart	Supraventricular arrhythmias, elevated pulmonary artery wedge pressure and mean arterial pressure, reduced ventricular stroke-work index, requirement for inotropes or vasopressors to maintain adequate mean arterial pressure	Development of supraventricular tachycardias with heart rate <140 beats/min and no fall in mean arterial pressure	PAWP 16-30 mm Hg; requirement for dopamine or dobutamine at dosage of <10 μ g/kg/min to maintain satisfactory cardiac output and PAWP	Requirement for vasopressors (eg, dopamine, epinephrine, norepinephrine, phenylephrine, vasopressin) to maintain mean arterial pressure >80 mm Hg
Central nervous system	Glasgow Coma Scale score, especially on components reflecting level of consciousness	Glasgow score 13-14	Glasgow score 10-12	Glasgow score \leq 9
Hematologic system	Thrombocytopenia, elevated PT and PTT, elevated fibrin degradation products	Platelet count >60,000/mL	Platelet count 20,000-60,000/mL; mild elevation of PT or PTT in absence of anticoagulation	Platelet count <20,000/mL
Metabolic and endocrine systems	Insulin requirements, levels of T ₄ and reverse T ₃	Insulin requirement \leq 1 unit/h	Insulin requirement 2-4 units/h	Insulin requirement \geq 5 units/h
Immunologic system	Impaired DTH responsiveness, reduced in vitro lymphocyte proliferation, infection with ICU pathogens (eg, <i>S. epidermidis</i> , <i>candida</i> , <i>pseudomonas</i> , <i>enterococcus</i>)	Reduced delayed type hypersensitivity reactivity	Cutaneous anergy	Cutaneous anergy, recurrent infection with ICU pathogens
Wound healing	Wound infection, impaired formation of granulation tissue, wound dehiscence	Wound infection	Impaired formation of granulation tissue	Decubitus ulcers wound dehiscence

From Holcroft J, Robinson MK: Shock: Identification and management of shock states. In: *Care of the Surgical Patient*. Scientific American, 1992.

Hyperglycemia is common and probably reflects the action of counterregulatory hormones such as epinephrine, cortisol, and glucagon. Elevation of the serum glucose concentration in a patient receiving intravenous hyperalimentation may be the first indicator of impending sepsis. Hypoglycemia is frequently a preterminal event. Increased lactate concentration is common and reflects cellular hypoperfusion. Liver chemistries reveal an increase in bilirubin, aminotransferase, and alkaline phosphatase concentrations.

Mixed substrate fuel consumption increases the respiratory quotient to near 0.8. Hypermetabolic protein turnover is reflected by a negative nitrogen balance. Total serum amino acid levels are increased with the exception of branched-chain amino acids (eg, leucine, isoleucine, and valine), which are decreased.

Arterial blood gas determinations typically indicate moderate hypoxemia and metabolic acidosis. Unless severe respiratory muscle weakness is present, P_{aCO_2} is usually normal or only minimally elevated. The extent of arterial hypoxemia is related to the severity of the accompanying respiratory distress syndrome. The decrease in bicarbonate concentration may be greater than the increase in lactic acid level, which may be increased owing to both cellular metabolic failure and failure of the liver to clear excess production. Blood lactate levels have been shown to have greater prognostic value than oxygen-derived variables. Venous blood gases reveal an increased hemoglobin saturation. Although peripheral oxygen delivery is elevated, peripheral oxygen consumption and oxygen extraction are depressed. The arterial-venous oxygen content gradient is narrowed and may be less than 3 mL/dL. As volume is administered and oxygen delivery is increased, a corresponding increase in $\dot{V}O_2$ also may be noted. This supply dependency of oxygen consumption is characteristic of sepsis.

C. Microbiology—Positive blood cultures are present in about 45% of patients with the septic syndrome and septic shock. The frequency of organisms present varies in different studies, although gram-negative aerobic species usually predominate. A study found that 26% of patients with aerobic gram-negative bacteremia developed shock, whereas only 12% of those with gram-positive bacteremia went on to shock. There are no consistent differences in the laboratory findings of those with and without positive blood cultures. Furthermore, the mortality rates in the two groups are about the same (30% without versus 36% with). Other infecting organisms include *Candida albicans* and *Bacteroides fragilis*. Fungal infections are particularly common in patients with disorders associated with systemic immunocompromise such as diabetes. The prolonged use of antimicrobials and a history of polymicrobial bacterial infections also predispose to fungal sepsis.

Differential Diagnosis

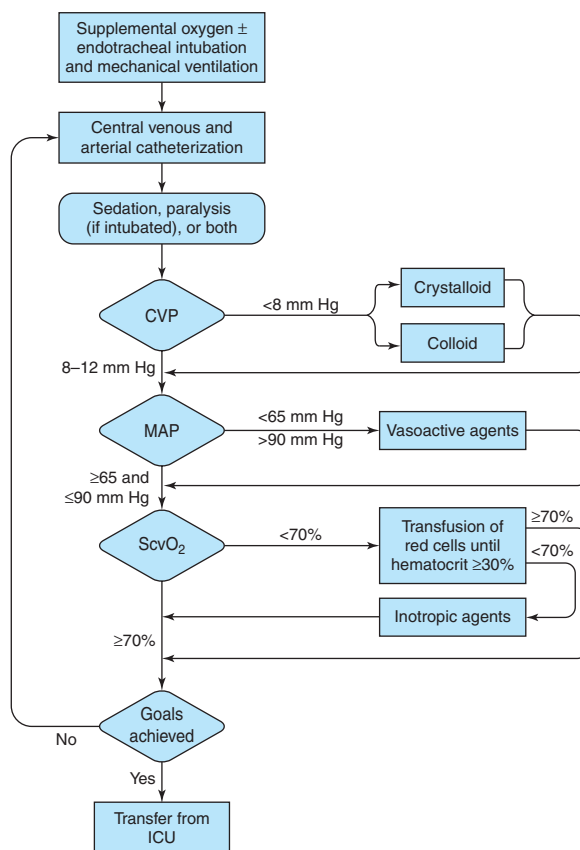

The difference between true septic shock and the septic syndrome is a matter of degree. The major differential factor is that hypotension is not part of the septic syndrome. Other

forms of distributive shock include anaphylaxis and neurogenic shock. A history of recent drug administration in the former and trauma in the latter should aid in diagnosis. Hemodynamic and cardiac shock rarely cause differential problems.

Treatment

A. Early Goal-Directed Therapy—Because of the numerous strategies available for the treatment of septic shock (BP <90 mm Hg), increased emphasis has been placed on evidence-based management. To this end, a protocol was developed as part of an international effort to create guidelines for the treatment of severe sepsis. The general protocol for such treatment is outlined in Figure 11-2.

B. Fluid Resuscitation—Restoration of adequate circulating blood volume is the first and most important therapy for septic shock. Loss of intravascular volume may be through capillary leaks, fistulas, diarrhea, or emesis. Patients may not

▲ **Figure 11-2.** A general protocol for early goal-directed therapy in the management of severe sepsis and septic shock.

have been receiving adequate oral intake or may have received insufficient maintenance intravenous fluid. Crystalloid is preferred by most physicians as the initial fluid for resuscitation. Rather than simply increase the infusion rate, patients should receive boluses of 500–1000 mL of fluid at a time. Because the extent of peripheral vasodilation may be massive, these patients may require large amounts of fluid. A central venous pressure catheter may be inserted to guide therapy. Bolus administration of volume should be titrated to maintain central venous pressure between 8 and 12 mm Hg. If a pulmonary artery flotation catheter is used, PCWP needs to be elevated to higher than normal levels before an adequate cardiac output and blood pressure are achieved. Typically, a PCWP of between 10 and 15 mm Hg will be required. This may call for the administration of several liters of balanced salt solution. Ongoing capillary leakage calls for continuing aggressive fluid replacement. Infusion should be monitored by watching for signs of pulmonary edema and congestive heart failure. Peripheral edema may be noted and is a normal consequence of the capillary leak that accompanies the systemic inflammatory response syndrome. The choice of crystalloid or colloid resuscitation remains controversial. Two meta-analyses that compared albumin and crystalloid found that mortality was higher among those who received albumin. However, some studies have found a trend toward reduced mortality when albumin was used. Because there is no clear benefit of either solution at this time, most clinicians prefer crystalloid solutions because of their reduced choice and universal availability.

C. Respiratory Support—Many patients with septic shock will have severe respiratory distress syndrome. They also may be unable to meet the increased demands of the work of breathing. Semiselective endotracheal or orotracheal intubation is recommended prior to the development of respiratory arrest. After intubation, mechanical ventilation always should be instituted to decrease the work of breathing. Many patients will require high inspired oxygen concentrations and positive end-expiratory pressures (PEEP). Inverse I:E ratio, pressure-controlled, and/or pressure-regulated volume-control ventilation may be required if pulmonary compliance is severely compromised. Airway pressure-release ventilation (APRV) is also useful in those with ARDS and poor oxygenation. The great advantage of APRV is that patients can be weaned from it directly without having to employ other modes. Treatment of respiratory failure is discussed in Chapter 3.

D. Pharmacologic Support—If intravascular volume resuscitation fails to restore blood pressure toward normal, pharmacologic support with pressor drugs is indicated. Target mean arterial pressure is between 60 and 65 mm Hg, although the optimal pressure is still debated. It is important not only to measure arterial pressure but also to evaluate overall perfusion based on SvO_2 , urine output, and resolution of increased arterial lactate. Both peripheral and cardiac adrenergic receptors appear to be downregulated in sepsis,

making the required dose of pressors higher than otherwise might be expected. Dopamine and norepinephrine are the most common pressors used for the treatment of septic shock. Although dopamine was used often initially in the past, there has been a trend toward the use of norepinephrine as the first-choice pressor (see below). Although no large-scale trials have been completed to determine which agents are associated with better outcomes, there is some evidence to suggest that patients who have not received dopamine have a lower 30-day mortality than those who have.

1. DOPAMINE—Dopamine is the immediate precursor of endogenous norepinephrine. Dopamine's hemodynamic effects are due to the release of norepinephrine from sympathetic nerves and the direct stimulation of alpha, beta, and dopaminergic receptors. Approximately 50% of dopamine's effect is due to the release of norepinephrine. When compared with dobutamine, dopamine's effect is less pronounced after endogenous norepinephrine stores have been depleted. At lower doses (2–5 $\mu\text{g}/\text{kg}$ per minute), dopamine increases cardiac contractility and cardiac output without increasing heart rate, blood pressure, or systemic vascular resistance. Renal blood flow and urine output increase in response to doses of 0.5–2 $\mu\text{g}/\text{kg}$ per minute as a result of selective stimulation of dopaminergic receptors. When doses reach 10 $\mu\text{g}/\text{kg}$ per minute, dopamine has both a chronotropic and an inotropic effect. At infusion rates in excess of 10 $\mu\text{g}/\text{kg}$ per minute, alpha-adrenergic stimulation occurs, along with an increase in systemic vascular resistance. The metabolic effects of dopamine administration include decreased aldosterone secretion, inhibition of thyroid-stimulating hormone and prolactin release, and inhibition of insulin secretion. Because it increases cardiac output, dopamine can increase pulmonary shunting by augmenting flow to poorly ventilated lung regions.

After ensuring adequate fluid resuscitation, dopamine infusion is usually started at a dose of 5 $\mu\text{g}/\text{kg}$ per minute and advanced until blood pressure increases. Used in low doses with norepinephrine, dopamine's selective effect on the renal vasculature may continue to allow adequate urine production while norepinephrine supports the blood pressure by its vasoconstrictive effect.

2. DOBUTAMINE—Dobutamine has predominantly β -adrenergic inotropic effects. It has a relatively minor chronotropic effect. Unlike dopamine, it does not cause the release of endogenous norepinephrine. It produces less increase in heart rate and peripheral vascular resistance than an equally inotropic dose of isoproterenol. It is the pressor of choice in patients with adequate blood pressure but depressed cardiac output. Onset of action is within 1–2 minutes, although the peak effect may not be reached until 10 minutes after administration. The plasma half-life is 2 minutes. The drug is methylated and excreted in the urine. Dobutamine tends to lose its hemodynamic effect after prolonged administration probably because of downregulation of receptors. However, dobutamine is a better choice for long-term infusion than

dopamine because the latter depletes myocardial norepinephrine stores. Dosage typically ranges from 5–15 $\mu\text{g}/\text{kg}$ per minute. Increased urine output also may be achieved after dobutamine administration because of increased renal perfusion from elevated cardiac output. Infusion is begun at a rate of 2–5 $\mu\text{g}/\text{kg}$ per minute and titrated to the desired effect. Maximal benefit is usually achieved at levels between 10 and 15 $\mu\text{g}/\text{kg}$ per minute.

3. ALPHA-ADRENERGIC AGENTS—Despite adequate volume resuscitation and improved cardiac output, blood pressure may remain depressed. Phenylephrine and norepinephrine are two agents commonly used to increase systemic vascular resistance.

Norepinephrine is the biosynthetic precursor of epinephrine, and as such possesses both α - and β -adrenergic activity. In low doses, its major effect is β -adrenergic. It increases cardiac contractility, conduction velocity, and heart rate. At higher doses, both α - and β -adrenergic effects occur, which include peripheral vasoconstriction, increased cardiac contractility, cardiac work, and stroke volume. Norepinephrine causes splanchnic vasoconstriction, which may lead to end-organ ischemia. The drug is cleared rapidly from the plasma with a half-life of approximately 2 minutes. Initial infusion rates are 0.5–1 $\mu\text{g}/\text{min}$. The usual maximum dose is 1 $\mu\text{g}/\text{kg}$ per minute.

4. VASOPRESSIN—Vasopressin (antidiuretic hormone) is normally released by the hypothalamus and produces vasoconstriction of vascular smooth muscle in addition to its antidiuretic effect on the renal collecting system. At low plasma concentrations it causes vasodilation of the coronary, cerebral, and pulmonary vessels. Vasopressin levels increase in early septic shock and later fall as sepsis worsens. When given in doses of 0.01–0.04 units/min, vasopressin infusion increases serum vasopressin levels and decreases the need for other vasopressors. At this dose, urinary output may increase, and pulmonary vascular resistance may decrease. Doses higher than 0.04 units/min can cause undesirable vasoconstrictive effects.

5. VASODILATORS—Because decreased vascular resistance is the primary cause of hypotension in septic shock, further pharmacologic vasodilation is contraindicated. Occasionally, severe myocardial depression is accompanied by an increase in systemic vascular resistance. This preterminal event puts further strain on the left ventricle and may cause complete hemodynamic collapse. Judicious use of vasodilators such as nitroprusside may be tried. Nitroglycerin is probably an inferior choice because it also reduces preload.

E. Antimicrobial Agents—Identification of the source of sepsis is imperative. If the offending tissue bed is not drained or if bacteremia is not treated, outcome will be adversely affected. Evaluation of the patient's history is essential to determine likely sources. Once the probable origin has been identified, appropriate antimicrobial therapy can be instituted to provide coverage for organisms commonly encountered. The details of diagnosis and therapy of infections are presented in Chapters 15 and 16. When a likely source cannot be identified,

empirical broad-spectrum therapy should be instituted with drugs known to be effective against gram-positive, gram-negative, and anaerobic organisms. In surgical patients who have had abdominal procedures, enteric gram-negative and anaerobic organisms are of particular concern. Attention must be given to dosing in these patients because alterations in renal function may affect degradation and because an expanded plasma volume affects the volume of distribution and therefore the size of the loading dose that must be given.

F. Glycemic Control—Hyperglycemia is defined as a blood glucose concentration of greater than 110 mg/dL and is common in critically ill patients. Multiple factors contribute to hyperglycemia, including increased levels of stress hormones, peripheral insulin resistance, drugs, and exogenous dextrose infusion. Hyperglycemia has a number of detrimental effects, including decreased leukocyte adhesion, impaired neutrophil chemotaxis, and phagocytosis. Hyperglycemia also may be prothrombotic.

Rigid control of hyperglycemia has been shown to improve outcome, likely by reducing the incidence of sepsis-induced multiple-organ failure. Additionally, tight control has been shown to reduce the length of stay in the ICU, attenuate the inflammatory response, decrease antibiotic use, reduce the incidence and duration of critical-illness polyneuropathy, and reduce the number of ventilator days.

Glucose control may be provided with either a glucose concentration-dependent dose ("sliding scale") or a constant infusion for higher serum glucose levels. Typically, glucose levels should remain below 130 mg/dL.

G. Corticosteroids—While older studies demonstrated no benefit to the use of supraphysiologic doses of corticosteroids, more recent work has found that lower physiologic doses for longer periods of time may be beneficial. Patients should undergo a Cortrosyn stimulation test. After obtaining blood for a baseline concentration of serum cortisol, 250 μg Cortrosyn is given intravenously, and blood for a repeat serum cortisol assay is collected 30–60 minutes later. If there is concern that the patient is hypoadrenal, 4 mg dexamethasone can be given prior because it does not interfere with the test. If the increase after Cortrosyn is less than 9 $\mu\text{g}/\text{dL}$, there is insufficient adrenal reserve, and 50 mg hydrocortisone should be given every 6 hours for 7 days. This should be supplemented with fludrocortisone 50 μg orally every day. It is likely that all patients should be started on replacement corticosteroid until the results of the stimulation study are known, at which time supplementation can be withdrawn from those who responded to the stimulation test.

H. Drotrecogin Alfa—Drotrecogin alfa is a glycoprotein analogue of protein C that is activated by thrombin. Activated protein C inhibits coagulation, increases fibrin breakdown, and possibly inhibits the synthesis of TNF. A large clinical study of drotrecogin alfa found a reduction in mortality from 30.8% in patients treated with placebo to 24.7% in those treated with the drug. The most important adverse effect of

the drug is bleeding, which occurred in 3.5% of those treated with the drug compared with 2% treated with placebo. Although the incidence of bleeding did not reach statistical significance, the drug is contraindicated in patients with active or recent bleeding or a high risk of bleeding, an epidural catheter, or intracranial hemorrhage. It should be used cautiously in those at risk for bleeding. Drotrecogin alfa is administered intravenously at a continuous dose of 24 µg/kg per hour for 96 hours. No alteration in the dose is required for those with renal or hepatic compromise. The drug's cost is approximately \$8000 for a 4-day regimen in a 70-kg patient.

I. Transfusion—The traditional transfusion threshold of 10 mg/dL has been challenged by the finding that patients are not adversely affected by withholding transfusion until hemoglobin concentration drops to between 7 and 9 g/dL. Further, there may be some advantage to lower hemoglobin concentrations in patients older than age 55. Such data come from broad groups of patients, and specific conclusions cannot be drawn. It is likely, however, that more restrictive thresholds are not harmful and actually may reduce mortality. The availability of recombinant human erythropoietin may be a useful adjunct to reducing the need for transfusion in critically ill patients.

J. Other Modalities—Septic patients require multimodality support, including gastrointestinal and renal. To this end, proper prophylaxis against gastric stress ulceration should be provided with either H₂-receptor blockade or proton pump inhibitors. Additionally, renal function must be monitored closely, and appropriate support with either hemofiltration and/or dialysis should be provided. Adequate prophylaxis against deep venous thrombosis includes either unfractionated or low-molecular-weight heparin. The dose of some low-molecular-weight heparins needs to be adjusted or withheld in patients with renal failure. Lower extremity compression stockings are valuable adjuncts.

Current Controversies and Unresolved Issues

A. Fluid Resuscitation—The choice of fluid for the initial and continued resuscitation of septic patients is widely debated. Proponents of balanced salt solutions claim that pulmonary dysfunction is not worsened by judicious administration guided by endpoints such as ventricular filling pressure and cardiac output. Colloids increase the circulating plasma volume more effectively than do crystalloids, but they are expensive. When pulmonary microvascular permeability is increased, colloids actually may worsen respiratory function by increasing the osmotic gradient favoring translocation of fluid into the alveolar and pulmonary interstitial spaces.

▶ Anaphylactic Shock & Anaphylactoid Reactions

ESSENTIALS OF DIAGNOSIS

- ▶ Cutaneous flushing, pruritus.
- ▶ Abdominal distention, nausea, vomiting, diarrhea.
- ▶ Airway obstruction owing to laryngeal edema.
- ▶ Bronchospasm, bronchorrhea, pulmonary edema.
- ▶ Tachycardia, syncope, hypotension.
- ▶ Cardiovascular collapse.

General Considerations

Anaphylactic shock and anaphylactoid reactions are due to the sudden release of preformed inflammatory mediators from mast cells and basophils. After exposure to the offending stimulus, initial symptoms may appear within seconds to minutes or may be delayed as long as 1 hour. *Anaphylactic*

Table 11-6. Frequency of anaphylactic events and deaths.

Agent	Frequency of Events		Deaths per Year (USA)
	Mild	Severe	
Penicillin	0.5-1%	0.04%	400-800
Hymenoptera stings	0.5%	0.05%	≥100
Contrast media	5%	0.10%	250-1000

From Lavine SJ, Shelhamer JH: Anaphylaxis. In: *Critical Care*. Civetta JM, Raylor RW, Kirby RR (editors). Lippincott, 1992.

shock is differentiated from anaphylactoid reactions in that the former is a true anamnestic response in which a sensitized individual comes in contact with an antigenic substance. This reaction stimulates membrane-bound IgE, causing mast cells and basophils to release histamine and PAF into the circulation. These mediators result in vasodilation, bronchoconstriction, pruritus, bronchorrhea, platelet aggregation, and increased vascular permeability. The latter may lead to laryngeal edema that culminates in airway obstruction. The frequency and outcome of anaphylactic reactions are summarized in Table 11-6. *Anaphylactoid reactions* occur when the offending agent causes the direct release of these substances without mediation by IgE. This may involve a number of pathways, including complement-mediated reactions, nonimmunologic activation of mast cells, and production of arachidonic acid mediators. Reactions to nonsteroidal anti-inflammatory drugs (NSAIDs) are particularly dangerous because NSAID inhibition of the cyclooxygenase pathway favors the formation of lipoxygenase pathway mediators from arachidonic acid. Some of these include leukotrienes C₄, D₄, E₄ (slow-reacting substance of anaphylaxis), and B₄. These leukotrienes and their intermediate products (5-HETE and 5-HPETE) increase vascular permeability and produce bronchoconstriction. Leukotriene B₄ is an eosinophilic and neutrophilic chemoattractant. If the cyclooxygenase pathway is activated by the inciting agent, the production of prostaglandin D₂ further bronchoconstriction. The most common agents causing anaphylactic shock and anaphylactoid reactions are listed in Tables 11-7 and 11-8. Anaphylactoid reactions may occur in up to 10% of patients. When an initial reaction occurs after the infusion of radiocontrast agents, the risk of a similar reaction on reexposure approaches 35%.

Clinical Features

A. Symptoms and Signs—The initial symptoms are often complaints of pruritus and a sense of impending doom. These can progress to overt signs over several seconds or may be delayed for up to an hour. Respiratory symptoms may

start with complaints of a lump in the throat, progressing to dyspnea, dysphonia, hoarseness, and cough. If pulmonary edema develops as a result of increased capillary permeability, dyspnea and cyanosis result. Cardiovascular findings begin with symptoms of weakness and faintness that may be accompanied by palpitations. As shock progresses, tachycardia

appears along with arrhythmias, conduction disturbances, and myocardial ischemia. Cutaneous symptoms include flushing and pruritus that progress to urticaria, angioedema, and diaphoresis. Patients may complain of abdominal pain or bloating, cramps, and nausea. These progress to emesis, diarrhea, and occasionally hematemesis and hematochezia. Other signs include syncope, seizures, conjunctival injection, lacrimation, rhinorrhea, and nasal congestion.

B. Laboratory Findings—An increased hematocrit is found commonly as a result of hemoconcentration from vascular permeability. Serum mast cell tryptase is usually elevated.

Differential Diagnosis

Several common disorders seen in the ICU may be confused with anaphylactic shock and anaphylactoid reactions: myocardial ischemia and infarction, cardiac arrhythmias, hypovolemic shock, septic shock, pulmonary embolism, aspiration of feedings, bronchitis, acute exacerbation of chronic obstructive pulmonary disease (COPD), seizure disorder, hypoglycemia, and cerebrovascular accidents. Relationship to administration of medications, blood, and new intravenous solutions should suggest the possibility of anaphylaxis.

Treatment

A. Airway—The first mandate is to ensure a secure airway. If the patient was intubated prior to the reaction, one should take care that the endotracheal or nasotracheal tube does not become dislodged during resuscitation. If the patient was not intubated, emergency airway control by bag and mask or intubation probably will be necessary. It is far better to intubate these patients before laryngeal edema develops because subsequent intubation is extremely difficult. Some clinicians recommend the use of inhaled racemic epinephrine (0.3 mL in 3 mL of saline administered by nebulizer) if upper airway compromise occurs because of edema. It is far safer to intubate the patient.

B. Circulatory Support—Most patients who develop anaphylactic shock or an anaphylactoid reaction in the ICU will already have intravenous access. However, this catheter may be small and will not permit the administration of large volumes of fluid over a short period of time. Large-bore peripheral intravenous lines are mandatory for fluid and drug administration. Do not attempt central line placement in a hypotensive patient who is hypovolemic. Collapse of the large veins normally used for central catheter placement increases the risk of a life-threatening complication.

1. EPINEPHRINE—Drug therapy should begin with epinephrine (1:1000), 0.3–0.5 mL subcutaneously. The dose of epinephrine may be repeated every 5–10 minutes as needed. If the patient does not respond to the initial dose—or if severe laryngospasm or frank cardiovascular collapse is present—5–10 mL of epinephrine (1:10,000) may be administered

intravenously. If intravenous access is not available, either 0.5 mL of a 1:1000 dilution may be given intramuscularly or 10 mL of a 1:10,000 dilution may be instilled into the endotracheal tube. When epinephrine is given intravenously, severe tachycardia, myocardial ischemia, vasospasm, and hypertension may result. Epinephrine decreases mediator synthesis by increasing intracellular concentrations of cAMP. Furthermore, it counteracts many of the deleterious effects of the mediators of anaphylaxis.

2. HISTAMINE ANTAGONISTS—Histamine antagonists should be administered as early as possible. Diphenhydramine (1 mg/kg intravenously) and ranitidine (50 mg intravenously over 5 minutes) are the preferred drugs. Cimetidine must be used with extreme caution because rapid intravenous administration may result in hypotension or asystole.

3. PRESSORS—If hypotension persists after the repeated administration of epinephrine and histamine antagonists, aggressive fluid resuscitation is required. If this fails, dopamine may be started at an initial dose of 5 µg/kg per minute and increased until the dose reaches 20 µg/kg per minute. A plateau effect occurs above this dose, requiring that a second pressor be used if an adequate response has not yet been achieved. Because of the extreme vasodilation, norepinephrine should be started in the range of 3–4 µg/min and titrated until a mean arterial pressure between 60 and 80 mm Hg is reached. The patient should be weaned from pressors as quickly as possible.

C. Other Measures—Continued observation in the ICU is indicated. An arterial catheter should be inserted for pressure monitoring and to aid in securing blood gas samples for ventilator management. In patients who remain unstable or who require continuing pressor infusion, a pulmonary artery catheter should be placed. Biphasic anaphylaxis may occur in up to 25% of patients. Life-threatening reactions reappear after an asymptomatic interval of up to 8 hours following resuscitation. Hydrocortisone, 100–250 mg intravenously every 6 hours, may help to prevent the late manifestations of biphasic anaphylaxis. Steroids probably have no role in the immediate treatment of acute anaphylaxis.

Patients who are receiving beta-blockers at the time of an anaphylactic reaction may be resistant to the effects of administered epinephrine. Atropine and glucagon may be useful adjuncts to reverse the cardiac manifestations of anaphylaxis in these patients.

Prognosis

The patient's overall medical condition, the delay between exposure to the antigen and the onset of anaphylaxis, and the severity of symptoms all influence the outcome.

▶ Neurogenic Shock

ESSENTIALS OF DIAGNOSIS

- ▶ Preceded by trauma or spinal anesthesia.
- ▶ Hypotension with tachycardia.
- ▶ Cutaneous warmth and flushing in the denervated area.
- ▶ Venous pooling.

General Considerations

Neurogenic shock is produced by loss of peripheral vasomotor tone as a result of spinal cord injury, regional anesthesia, or administration of autonomic blocking agents. Blood becomes pooled in the periphery, venous return is decreased, and cardiac output falls. If the level of interruption is below the midthorax, the remaining adrenergic system above the level of injury is activated, resulting in increased heart rate and contractility. If the cardiac sympathetic outflow is affected, bradycardia results. Blood pressure can decrease to extremely low levels as blood pools peripherally in the venous reservoir. All patients who have sustained spinal trauma should be assumed to have hypovolemic shock from associated injuries until proved otherwise.

Clinical Features

A. Symptoms and Signs—Patients may be alert and responsive if head injuries are absent. Extremities are warm above the level of injury and cool below. Blood pressure may be extremely low, with a very rapid heart rate. Skeletal musculature is affected after trauma. Loss of the peripheral venous muscular pump may further decrease venous return. Signs and symptoms of spinal cord injury and spinal shock will be present.

B. Laboratory Findings—Laboratory studies are not helpful in diagnosis. Because capillary permeability is normal, plasma leaks do not occur. Prior to volume resuscitation, hematocrit is usually normal.

C. Imaging Studies—Radiographs of the cervical, thoracic, and lumbosacral spine are important to determine whether fractures are present that may be unstable. These typically will have been completed before the patient was admitted to the ICU, but the intensivist must review the films so that patient manipulations will not cause further spinal cord injury. CT and MRI may be useful to determine whether fragments within the spinal canal may be causing cord compression. When present, they may be amenable to neurosurgical decompression.

Differential Diagnosis

Trauma patients considered for admission to a critical care unit after spinal injury must have thorough surgical and neurosurgical evaluation before transfer. The presence of concomitant hypovolemic shock from unrecognized bleeding sites within the abdomen, chest, and extremities must be excluded. Isolated head injury does not cause shock. Rather, it may increase the blood pressure while slowing the heart rate (Cushing's reflex).

Treatment

A. Supportive Measures—A secure airway and adequate intravenous access are urgent priorities. If intubation is required and there is concern regarding the stability of the cervical spine, fiberoptic or nasotracheal intubation may be required. A diligent search must be made for other injuries in trauma patients. When neurogenic shock arises from a spinal anesthetic procedure in which the level of blockade has become too high, intubation also may be necessary because of compromise of the muscles of respiration.

Depending on the level of the injury, patients may have loss of bladder function. A Foley catheter should be inserted to decompress the bladder and aid in monitoring urine output.

B. Fluid Resuscitation—Effective circulating blood volume decreases dramatically because of venous pooling. Fluid resuscitation is usually necessary and typically begins with several liters of balanced salt solution. In some patients, this may be all that is required to increase blood pressure.

C. Pharmacologic Support—If volume infusion fails to restore the blood pressure, infusion of an alpha-adrenergic agent is required to provide direct vasoconstriction. Either phenylephrine or norepinephrine may be used. These drugs are started in low doses and increased slowly until just sufficient to restore blood pressure to a mean between 60 and 80 mm Hg. Weaning usually can be achieved fairly quickly, so central venous or pulmonary artery catheterization is not often required.

D. Surgery—If spinal cord transection is complete, the only role for surgery is stabilization of vertebral fractures to prevent further injury. If a foreign body is present, removal may promote return of function if the cord is intact.

E. Rehabilitation—After the acute stage has passed and the patient has been stabilized, planning should be undertaken to provide long-term care. This is the most difficult part of the management of these patients. Demands on nursing and support personnel are extreme in order to prevent pressure ulcers and urinary and respiratory tract infections and to provide nutritional support. Early consultation with a psychiatrist is recommended to help the patient adjust to complete and permanent loss of function.

CARDIAC SHOCK

Cardiac shock occurs when the heart fails to adequately pump the blood volume presented to it. There are two general categories: cardiogenic shock and cardiac compressive shock. Cardiogenic shock develops when the heart loses its ability to function as a pump. Cardiocompressive shock is due to compression of the great veins and cardiac chambers, restricting their normal filling and emptying.

▶ Cardiogenic Shock

ESSENTIALS OF DIAGNOSIS

- ▶ Decreased urine output.
- ▶ Impaired mental function.
- ▶ Cool extremities.
- ▶ Distended neck veins.
- ▶ Hypotension with evidence of peripheral and pulmonary venous congestion.

General Considerations

Cardiogenic shock occurs most commonly either after relentless progression of cardiac disease or after an acute event such as myocardial infarction or rupture of a cardiac valve or septum. These causes are summarized in Table 11-9. The absolute amount of myocardium involved is probably

Table 11-9. Causes of cardiogenic shock.

Nonmechanical Causes	Mechanical Causes
Acute myocardial infarction	Rupture of septum or free wall
Low cardiac output syndromes	Mitral or aortic insufficiency
Right ventricular infarction	Papillary muscle rupture or dysfunction
End-stage cardiomyopathy	Critical aortic stenosis
	Pericardial tamponade

From Farmer JA: Cardiogenic Shock. In: *Critical Care*. Civetta JM, Taylor RW, Kirby RR (editors). Lippincott, 1992.

the most important prognostic factor. When more than 45% of the left ventricular myocardium is necrotic, cardiogenic shock becomes evident clinically.

Bradycardia and arrhythmias may underlie cardiogenic shock. Heart rates less than about 50 beats/min may be inadequate to support cardiac output. Similarly, arrhythmias may significantly alter cardiac filling patterns and prevent adequate pumping.

A staging system has been developed for the classification of cardiogenic shock that develops on a chronic basis.

A. Stage I (Compensated Hypotension)—The decreased cardiac output and resulting hypotension invoke compensatory mechanisms able to restore blood pressure and tissue blood flow to normal levels. These reflexes are mediated by the arterial baroreceptors, which increase the systemic vascular resistance.

B. Stage II (Decompensated Hypotension)—Cardiac output falls below that which enables the peripheral vasculature to maintain blood pressure by vasoconstriction. Blood pressure and tissue perfusion fall.

C. Stage III (Irreversible Shock)—Profound reduction in flow activates ischemic mediators such as the complement cascade. Membrane injury develops that further aggravates the ischemic insult. Irreversible myocardial and peripheral tissue damage occur.

Clinical Features

A. Symptoms and Signs—When cardiogenic shock occurs as a result of an acute event, pain may be a prominent finding. Details of diagnosis and management of acute myocardial infarction are presented in Chapter 22. When shock is an acute exacerbation of a relentless process or the result of another disease, symptoms may be less pronounced.

Physical examination will reveal signs consistent with the underlying pathophysiologic mechanism of decreased cardiac output and absolute hypervolemia. Blood pressure is less than 90 mm Hg. The heart rate may be extremely high and exceed the maximum aerobic limit (230—the patient's age in years). When decompensation occurs, bradycardia usually develops. Neck veins are distended, and pulsations frequently can be observed more than 4 cm above the clavicle with the patient in the semierect position. Peripherally, the extremities are cool, reflecting inadequate perfusion. Abdominal examination may reveal a congested and distended liver that is tender to palpation. Rales are detected on auscultation of the lungs in a patient who has a normal right ventricle. With biventricular failure or pulmonary hypertension, pulmonary auscultation may be normal. Cardiac examination typically reveals a third heart sound, and there may be a murmur characteristic of valvular disease.

B. Hemodynamic Effects—Virtually all patients with cardiogenic shock will require a pulmonary artery catheter for monitoring and evaluation of the response to therapy. The

usual findings are elevation of central venous and pulmonary capillary wedge pressures and a cardiac index less than about 1.8 L/min/m².

C. Laboratory Findings—If acute myocardial infarction is the precipitating cause, elevated cardiac bands of creatine kinase will be observed. Plasma drug levels of medications the patient has been receiving should be measured to determine whether they are in the toxic or subtherapeutic ranges. A routine chemistry panel is required to evaluate K⁺ and HCO₃⁻. Serum lactate may be elevated when shock has been prolonged. Hematocrit and hemoglobin should be determined to evaluate the need for transfusion.

D. Imaging Studies—Chest radiography often will reveal a pattern of pulmonary edema. Radionuclide ventriculography may be helpful in evaluating ventricular ejection fraction. Echocardiography is also useful in the evaluation of valvular and ventricular function. If pericardial tamponade is suspected, echocardiography is the examination of choice to establish that diagnosis.

Differential Diagnosis

Cardiogenic shock should be suspected in patients with chronic myocardial disease who experience a sudden worsening of symptoms. Acute myocardial infarction may be complicated by ventricular septal rupture, papillary muscle rupture, and papillary muscle dysfunction, which can lead to cardiogenic shock. Constrictive pericarditis and rupture of a cardiac ventricular aneurysm may lead to cardiac compressive shock. Rupture of an abdominal aortic aneurysm in a patient with coronary artery disease may cause diagnostic confusion. Abdominal pain owing to rupture of the aneurysm may simulate the pain of acute myocardial infarction. Electrocardiography typically reveals myocardial ischemia. The absence of distended neck veins is the critical distinguishing feature. Myocardial contusion after blunt trauma may cause severe cardiogenic shock.

Treatment

A. General Measures—Patient comfort and relief of anxiety should be addressed immediately. Opioids not only relieve pain and provide sedation—but they also block adrenergic discharge and lessen cardiac stress. Intravenous morphine should be given starting with a bolus of 2–4 mg. Dosing should be titrated to both subjective response and effect on blood pressure. Because morphine is a vasodilator, it may decrease right ventricular filling and adversely affect blood pressure in a hypovolemic patient. An arterial catheter and a pulmonary artery flotation catheter usually are mandatory to manage these patients effectively.

When cardiogenic shock is the result of acute myocardial infarction, early efforts should be directed at controlling the infarct size. An imbalance between oxygen delivery and increased oxygen consumption prompted by changes in heart rate, blood pressure, and contractility may extend the

size of the infarction. If therapy is begun within 3 hours of myocardial infarction, the incidence of cardiogenic shock is 4%. However, if therapy is delayed, cardiogenic shock occurs in up to 13% of patients. Intravenous nitroglycerin and beta-blockers are the main features of early treatment.

Nitroglycerin reduces right ventricular preload and decreases left ventricular afterload. The reduction in afterload decreases end-diastolic pressure and reduces wall stress and myocardial oxygen consumption. Furthermore, it dilates epicardial vessels and may improve oxygen delivery to ischemic areas. The early use of nitroglycerin both decreases infarct size and reduces early mortality. The possibility of right ventricular infarction and pericardial tamponade must be excluded before therapy with nitroglycerin is begun.

Beta-blockers decrease myocardial oxygen demand, antagonize circulating catechols, and have antiarrhythmic activity. A particular benefit may accrue when beta-blockers are combined with thrombolytic agents. Beta-blockers are best started within 2 hours of infarction. Calcium channel blockers also have been investigated for this purpose but have failed to demonstrate efficacy in acute situations. The mortality rate may be increased if calcium channel blockers are used in patients with pulmonary edema.

B. Resuscitation—Although cardiogenic shock may occur in patients with whole body fluid overload, they may be effectively hypovolemic. If PCWP is less than 10–12 mm Hg, balanced salt solution should be administered in an attempt to increase filling pressures. Cardiac output should be measured after each change of 2–3 mm Hg in PCWP. Filling pressures near 20 mm Hg may be required before cardiac output increases.

If laboratory studies reveal that the patient is hypoxemic, supplemental oxygen should be provided. Oxygen delivery should be maximized by ensuring complete arterial hemoglobin saturation. Intubation with PEEP may be required to accomplish this when pulmonary edema is present. Judicious use of PEEP is required because it adversely affects ventricular preload and cardiac output.

C. Pharmacologic Support—Once volume status has been optimized, support of the failing myocardium is often necessary. Inotropes, vasodilators, and diuretics all may be used.

1. INOTROPES—

a. Dobutamine—Dobutamine is the inotropic drug of choice for the management of congestive heart failure and cardiogenic shock. It is a β₁-adrenergic agonist that has minimum chronotropic and peripheral vasoconstrictive effects. It has a significant advantage over dopamine in that it does not cause the release of norepinephrine. Furthermore, it does not require the presence of norepinephrine at the nerve terminals for effect. Because of its minimum chronotropic effect, dobutamine can improve ventricular performance without significantly increasing myocardial oxygen demand. Dobutamine's greatest potential is realized in patients with reduced cardiac indices and increased filling pressures.

Because it is a vasodilator, dobutamine reduces filling pressures and wall tensions in patients with dilated ventricles. This permits better myocardial nutrient flow during diastole. A recent study found a 33% improvement in cardiac index, a decrease in systemic vascular resistance, and no change in heart rate or systemic blood pressure when dobutamine was given in doses that averaged 8.5 $\mu\text{g}/\text{kg}$ per minute. The drug may be given in doses up to 40 $\mu\text{g}/\text{kg}$ per minute without significantly increasing heart rate. When three-vessel coronary artery disease is present, dobutamine may create a steal and direct blood away from ischemic areas.

b. Dopamine—The effects of dopamine depend on the dose administered. In lower doses (<4 $\mu\text{g}/\text{kg}$ per minute), dopamine increases renal blood flow by stimulating dopaminergic (D_1) receptors in the kidney and causes peripheral vasodilation through D_2 receptors that inhibit the release of norepinephrine. At intermediate dosages (5–10 $\mu\text{g}/\text{kg}$ per minute), dopamine improves cardiac function and increases blood pressure without elevating myocardial oxygen consumption. Systemic vascular resistance is usually not increased. At higher doses (>10 $\mu\text{g}/\text{kg}$ per minute), dopamine elevates systemic vascular resistance by stimulating alpha-adrenergic receptors and heart rate by stimulating beta-adrenergic receptors. A recent study found that an average dose of 17 $\mu\text{g}/\text{kg}$ per minute was needed to optimize coronary perfusion pressure in a group of patients that developed cardiogenic shock after myocardial infarction. Dopamine at such high levels increases myocardial oxygen demand, produces tachycardia, and may limit renal perfusion. It should be used with caution in patients with cardiogenic shock because it may adversely influence the balance of myocardial oxygen delivery and consumption.

c. Digoxin—Although digitalis preparations have modest inotropic effects, they are probably of little importance in the treatment of cardiogenic shock except for the treatment of atrial fibrillation with rapid ventricular response. Small intravenous doses of digoxin may improve diastolic filling time and increase cardiac output in these situations.

d. Isoproterenol—This agent causes tachycardia, increased myocardial contractility, and decreased peripheral vascular resistance through its stimulation of both α_1 and β_2 receptors. Myocardial oxygen consumption is increased dramatically. Although isoproterenol increases coronary blood flow, it actually may shunt blood away from ischemic areas and increase the infarct size. Highly restricted indications include the presence of bradycardia and severe aortic valvular insufficiency. Intravenous administration is started at a dose of 0.01 $\mu\text{g}/\text{kg}$ per minute and increased until the desired effect is obtained.

e. Norepinephrine—Norepinephrine has both alpha- and beta-adrenergic effects. At low doses, it causes beta stimulation of the heart and increases blood pressure and cardiac output. At higher doses, it primarily affects the alpha-adrenergic receptors and supports blood pressure by increasing systemic vascular resistance. At higher doses it also tends to produce tachycardia, arrhythmias, and peripheral visceral ischemia. Norepinephrine should be used with extreme caution

because at higher doses it increases left ventricular afterload and may worsen myocardial ischemia. If cardiogenic shock proves resistant to both dobutamine and dopamine, norepinephrine may be started at doses of 1–2 $\mu\text{g}/\text{min}$ and increased until blood pressure increases. Of particular concern are the visceral and renal vasoconstrictive effects that may produce end-organ ischemia in the face of apparently satisfactory blood pressure.

f. Other agents—*Amrinone* is a weak inotrope that increases contractility independently of the catechol pathways. Although its exact mechanism of action is not known, it increases intracellular cAMP and calcium concentrations. The increased cAMP concentration in smooth muscle decreases peripheral and pulmonary vascular resistance and dilates coronary arteries. *Amrinone* increases stroke volume without increasing heart rate. The usual loading dose is 0.75 mg/kg over 3–5 minutes, followed by a second bolus 30 minutes later. The boluses are followed by a continuous intravenous infusion of 5–10 $\mu\text{g}/\text{kg}$ per minute. The total daily dose should not exceed 10 mg/kg. After the bolus is given, effects are seen within several minutes.

Glucagon increases cardiac contractility and decreases peripheral vascular resistance. The onset of action is extremely rapid. A test dose of 4–6 mg should be given intravenously to determine whether any effect is produced. If successful, this is followed by a constant infusion of 4–12 mg/h. The agent appears to be useful for the treatment of cardiogenic shock and left ventricular failure. It probably merits consideration in patients who have failed to respond to other agents or when dysrhythmias develop. It may be helpful when left ventricular dysfunction is a result of treatment with beta-blockers. Hyperglycemia is a side effect of the drug.

2. VASODILATORS—Vasodilators are used to lower left ventricular afterload, which decreases myocardial oxygen consumption. Their use is limited by their hypotensive effect, which may compound the difficulties associated with peripheral oxygen delivery.

a. Nitroprusside—Nitroprusside decreases both afterload and preload. When nitroprusside is used optimally, the increase in left ventricular ejection fraction partially offsets the decrease in systemic vascular resistance. Therapy begins with a dose of 5–10 $\mu\text{g}/\text{min}$ and is advanced in increments of 2.5–5 $\mu\text{g}/\text{min}$ every 10 minutes until an increase in cardiac output is noted. The dose should be reduced if systolic blood pressure falls below 90 mm Hg. Nitroprusside may produce an intracoronary steal that may aggravate areas of ischemia. The drug is metabolized to cyanide and subsequently to thiocyanate. Doses above 3 $\mu\text{g}/\text{min}$ may lead to toxicity, especially when the drug is used for more than 3 days. Free cyanide ions combine with cytochromes, leading to anaerobic metabolism and increased lactate levels. This results in a metabolic acidosis that eventually culminates in confusion, hyperreflexia, and coma. Thiocyanate levels should be monitored and not permitted to rise above 10 mg/dL. Prophylactic infusion of hydroxocobalamin may avert toxicity by combining with cyanide to form cyanocobalamin.

b. Nitroglycerin—Nitroglycerin is a nitrate derivative whose greatest effect is preload reduction, which reflexly decreases left ventricular filling. It has the additional advantage of dilating the coronary vasculature and is the drug of choice when cardiogenic shock is due to ischemia. Nitroglycerin is also effective in the treatment of acute valvular incompetence. Care must be exercised to ensure that patients are not hypovolemic prior to its administration because the increased venous capacity will decrease venous return and further lower the cardiac output. The normal starting dose is 10 $\mu\text{g}/\text{min}$, which can be increased by 10 $\mu\text{g}/\text{min}$ every 5–10 minutes to a total dose of 50–100 $\mu\text{g}/\text{min}$. Doses as high as 400 $\mu\text{g}/\text{min}$ can be tolerated for several days.

D. Other Modalities—The management of acute myocardial infarction is discussed in Chapter 22. Newer modalities available to improve cardiac function after infarction include thrombolytic therapy, percutaneous angioplasty, balloon pumping, and left ventricular assist devices. Emergency coronary artery bypass grafting is an option for patients who fail to respond to other forms of treatment.

Prognosis

Fulminant cardiogenic shock continues to carry a mortality rate of 90% when only pharmacologic therapy is used. Application of percutaneous transluminal coronary angioplasty, left ventricular assist devices, and early surgical revascularization may help to improve this outcome.

► Cardiac Compressive Shock

ESSENTIALS OF DIAGNOSIS

- Hypotension with tachycardia.
- Oliguria.
- Mental status changes.
- Distended neck veins.

General Considerations

Cardiac compressive shock is a low-output state that occurs when the heart or great veins are compressed. Compression either impedes the return of blood to the heart or prevents

effective pumping action of the heart itself. Pericardial tamponade is due to fluid within the pericardial sac that constricts the cardiac chambers and prevents them from filling properly. This may occur acutely after penetrating trauma with laceration of a coronary artery, or it may be progressive with chronic diseases such as uremia and connective tissue disorders. Distention of the abdomen with elevation of the diaphragm compresses the heart and may produce a form of shock. PEEP used with mechanical ventilation increases the intrathoracic pressure, which both collapses the superior and inferior venae cavae and reduces the transmural pressure gradient, thereby decreasing cardiac filling. In similar fashion, tension pneumothorax increases the intrathoracic pressure and decreases venous return.

Clinical Features

A. Symptoms and Signs—Signs associated with poor peripheral perfusion such as hypotension, tachycardia, cool extremities, oliguria, and altered mental status are usually present. The presence of distended neck veins is central to the diagnosis, although they may be absent if the patient is hypovolemic. When tension pneumothorax is the cause, hyperresonance is noted on thoracic percussion, breath sounds are absent on the affected side, and the mediastinum is shifted away from the involved chest. Displacement of the trachea in association with distended neck veins is pathognomonic of tension pneumothorax. For patients who are breathing spontaneously, inspiration increases the degree of venous distention (Kussmaul's sign). Paradoxical pulse also may occur with spontaneous breathing and consists of a decrease in systolic pressure of more than 10 mm Hg with inspiration.

When cardiac compressive shock occurs after injury, penetrating trauma to the chest is usually present. Pericardial tamponade is uncommon after blunt injuries. Patients admitted for exacerbations of chronic disease often have a history of pericardial effusion. When mechanical ventilation is used, cardiac compressive shock occurs because (1) the inflated lungs compress the superior and inferior venae cavae, (2) the right atrium and ventricle are compressed, and (3) expansion of the lungs compresses the pulmonary vasculature and increases the resistance to right ventricular ejection. Hypotension and tachycardia worsen in these patients as PEEP is increased. The correlation between the two may not be apparent at first, although careful examination of the patient's flowsheet will reveal changes in hemodynamics that correspond to ventilator manipulations.

B. Hemodynamic Monitoring—Central venous pressure is increased, as are pulmonary artery and pulmonary capillary wedge pressures. Equalization of central venous pressure, pulmonary artery, and pulmonary capillary wedge pressures strongly suggests pericardial tamponade.

C. Imaging Studies—Upright posteroanterior chest radiographs may show an enlarged cardiac shadow, but this is nonspecific. If tension pneumothorax is suspected, treatment

must not be delayed while x-rays are obtained. If an incidental chest radiograph is available, it will reveal hyperlucency of one or both hemithoraces with displacement of the mediastinal structures to the contralateral side. Transesophageal two-dimensional echocardiography is very sensitive and can be used to establish the diagnosis in nonemergent situations. Treatment of suspected decompensated traumatic pericardial tamponade should never be postponed while awaiting imaging studies.

Differential Diagnosis

Primary cardiogenic shock without compression presents the major differential dilemma because both types present with low cardiac output and high venous pressure. An acute myocardial infarction or progressive deterioration in a critically ill patient suggests cardiogenic shock. Most patients who develop tension pneumothorax or pericardial tamponade after injury will have had the diagnosis established and therapy instituted before arrival in the critical care unit. Missed injuries occur occasionally and must be differentiated from traumatic air embolism to the coronary arteries. The latter usually causes severe dysrhythmias and a rapid downhill course.

Treatment

A. Fluid Resuscitation—Rapid fluid infusion may transiently compensate for the decrease in ventricular filling. Central venous pressure cannot be used to guide such infusion because central venous pressure always will be elevated prior to the administration of fluid.

B. Operative Treatment—Surgical decompression of the offending site is indicated. For tension pneumothorax, immediate insertion of a large-bore intravenous catheter into the affected hemithorax will rapidly release the increased pressure. After pulse and blood pressure return to normal, this small catheter can be replaced with a larger tube thoracostomy connected to a chest evacuation device. Placement of the smaller catheter never should be delayed pending procurement and placement of a more definitive thoracostomy tube. If cardiac compression is due to gastric distention, placement of a nasogastric tube may be helpful. When distention is due to other causes, surgical exploration is usually warranted. Pericardial decompression should be performed for pericardial tamponade. Reduction of ventilatory pressures and augmentation of the circulating blood volume, if possible, usually correct compression resulting from the use of PEEP.

Respiratory Failure

Darryl Y. Sue, MD
Janine R. E. Vintch, MD

12

PATHOPHYSIOLOGY OF RESPIRATORY FAILURE

Respiratory failure is inability of the respiratory system to maintain a normal state of gas exchange from the atmosphere to the cells as required by the body. Simply, the role of the respiratory system is to maintain normal arterial blood PO_2 , PCO_2 , and pH. Respiratory failure can result from disorders of the lungs, heart, chest wall, respiratory muscles, and central ventilatory control mechanisms. In addition, dysfunctions of the heart, the pulmonary and systemic circulations, the oxygen-carrying capacity of the blood, and systemic capillaries have important implications for patients with respiratory failure.

Definition

Respiratory failure is present (1) if arterial PO_2 (PaO_2) is less than 60 mm Hg or (2) if arterial PCO_2 ($PaCO_2$) is greater than 45 mm Hg. A PaO_2 of less than 60 mm Hg, indicating hypoxemic respiratory failure, is valid during room air breathing (inspired O_2 fraction [FIO_2] = 0.21), but hypoxemia while breathing supplemental oxygen also indicates respiratory failure. An exception to the rule that $PaCO_2$ greater than 45 mm Hg defines hypercapnic respiratory failure is metabolic acidosis. Patients with metabolic acidosis normally decrease $PaCO_2$ to compensate for low pH, but if $PaCO_2$ is abnormally elevated even though below 45 mm Hg during metabolic acidosis, respiratory failure is present.

Effectiveness and Efficiency of the Respiratory System

It is useful to distinguish between the *effectiveness* and the *efficiency* of the respiratory system in maintaining arterial blood gases. An arterial PO_2 of 100 mm Hg, for example, indicates effective oxygenation (more than adequate). Effective elimination of CO_2 is evidenced by an arterial PCO_2 of 40 mm Hg if this $PaCO_2$ is consistent with an acceptable acid-base status. On the other hand, there is an obvious difference between two

patients who each have a PaO_2 of 100 mm Hg if the first patient is breathing room air ($FIO_2 = 0.21$) and the other is breathing 100% O_2 ($FIO_2 = 1.0$). The first patient is exchanging oxygen more efficiently from the atmosphere to the arterial blood than the latter. PaO_2 determines the effectiveness of oxygenation; the relationship between inspired oxygen concentration and PaO_2 is a marker of efficiency.

$PaCO_2$ measures the effectiveness of ventilation. Two patients with $PaCO_2$ of 40 mm Hg have equally effective ventilation. If one of them needs a higher minute ventilation (respired gas volume in 1 minute) than the other, however, the patient requiring the higher minute ventilation is less efficiently eliminating CO_2 than the one with the lower minute ventilation. Thus the relationship between $PaCO_2$ and minute ventilation ($\dot{V}E$) reflects the efficiency of ventilation. Measurement of the degree of inefficiency of oxygenation and ventilation is discussed below.

Classification of Respiratory Failure

One classification of respiratory failure separates disorders that affect the lungs (airways, alveolar spaces, interstitium, and pulmonary circulation) from those that affect primarily the nonlung components of the respiratory system. Respiratory failure from diseases that directly affect the lungs almost always has hypoxemia, but these patients may or may not have hypercapnia depending on the type of disease and its severity. Examples include pneumonia, aspiration of gastric contents, acute respiratory distress syndrome (ARDS), pulmonary embolism, asthma, and interstitial lung diseases.

Disorders of the nonpulmonary respiratory system usually cause hypercapnia plus hypoxemia. Examples include diseases that cause weakness of the respiratory muscles, CNS diseases that disrupt ventilatory control, and conditions that affect chest wall shape or size, such as kyphoscoliosis. In hypercapnic respiratory failure, the lungs may in fact be normal, so hypoxemia out of proportion to hypercapnia most

likely indicates additional lung disease. An example might be a patient with neuromuscular weakness from myasthenia gravis who initially presents with hypercapnic respiratory failure but who subsequently develops pneumonia from an inability to clear tracheal secretions. At this point, the patient may be considered to have hypoxemic respiratory failure in addition to hypercapnia.

► Hypercapnic Respiratory Failure

Patients with hypercapnic respiratory failure have an abnormally high PaCO_2 . Because CO_2 is elevated in the alveolar spaces, O_2 is displaced from the alveoli, and PaO_2 decreases. Thus these patients usually have both hypercapnia and hypoxemia unless the inspired gas is enriched with oxygen. The lungs themselves may or may not be abnormal, especially if the primary disease affects nonlung parts of the respiratory system such as the chest wall, respiratory muscles, or brain stem. On the other hand, chronic obstructive lung disease not infrequently leads to hypercapnic respiratory failure, and some patients with severe asthma, end-stage pulmonary fibrosis, and severe ARDS can develop hypercapnia.

► Physiologic Considerations

A. Alveolar Hypoventilation—In the steady state, a patient produces CO_2 from metabolic processes each minute and must eliminate that CO_2 from the lungs each minute. If the minute output of CO_2 (\dot{V}_{CO_2}) exchanges into the gas-exchanging spaces of the lungs, the fractional concentration of CO_2 in the alveolar space is:

$$F_{\text{ACO}_2} = \frac{\dot{V}_{\text{CO}_2} (\text{L/min STPD})}{\dot{V}_A (\text{L/min BTPS}) \times 0.826}$$

where F_{ACO_2} is the fractional concentration of CO_2 in the alveoli, \dot{V}_A is the volume of air exchanging in the alveoli during that minute (alveolar ventilation), and 0.826 adjusts for temperature and water vapor. The sum of partial pressures of individual gases equals the total pressure, so the fraction of alveolar gas that is CO_2 also can be written as

$$F_{\text{ACO}_2} = \frac{\text{PACO}_2 (\text{mm Hg})}{\text{PB} (\text{mm Hg})}$$

where PACO_2 is the alveolar partial pressure of CO_2 and PB is barometric pressure. Because PACO_2 cannot be measured, PaCO_2 is usually substituted. Substituting and rearranging the preceding equation gives

$$\dot{V}_{\text{CO}_2} (\text{L/min}) = \text{PaCO}_2 (\text{mm Hg}) \times \dot{V}_A (\text{L/min}) \times \frac{1}{863}$$

where 863 includes factors that adjust for \dot{V}_{CO_2} at standard temperature and pressure, dry (STPD); for \dot{V}_A at body temperature and pressure, saturated (BTPS); and for PaCO_2 in millimeters of mercury. For constant CO_2 output, the relationship between PaCO_2 and \dot{V}_A describes a “ventilatory hyperbola” in which PaCO_2 and \dot{V}_A are inversely related. Thus hypercapnia is always means alveolar hypoventilation, and hypocapnia is synonymous with alveolar hyperventilation. Because alveolar ventilation cannot be measured, estimation of alveolar ventilation can be made only by using PaCO_2 and this formula.

B. Minute Ventilation—In a patient with alveolar hypoventilation, \dot{V}_A is reduced and PaCO_2 is increased. Although \dot{V}_A cannot be measured directly, the total amount of gas moving into and out of the lungs each minute can be measured easily. This is defined as the *minute ventilation* (\dot{V}_E , L/min). \dot{V}_E is the sum of the \dot{V}_A (the portion participating in gas exchange) and any wasted or dead-space ventilation (\dot{V}_D):

$$\dot{V}_E = \dot{V}_A + \dot{V}_D \quad \text{and} \quad \dot{V}_A = \dot{V}_E - \dot{V}_D$$

Substituting, $\dot{V}_A = f \times V_A$; $\dot{V}_E = f \times V_T$; and $\dot{V}_D = f \times V_D$ —where f is the respiratory frequency, V_T is tidal volume, and V_D is dead-space volume:

$$\dot{V}_A = \dot{V}_E \times \left(1 - \frac{V_D}{V_T} \right)$$

where V_D/V_T is the dead space:tidal volume ratio. Substituting and rearranging gives

$$\dot{V}_E = \frac{\dot{V}_{\text{CO}_2} \times 863}{\text{PaCO}_2 \times \left(1 - \frac{V_D}{V_T} \right)}$$

V_D/V_T reflects the degree of ventilatory inefficiency of the lungs. In a normal subject, V_D/V_T is about 0.30, meaning that about 30% of the minute ventilation is not participating in gas exchange. In most lung diseases, the wasted proportion of \dot{V}_E increases, so V_D/V_T rises. From the preceding formula for a constant V_D/V_T and \dot{V}_{CO_2} , the relationship of PaCO_2 and \dot{V}_E is described by a hyperbola transposed upward from the hyperbola described by the relationship between PaCO_2 and \dot{V}_A . For different values of V_D/V_T , these relationships are described by a family of hyperbolic curves (Figure 12–1). These curves are useful in estimating V_D/V_T from measurement of PaCO_2 and \dot{V}_E , or they can be used to determine the change in \dot{V}_E needed to cause a desired change in PaCO_2 .

C. Mechanisms of Hypercapnia—Hypercapnia (alveolar hypoventilation) occurs when \dot{V}_E is abnormally low or when \dot{V}_E is normal or high but V_D/V_T is abnormally increased. It is emphasized that *hypoventilation* refers to *alveolar*

▲ Figure 12-1. Alveolar ventilation (\dot{V}_A) or minute ventilation (\dot{V}_E) as a function of PaCO_2 for a constant CO_2 output of 200 mL/min. Increased PaCO_2 (hypercapnia) is due to alveolar hypoventilation; decreased PaCO_2 (hypocapnia) is the same as alveolar hyperventilation. The other two curves show the relationship of \dot{V}_E and PaCO_2 for normal dead space:tidal volume ratio ($V_D/V_T = 0.3$) and abnormal dead space:tidal volume ratio ($V_D/V_T = 0.6$).

hypoventilation, and for this reason, hypercapnia may be present even though the patient's \dot{V}_E is greater than normal if V_D/V_T is abnormally high or CO_2 output is increased (exercise or other increased metabolic rate).

Alveolar dead space and V_D/V_T are useful physiologic concepts that may or may not have anatomic counterparts. The trachea and airways are conduits for gas moving into and out of the lungs during the respiratory cycle but do not participate in gas exchange with the pulmonary capillary blood. These spaces make up the anatomic dead space. An artificial airway or part of a mechanical ventilator circuit that is common to both inspiratory and expiratory pathways also contributes to anatomic dead space. However, in patients with lung disease, most of the increase in total dead space consists of "physiologic dead space," in which regional ventilation exceeds regional blood flow (ventilation-perfusion [\dot{V}/\dot{Q}] mismatching). While \dot{V}/\dot{Q} mismatching usually is considered as a mechanism of hypoxemia rather than hypercapnia, it theoretically should cause elevated PaCO_2 as well. However, in all but severe instances of \dot{V}/\dot{Q} mismatching, hypercapnia stimulates increased ventilation, returning PaCO_2 to normal. Thus \dot{V}/\dot{Q} mismatching does not usually result in hypercapnia but in normocapnia with increased \dot{V}_E . As can be seen in Figure 12-1, increased \dot{V}_E in the face of normal PaCO_2 indicates increased V_D/V_T —in this case an increase in physiologic dead space.

Clinical Features

Acute hypercapnia acts largely on the CNS (Table 12-1). Increased PaCO_2 depresses the CNS, and the mechanism is primarily through a fall of pH in the cerebrospinal fluid (CSF) resulting from acute elevation of PaCO_2 . Because CO_2 rapidly diffuses into the CSF, pH falls rapidly and severely with acute hypercapnia. With chronic elevation of PaCO_2 , however, the increase in PaCO_2 is present long enough for plasma and CSF bicarbonate to increase in compensation for the chronic respiratory acidosis. This explains why low pH rather than absolute level of PaCO_2 best correlates with altered mental status and other clinical changes.

Symptoms of hypercapnia may overlap those of hypoxemia. In addition, while hypercapnia stimulates ventilation in normal subjects, hypercapnic patients may have either decreased or increased minute ventilation depending on the primary disorder leading to respiratory failure. Dyspnea, tachypnea, and hyperpnea may be associated with hypercapnic respiratory failure just as often as bradypnea and hypopnea.

The major differential distinguishing point is between hypercapnic respiratory failure owing to lung disease and that resulting from nonlung disorders. Patients with lung disease often will have hypoxemia out of proportion to the degree of hypercapnia. This can be assessed using the alveolar-arterial PO_2 difference. However, patients with nonlung problems may have secondary hypoxemia because the effects of neuromuscular weakness, for example, contribute to atelectasis or aspiration pneumonia. Disorders of the lungs—in contrast to disorders of other components of the respiratory system—are associated with increased V_D/V_T , elevated \dot{V}_E , and respiratory frequency. Patients with respiratory muscle weakness also may be tachypneic. The effects of hypercapnia and hypoxemia may mask neurologic disorders, overmedication with sedatives, myxedema, or head trauma. Alteration of mental status may make it difficult to assess muscle strength, and the strength of muscles in the extremities may not correlate with respiratory muscle strength.

Table 12-1. Clinical manifestations of hypercapnia and hypoxemia.

Hypercapnia	Hypoxemia
Somnolence	Anxiety
Lethargy	Tachycardia
Coma	Tachypnea
Asterixis	Diaphoresis
Restlessness	Arrhythmias
Tremor	Altered mental status
Slurred speech	Confusion
Headache	Cyanosis
Papilledema	Hypertension
	Hypotension
	Seizures
	Lactic acidosis

► Hypoxemic Respiratory Failure

Hypoxemic respiratory failure is much more commonly encountered than hypercapnic respiratory failure. These patients have abnormally low PaO_2 but normal or low PaCO_2 . The latter distinguishes them from hypercapnic respiratory failure, in which the primary problem is alveolar hypoventilation. Outside of unusual environments in which the atmosphere has a severely reduced amount of oxygen, such as high altitude or when oxygen has been replaced with other gases, hypoxemic respiratory failure indicates disease affecting the lung parenchyma or pulmonary circulation. Common situations in which hypoxemia without elevated PaCO_2 are seen include pneumonia, aspiration of gastric contents, pulmonary embolism, asthma, and acute respiratory distress syndrome (ARDS).

Physiologic Considerations

A. Hypoxemia and Hypoxia—The term *hypoxemia* most often denotes low PO_2 in arterial blood (PaO_2), but it can be used to mean low capillary, venous, or pulmonary capillary PO_2 as well. It also may be used to signify low blood O_2 content or reduced saturation of hemoglobin with oxygen. Hypoxemia should be distinguished from hypoxia, which is decreased O_2 delivery to the tissues or the effects of decreased tissue O_2 delivery. While hypoxia will result from severe hypoxemia, hypoxia also can be a consequence of decreased O_2 delivery owing to low cardiac output, anemia, septic shock, or carbon monoxide poisoning, in which the PaO_2 may be normal or even elevated.

B. Mechanisms of Hypoxemia—The physiologic mechanism of arterial hypoxemia has important implications for

identifying the type of lung disease and the response to therapy with oxygen or other treatment. Five distinct mechanisms of hypoxemia can be identified, but these five can be divided conceptually into two major groups (Table 12–2): (1) decreased alveolar PO_2 (PAO_2) and (2) increased influence of venous admixture.

Mechanisms of arterial hypoxemia can be demonstrated by analysis of the possible extremes of oxygenation of the arterial blood. If desaturated systemic venous blood returning to the lungs gained no oxygen during transit through the lungs, the arterial blood would have the same oxygen content and partial pressure as the systemic venous blood (obviously a situation incompatible with life). Systemic venous blood PO_2 ($\text{P}\bar{\text{V}}\text{O}_2$) determines the lower limit for arterial PO_2 . On the other hand, if all the desaturated venous blood passing through the lungs reaches equilibrium with gases in the alveolar space, then PaO_2 equals PAO_2 . Thus alveolar PAO_2 determines the hypothetical upper limit for arterial PO_2 . Therefore, all possible values of PaO_2 must be between $\text{P}\bar{\text{V}}\text{O}_2$ and PAO_2 .

Arterial hypoxemia is always the result either of decreased PAO_2 or of a greater quantity of desaturated venous blood (venous admixture) mixing with pulmonary capillary blood (see Table 12–2). In some patients with hypoxemic respiratory failure, both these mechanisms play a role.

C. Decreased PAO_2 —The total pressure in the alveolar space is the sum of PO_2 , PCO_2 , PH_2O , and PN_2 . Because PH_2O and PN_2 do not change appreciably, any increase in PACO_2 must cause a fall in PAO_2 . Thus alveolar hypoventilation causes decreased PAO_2 , which must result in decreased PaO_2 . The alveolar gas equation, in simplified form, shows the relationship between alveolar PO_2 and PCO_2 :

Table 12-2. Mechanisms of hypoxemia.

Mechanism	PaCO_2 (PaCO_2)	PAO_2	$\text{P(A-a)}\text{O}_2^*$	PO_2 on 100% O_2 (mm Hg) [†]	Example
Alveolar PO_2 ↓ Inspired PO_2 Hypoventilation	↓ ↑	↓ ↓	Normal [‡] Normal	>550 >550	High altitude. Neuromuscular disease, obesity-hypoventilation syndrome.
Venous admixture Right-to-left shunt \dot{V}/\dot{Q} mismatching Diffusion limitation	Normal or low Normal or low Normal or low	Normal Normal Normal	Increased Increased Increased	<550 >550 >550	ARDS, septal defect. Pneumonia, asthma, COPD. Alveolar proteinosis.

* $\text{P(A-a)}\text{O}_2$ on room air. Normal <15–20 mm Hg.

[†] PaO_2 while breathing 100% O_2 distinguishes right-to-left shunt from other mechanisms.

[‡] $\text{P(A-a)}\text{O}_2$ calculated using PAO_2 from alveolar gas equation.

$$PAO_2 = FIO_2 \times PB - \frac{PACO_2}{R}$$

where FIO_2 is the oxygen fraction of the inspired gas, PB is the barometric pressure, and R is the respiratory gas exchange ratio, the steady-state ratio of CO_2 entering and O_2 leaving the alveolar space. In practice, $PACO_2$ substitutes for $PACO_2$. Because PAO_2 decreases with increased $PACO_2$, alveolar hypoventilation is a cause of hypoxemia (reduced PAO_2).

The alveolar gas equation also indicates that hypoxemia occurs if total barometric pressure is reduced, such as at high altitude or if FIO_2 is low (such as when breathing a gas in which some of the oxygen has been replaced by another gas). In hypoxemia owing to reduced PAO_2 alone, the decrease in PAO_2 approximately equals the fall in $PACO_2$, and the alveolar-arterial PO_2 difference is normal.

D. Venous Admixture—The other causes of hypoxemia result from increased amounts of deoxygenated venous blood reaching the arterial blood without becoming fully oxygenated by exposure to the alveolar gas. The alveolar-arterial PO_2 difference ($P[A-a]O_2$) is increased because of increased venous admixture. During room air breathing, $P[A-a]O_2$ is normally between 10 and 20 mm Hg, increasing with age and when the subject is in the upright position.

During room air breathing, $FIO_2 = 0.21$; if $R = 0.8$, $PACO_2 = 40$ mm Hg, and $PAO_2 = 55$ mm Hg, then

$$\begin{aligned} PAO_2 &= (0.21 \times 713) - (40/0.8) \\ &= 150 - 50 = 100 \text{ mm Hg} \end{aligned}$$

and

$$P(A-a)O_2 = 100 - 55 = 45 \text{ mm Hg}$$

In this example, arterial hypoxemia is present ($PAO_2 < 60$ mm Hg), and $P[A-a]O_2$ is increased (> 20 mm Hg). It should be concluded that hypoxemia is due to one of the causes of increased venous admixture.

1. RIGHT-TO-LEFT SHUNT—If some systemic venous blood bypasses the alveoli and then mixes with blood that did go through the lungs, the resulting arterial mixture must have a PO_2 between PAO_2 and $P\bar{V}O_2$. The exact PO_2 depends on the proportion of blood that bypassed the lungs and the values of PAO_2 and $P\bar{V}O_2$. This mechanism of hypoxemia is known as right-to-left shunt, one of the mechanisms of hypoxemia owing to increased venous admixture. Right-to-left shunt may occur because of complete atelectasis of a lung or lobe in which blood flow is maintained, or may be seen in patients with congenital heart disease in which there is a right-to-left shunt through a cardiac septal defect. Patients with ARDS may have such severe pulmonary edema, localized atelectasis, or alveolar collapse that right-to-left shunt occurs. Clues to the presence of right-to-left shunt include severe hypoxemia while breathing room air, only very small increases in PAO_2 when supplemental oxygen is administered, a need to give an FIO_2

greater than 0.6 to achieve an acceptable PAO_2 , and a PAO_2 of less than 550 mm Hg while breathing 100% O_2 . By convention, when PAO_2 is less than 550 mm Hg while breathing 100% O_2 , right-to-left shunt is confirmed.

2. VENTILATION-PERFUSION MISMATCHING—A second cause of hypoxemia owing to venous admixture is ventilation-perfusion (\dot{V}/\dot{Q}) mismatching. This mechanism, sometimes termed \dot{V}/\dot{Q} inequality, is the most frequent cause of hypoxemia. In contrast to right-to-left shunt, hypoxemia in \dot{V}/\dot{Q} mismatching does not result from venous blood completely bypassing ventilated areas of lung. Rather, some regions of the lungs have insufficient ventilation for the amount of blood flow, whereas others have excessive ventilation for the amount of regional blood flow. Pulmonary capillary blood draining those parts of the lungs that have relative “hypoventilation” is less well oxygenated and contributes to hypoxemia. The effects of \dot{V}/\dot{Q} mismatching on gas exchange are often quite complicated, but practically any lung disease that alters the distribution of ventilation or blood flow can result in \dot{V}/\dot{Q} mismatching. Thus hypoxemia owing to \dot{V}/\dot{Q} mismatching is seen in asthma and other chronic obstructive lung diseases in which variations in airway resistance distribute ventilation unevenly. \dot{V}/\dot{Q} mismatching also contributes to hypoxemia in pulmonary vascular diseases such as pulmonary thromboembolism, in which the distribution of perfusion is altered. In contrast to right-to-left shunt, most patients with \dot{V}/\dot{Q} mismatching respond dramatically to supplemental oxygen therapy. A clue to \dot{V}/\dot{Q} mismatching, therefore, is that the PAO_2 can be relatively easily brought up to acceptable values with the administration of supplemental oxygen.

3. DIFFUSION LIMITATION—The third mechanism of hypoxemia owing to venous admixture is diffusion limitation of O_2 transfer. This is an unusual cause of hypoxemia, and the basis for this mechanism is often misunderstood. Normally, there is more than sufficient time for blood passing through the lungs to become fully equilibrated with the gases in the alveoli. Rarely, however, pulmonary capillary blood passes so quickly through the lungs that there is insufficient time for pulmonary capillary PO_2 to equilibrate with PAO_2 , resulting in hypoxemia. This is a form of venous admixture because the hypoxemia results from the influence of deoxygenated venous blood. Diffusion limitation resulting in hypoxemia theoretically can occur if PAO_2 is very low—so that the diffusion of oxygen is slowed—or if the transit time for pulmonary capillary blood is very short. There are few diseases in which diffusion limitation for oxygen transfer is thought to be a major cause of hypoxemia. For example, hypoxemia in patients with pulmonary vascular disease may be due to diffusion limitation because of decreased mean transit time, especially if cardiac output is increased. Pulmonary alveolar proteinosis—a disease in which the alveolar spaces are filled with a homogeneous protein and lipid fluid—may slow diffusion of oxygen sufficiently to cause hypoxemia. In

most other lung diseases presenting with hypoxemia, \dot{V}/\dot{Q} mismatching and right-to-left shunt explain hypoxemia more often than diffusion limitation.

Clinical Features

Manifestations of hypoxemic respiratory failure are the result of a combination of features of arterial hypoxemia and tissue hypoxia (see Table 12–1). Arterial hypoxemia increases ventilation by stimulation of carotid body chemoreceptors, leading to dyspnea, tachypnea, hyperpnea, and usually, hyperventilation. The degree of ventilatory response depends on the ability to sense hypoxemia and the capacity of the respiratory system to respond. In hypoxemic patients with severe lung disease or ventilatory limitation, there may be little or no increase in ventilation and absence of hyperventilation. In patients who lack carotid body function, there will be no ventilatory response to hypoxemia. There may be cyanosis, especially marked in the distal extremities but also centrally prominent around the mucous membranes and lips. The degree of cyanosis depends on the hemoglobin concentration and the patient's state of perfusion.

Other effects attributable to hypoxemia are due to inadequate supply of oxygen to the tissues, or hypoxia. Hypoxia causes a shift to anaerobic metabolism, which is accompanied by generation of lactic acid. Increased blood lactic acid may further stimulate ventilation. Mild early hypoxia may cause impaired mental performance, especially for complex tasks or abstract thinking. More severe hypoxia can cause much more severe alteration of mental status, including somnolence, coma, seizures, and permanent hypoxic brain damage. Sympathetic nervous system activity is increased, and this contributes to tachycardia, diaphoresis, and systemic vasoconstriction, leading to hypertension. More severe hypoxia, however, can lead to bradycardia, vasodilation, and hypotension as well as myocardial ischemia, infarction, arrhythmias, and cardiac failure.

Manifestations of hypoxemic respiratory failure are magnified in the presence of impaired tissue oxygen delivery. Patients with reduced cardiac output, anemia, or circulatory abnormalities can be expected to have global and regional tissue hypoxia at less severe degrees of hypoxemia. Examples include the increased risk of myocardial ischemia from hypoxemia in a patient with coexisting coronary atherosclerosis or a patient with hypovolemic shock who shows evidence of lactic acidosis in the presence of mild arterial hypoxemia.

► Oxygen Delivery & Tissue Hypoxia

Adequate O_2 delivery to the tissues is the most important function of the respiratory system, and this aspect requires normal function of the lungs, heart, and circulation. Recognition and treatment of compromised systemic O_2 delivery should be primary goals in management of respiratory failure in addition to correcting abnormalities of arterial blood gases.

Physiologic Considerations

A. Oxygen Delivery—Systemic O_2 delivery is the product of arterial O_2 concentration (mL O_2 /L blood) and cardiac output (L/min). This calculation does not help to determine whether the blood and O_2 are distributed to organs in proportion to their needs, so even normal or high O_2 delivery may be insufficient under certain conditions such as shock, sepsis, or end-stage liver disease.

$$O_2 \text{ delivery (mL/min)} = \text{arterial } O_2 \text{ content (CaO}_2, \text{ mL } O_2/\text{L blood)} \times \text{cardiac output (}\dot{Q}, \text{ L/min)}$$

where CaO_2 , mL O_2 /L blood = $[O_2 \text{ saturation} \times \text{hemoglobin (g/dL)} \times 1.34 \text{ mL } O_2/\text{g hemoglobin} + PaO_2 \text{ (mm Hg)} \times 0.003 \text{ mL } O_2/\text{mm Hg/dL}] \times 10$.

In normal subjects at rest, normal arterial O_2 concentration is about 200 mL O_2 /L blood (O_2 saturation 97%, hemoglobin 15 g/dL of blood, PaO_2 100 mm Hg). Resting cardiac output is about 5 L/min, resulting in normal O_2 delivery = 1000 mL O_2 /min.

B. Causes of Decreased Oxygen Delivery—Factors included in the formula for O_2 delivery can be examined to identify pathologic states that result in potentially decreased O_2 delivery. First, arterial O_2 concentration can be reduced as a result of decreased O_2 saturation of hemoglobin from arterial hypoxemia (decreased PaO_2) or a rightward-shifted oxyhemoglobin dissociation curve (eg, acidemia, hyperthermia, or hemoglobinopathy). Anemia is an important factor because O_2 concentration is largely the product of hemoglobin concentration and O_2 saturation. A decrease in hemoglobin from 12 to 8 g/dL decreases O_2 concentration and O_2 delivery by 33%—considerably more than most changes in PaO_2 or O_2 saturation. Carbon monoxide, because of its high affinity for hemoglobin, displaces O_2 and reduces arterial O_2 concentration. In addition, carbon monoxide shifts the oxyhemoglobin curve leftward, which, although it tends to increase O_2 concentration at any given PaO_2 , causes problems in unloading O_2 at the tissue level.

Cardiac output depends on multiple factors, including adequate systemic venous return, right and left ventricular function, pulmonary and systemic resistance, and heart rate. Even in the absence of underlying intrinsic heart disease, patients with respiratory failure may have impaired or reduced cardiac output. Hypoxemia and acidosis have adverse effects on myocardial contractility or may cause tachycardia, bradycardia, or myocardial infarction. There is evidence that myocardial depression can be seen in conjunction with sepsis and septic shock, mediated through products of microorganisms, patient-produced cytokines, or other factors. Mechanical ventilation with positive pressure interacts in a number of ways with the heart and circulation. Although much of the decrease in cardiac output during positive-pressure ventilation is due to diminished systemic venous return, left ventricular diastolic compliance is impaired, pulmonary vascular resistance is increased, and

right ventricular afterload increases. The degree and significance of interaction vary with the type and severity of respiratory failure and the type of mechanical ventilation.

C. Assessment of Oxygen Delivery—The assessment of adequacy of O_2 delivery remains a topic of debate. In normal subjects, total O_2 consumption of the body is independent of O_2 delivery over a wide range. Increasing or decreasing O_2 delivery (except at extremely low rates) by changing cardiac output or hemoglobin does not result in a parallel increase or decrease in O_2 consumption. However, in some patients with septic shock, ARDS, or other critical illness, O_2 consumption may become functionally dependent on O_2 delivery even when O_2 delivery is in the normal range. This finding has been taken to indicate that adequate O_2 delivery in a given patient cannot be assumed even when O_2 delivery is normal; an increase in O_2 consumption in response to increased O_2 delivery above normal indicates that the original O_2 delivery was in fact inadequate. To explain this finding, investigators have proposed that distribution of blood flow in the peripheral circulation is poorly matched to O_2 requirements of individual organs—a form of “distributive shock.” In some studies, lactic acidosis has been associated with O_2 delivery dependency; this supports the concept of inadequate tissue oxygenation. In other studies, organ dysfunction is cited as evidence of hypoxia when O_2 consumption is no longer independent of O_2 delivery. On the other hand, some investigators believe that these findings are artifacts of measurements or do not reflect the responses of most patients with these disorders. There have been a few studies suggesting that increasing O_2 delivery has resulted in improved outcome from septic shock. Several other investigators, however, have been unable to find any difference in patient survival in critical illness by empirically increasing O_2 delivery. It is highly likely that this dependence of O_2 consumption on O_2 delivery is patient-specific. Therefore, attention should be paid to trying to identify evidence of inadequate O_2 delivery by monitoring renal, hepatic, cardiac, and other organ system functions.

► Temperature & Blood Gases

The blood gas analyzer maintains the sample of blood at 37°C while PaO_2 , $PaCO_2$, and pH are determined. For a given quantity of O_2 and CO_2 in an aliquot of blood, PaO_2 and $PaCO_2$ will change if the temperature of the blood changes. When the sample is cooled, PaO_2 and $PaCO_2$ decrease; when it is warmed, PaO_2 and $PaCO_2$ increase.

In patients with hypothermia or hyperthermia, some laboratories report “temperature-corrected” blood gases, that is, what the PaO_2 and $PaCO_2$ would be if measured at the patient’s actual temperature. These corrections are determined empirically and are derived easily from tables and nomograms or are displayed automatically by the analyzer.

However, temperature correction of a patient’s blood gas results may lead to an incorrect clinical interpretation unless they are compared with temperature-corrected *normal* blood gas values. For example, in a normal animal made hypothermic,

temperature-corrected PaO_2 and $PaCO_2$ decrease, and because HCO_3^- remains constant, pH increases. If compared with customary normal values measured at 37°C, interpretation of temperature-corrected PaO_2 , $PaCO_2$, and pH would lead to an erroneous conclusion of hypoxemia and respiratory alkalosis. One approach to avoiding this problem is to use reference normal values at each temperature for comparison.

A preferable method is to report all blood gas values at the 37°C at which the blood is analyzed regardless of the patient’s actual temperature. These results can then be compared with normal values for PaO_2 , $PaCO_2$, and pH determined at 37°C. Interpretation will be correct for both hypoxemia and acid-base status. Temperature correction of blood gases is unnecessarily complex and may be misleading if steps are not taken to provide corrected normal values.

TREATMENT OF ACUTE RESPIRATORY FAILURE

Respiratory failure is treated by a combination of specific treatment directed at the underlying compromise of the respiratory system plus supportive care of oxygenation and ventilation. The general principles of support are similar regardless of the type of respiratory system disorder.

► Physiologic Basis Of Treatment

Hypercapnic Respiratory Failure

Because hypercapnia is synonymous with alveolar hypoventilation, supportive care restores alveolar ventilation to normal until the underlying disorder can be corrected. Alveolar ventilation sometimes can be improved by establishing an effective airway—suctioning to remove secretions, stimulation of cough, postural drainage, or chest percussion—or by establishing an artificial airway with an endotracheal tube or tracheostomy.

Mechanical assistance may be necessary to maintain the desired alveolar ventilation until the primary problem is corrected. Although the mechanical ventilator theoretically can provide any desired amount of ventilation, care should be

taken to correct hypercapnia judiciously in patients with chronic hypercapnia. This is because correction of PaCO₂ to normal in these patients can result in severe, life-threatening alkalemia owing to their elevated plasma bicarbonate levels as compensation.

Hypoxemia is seen often in patients with hypercapnic respiratory failure—especially those with lung disease—and administration of supplemental oxygen is often necessary. In some patients with hypercapnia, however, supplemental oxygen may be hazardous if not titrated carefully. This group of patients with chronic lung disease (either obstructive or restrictive) or chest wall compromise (eg, kyphoscoliosis) appears to have particular insensitivity to hypercapnia and depend on hypoxemia to stimulate ventilation. If sufficient oxygen is given to overcome hypoxemia, ventilatory drive may be blunted subsequently, and the patient's hypercapnia may worsen.

Patients with hypercapnic respiratory failure owing to sedative drug overdose or botulism—and most patients with chest trauma—will improve with time, and treatment is largely supportive. Some primary diseases associated with hypercapnia require specific treatment, including myasthenia gravis, electrolyte abnormalities, obstructive lung disease, obstructive sleep apnea, and myxedema.

Hypoxemic Respiratory Failure

Oxygen supplementation is the most important therapy for hypoxemic respiratory failure. In severe disorders such as ARDS, mechanical ventilation, positive end-expiratory pressure (PEEP), and other types of respiratory therapy may be necessary. Although not a feature of most cases, hypercapnia may develop because the high work of breathing leads to respiratory muscle fatigue. Attention to oxygen transport is important, and severe anemia should be corrected and adequate cardiac output maintained. The underlying disease leading to hypoxemic respiratory failure must be addressed, especially if pneumonia, sepsis, or other cause is identified. Treatment may include diuretics, antibiotics, and bronchodilators as well as other measures.

In some patients with nonuniform lung disease, dependent positioning of uninvolved or less involved lung areas may improve oxygenation. Gravity and the weight of the lungs increase perfusion and ventilation to dependent lung regions. Patients with hemoptysis or heavy respiratory secretions, however, should not be placed in this position because of the likelihood of aspiration of blood or secretions into uninvolved areas. In ARDS with diffuse noncardiogenic pulmonary edema, there has been considerable interest in placing the patient prone. Prone ARDS patients appear to have less tendency of dependent lung regions to collapse as well as smaller areas of the lungs compressed by the heart or abdominal contents. In some patients, improvement in arterial hypoxemia is transient after turning from supine to prone, but in others the effects persist for at least several hours.

► Airway

When upper airway obstruction is the patient's only problem, prompt restoration of an adequate airway is all that is required to reverse respiratory failure. In all patients, establishment of the airway is essential for ventilation, oxygenation, and delivery of respiratory medications.

Upper Airway Obstruction

Primary upper airway obstruction should be considered in all patients with respiratory difficulty—but especially if they present with any of the following: head and neck trauma, suspected malignancy of the larynx or trachea, acute dyspnea with wheezing (ie, inspiratory, expiratory, or both), dysphagia, neurologic disease affecting motor or sensory function, speech difficulty, masses in the neck owing to thyroid enlargement or lymphadenopathy, or pain, infection, or inflammation of the pharynx, larynx, or trachea. Patients with asthma or chronic obstructive pulmonary disease (COPD) also may have upper airway obstruction from tracheal or subglottic stenosis if there is a history of recent or remote endotracheal intubation or tracheostomy. Acute respiratory distress, especially in the elderly and in children, should arouse suspicion of a foreign body in the airway. A frequent intermittent cause of upper airway obstruction is seen in obstructive sleep apnea syndrome (see below), in which obstruction occurs during certain stages of sleep. It is important to consider this not uncommon problem as a complicating factor in patients with respiratory failure from other causes.

Natural Airway

The normal natural airway permits speech, humidifies inspired gas, and protects against aspiration and infection; coughing is effective, and the mucociliary function of the trachea is maintained. When a decision is made to insert an artificial airway, the benefits and risks of the endotracheal tube must outweigh the benefits of the natural airway (Table 12–3). In patients with severe upper airway obstruction, the choice is usually easy. In other patients with acute respiratory failure, the decision rests primarily on whether oxygen, respiratory medications, and respiratory therapy via the natural airway will be adequate or whether an artificial airway would be preferable. A trial of aggressive treatment before intubation often provides useful information. Guidelines (Table 12–4) for selecting patients who need endotracheal intubation may be helpful, but clinical assessment of the response to therapy is usually more so. Noninvasive positive-pressure ventilation does not require endotracheal intubation and is an important alternative in patients who meet criteria.

Endotracheal Tubes

Endotracheal tubes are usually made of relatively stiff plastic, with soft, low-pressure, easily deformable inflatable tracheal

Table 12-3. Risks and benefits of the artificial airway.

Risk	Benefits
Trauma of insertion	Bypasses upper airway obstruction
Oro- or nasopharyngeal trauma due to chronic pressure	Route for oxygen and other medications
Tracheal damage (erosion, tracheomalacia)	Facilitates positive-pressure ventilation and PEEP
Impaired cough response	Route for respiratory medications
Increased aspiration risk	Facilitates suctioning of secretions
Impaired mucociliary function	Fiberoptic bronchoscopy route
Increased infection risk	
No speech	
Increased resistance and work of breathing	

cuffs. Skilled practitioners should insert these tubes with attention to prevention of aspiration of gastric contents; adequate oxygenation during the procedure; avoidance of trauma to the mouth, tongue, nose, epiglottis, and vocal cords; and selection of a tube of proper size for the patient. Experience with sedation using opioid analgesics or rapid-acting sedatives (eg, benzodiazepines such as midazolam) and muscle relaxants should be available for intubation of awake patients.

Nasotracheal intubation offers greater patient comfort, less severe positioning of the head and neck during placement, and better stabilization of the tube. However, the route of the tube and its smaller size sometimes can complicate suctioning and weaning from a mechanical ventilator. The smaller radius of curvature of the nasotracheal route has been linked to higher tube resistance compared with the

Table 12-4. Indications for intubation and mechanical ventilation.*

Physiologic
Hypoxemia persists after oxygen administration
$P_{aCO_2} > 55$ mm Hg with pH < 7.25
Vital capacity < 15 mL/kg with neuromuscular disease
Clinical
Altered mental status with impaired airway protection
Respiratory distress with hemodynamic instability
Upper airway obstruction [†]
High volume of secretions not cleared by patient, requiring suctioning

*These are guidelines that must take into account the patient's clinical status and other factors.

[†]Consider need for tracheostomy if obstruction is above trachea.

same tube passed orally, but this finding has been questioned. The nasotracheal route generally is appropriate in patients who require intubation for reasons unrelated to lung disease, for example, sedative drug overdose. Otherwise, orotracheal intubation should be used, especially if a larger tube diameter is needed to facilitate airway suctioning or for fiberoptic bronchoscopy. Placing an orotracheal tube requires a laryngoscope for inspection of the vocal cords. Laryngoscopes with straight or curved blades to hold the tongue and other structures away are used most often, but fiberoptic laryngoscopes have proved extremely useful for difficult intubations or special circumstances.

Smaller-diameter endotracheal tubes impose less risk of trauma to the vocal cords and may be more comfortable for the patient. Larger tubes provide better access for tracheal suctioning, delivery of medications, and fiberoptic bronchoscopy and generally will create an adequate seal between the tube and the trachea with lower cuff pressure. Weaning from mechanical ventilation may be easier with a larger tube because of lower airflow resistance. Most women can accommodate endotracheal tubes of 7.5–8 mm in inner diameter; men generally will accept tubes of 8.5 or 9 mm in inner diameter. If fiberoptic bronchoscopy is a consideration, a tube with at least 8 mm in inner diameter is required, and 8.5 mm is preferable.

Care of the Artificial Airway

The intubated patient must be suctioned frequently because both cough and the mucociliary clearance mechanism are impaired. The frequency of suctioning depends on the amount and nature of secretions. Although the artificial airway becomes rapidly colonized with bacteria, suctioning should be done using sterile technique to prevent introduction of additional organisms. A sealed system (ie, suction catheter contained within a sheath in-line with the endotracheal tube) facilitates frequent suctioning and may minimize nosocomial contamination. For some patients, disposable suction catheters are more effective—especially catheters with bent tips that can be directed into the right or left main bronchus as desired. It has become common practice to instill small aliquots of sterile normal saline into the endotracheal tube to facilitate suctioning of secretions, but this should be done only if increased amounts of secretions are obtained.

Hypoxemia and tracheal trauma are the most common complications of suctioning. Minimal negative pressure should be used, and the suction catheter should be introduced gently. During suctioning, P_{aO_2} may fall rapidly, particularly if the patient is receiving high concentrations of inspired O_2 and suctioning is performed for more than 10–15 seconds. In patients with focal infiltrates or known collections of secretions in particular parts of the tracheobronchial tree, selective bronchial suctioning can be tried. By using bent-tip catheters and by positioning the patient's body or head properly, successful suctioning of the left main bronchus, for example, often can be accomplished.

In order to provide positive-pressure ventilation, the inflated tracheal cuff of the endotracheal tube exerts pressure on the interior of the trachea to create an effective seal. Almost all endotracheal and tracheostomy tubes incorporate low-pressure, high-volume cuffs made of highly compliant rubber or plastic. These cuffs provide a tracheal tube seal after inflation to a relatively low pressure. If higher than normal pressures are needed to achieve a seal, damage to the trachea may occur, including erosion, inflammation, softening of the cartilage rings with tracheal dilation (tracheomalacia), and hemorrhage. Endotracheal cuff pressure must be monitored to anticipate these complications and to make certain that the smallest effective pressure and volume are used. The best way to do this is to slowly inflate the cuff with air, using a small syringe, until there is minimal leak around the cuff with inspiration and adequate tidal volume and ventilation. The pressure read on a manometer and the amount of air put into the cuff are recorded. The desired cuff pressure is the smallest possible that will maintain an adequate seal between the tube cuff and the trachea, and the pressure is ideally less than 15 cm H₂O. The incidence of tracheal complications rises when cuff pressures exceed 20–25 cm H₂O for prolonged periods. An automated system for maintaining optimal cuff pressure is under investigation.

Complications from Endotracheal Tubes

Complications from endotracheal tubes may be classified as early and late. Early complications are due to the trauma of tube insertion or to malpositioning of a tube into a main bronchus or in the esophagus. Confirmation of the tube's position by physical examination and chest x-ray are essential. The tip of the tube should be in the center of the trachea and 3–5 cm above the carina, but head flexion or extension can cause 1–5 cm of movement of the endotracheal tube tip on chest x-ray. If the carina is difficult to see, the position of the tip of the tube relative to the aortic arch on chest x-ray is helpful. Analysis of expired CO₂ gives reliable assurance of tracheal rather than esophageal placement; fiberoptic bronchoscopy also can be valuable for this purpose in selected patients.

Unplanned extubations are a complication of endotracheal intubation, occurring in 3–10% of placements. The endotracheal tube should be secured carefully, and the patient should be educated about the need for and importance of the tube. Agitation and patient movement are associated with extubation, and sedation and physical restraints should be used as necessary. Several studies have shown that unplanned extubations led to reintubation in about half of patients, but some patients can be observed carefully for respiratory distress and deterioration of arterial blood gases rather than immediate reintubation. Factors predictive of a high likelihood for reintubation include severity of the underlying disease, a high minute ventilation requirement during the preceding 24 hours, a high FIO₂ requirement, and altered mental status.

Aspiration of oral secretions or refluxed gastric secretions is a common problem in intubated patients. Contrary to common belief, the inflated tracheal cuff does not reliably protect against aspiration of secretions around the tube. Endotracheal tubes with a port above the cuff reduce the incidence of ventilator-associated pneumonia when the port is connected to continuous suction.

A randomized trial of orotracheal compared with nasotracheal intubation showed that there was a slightly greater frequency of radiographic sinusitis (by CT scan) with nasotracheal intubation. The incidence was relatively high in both groups (30% nasotracheal and 22% orotracheal), however, indicating that this was a frequent complication in all patients needing endotracheal intubation for more than 7 days.

Most late complications arise from prolonged pressure of the tube against anatomic structures. The curve of the tube puts maximum pressure on the side of the mouth, the palate, and the posterior pharynx (from oral intubation) or the nasal turbinates and the posterior pharynx (nasal intubation). The greatest pressure is exerted on the vocal cords, the narrowest part of the passage. Most late complications are due to laryngeal trauma, followed by the development of glottic injury and subglottic stenosis. The incidence of subglottic stenosis is estimated to be less than 5% of patients intubated for more than 10–14 days. A study of patients with translaryngeal intubation (oro-tracheal or nasotracheal) found that the extent of injury estimated by laryngoscopy was not predictive of late complications. The duration of translaryngeal intubation did not influence the ability of the larynx to heal without future ill effects.

Despite the inability to correlate late complications with the duration of intubation, early tracheostomy (within 5–7 days) is recommended if prolonged intubation is anticipated. Translaryngeal intubation for up to 10 days does not usually cause an appreciable increase in complications, and tracheostomy is preferred if intubation for 21 days or more can be anticipated. This conclusion is based on a similar incidence of complications from translaryngeal intubation and tracheostomy. Thus translaryngeal intubation for as long as 21 days may be acceptable unless a longer need for an artificial airway is expected or whenever there is reason to suspect greater potential laryngeal trauma (eg, patient movement, malnutrition, and local or systemic infection). In such cases, earlier tracheostomy is advised, especially in view of studies that demonstrate reduced complications when tracheostomy is performed at 5 days.

Tracheostomy, of course, prevents or avoids laryngeal injury but does not prevent tracheal injury from the tracheostomy cuff. Attention to cuff pressure and cuff volume is essential for tracheostomy tubes as well as endotracheal tubes. Tracheostomy may be contraindicated if the patient has a bleeding disorder, local infection, or neck mass. Percutaneous tracheostomy with and without fiberoptic bronchoscopic assistance potentially reduces complications.

Not only is the timing of tracheostomy controversial, but so is the role of tracheostomy itself. This is based on

studies suggesting that the overall outcome of patients requiring tracheostomy for long-term mechanical ventilation is often poor.

► Oxygen

Supplemental oxygen is required in almost all patients with respiratory failure. The amount of oxygen needed above that present in room air depends on the mechanism of hypoxemia. The type of oxygen delivery device depends on the amount of oxygen required, patient and physician preference, the potential for adverse effects of varying concentrations of oxygen, and the minute ventilation of the patient. Because high concentrations of oxygen are damaging to the lungs, efforts should be made to minimize the amount and duration of oxygen therapy.

PaO₂ and P(A-a)O₂

For normal subjects, the range for PaO₂ during air breathing at sea level is 75–100 mm Hg, with a decline in PaO₂ with age. One formula for calculating the average PaO₂ decline with age in supine subjects is PaO₂ = 109 – 0.43 × age (in years). Because the PaCO₂ in normal subjects does not change appreciably with aging, the usual value for PaCO₂ is about 40 mm Hg. Therefore, PAO₂ during room air breathing at sea level is always about 100 mm Hg. Combining this with the predicted value for average PO₂, the normal range for P(A-a)O₂ is 0–30 mm Hg during air breathing, with the high end of the range seen in normal elderly subjects. P(A-a)O₂ increases when breathing supplemental O₂ and can be as much as 100 mm Hg in normal subjects breathing 100% O₂. The increase in P(A-a)O₂ reflects the small amount of physiologic right-to-left shunt found in normal subjects.

When FIO₂ increases, P(A-a)O₂ does not remain constant and cannot be used easily as a measure of the severity of gas exchange or for predicting the response to a changed FIO₂. Some authors have recommended comparing the ratio of PaO₂ to PAO₂ rather than the difference between PAO₂ and PaO₂ because the ratio tends to be more constant as FIO₂ is changed in a given patient. The physiologic behavior of PaO₂ with respect to PAO₂, however, shows that PaO₂:PAO₂ is often not sufficiently constant to predict PaO₂ when FIO₂ is altered. Therefore, changes in FIO₂ must be followed by measurement of arterial blood gases. In recent years, the ratio of PaO₂ to FIO₂ has been used as a marker of the severity of gas exchange abnormality in hypoxemic respiratory failure and in the definition of refractory hypoxemia as seen in ARDS.

Oxygen Saturation and Oxygen Content

Oxygen saturation and oxygen content increase little when PaO₂ increases above about 60 mm Hg, although there is a small linear increase in O₂ content owing to increased O₂ dissolved in the plasma (Figure 12–2). Oxygen saturation is about 92% when PaO₂ is 60 mm Hg if the oxyhemoglobin curve is not shifted rightward or leftward by temperature or

▲ **Figure 12–2.** Normal oxyhemoglobin dissociation curve. At point *a*, PaO₂ = 60 mm Hg results in O₂ saturation of about 90%. At point *b*, the saturation of hemoglobin is 50% (P-50) at a PaO₂ of about 26 mm Hg for hemoglobin at normal body temperature, pH, and 2,3-DPG. Increased temperature, decreased pH, and increased 2,3-DPG shift the curve to the right; decreased temperature, increased pH, decreased 2,3-DPG, and carbon monoxide shift the curve leftward.

pH changes. The PaO₂ at which hemoglobin is 50% saturated with oxygen (P-50) can be used to indicate the degree of shift of hemoglobin. With normal unshifted hemoglobin, increasing PaO₂ above 60 mm Hg can only increase O₂ saturation from 92–100%. Therefore, for almost all purposes, an acceptable arterial PO₂ is 60 mm Hg or more. Nevertheless, in most clinical situations, a higher PaO₂ is desired (80–100 mm Hg) to anticipate changes in lung gas exchange during suctioning or changes in the patient's condition. However, there is almost never a need for a PaO₂ greater than 150 mm Hg unless the patient is anemic (prior to transfusion) or has carbon monoxide poisoning—or in some other special circumstances.

Inspired Oxygen Concentration

The mechanism of hypoxemia determines how much the PaO₂ will increase with O₂ therapy. Figure 12–3 shows how the PaO₂ of patients with pure right-to-left shunts theoretically responds to increasing concentrations of inspired O₂ compared with patients who have \dot{V}/\dot{Q} mismatching. Most patients with \dot{V}/\dot{Q} mismatching will have a relatively large increase in PaO₂ for a small increase in inspired O₂ concentration; increasing FIO₂ from 0.21 to about 0.30–0.40 with O₂ masks, cannulas, or other devices often will raise PaO₂ to

▲ Figure 12-3. Relationship between P_{aO_2} and F_{iO_2} for pure right-to-left shunt (\dot{Q}_s/\dot{Q}_T) of 0%, 10%, 20%, and 30%. Line *a* shows a representative relationship of P_{aO_2} and F_{iO_2} for a patient with mild ventilation-perfusion (\dot{V}/\dot{Q}) mismatching. Line *b* demonstrates the relationship for severe \dot{V}/\dot{Q} mismatching. With right-to-left shunt, P_{aO_2} remains less than 550 mm Hg when breathing 100% O_2 , but the P_{aO_2} is greater than 550 mm Hg during 100% O_2 breathing even with severe \dot{V}/\dot{Q} mismatching.

greater than 70–100 mm Hg in these patients. On the other hand, most patients who are hypoxemic owing to right-to-left shunting are refractory to O_2 therapy, demonstrating only a small increase in P_{aO_2} when the inspired O_2 concentration is increased from 0.21 to as much as 1.0. These patients often will require a very high F_{iO_2} (>0.60) to correct hypoxemia. In a patient with a right-to-left shunt, some venous blood (by definition) always will bypass alveolar spaces and fail to pick up O_2 . Because only the blood exposed to the alveolar gas will pick up O_2 , we can take advantage of this mechanism of hypoxemia to further distinguish right-to-left shunt from \dot{V}/\dot{Q} mismatching. When given 100% O_2 ($F_{iO_2} = 1.0$) and after the alveolar spaces are completely washed out by O_2 , patients with right-to-left shunting always will have some degree of reduced P_{aO_2} , whereas patients with \dot{V}/\dot{Q} mismatching will have a P_{aO_2} value close to that of normal subjects breathing 100% O_2 . For clinical purposes, normal subjects and patients with \dot{V}/\dot{Q} mismatching will have a P_{aO_2} of greater than 550 mm Hg during 100% O_2 breathing; the P_{aO_2} of patients with right-to-left shunts will be less than 550 mm Hg (see Table 12-2).

Patients with asthma, COPD, mild pneumonia, and pulmonary embolism usually need only relatively low concentrations of supplemental O_2 ($F_{iO_2} = 0.24$ – 0.40) with a reasonable expectation that their P_{aO_2} will correct satisfactorily to a safe level. Hypoxemia in these patients, therefore, is due to \dot{V}/\dot{Q} mismatching. Patients with more severe lung disease—especially those with pulmonary edema, collapse of lungs or lobes, severe lobar pneumonia, or ARDS—usually can be assumed to have right-to-left shunting as the mechanism of hypoxemia. These patients require higher inspired concentrations of O_2 (in the range of 0.50–1.0) to achieve the same P_{aO_2} goal.

Supplemental Oxygen Delivery Devices

Supplemental oxygen delivery devices are divided into low-flow and high-flow systems (Table 12-5). Low-flow O_2 devices include nasal cannulas and simple O_2 masks patients can use to draw small supplemental amounts of 100% O_2 while the bulk of the inspired tidal volume is provided by room air entrainment from around or outside the device. Because the flow of supplemental O_2 is constant, the inspired concentration of O_2 varies inversely with the patient's minute ventilation. Thus, at a constant flow of 2 L/min into nasal cannulas, a patient with a low minute ventilation will have a higher F_{iO_2} than another with a high minute ventilation who entrains a greater amount of room air per minute. For a nasal cannula, the O_2 flow rate should be 0.5–4 L/min; for a simple mask, the O_2 flow should be a minimum of 4 L/min—in order to flush CO_2 out of the mask—and a maximum of 6–8 L/min.

High-flow oxygen delivery devices, including Venturi-type masks and nonbreathing masks, generate the total air-oxygen mixture inhaled by the patient. Venturi-type masks direct O_2 through a constricted tube that increases gas velocity. The jet of O_2 exiting from the constriction generates sufficient negative pressure to draw a much higher volume of air into the breathing circuit. The relationship between O_2 flow, orifice size, and room air entrainment in Venturi-type masks is designed to generate a known total flow of gas at a relatively constant concentration of O_2 . Different F_{iO_2} concentrations and different total flow amounts are generated by using a different-sized orifice or by changing the amount of air entrainment depending on the design of the system. Venturi-type masks are ideal when a constant known F_{iO_2} in the range of 0.24–0.40 is needed. Maximum F_{iO_2} usually is considered to be about 0.50, and the total gas volume provided decreases as higher F_{iO_2} values are administered, making this type of mask less suitable for patients who have both minute ventilation requirements greater than 10–12 L/min and high F_{iO_2} requirements.

Another kind of high-flow device is the nonbreathing mask, consisting of a bag reservoir that fills with 100% O_2 and one-way valves that permit inspiration only from the reservoir and prevent room air entrainment. The reservoir guarantees that even with vigorous inspiratory effort and high inspiratory flow, patients will inhale essentially 100% O_2 .

Table 12–5. Oxygen delivery devices.

Device	O ₂ Flow Rate (L/min)	F _{IO₂}	Advantages	Disadvantages
Low-flow delivery devices				
Nasal cannula	2–6	0.24–0.35	Patient comfort	F _{IO₂} varies with \dot{V}_E .
Simple mask	4–8	0.24–0.40	None	F _{IO₂} varies with \dot{V}_E .
High-flow delivery devices				
Venturi mask	2–12*	0.25–0.50	Constant F _{IO₂} with \dot{V}_E	Inadequate flow at high F _{IO₂} . Not comfortable; F _{IO₂} not adjustable.†
Nonrebreathing mask	6–15	0.70–0.90	High F _{IO₂}	
High-flow O ₂ blender‡	6–20	0.50–0.90	High F _{IO₂} at high total flow	

*The total inspiratory gas flow is the O₂ flow plus the amount of room air entrained. See specification for each model.

†F_{IO₂} can vary with O₂ flow rate set; however, the F_{IO₂} is most dependent on the amount of inadvertent room air entrained. In addition, total O₂ flow may be inadequate in patients with high inspiratory flow demand.

‡O₂ is delivered from various types of “high-flow” O₂ blenders with room air entrainment. Different types of masks may be used.

The nonrebreathing mask is used primarily for patients who require very high F_{IO₂} levels (in the range of 0.7–1.0). Limitations include an inability to provide very high total gas volumes and patient discomfort. Because this mask is used in patients with severe hypoxemia requiring high inspired concentrations of O₂, a high percentage of them may have further deterioration and require other forms of treatment. Other high-flow oxygen delivery devices usually generate an oxygen-air mix similar to what is achieved with the Venturi-type masks but more reliably provide a larger total flow and higher O₂ concentration. They can be used also to produce cool or warm aerosols along with high O₂ concentrations.

An air-oxygen blender provides oxygen during mechanical ventilation. The concentration can be varied from 0.21–1.0. Devices for intermittent positive-pressure breathing, continuous positive airway pressure (CPAP) masks, nasal CPAP, nebulizers for inhaled medications, and others can provide supplemental O₂ as needed in patients with hypoxemia.

Complications of Oxygen Therapy

Complications of oxygen therapy are uncommon. Aside from increased combustion risk from smoking or open flames, patients occasionally may have hypoventilation from loss of hypoxic drive or excessive drying of mucous membranes. On the other hand, more subtle toxic effects of O₂ and its metabolites are recognized.

Although O₂ itself is relatively nontoxic to biologic tissues, more reactive chemical relatives of O₂ resulting from spontaneous and facilitated conversion have potential for

damage to the lungs. Inflammation and other biologic processes may increase the generation of more energetic and toxic oxygen moieties such as hydrogen peroxide, hydroxyl ion, and superoxide anion. In the presence of myeloperoxidase and hydrogen peroxide, chloride anion is converted to hypochlorous acid, which has potent biologic effects. The production of toxic products in a localized region of lung or other tissues is enhanced when PO₂ is increased.

Toxicity from oxygen occurs primarily in the lungs in adults and is related not to the PaO₂ but rather to the inspired oxygen partial pressure. Subjects at sea level given 100% O₂ to breathe have complained of chest pain, dry cough, and other discomfort after 6 hours. More severe oxygen toxicity has been demonstrated in humans and in experimental animals when 100% O₂ is given for 24–48 hours. In normal lungs, capillary leakage of fluid and protein has been demonstrated with accompanying increased F_{IO₂}. Findings similar to those of ARDS, with exudative pulmonary edema, inflammatory changes, and subsequent fibrosis, have been attributed to oxygen toxicity, but the relationship to underlying disease requiring the high oxygen concentration is unclear.

Because of potential adverse effects, it is advisable to limit high concentrations of oxygen (F_{IO₂} >0.5) to short duration (<72 hours) if possible. It is not known whether the presence and nature of coexisting lung injury enhances or protects against oxygen toxicity, but there is some evidence that viral pneumonia increases sensitivity to oxygen toxicity. It is highly likely that inflammatory cells—such as neutrophils—that encourage development of toxic oxygen products also increase the risk of oxygen toxicity. Infection, inflammation from any cause, and increased inflammatory cell function

owing to cytokine activation probably will correlate with potential oxygen-mediated tissue injury. A number of investigators have suggested that antioxidants (eg, vitamin A, vitamin E, and acetylcysteine) and scavengers of toxic oxygen products (eg, superoxide dismutase) may modulate lung damage from oxygen.

► Bronchodilators

Increased airway resistance is the major feature of asthma and other chronic obstructive pulmonary diseases. Resistance increases because of airway smooth muscle contraction, excessive secretions, airway inflammation and edema, and decreased lung elastic recoil. Bronchodilators affect directly only smooth muscle contraction, although some may have indirect effects on edema and inflammation. Bronchodilators are primary treatment for obstructive lung diseases, but increased airway resistance is a feature of many other kinds of lung diseases such as pulmonary edema, ARDS, and pneumonia. Bronchodilator drugs are used often in these and other respiratory failure settings. The benefits and risks of adverse effects must be considered when these drugs are prescribed.

There are five classes of bronchodilators: β -adrenergic agonists, anticholinergics, methylxanthines, calcium antagonists, and a miscellaneous group of agents including magnesium sulfate. Calcium antagonists have been used as bronchodilators experimentally but are not approved for clinical use. Calcium antagonists are weak bronchodilators, and their primary value is that they can generally be used safely to treat hypertension, arrhythmias, and ischemic heart disease in patients with coexisting obstructive lung disease and respiratory failure.

Beta-Adrenergic Agonists

These drugs—also called *sympathomimetics*—are derivatives of epinephrine, with modifications to improve activity, specificity, dosing, and pharmacokinetic properties. Identification of subclasses of adrenergic receptors using specific antagonists has led to designation of different drugs as having α -, β_1 -, or β_2 -adrenergic agonist activity. Stimulation of α -adrenergic receptors—present largely on systemic blood vessels—increases vascular tone and, in the presence of normal cardiac function, raises blood pressure. β_1 -receptor stimulation leads to increased rate and force of cardiac contraction and peripheral vasodilation, whereas β_2 -receptor agonists relax airway smooth muscle. In comparison with epinephrine and isoproterenol, albuterol and terbutaline have increased β_2 -adrenergic activity with decreased β_1 activity, making these drugs more potent bronchodilators with fewer undesired cardiac effects.

A. Route of Administration—These agents are more effective when given by inhalation rather than when given orally or parenterally. For a given degree of bronchodilation, side effects are considerably less for the inhaled route, allowing a larger

and longer-acting dose to be administered. Oral β -adrenergic agonists are not as useful in acute respiratory failure.

When given by inhalation, the onset of action of the β -adrenergic agonists is rapid, and newer agents are metabolized slowly enough to allow for relatively long intervals between doses in most stable patients. Metered-dose inhalers (MDIs), if used properly, are as effective as gas-driven nebulizers or intermittent positive-pressure breathing for delivering bronchodilators. Most clinicians now recommend that patients use an MDI with a spacer device between the MDI and the mouth to facilitate correct use. For patients receiving mechanical ventilation, there are a number of devices that incorporate reservoirs in the ventilator circuit so that MDIs can be used. However, the comparative effectiveness of MDIs and gas-driven nebulizers during mechanical ventilation is unclear. Either type of device can be used, and some objective measurement should be employed to determine whether effective bronchodilation is achieved in an individual patient. MDIs previously used chlorofluorocarbon propellants, but these are being replaced by hydrofluoroalkanes. The new propellants are associated with improved distribution of the bronchodilator and potentially greater clinical effectiveness.

B. Dose and Selection of Drug—Effective therapy may require two to four times the amount of β -adrenergic agonists than is usually recommended for patients with stable obstructive lung disease, so increased doses (ie, more puffs from the MDI or increased quantity in the nebulizer) and increased frequency of administration (up to every hour or by continuous nebulization) are often needed. Some protocols call for increasing amounts of β -adrenergic agonists until a plateau in improved lung function is reached or until side effects such as tachycardia or muscle tremors are observed. Several studies have advocated use of continuous nebulization of β -adrenergic agonists rather than frequent intermittent therapy (eg, every hour), but benefit is not conclusive.

Selection of a particular β -adrenergic agonist is based on potency, efficacy, ease of administration, and limitation of side effects. Albuterol—the most often used agent—can be given in a wide range of dosages as needed to treat bronchospasm. It has an early onset of action and is available in MDIs, in solution for nebulization, and in oral form. MDIs containing albuterol in fixed combination with ipratropium bromide are used mostly for stable patients with asthma and COPD. Levalbuterol is the (*R*)-enantiomer of racemic albuterol, thought to be the active β -adrenergic agonist molecule. Some studies have linked increased undesirable bronchoreactivity to the (*S*)-isomer, but it is unclear if levalbuterol has any clinical advantage over the racemic mixture. Metaproterenol is available for inhalation and orally. Terbutaline can be given subcutaneously or orally, but there are no currently available parenteral forms of metaproterenol or albuterol.

Epinephrine is a potent β -adrenergic agonist with strong cardiovascular effects owing to its lack of specificity for β_2 receptors. In general, this drug offers no advantages for the treatment of bronchospasm when compared with more selective

agents. Salmeterol is a long-acting β -adrenergic agonist useful for chronic treatment of asthma to prevent rather than treat bronchospasm. It is not recommended for acute bronchospastic attacks. In fact, some asthmatics appear to have worsening of asthma with use of long-acting β -adrenergic agonists, including increased risk of death. Fomoterol is a potent long-acting β -agonist with a short onset of action; its effects are likely to be similar to that of salmeterol.

Albuterol can be given as two to four puffs from an MDI every 4–6 hours in stable patients with obstructive lung disease and bronchospasm. In patients with acute exacerbations of bronchospasm, the number of puffs can be increased to six to eight (or more, if tolerated) and the frequency to every 1–2 hours if needed. The response should be objectively measured, preferably by FEV₁ or peak flow, to document the need for the higher dose; adverse effects should be monitored carefully, especially when the doses given exceed usual recommendations. Waiting 3–5 minutes between puffs improves the effectiveness of a given dose. A nebulized solution of 0.2–0.5 mL of albuterol (0.5%) or metaproterenol (5%) diluted in 2–3 mL of normal saline can be given by gas-powered nebulizer or intermittent positive-pressure breathing every 2–6 hours, but there is no evidence that this is more effective than administration by MDI. Individual patients may have a better response with certain routes of delivery, and poor response to one route does not rule out beneficial effects from another.

Patients receiving mechanical ventilation have been treated by incorporating a nebulizer or aerosol generator in the ventilator circuit. MDIs have been adapted successfully for use with ventilators, but the type of adaptor and, most important, the dose of medication administered greatly affect the degree of bronchodilation. Patients who do not have the desired effect using a nebulizer or MDI should be considered for the alternative form of delivery, or the dose of β -adrenergic agonist should be adjusted.

C. Adverse Effects—Side effects particularly important in the ICU and that may limit β -adrenergic agonist use include tremors, tachycardia, palpitations, arrhythmias, and hypokalemia. Cardiac effects other than tachycardia may become important in patients with ischemic heart disease, but chest pain and ischemia are unusual. Tachycardia is sometimes more associated with respiratory distress and hypoxemia than with β -adrenergic agonists and may resolve after bronchodilator therapy. Hypokalemia is exacerbated by thiazide diuretics and is caused by shifts of potassium from extracellular to intracellular compartments in response to β -adrenergic stimulation.

An uncommon complication of β -adrenergic agonists is worsening of hypoxemia from exacerbation of ventilation-perfusion mismatching. This may occur because these drugs oppose appropriate localized pulmonary artery vasoconstriction in areas of low ventilation-perfusion ratio; increased blood flow to these regions increases hypoxemia.

Systemic side effects result largely from absorption through the mucous membranes of the mouth, and their incidence may be reduced by spacers or reservoirs that

generate a mix of aerosol particles that more effectively reaches the intrathoracic airways. Patients should be instructed to rinse the mouth after each inhalation of the medication.

Heavy use of β -adrenergic agonist therapy in asthma is associated with an increased risk of death and exacerbation of bronchospasm. The mechanism is unknown but may relate to side effects of the medications or, paradoxically, to their effectiveness as bronchodilators but not as drugs that address the underlying cause of asthma. Of particular concern are adverse responses, including death, related to long-acting β -adrenergic agonists such as salmeterol. Concomitant corticosteroids are associated with a reduction in this risk. These findings may or may not be relevant in the management of status asthmaticus in the ICU.

β -adrenergic blockers are used commonly in ICU patients for hypertension, ischemic heart disease, and cardiac arrhythmias. β -adrenergic agonists are less effective when receptors are blocked, and variable effects on both bronchodilation and the underlying cardiovascular condition are likely to be encountered. Caution should be exercised with β -adrenergic agonists in patients with cardiac disease, hypokalemia, or other potential complicating factors.

Anticholinergics

The bronchodilator response to anticholinergic (parasympatholytic) drugs depends on the degree of intrinsic parasympathetic tone. These agents play a somewhat smaller role in asthma, a disorder in which the mechanism of airway obstruction is inflammation, than in chronic bronchitis, in which more parasympathetic tone is present.

Ipratropium bromide is the only anticholinergic agent used for acute exacerbation. Atropine sulfate should no longer be given as a bronchodilator because of its systemic toxicity, including decreased airway and salivary gland secretions, decreased gastrointestinal (GI) motility, tachycardia, decreased urinary bladder function, pupillary dilation, and increased intraocular pressure. On the other hand, ipratropium bromide given by inhalation is barely detectable in the blood and, because it is a quaternary ammonium compound, does not pass easily through lipid membranes, including the blood-brain barrier. Therefore, ipratropium's effects are strongly limited to bronchodilation, and only a very few complaints of other systemic parasympatholytic action have been encountered even when large doses are administered. Tiotropium, a long-acting anticholinergic inhaled powder, is intended for chronic prevention of bronchospasm and has no role in acute exacerbations.

A. Indications—Anticholinergics are recommended primarily for bronchodilation in patients with chronic bronchitis. Some investigators have recommended ipratropium bromide as first-line outpatient therapy, but ipratropium always should be used in combination with β -adrenergic agonists when treating respiratory failure. Because the effectiveness of anticholinergics depends on the degree of parasympathetically

mediated increased smooth muscle contraction, other diseases in which airway secretions are prominent such as cystic fibrosis may respond well. Acute exacerbation of asthma usually responds better to other agents, but studies support adding ipratropium to β -adrenergic agonists and corticosteroids.

B. Route and Dose—Ipratropium bromide is available in MDIs (alone and combined with albuterol) or in solution for nebulization. Each puff of the MDI provides 18 μg of the drug. The onset of action appears to be somewhat longer than that of β -adrenergic agonists—approximately 30 minutes—and the peak effect occurs at around 60 minutes. The dose of ipratropium bromide recommended has increased with clinical experience from as few as two inhalations every 6 hours to as many as four to eight inhalations every 4 hours, with increasing effectiveness at the higher dose range in some cases. For nebulization of ipratropium, an effective dose appears to be 0.5 mg given every 6–8 hours, and the drug is available in unit-dose vials containing 0.5 mg ipratropium in 2.5 mL normal saline. Even at the highest doses, side effects of ipratropium are minimal, and these doses appear to be safe. As with β -adrenergic agonists given by MDIs, delivery appears to be more efficient with the aid of spacers or reservoirs.

C. Adverse Effects—Very few adverse effects are reported—rarely, tachycardia, palpitations, and urinary retention.

Theophylline

Theophylline is a methylxanthine bronchodilator. It is considerably less potent as a bronchodilator than the β -adrenergic agonists. The role of this drug is limited, but it may have effects other than bronchodilation.

A. Mechanism of Action—Theophylline has a long history of use as a bronchodilator. Although inhibition of phosphodiesterase was thought to be its mechanism, therapeutic concentrations do not inhibit phosphodiesterase strongly, and it has been difficult to demonstrate a synergistic relationship with β -adrenergic agonists, which stimulate cyclic AMP production. Other proposed mechanisms include effects on translocation of calcium, antagonism of adenosine, stimulation of β -adrenergic receptors, and anti-inflammatory activity. Recently, studies of highly specific inhibitors of different phosphodiesterases have been carried out in patients with COPD and other disorders.

Theophylline has been relegated by to second-line therapy because of the availability of potent β -adrenergic agonists and other agents.

B. Pharmacokinetics—Theophylline generally is thought to be effective at a plasma level of 10–20 $\mu\text{g}/\text{mL}$; toxicity is increasingly likely when levels exceed 20–30 $\mu\text{g}/\text{mL}$, and severe toxicity is encountered above 40 $\mu\text{g}/\text{mL}$. The dose-response is curvilinear, with the increase in benefit being greatest when the theophylline level increases from 5–10 $\mu\text{g}/\text{mL}$ and much less when the level increases from 15–20 $\mu\text{g}/\text{mL}$. About 90% of theophylline is metabolized by the

liver to inactive products by the P450 cytochrome system. This enzyme system is stimulated by tobacco or marijuana smoking and phenobarbital but is decreased in activity by cimetidine, erythromycin, oral contraceptives, and many other drugs. Theophylline metabolism is greatly reduced with fever, advanced age, cessation of smoking or of a drug that enhances metabolism, liver disease, and heart failure. Hepatic failure and heart failure patients often will metabolize theophylline at less than 50% of normal rates.

C. Dose and Route of Administration—In the ICU, theophylline usually is given intravenously. Theophylline is available premixed in 5% dextrose in water at a concentration of 0.8 mg/mL. To achieve rapid therapeutic levels, intravenous loading is used, with 5 mg/kg of theophylline given over 20–30 minutes to patients who have not been receiving the drug. If the patient has been receiving theophylline during the last 24 hours, about 2 mg/kg should be given as the loading dose. This loading dose and the volume of distribution of theophylline are intended to achieve a plasma level of about 10 $\mu\text{g}/\text{mL}$. Most studies have been based on actual rather than ideal body weight, but it is likely that the volume of distribution does not increase in proportion to increased body fat. Because metabolism of the drug begins immediately, a constant infusion is necessary to maintain this level. In the absence of factors that affect theophylline metabolism, the constant infusion is chosen to be 0.5–0.6 mg/kg per hour, but this should be reduced to 0.1–0.2 mg/kg per hour in patients with liver disease or heart failure or those who are taking cimetidine or erythromycin. Elderly patients have decreased clearance of theophylline, and a constant infusion of 0.2–0.4 mg/kg per hour is recommended. When a steady state is reached after five half-lives have passed (about 18–36 hours), plasma levels should be checked to adjust the infusion rate accordingly.

D. Adverse Effects—Tachycardia, nausea, and vomiting can occur even at therapeutic plasma levels but are more common at levels over 20 $\mu\text{g}/\text{mL}$. Severe complications include cardiac arrhythmias, hypokalemia, altered mental status, and seizures, usually seen when theophylline levels exceed 35 $\mu\text{g}/\text{mL}$. Many drugs interfere with theophylline metabolism by hepatic enzymes, causing plasma levels to rise (eg, erythromycin, cimetidine and ranitidine, and quinolones), and phenobarbital, rifampin, and smoking increase the rate of metabolism, sometimes causing plasma levels to be low.

Magnesium Sulfate

Intravenous magnesium sulfate is a bronchodilator used in asthma. The mechanism of action appears to be direct airway smooth muscle relaxation.

A. Indications—Clinical studies, including double-blind, placebo-controlled trials, have tested this drug in combination with β -adrenergic agonists or other bronchodilators in asthmatics.

B. Route and Dose—Magnesium sulfate is given as 1–2 g (8–16 meq) intravenously over 10–20 minutes. This dose can be repeated every 1–2 hours as long as the patient does not have renal insufficiency and does not develop signs of magnesium toxicity. Plasma magnesium levels may be helpful in monitoring for toxicity.

C. Adverse Effects—Adverse effects are due to hypermagnesemia and include loss of deep tendon reflexes, bradycardia, hypotension, somnolence, muscle weakness, respiratory failure owing to muscle weakness or paralysis, and cardiac arrest.

► Other Drugs

Corticosteroids

Although both corticosteroids and cromolyn have been used as anti-inflammatory drugs for respiratory diseases, there is little or no experience with the latter drug in acute respiratory failure in adults. Corticosteroids have been used for obstructive lung disease, including asthma and chronic bronchitis, to decrease airway obstruction from inflammation, edema, and airway lumen debris, and in ARDS in an effort to moderate its severity and prevent late fibrotic complications. Pharmaceutical preparations of corticosteroids have greater potency than cortisol, fewer mineralocorticoid effects, longer duration of action, different solubility and degree of systemic absorption, and different rates of metabolism. The precise mechanism of anti-inflammatory action of these agents is unknown, but they have effects on lymphocytes, cytokine production, interleukin release, macrophage function, immunoglobulin production, eosinophil activation and production, and other immune and allergic responses. The mechanism of corticosteroids in reducing airway inflammation is similarly unknown, but changes in inflammatory cell nature and number have been demonstrated after both systemic and topical administration.

A. Route of Administration—Corticosteroids used in asthma and COPD can be given orally, intravenously, or by aerosol. Aerosolized corticosteroids are useful for the treatment of stable mild to moderate asthma. The several available agents are designed to maintain activity at mucosal surfaces but have poor systemic absorption. In addition, any amount swallowed is rapidly and almost completely taken up by the liver and eliminated. Comparison studies have found few differences between beclomethasone dipropionate, triamcinolone acetonide, and flunisolide. More potent anti-inflammatory corticosteroids such as budesonide and fluticasone are highly effective in chronic asthma and have been shown to have some value in patients with COPD.

Aerosolized corticosteroids are potentially poorly distributed in acute respiratory failure, and oral or parenteral forms are almost always used. Prednisone and methylprednisolone are given orally; methylprednisolone and hydrocortisone are given intravenously. Some studies have shown little difference

between oral and intravenous administration, but comparisons are difficult because of different potencies of the agents used.

B. Dose—For treatment of obstructive lung disease with acute exacerbation, most investigators recommend giving large doses initially and continuing for several days before tapering and discontinuing, if possible within 7–14 days. Others have suggested that tapering is not needed to avoid exacerbation of airway inflammation and that the practice unnecessarily prolongs treatment; they suggest that the corticosteroids can be stopped abruptly. Severe asthma and exacerbation of chronic bronchitis have been treated with 20–120 mg methylprednisolone intravenously four times a day, usually in the range of 40–60 mg/dose. There is no evidence that higher doses achieve better outcomes or shorter duration of disease. Almost all patients can be switched to oral prednisone after 3–5 days of clinical response, usually in a dosage of 30–60 mg daily. There is evidence that oral prednisone and intravenous methylprednisolone are equally effective when given acutely to patients with moderately severe asthma, but the parenteral route is often preferred. Inhaled corticosteroids are generally withheld during severe acute exacerbations.

C. Adverse Effects—Side effects of parenteral corticosteroids particularly important in the ICU include hyperglycemia, hypokalemia, sodium and water retention, acute steroid myopathy (especially at larger doses), impairment of the immune system, and psychiatric disorders. An association with gastritis and GI bleeding has been suggested but is debated. Inhaled corticosteroids are relatively free of systemic side effects except for cough, perhaps provocation of bronchospasm, and oral and pharyngeal candidiasis. However, the more potent inhaled corticosteroids have long-term adverse effects on growth, osteoporosis, and cataract development. Prolonged muscle weakness precluding weaning from mechanical ventilation has been associated with simultaneous use of corticosteroids and nondepolarizing neuromuscular blocking drugs. Patients for whom corticosteroids are prescribed chronically are at risk for inhibition of the normal pituitary-adrenal axis; they may develop acute adrenal insufficiency with withdrawal of therapeutic corticosteroids.

Systemic corticosteroids should be discontinued as soon as possible to avoid side effects. However, too early and too rapid cessation can lead to exacerbation of disease. In most patients, close monitoring during this phase can identify potential problems, and selected patients can benefit from a longer course of corticosteroids. Corticosteroids are often started by inhalation if persistent airway inflammation is anticipated and the clinical course warrants continuation of this mode of therapy. Finally, some patients are unable to tolerate discontinuation of systemic corticosteroids; every effort should be made to reduce the dose to the lowest possible therapeutic level, and the risks and benefits of this therapy should be thoroughly reviewed.

Leukotriene Antagonists and Inhibitors

Leukotrienes are products of arachidonic acid metabolism and may have a role in certain kinds of asthma. In chronic asthma, inhibition of the effect of leukotrienes by leukotriene receptor antagonists (eg, montelukast or zafirlukast) or inhibition of leukotriene production (eg, zileuton, a 5-lipoxygenase inhibitor) has beneficial effects on the severity and course of the disease. There is no role for these agents in acute asthma exacerbations, but they generally can be continued in patients who are taking them already.

Expectorants and Nucleonics

There is little evidence that vigorous administration of fluids improves either the volume or the characteristics of abnormal sputum except perhaps in patients who are volume-depleted. Oral potassium iodide may have some value in increasing the volume and thinning tenacious sputum. Iodinated glycerol has been shown to benefit stable COPD patients by increasing the force and frequency of coughing and thus perhaps aiding sputum clearance. The potential value of this drug in acute exacerbation of asthma or COPD is unknown. Other expectorants appear to be of little value, and cough suppressants such as codeine may be contraindicated when removal of secretions by coughing is desired.

Mucolytic agents can be applied directly to airway secretions, especially through endotracheal tubes. Small amounts (3–5 mL) of normal saline, hypertonic saline, and hypertonic sodium bicarbonate can be instilled prior to suctioning and the results judged by the removal of greater amounts of secretions. Acetylcysteine disrupts disulfide bonds found in sputum proteins and can be a potent mucolytic agent. However, aerosolized acetylcysteine is relatively ineffective and may provoke bronchospasm in asthmatics. Small aliquots of acetylcysteine have been given by flexible bronchoscopic lavage into specific airways if necessary.

Respiratory Stimulants

There is no indication for respiratory stimulant drugs. Most patients with respiratory failure have mechanical and gas exchange abnormalities that must be corrected, whereas very few patients solely lack sufficient ventilatory drive. In the small number of patients who could benefit from stimulation of the respiratory centers—such as those with CNS depression from sedative drug overdosage or immediately postanesthesia—temporary mechanical ventilatory support is effective and safe.

Sedatives and Muscle Relaxants

In patients not receiving mechanical ventilation, sedative drugs, including barbiturates and benzodiazepines, and drugs with respiratory depression potential, such as opioids, are contraindicated in most forms of respiratory failure. Attempts to attenuate but not eliminate respiratory drive with these agents in order to lessen dyspnea have not been

successful. In patients with chest or abdominal pain from trauma or surgery limiting ventilation, analgesia is very important; tidal volume and minute ventilation may increase after treatment.

In patients who are receiving mechanical ventilation, sedation is often necessary, especially shortly after intubation and initiation of ventilatory support. Benzodiazepines such as diazepam and lorazepam are often used, and the dosage should be titrated as necessary. Lorazepam has the advantage of longer duration of action, which may be beneficial in patients requiring sedation for several days. All benzodiazepines will accumulate in body fat after repeated or prolonged use; they are metabolized by the liver, and hepatic dysfunction also prolongs their effect. Agitation caused by pain should be treated with analgesics such as morphine sulfate rather than increased doses of sedatives. Propofol, which must be given by continuous intravenous infusion, is an attractive sedative because awakening of the patient occurs 10–20 minutes after the infusion is stopped, unless the drug is used for a prolonged period of time. Propofol has a rapid onset of action and generally rapid termination of sedative effect when discontinued (unless use is prolonged). Many patients who might require muscle relaxants to tolerate mechanical ventilation can be managed successfully using propofol.

In an important randomized, controlled trial, adult patients receiving mechanical ventilation had sedation interrupted until they were awake every day. They were compared with a control group who had sedation stopped at the discretion of their physicians. The daily interruption group had a shorter median duration of mechanical ventilation and significantly shorter stays in the ICU. No difference in complications, including those associated with extubation, was found. This study suggests that many mechanically ventilated patients require less sedation than is usually thought to be necessary.

In a very few patients, muscle relaxants are needed to facilitate oxygenation or ventilation. Continuous intravenous infusion of pancuronium or atracurium is used most often. With these agents, great care is needed to ensure adequate sedation and maintenance of ventilation. These drugs should be used only by experienced physicians, and drug dosage should be titrated carefully using a peripheral nerve stimulator. Because pancuronium has vagolytic effects and is associated with histamine release, it should be avoided in patients with unstable hemodynamics. Atracurium is metabolized in the plasma, and the duration of action is not affected by renal or hepatic insufficiency. These agents may cause prolonged neuromuscular weakness, especially when given in association with high dosages of corticosteroids.

► Chest Physiotherapy

Chest physiotherapy is applied to the airways or to the outside of the chest. Techniques include incentive spirometry, intermittent positive-pressure breathing (IPPB), postural drainage, chest percussion, rotational therapy, and fiberoptic bronchoscopy.

Incentive Spirometry

Atelectasis is a common problem in postoperative patients and those with neuromuscular or chest wall disease. Incentive spirometers encourage expansion of the lungs as much as possible above spontaneous breathing; these have proved to be beneficial in controlled studies. Patients should be instructed to expand their lungs as much as possible for as long as they can rather than generate a high negative inspiratory pressure for a short time.

Intermittent Positive-Pressure Breathing

The benefit of IPPB has been difficult to demonstrate. Although sometimes used to deliver bronchodilator medications, IPPB is usually intended to prevent or treat atelectasis. In objective studies, patients can improve atelectasis if and only if IPPB can increase the depth of breathing more than the patient alone can achieve. IPPB can be tried in patients with respiratory muscle weakness owing to neuromuscular disease, those with chest wall abnormalities, and after abdominal surgery. In general, incentive spirometry should be tried first and IPPB used only when there is proof that larger inspired volumes can be reached with this technique.

Postural Drainage and Rotational Therapy

The patient may be placed in various positions to encourage drainage of airway secretions from specific segments or lobes of the lungs. This procedure may be particularly important in patients with lung abscess or bronchiectasis when large volumes of purulent secretions are present and one or a few regions of involvement can be identified. The objective measure of benefit is the increase in volume of expectorated secretions. It is less clear that patients with pneumonia are helped by postural drainage, but this measure might be tried to see if it encourages production of sputum. Patients with respiratory failure from diffuse airway disease are probably little benefited by postural drainage, and there is a risk that worsening of gas exchange may occur in some positions. Postural drainage and chest percussion should be withheld if there is no objective evidence that sputum expectoration is increased after treatment.

There are a number of different kinds of patient care beds that provide programmed rotation of the patient as well as vibration therapy or percussion to the chest wall. Of these modes, rotational therapy may be helpful in preventing or treating aspiration of secretions and pneumonia.

Chest Percussion

Chest percussion is often added to postural drainage and has the same indications. It should be discontinued if increased volume of secretions does not result. Chest percussion can cause worsening of hypoxemia, rib fractures, and skin abrasions. A recent study found that cardiac arrhythmia was a common complication of chest percussion and postural drainage, especially in the elderly and those with underlying

heart disease. Patients with atelectasis and no evidence of increased airway secretions do not improve with chest percussion.

Fiberoptic Bronchoscopy

Fiberoptic bronchoscopy allows inspection of the airways out to several generations and provides a means of suctioning airway secretions. In respiratory failure, patients with segmental or lobar collapse owing to mucous plugs who fail to respond to other forms of treatment may be helped by fiberoptic bronchoscopy; in these cases, the bronchoscope is essentially used as a visually directed suction catheter. Occasionally, unsuspected foreign bodies or airway tumors are found. Patients with atelectasis who have visible "air bronchograms" on chest x-rays appear to benefit less from bronchoscopy than those whose airways leading to the involved region are airless. The air bronchogram sign indicates that the airway is probably patent and not obstructed by secretions that can be removed by fiberoptic bronchoscopy. Because of cost and potential complications, fiberoptic bronchoscopy should not be the initial treatment of atelectasis or lobar collapse unless there is a strong likelihood of endobronchial obstruction. Likewise, routine fiberoptic bronchoscopy for postoperative patients should be discouraged.

▶ Mechanical Ventilation

Mechanical ventilation in acute respiratory failure has been viewed as largely supportive, but it is now recognized that proper management of the patient-ventilator system can have a positive effect on outcome. The need for and the type of mechanical ventilatory support depend on the mechanism of respiratory failure. Potential complications of mechanical ventilation are also determined to some extent by the severity and mechanism of disease. The choice of ventilator, mode, and settings should be made by the critical care physician in consultation with respiratory care practitioners. Because changes in ventilator settings affect not only respiratory parameters but also hemodynamic and other organ system functions, monitoring of the mechanically ventilated patient can be a complex task. Decisions to initiate and terminate mechanical ventilation require both physiologic understanding and clinical judgment.

In the past, the goal of mechanical ventilation was to correct arterial blood gases to normal. It is recognized now that tidal volume and respiratory rate settings needed to achieve normal PaCO_2 in patients with abnormal lungs may further damage the lungs. Now, when a low-tidal-volume strategy is used in ARDS or asthma, for example, hypercapnia may be “permitted.” As a result, the lungs undergo less damage, and mortality is decreased.

The Patient-Ventilator System

The normal, spontaneously breathing subject has an intact ventilatory control system, effective bellows (ie, chest wall and diaphragm), and efficient gas exchanger (ie, lung parenchyma and circulation). Feedback from chemoreceptors sensing PaO_2 and pH (and indirectly PaCO_2) and mechanoreceptors of the lung and chest wall provide input to a central integrator-controller that generates neural output at an appropriate frequency to signal the inspiratory effort. The bellows system produces negative intrathoracic pressure by contraction of the inspiratory muscles, thereby drawing gas into the lungs. The timing and amount of negative pressure determine the rate of inspiratory flow. The gas

exchanger (lungs) distributes inspired gas in proportion to pulmonary blood flow, and O_2 and CO_2 move into and out of the circulation by diffusion. Exhalation occurs when the ventilatory control mechanism signals relaxation of the inspiratory muscles. Exhalation is complete in the relaxed subject when passive mechanical forces of the lungs and chest wall equalize. The lung volume remaining is the functional residual capacity (FRC). The relative amounts of time spent during inspiration and expiration are determined by the magnitude of respiratory drive and the interactions between stimuli received by other receptors.

Mechanical ventilation can be understood by comparing the parameters chosen by the clinician during controlled-mode positive-pressure volume-cycled ventilation with a spontaneously breathing normal person (Table 12–6). In this mode, the ventilator is set at a specific number of breaths per minute to be delivered to the patient. There is no negative or positive feedback from chemoreceptors or other sources that determine the respiratory rate. The clinician chooses the tidal volume on the ventilator, and this volume is delivered each time the ventilator delivers a breath. The rate at which the tidal volume is delivered to the patient can be adjusted, and the inspiratory time is determined as the quotient of tidal volume divided by inspiratory flow rate. The amount of positive pressure generated by the ventilator depends on the inspiratory flow, the resistance of the airways, and the compliance of the lungs and chest wall. Passive exhalation begins

Table 12–6. Variables to be set during mechanical ventilation.*

Mode	How should each breath be initiated?
Tidal volume	What is the volume of each ventilator breath?
Respiratory rate	At what rate should the ventilator deliver breaths in the event of apnea?
FiO_2	What is the concentration of O_2 in the inspired gas?
Inspiratory flow	How fast should inspiratory flow be delivered?
PEEP	How much end-expiratory pressure is needed?
Peak pressure	At what peak airway pressure should inspiratory flow be stopped?
I:E ratio	What is the ratio of inspiratory:expiratory time?
Flow pattern	Should inspiratory flow be constant or follow some other pattern (descending or sinusoidal)?

*For volume preset (volume-cycled) ventilation.

immediately after the specified tidal volume has been delivered and lasts until the next inspiration begins.

Respiratory Mechanics and Mechanical Ventilation

Lung compliance and airway resistance are the two most important physiologic concepts in understanding mechanical ventilation. Both are commonly altered from normal in patients with acute respiratory failure, especially lung compliance in ARDS, chest wall compliance in a variety of disorders, and resistance in asthma and COPD exacerbations.

A. Compliance—When the lungs are expanded, elastic tissues in the lungs and surface tension in the alveoli oppose expansion. At lung volumes near total lung capacity, the chest wall also exerts an opposing force. The amount of pressure needed to overcome these forces, when related to a given change in lung or chest wall volume, is the respiratory system compliance (C_{rs}), the ratio of change in volume of the lungs or chest wall to the change in pressure ($\Delta V/\Delta P$). ΔP is the change in pressure measured between the inside and outside of the system, in this case alveolar pressure minus chest wall surface (atmospheric) pressure. Because pressure is needed to overcome both lung and chest wall elastic recoil, both lung compliance (C_l) and chest wall compliance (C_{cw}) are components of respiratory system compliance:

$$\frac{1}{C_{rs}} = \frac{1}{C_l} + \frac{1}{C_{cw}}$$

The pressure-volume relationship of the respiratory system is curvilinear (Figure 12-4). The individual components—lung compliance and chest wall compliance—can be determined only by measuring intrapleural pressure using an esophageal balloon. However, most often in the ICU the respiratory system as a whole is measured, and it is not partitioned into the two components.

All types of mechanical ventilators measure airway pressure throughout the respiratory cycle, but the following analysis assumes that a volume-cycled ventilator with a set tidal volume is being used. If, after the tidal volume is delivered to the patient by a positive-pressure ventilator, exhalation is delayed briefly and the patient makes no inspiratory or expiratory efforts, the pressure in the ventilator circuit (ie, inspiratory plateau pressure) equals the amount of pressure needed to distend the lungs and chest wall by the tidal volume delivered (Figure 12-5). Therefore, $C_{rs} = \text{tidal volume}/(\text{inspiratory plateau pressure} - \text{end-expiratory pressure})$. C_{rs} is sometimes called *static respiratory system compliance*. Normal C_{rs} is approximately 100 mL/cm H_2O in the range of usual operational lung volume. Thus, for a tidal volume of 800 mL in a mechanically ventilated patient with normal chest wall and lung compliance, the inspiratory plateau pressure will be about 8–10 cm H_2O .

▲ **Figure 12-4.** Hypothetical respiratory system pressure-volume curves during positive-pressure breathing. The normal curve is steeper at low lung volume than the curve for a patient with less compliant lung or chest wall (low C_{rs}). Mean respiratory system compliance for the tidal volume shown is $C_{rs} = \Delta V/\Delta P_1$ (normal curve) or $C_{rs} = \Delta V/(\Delta P_1 + \Delta P_2)$ for the less compliant system.

▲ **Figure 12-5.** Airway pressure schematically shown during respiratory cycle for positive-pressure respiration. Peak airway pressure, pressure during inspiratory plateau, and positive end-expiratory pressure (PEEP) are shown. The difference between peak and inspiratory plateau pressures provides an indication of airway resistance. The tidal volume/(inspiratory plateau pressure – PEEP) is an estimate of respiratory system compliance.

When a patient has a higher than expected inspiratory plateau pressure for a given tidal volume (decreased C_{rs}), there must be decreased lung compliance (eg, pulmonary edema or interstitial fibrosis) or decreased chest wall compliance, such as in obesity, ascites, or kyphoscoliosis. High inspiratory plateau pressures also can be found at extremes of lung volume. For example, at very low lung volume relative to total lung capacity, alveolar collapse leads to the tidal volume's being distributed over fewer lung units, resulting in a higher inspiratory plateau pressure. On the other hand, at high lung volumes relative to total lung capacity, lung units become overdistended, and the lung is less compliant. Atelectasis, pulmonary edema, pleural effusions, acute changes in chest wall compliance, pneumothorax, and potentially dangerous overdistention of the lung are suggested by a decrease in C_{rs} .

B. Resistance—Gas flows from a region of high pressure to a region of low pressure. Respiratory resistance arises from the loss of energy of gas moving through the airways from friction along the conduit walls. Resistance is a complex function of gas density and viscosity, velocity, the degree of turbulence, and the nature of the conduits, but resistance is always proportionate to the difference in pressure of the gas between upstream and downstream points. Resistance determines the rate of gas flow into or out of the lungs at a given pressure or the necessary pressure for a given flow. In mechanically ventilated patients, an estimate of relative airway resistance during inspiration can be made from the peak airway pressure during volume-cycled ventilation with constant inspiratory flow. More complex measurements are needed to determine airway resistance more accurately or under different circumstances.

In contrast to inspiratory plateau pressure—used earlier to estimate respiratory compliance—peak airway pressure is the sum of the pressure needed to expand the lungs and chest wall plus the pressure needed to push the gas through the airways. Thus peak pressure always exceeds inspiratory plateau pressure by the amount needed to overcome airway resistance. A large difference between peak pressure and inspiratory plateau pressure (ie, >5 – 10 cm H_2O) indicates that bronchospasm, airway secretions, or other causes of increased airway resistance are present. Dynamic respiratory system compliance is defined as the ratio of tidal volume to the difference between peak airway pressure and end-expiratory pressure. This variable reflects both lung compliance and airway resistance and may be useful in conceptualizing the work of breathing, but it is not strictly a measure of compliance.

Peak airway pressure is a function of resistance (R) and C_{rs} , as well as tidal volume (V_T), inspiratory flow rate (\dot{V}), and positive end-expiratory pressure (PEEP). The inspiratory plateau pressure is the “static” component of peak airway pressure, consisting of the quotient of V_T and C_{rs} .

$$P_{\text{peak}} = \dot{V} \times R + \frac{V_T}{C_{rs}} + \text{PEEP}$$

C. Mean Airway Pressure—Mean airway pressure is the time-averaged pressure in the airway during the respiratory cycle. It reflects both the amount of pressure needed to overcome resistive and recoil forces during inspiration and any pressure imposed on the airway during expiration, for example, positive end-expiratory pressure. Mean airway pressure has been suggested as a measure of potential barotrauma to the lungs, as a predictor of impairment of cardiovascular function, and as a marker of improved distribution of ventilation. However, there is no agreement on how best to interpret this variable.

D. Dynamic Hyperinflation and Intrinsic PEEP—Tidal volume in patients receiving positive-pressure ventilation is provided by increasing the pressure in the ventilator circuit, and gas flows from the ventilator into the patient. In contrast, expiration is passive and continues until the lung volume returns to the functional residual capacity (FRC). At this point, elastic inward recoil of the lungs and outward recoil of the chest wall are balanced, and—unless PEEP is set on the ventilator (see below)—alveolar pressure is equal to atmospheric pressure. By convention, pressure is expressed relative to atmospheric pressure, so alveolar pressure = 0 cm H_2O .

Dynamic hyperinflation occurs when the volume of gas in the lung at end expiration is greater than the expected FRC. With mechanical ventilation, dynamic hyperinflation is most common in patients with obstructive lung disease (eg, asthma and COPD) who have slow expiratory airflow or in any patient who requires very large minute ventilation. In the latter case, large minute ventilation requires high respiratory rate, high tidal volume, or both. Dynamic hyperinflation results when there is insufficient time to empty the lungs such that expiratory tidal volume is smaller than inspiratory tidal volume. The net increase in lung volume (hyperinflation) quickly results in a new steady state in which tidal volumes are equal. But now the FRC is increased above normal.

Intrinsic PEEP (PEEP_i), sometimes called *auto-PEEP*, denotes the difference in pressure between the alveolar space at end expiration and the pressure in the proximal airway or ventilator circuit. PEEP_i is seen in two common situations. First, PEEP_i is associated with dynamic hyperinflation. This is evident because patients with dynamic hyperinflation continue to exhale right up to end expiration, indicating a positive alveolar pressure relative to proximal airway pressure (hence PEEP_i). Second, any patient who actively contracts expiratory muscles at end expiration develops positive alveolar pressure relative to external airway pressure. Note, however, that PEEP_i in this situation is associated with a smaller FRC rather than hyperinflation. Estimation of PEEP_i is described below in the section on respiratory failure in COPD.

Dynamic hyperinflation has marked consequences for the pulmonary and systemic circulations, resulting in hypotension and decreased cardiac output. It also may greatly increase the work of breathing and may be associated with barotrauma. Because alveolar pressure is elevated, dynamic hyperinflation makes it more difficult for patients to trigger mechanical ventilation in the assist-control or pressure-support

modes (see below). Dynamic hyperinflation and its marker, PEEP_i, should be suspected in any patient with obstructive lung disease receiving mechanical ventilation—and in others with unexplained hypotension or worsening of gas exchange. Features suggesting dynamic hyperinflation include worsening of gas exchange with increasing minute ventilation, hypotension, presence of expiratory flow at end expiration, high minute ventilation requirements (especially if greater than 15–20 L/min), and short expiratory time.

Common Methods of Mechanical Ventilation

The most common modes of mechanical ventilation (summarized in Table 12–7) include (1) volume-preset (volume-cycled), assist-control ventilation, (2) pressure-controlled ventilation, (3) pressure-support ventilation, (4) intermittent mandatory ventilation, and (5) airway pressure-release ventilation. Other methods are used less often or are available only on a limited number of ventilators. New modes are constantly being introduced, but it is not clear whether any of these offer useful improvements. Discussions of mechanical ventilation in patients with neuromuscular and chest wall disorders, ARDS, and obstructive lung diseases are found in the sections devoted to management of those disorders later in this chapter.

A. Classification of Mechanical Ventilators—A universally accepted classification of mechanical ventilators has not been developed. Historically, successive generations of ventilators have offered a variety of complex capabilities. First-generation ventilators were limited to the assist-control mode only. Second-generation ventilators added intermittent mandatory ventilation (IMV), PEEP, and improved monitoring capabilities. Later machines used microprocessors to provide a broader range of options, including pressure-control and pressure-support modes, time or volume cycling, and various combinations. Some ventilators incorporate circuits that minimize the work of breathing and enhance monitoring capabilities with graphic displays. The newest mechanical ventilators have modes that allow patients to breathe spontaneously with pressure-support assistance and can provide additional ventilation to meet preset targets. Some newer modes can tailor the inspiratory flow pattern to limit the rise in airway pressure.

1. INSPIRATORY PHASE—The *ventilator mode* indicates how the patient-ventilator system initiates inspiration. The start of inspiration can be completely machine-controlled (control mode) or chosen by the patient (assist-control mode). A respiratory rate is set by the clinician, but in the assist-control mode, if the patient chooses to breathe at a faster rate, this overrides the set rate.

The changeover from the inspiratory to the expiratory phase is how the ventilator is *cycled*. A useful scheme divides mechanical ventilator methods into those in which the primary preset independent variable is tidal volume (volume-preset), airway pressure (pressure-preset), or time. The ventilator is volume-cycled, time-cycled, or pressure-cycled depending on whether the inspiratory phase ends

when a preset tidal volume, inspiratory time, or circuit pressure is reached. The inspiratory flow rate and pattern often can be adjusted to provide an increasing, decreasing, or sinusoidal flow pattern during inspiration. Tidal volume, airway pressure, inspiratory flow rate, and inspiratory time are necessarily interactive. Thus, with different methods of mechanical ventilation, several variables are independent, whereas the others are dependent.

2. EXPIRATORY PHASE—Exhalation is passive, occurring because lung recoil and chest wall recoil create positive pressure in the alveolar space relative to atmospheric pressure. If the exhalation is stopped before completion, end-expiratory lung volume rises and end-expiratory pressure is positive relative to atmosphere. Positive end-expiratory pressure (PEEP) is often chosen to stabilize alveoli, prevent collapse of lung units, and improve hypoxemia in certain situations. All modes of positive-pressure mechanical ventilation described below can have PEEP added.

B. Volume-Preset Ventilation—Also called the *volume-cycled assist-control mode*, this is the most frequently used method of mechanical ventilatory support and is suitable for almost all types of respiratory failure. Basically, the ventilator delivers a preset tidal volume at a constant inspiratory flow at a respiratory frequency set on the machine.

In the assist-control mode, the physician chooses a respiratory frequency. However, the assist-control mode allows the patient to initiate a ventilator-delivered breath by making an inspiratory effort. The ventilator senses this effort as a fall in ventilator circuit pressure. If the patient makes an inspiratory effort sufficient to “trigger” the ventilator at a frequency greater than the set respiratory frequency, the patient effectively determines the respiratory rate. If no inspiratory efforts are made or detected, the respiratory rate is equal to the preset rate. In general, the preset respiratory rate should be chosen to be slightly less than the patient’s spontaneous rate, if any. This will guarantee that the patient will receive a relatively safe amount of ventilation in the event of patient apnea or hypopnea. The amount of patient effort needed to trigger the ventilator (sensitivity) can be adjusted on the ventilator. Sensitivity is usually chosen to be 1–2 cm H₂O less than the end-expiratory pressure, although many ventilators sense “flow” as the triggering event. However, water condensed in the ventilator tubing, unavoidable delay in the triggering mechanism, and the presence of PEEP_i may make it more difficult to trigger the ventilator.

Using volume-preset ventilation, recommended tidal volume has been as much as 10–12 mL/kg of ideal body weight, but current recommendations of between 6 and 8 mL/kg of ideal weight minimize barotrauma, decrease lung injury, and improve survival in ARDS. These tidal volumes should result in an inspiratory plateau pressure of less than 30 cm H₂O, although even that pressure is debated. The actual delivered tidal volume may be smaller or larger than what is selected. Patients who inspire vigorously along with the ventilator-delivered breath may draw additional volume from the ventilator. A smaller than expected tidal volume

Table 12-7. Ventilator modes.

Mode	I-E Changeover	Independent Parameters	Dependent Variables	Secondary Modes	Advantages	Disadvantages	Application
Volume-cycled ventilation (VCV) (assist-control, volume-preset)	Set V_T delivered	V_T \dot{V}_I (flow rate) Backup f	Peak P_{aw} I:E ratio	PEEP; inverse I:E ratio (IRV)	Set V_T and backup rate always delivered.	May have high peak P_{aw} when set V_T is delivered.	Primary ventilatory mode.
Pressure-controlled ventilation (PCV) (assist-control pressure-preset)	Set inspiratory time elapsed or set I:E ratio reached	Peak P_{aw} , T_I , or I:E ratio	V_T \dot{V}_I (flow rate)	PEEP; inverse I:E ratio (IRV)	Peak P_{aw} cannot be exceeded; can set I:E ratio. Gas exchange may improve.	V_T , \dot{V}_E may vary and not guaranteed; T_I and I:E ratio may conflict.	Primary ventilatory mode.
Pressure-support ventilation (PSV)	Patient-determined	Pressure support pressure	V_T T_I I:E ratio f	PEEP	Patient-selected V_T , f , T_I . May be better tolerated than other modes.	V_T , \dot{V}_E , f not guaranteed. Limited data on improve weaning of difficult patients.	Weaning; primary ventilatory mode.
Intermittent mandatory ventilation (IMV)	Ventilator breaths: Set V_T delivered (volume-cycled V_T)	Mandatory f and V_T	Peak P_{aw} Spontaneous V_T , f	PEEP PSV	Mandatory backup V_T , f ; spontaneous breaths interposed.	Fixed mandatory f , V_T , \dot{V}_E ; spontaneous breaths may vary. Some ventilators have high work of breathing. Not shown to improve weaning.	Weaning; primary ventilatory mode.
Airway pressure-release ventilation (APRV)	N/A*	P[high] P[low] Time [high] Time [low]	V_T^*	PEEP (P[low])	High mean airway pressure aids lung recruitment. Spontaneous patient ventilation.	Spontaneous V_T during P[high] may exceed desired volume limits.	Primary ventilatory mode (ARDS).

Key: V_T = Tidal volume
 \dot{V}_E = Minute ventilation
 \dot{V}_I = Inspiratory flow rate
 P_{aw} = Airway pressure
PEEP = Positive end-expiratory pressure
P[high] = high airway pressure
P[low] = low airway pressure
Time [high] = time at high airway pressure
Time [low] = time at low airway pressure

IRV = Inverse ratio ventilation
 f = Respiratory rate
I:E ratio = Inspiratory:expiratory time ratio
 T_I = Inspiratory time

*The airway pressure change from "high" to "low" (release) is time-cycled, but this is not truly an I-E changeover. V_T is determined by spontaneous patient efforts.

can occur if the pressure limit is reached while the inspired gas is delivered. The pressure limit is set by the operator and is intended to prevent injury to the patient if the chosen tidal volume would generate an excessively high pressure.

An inspiratory flow rate of about 1 L/s is set initially for most patients using volume-cycled ventilation, but higher flow rates may be essential in patients with status asthmaticus or COPD or those with high minute ventilation. The flow can be adjusted according to the respiratory drive of the patient and the inspiratory time desired. Most volume-cycled ventilators used in the ICU are capable of constant inspiratory flow. This means that inspiratory flow will be constant even in patients with low lung or chest wall compliance or high airway resistance, and inspiratory flow will not decrease when a patient develops bronchospasm, airway secretions, atelectasis, or other conditions. Therefore, inspiratory time for a set tidal volume will remain relatively constant. In special circumstances such as severe hypoxemic respiratory failure, a decelerating inspiratory flow pattern may be helpful, and this pattern has been described as being similar to pressure-controlled ventilation.

Inspiratory time is usually chosen to be relatively short compared with expiratory time. An inspiratory time:expiratory time (I:E) ratio of 1:2–4 is used most often. An I:E ratio at or near 1:1 may improve oxygenation in selected patients. Inverse-ratio ventilation may be used with volume-preset ventilation (see below) in patients with ARDS. On the other hand, patients with high airway resistance need longer expiratory times to complete exhalation; they may require an I:E ratio as much as 1:5–10.

Volume-preset, assist-control mechanical ventilation can be used to ventilate most patients with respiratory failure. The chief advantage of this mode is that a known tidal volume and—if the patient does not trigger the machine—a known respiratory frequency are provided. The tidal volume will not vary with changes in lung and chest wall mechanics. Another advantage is that clinicians are most often familiar with this mode.

C. Pressure-Controlled Ventilation (PCV)—In pressure-controlled ventilation (PCV), airway pressure is preset on the ventilator (rather than tidal volume), and tidal volume becomes a dependent variable. Although PCV is often thought of as a way of protecting the lungs from the effects of excessive airway and alveolar pressure and avoiding barotrauma, the major potential advantage of PCV is improved distribution of inspired gas with improved gas exchange. PCV might be considered for patients with ARDS, for which most of the clinical experience has been gathered, although outcome data are limited. It should not be used for mechanical ventilation of asthmatics or those with COPD.

With PCV, the patient is provided with a preset constant positive pressure through the ventilator circuit throughout inspiration. The inspiratory flow pattern is complex and reflects the decreasing pressure gradient between airway and alveolar pressure during the inspiratory phase. The duration of inspiration is determined by setting either the inspiratory time or the I:E ratio and respiratory rate. Tidal volume is a function

of the inspiratory flow rate and pattern and inspiratory time. PCV can be used in the assist-control mode, in which the respiratory rate is chosen either by the patient or, in the absence of sufficient respiratory drive, by the ventilator. Airway pressure must be chosen carefully with respect to chest wall and lung compliance and airway resistance. In most patients, it is desirable to limit airway pressure with this mode to 30–40 cm H₂O and a maximum tidal volume of 6–8 mL/kg of ideal weight.

The potential advantages of PCV compared with volume-preset ventilation include reduced peak airway pressure and improved distribution of inspired gas. In theory, for the same tidal volume, peak airway pressure may not differ between the two modes. In practice, however, as the tidal volume is delivered during PCV, the difference between airway pressure and alveolar pressure falls, resulting in a progressive decline in flow rate—in contrast to constant flow during volume-preset ventilation. This mechanism is also responsible for the theoretical improvement in gas distribution. The highest flow and largest proportion of tidal volume are delivered at the beginning of the breath, increasing the time available for gas to move to poorly ventilated lung regions. In several studies of patients with severe hypoxemia from ARDS, changing from conventional volume-preset ventilation to PCV was associated with improved PaO₂ and a decrease in inspiratory oxygen concentration.

PCV has been used frequently with inverse-ratio ventilation (IRV), and some studies have not clearly distinguished each aspect's physiologic and clinical effects. IRV is set by choosing a prolonged inspiratory time (or shortened expiratory time) such that the time spent on each breath during inspiration exceeds expiratory time. That is, the I:E ratio varies from 1:1 to 4:1 rather than the conventional 1:2–4. Current understanding of IRV does not attribute any intrinsic value to the inverse ratio but views the I:E ratio as a continuum. Advocates of IRV argue that the shortened expiratory time increases end-expiratory volume, preventing or reducing atelectasis, whereas the lengthened inspiratory time improves inspiratory distribution of gas. However, increasing the time in which positive pressure is applied to the lungs should predictably impair cardiac output. IRV should be restricted to very careful use in selected patients with ARDS who demonstrate refractory hypoxemia when managed with other forms of treatment. IRV also can be used with more conventional volume-preset ventilation. One disadvantage of IRV is that patients usually require muscle relaxants or moderately heavy sedation.

D. Pressure-Support Ventilation (PSV)—Pressure-support ventilation (PSV) is the other major type of pressure-preset ventilation. This mode of ventilation provides a spontaneously breathing patient with a chosen amount of mechanical assistance during inspiration. Basically, when the patient initiates a breath, the pressure-support ventilator provides a preset positive pressure in the ventilator circuit. As long as the patient continues to inhale, the pressure is maintained at this constant level; when the patient stops inhaling, the pressure immediately falls to

baseline. Thus the patient's inspiratory effort is "supported" throughout inspiration, thereby unloading the inspiratory muscles. The net driving pressure is equal to the pressure-support pressure minus the alveolar pressure produced by the patient. The tidal volume is determined by the net driving pressure and the patient-selected duration of inspiration.

PSV allows the patient to inspire tidal volumes that might not be reached using only the patient's efforts while the patient and not the ventilator selects the rate and tidal volume. PSV has been used both during weaning from mechanical ventilation and as a primary mode of ventilation. Potential advantages during weaning include the possibility that inspiratory muscles can contract to their accustomed length, respiratory rate may be slowed (because tidal volume is maintained), and patients may tolerate pressure support for prolonged duration. The respiratory muscles experience less afterload and therefore may be less prone to early fatigue. PSV can be used as a primary ventilatory mode in suitable patients who are awake, alert, have adequate ventilatory drive, and have mild to moderately severe lung disease. The major advantage is that the patient and ventilator system often work more in synchrony, and in several studies patients have noted less discomfort and anxiety when PSV was used.

The level of PSV is chosen with consideration of respiratory system compliance, patient effort, desired tidal volume and minute ventilation, and severity of lung disease. Pressure-support pressure can be set to 10–15 cm H₂O as a starting point, and the tidal volume and rate measured can be used to decide on increasing or decreasing the pressure. Another method is to set pressure support at about two-thirds of the ventilator pressure needed during conventional mechanical ventilation to achieve a tidal volume of 6–8 mL/kg. Pressure-support pressure also may be set to achieve a selected minute ventilation or to provide enough support to inhibit accessory respiratory muscle contractions.

E. Intermittent Mandatory Ventilation (IMV)—In this mode, usually employed for weaning from mechanical ventilation but also occasionally for primary support, the ventilator provides tidal volume breaths at a preset fixed rate. In between ventilator-delivered breaths, the patient is able to breathe spontaneously at any rate, tidal volume, or pattern. In newer mechanical ventilators, the spontaneous breaths can be augmented by increased inspiratory pressure (ie, PSV) in combination with the ventilator-delivered breaths. For weaning purposes, the ventilator rate is reduced progressively as the patient's spontaneous rate and tidal volume are found to increase. The patient assumes an increasingly greater role in supplying the minute ventilation. As a primary support mode, it is believed by some investigators that the IMV mode is particularly well tolerated by patients who can, during the spontaneous breaths, adjust their minute ventilation and synchronize their breathing pattern more easily than with assist-control, volume-cycled mechanical ventilation. The benefit of IMV remains unclear in patients who are difficult to wean from ventilatory support. There is no study

supporting IMV as superior to other methods of weaning (see below). In addition, a high work of breathing may be engendered from the IMV breathing circuit in some mechanical ventilators that offer this mode.

F. Airway Pressure-Release Ventilation (APRV)—This mode has features of PCV with a preset airway pressure during "inspiration" (P[high]) but with three important differences. First, P[high], generally chosen to be at the desired P_{plat}, is maintained constant much of the time (70–80%). Second, this pressure is "released" periodically to a lower pressure or zero, termed P[low]. Third, the ventilator allows the patient to breathe spontaneously, similar to PSV or IMV, at both P[high] and P[low]. The intent of APRV is to maintain a higher mean airway pressure for lung recruitment, reduce the number of cycles per minute to avoid stress-relaxation trauma, and use the pressure-release change in lung volume plus spontaneous respirations to eliminate CO₂. APRV is time cycled but may be patient-triggered. The clinician sets the P[high] and P[low], as well as the time at P[high] and P[low].

APRV has been studied mostly in acute lung injury (ALI)/ARDS. Potential advantages include better lung recruitment and reduced lung stress, thereby improving oxygenation while guarding against volutrauma. However, while studies indicate that gas exchange and hemodynamics are acceptable, and the mode appears safe, there are no controlled studies demonstrating improved outcome in patients with ALI/ARDS.

G. Noninvasive Ventilation—As the name implies, noninvasive ventilatory support devices (ranging from negative-pressure mechanical ventilators to positive pressure administered by a nasal or full face mask) have the advantage of not requiring an endotracheal or tracheostomy tube. As a result, patients are not subject to the potential complications associated with intubation, loss of airway defense mechanisms, and inadvertent extubation. On the other hand, noninvasive modes do not provide the airway protection or access to respiratory secretions available when ventilation is delivered via the endotracheal route. Noninvasive positive-pressure ventilation now clearly has been shown to be useful in selected patients with acute respiratory failure.

1. NEGATIVE-PRESSURE VENTILATION—Negative-pressure ventilation may be successful in selected patients for temporary or long-term management, but this mode generally has limited use in the ICU. Current devices either use a shell fitted and sealed over the anterior chest (cuirass-type) or a pneumatic vest-like garment. A mechanical pump provides negative pressure to the outside of the chest wall. Suitable patients may be those with neuromuscular weakness who do not have high airway resistance, low respiratory compliance, or high ventilatory requirement. Negative-pressure devices have the disadvantages of reducing patient mobility, causing skin irritation and breakdown and limiting access to the chest or back for examination and routine nursing care. In

addition, negative-pressure mechanical ventilation has been implicated in the development of upper airway obstruction during sleep in some patients, presumably owing to a lack of synchrony between upper airway dilator muscles and ventilator-initiated breaths.

2. POSITIVE-PRESSURE VENTILATION—These devices administer positive pressure to the airway via a nasal or nasal-oral circuit incorporating a nonbreathing valve close to the patient to minimize added dead space. A large number of delivery circuits—ranging from snug-fitting nasal prongs to nasal, nasal-oral, and full face masks—are available in several sizes and shapes to accommodate most patients. Positive-pressure ventilation (PPV) may be provided by certain conventional mechanical ventilators (those able to tolerate and compensate for air leaks) or, more commonly, by bilevel positive-pressure devices specifically designed for noninvasive use. Supplemental oxygen may be added using either a fixed liter-flow rate added to the inspiratory circuit (resulting in a potentially variable FiO_2) or, on newer models, via oxygen blenders capable of providing an FiO_2 as high as 1.0. Early bilevel machines were designed primarily for home use (for the treatment of obstructive sleep apnea) but quickly found use in the ICU. Newer devices provide higher pressures (up to 35 cm H_2O) and better monitoring and alarm functions, making them better suited for use in the treatment of acute respiratory failure.

The success of these devices generally depends on having a cooperative patient and obtaining a proper fit of the circuit and attachment headgear (to maximize comfort and minimize potential air leaks). These devices are best used in patients who do not require continuous or prolonged ventilatory support because pressure sores can develop even with properly fitted masks. Other potential complications include nasal congestion, sinusitis, dry eyes, headaches, and gastric distention owing to air swallowing. Compared with endotracheal mechanical ventilation, the use of noninvasive methods increases the level of care provided by nurses and respiratory therapists during the initiation of therapy (for mask fitting, monitoring, and ventilator adjustments). Administration of bronchodilators (or other treatments by inhalation) and eating generally require temporary removal of the circuit, further adding to the level of care required.

Nasal continuous positive airway pressure (nasal CPAP) is the treatment of first choice for most patients with obstructive sleep apnea syndrome but also may be useful in the treatment of other ICU patients. CPAP administered via a nasal or nasal-oral mask (at pressures of 5–10 cm H_2O) can improve gas exchange in patients with pulmonary edema and has the added advantage of reducing left ventricular afterload and improving cardiac output in patients with congestive cardiomyopathies.

While the addition of a low level of CPAP may be helpful in treating other nonapneic causes of respiratory failure, noninvasive ventilatory support is usually more successful when the inspiratory pressure (IPAP) and expiratory pressure (EPAP)

can be adjusted independently, as with bilevel ventilatory support devices. When operating in the “spontaneous” mode, these devices can be thought of as being similar to inspiratory pressure support with PEEP. Airflow into the patient circuit is adjusted automatically to maintain the preset pressure levels. As a result, these devices are able to compensate for the air leaks inevitably seen with mask delivery systems. Patient-initiated breaths are sensed as a demand for an increase in airflow into the patient circuit, which then triggers the switch to the higher IPAP level. IPAP is maintained until the required flow returns to a lower level, at which time the pressure returns to the set EPAP level. The actual tidal volume delivered during a given breath will depend on the differential pressure (IPAP – EPAP), the respiratory system compliance, and the amount of inspiratory effort generated by the patient. Some devices also offer a “timed” mode (similar to pressure-controlled IMV) and a “spontaneous or timed” mode (similar to pressure-controlled IMV plus pressure support). However, these are generally less useful in treating patients with acute respiratory failure.

Noninvasive mechanical ventilation is often provided for obstructive sleep apnea patients unable to tolerate the CPAP levels required to maintain airway patency or in those with superimposed central hypoventilation. For these conditions, EPAP is increased until obstructive apneas are abolished, and IPAP is titrated upward as necessary to reduce or eliminate hypopneas, oxygen desaturations, and snoring.

Several randomized, controlled studies in patients with acute exacerbation of COPD demonstrate that the early administration of noninvasive ventilatory support improves gas exchange, vital signs, and dyspnea scores and reduces the need for invasive mechanical ventilation. Noninvasive mechanical ventilation may reduce morbidity and mortality rates as well as the number of both ICU and total hospital days. The mechanism of benefit is probably related both to the inspiratory assist provided by IPAP and the low levels of EPAP (3–6 cm H_2O), which reduce the amount of isometric contraction of inspiratory muscles needed to overcome PEEPi. Noninvasive ventilation is also helpful in the treatment of acute respiratory failure caused by pneumonia and acute cardiogenic pulmonary edema, with reduced intubation rates, fewer ICU days, and a decrease in nosocomial infections (as compared with endotracheal mechanical ventilation). Finally, noninvasive ventilation can be used to facilitate weaning from invasive mechanical ventilation, resulting in higher overall weaning rates, shorter duration of ventilatory support, fewer ICU days, and improved 60-day mortality compared with routine weaning.

Patients most likely to benefit from noninvasive positive-pressure ventilation are those with moderate to severe dyspnea accompanied by tachypnea, accessory muscle use, paradoxical breathing, and gas-exchange abnormalities (eg, $\text{PaCO}_2 >45$, $\text{pH} <7.35$, or $\text{PaO}_2/\text{FiO}_2 <200$). Severely ill patients (eg, those with respiratory arrest, hypotensive shock, uncontrolled arrhythmias, or ischemia) and those with excessive secretions or a loss of airway protection are better

treated with intubation and mechanical ventilation. Furthermore, patients who are agitated or uncooperative and those with facial injuries or abnormalities interfering with mask fit generally are not candidates for noninvasive ventilation.

After selecting and fitting the mask, recommended initial settings are IPAP = 8–12 cm H₂O and EPAP = 3–5 cm H₂O. The IPAP is increased gradually as tolerated (generally to 10–20 cm H₂O) with therapeutic goals of dyspnea relief, good patient-ventilator synchrony, and improved gas exchange. The EPAP may be increased if needed for alveolar recruitment (similar to PEEP changes in standard mechanical ventilation), but in patients with COPD, EPAP should be kept below the level of PEEPi to avoid worsening hyperinflation. Supplemental oxygen is added to maintain O₂ saturation greater than 90%. Most patients benefit from ongoing encouragement and reassurance. Occasionally, light sedation is helpful in anxious and agitated patients; however, these medications have the potential for compromising airway patency, so close monitoring is essential.

H. Other Methods of Mechanical Ventilation—Rarely used methods of mechanical ventilation in critical care areas include high-frequency ventilation and supplemental extracorporeal membrane oxygenation or CO₂ elimination. High-frequency ventilation uses very small tidal volume—sometimes less than anatomic dead space volume—and respiratory frequencies greater than 1 breath/s (>1 Hz). The tidal volume is provided by one of several means, including a high-velocity air-oxygen jet, a high-frequency inspiratory valve, or

a mechanical or electromagnetic oscillator. The mechanism of gas movement is not known, although facilitation of gas diffusion has been postulated. Several years ago there was considerable interest in these ventilators for severe hypoxemic respiratory failure, but studies failed to demonstrate advantages of these devices in adults. A review of high-frequency ventilation in ARDS and ALI concluded that high-frequency oscillation (HFO) may be promising but still should be considered experimental.

Extracorporeal membrane oxygenation and CO₂ elimination have been the subject of several studies of patients with severe acute respiratory failure, especially ARDS. Conceptually, membrane oxygenation was used to manage patients with refractory hypoxemia, but mortality was very high and unchanged by this treatment. More recently, partial bypass with focus on CO₂ elimination was viewed as a lung-protective strategy, but data do not support benefit at this time. These therapies should be viewed as experimental.

Clinical Applications

The mode of mechanical ventilation and the settings to be used should be chosen in consultation with physicians and respiratory care practitioners who have experience in the management of respiratory failure. Some criteria for selection of modes in different types of respiratory failure are presented in Table 12–8, and further details are found in discussions of the various disorders. Proper monitoring of the patient-ventilator system greatly facilitates patient care, as shown in Table 12–9.

Table 12–8. Suggested ventilator strategies and tactics in respiratory failure.

Respiratory Failure	Strategy	Tactic
Neuromuscular or chest wall disorder	Avoid barotrauma. Minimize effects on cardiac output. Avoid hyperventilation. Prevent atelectasis and worsening Pao ₂ .	V _T 6–8 mL/kg; peak Paw <40 cm H ₂ O Adjust Paco ₂ to pH in presence of elevated HCO ₃ ⁻ PEEP 3–5 cm H ₂ O
COPD, asthma	Improve gas exchange by avoiding hyperinflation. Decrease adverse effects on cardiac output. Decrease work of breathing.	Long expiratory time; high V _I (>1 L/s), low f, V _T 6–8 mL/kg. Allow hypoventilation? Use muscle relaxants. PEEP < intrinsic PEEP?
ARDS	Improve arterial Pao ₂ . Decrease potential for O ₂ toxicity. Meet ventilatory demand. Reduce potential for barotrauma. Limit adverse effects on cardiac output and O ₂ delivery.	PEEP PCV or descending flow pattern (VCV)? Use Fio ₂ <0.50 High V _I , high f Low V _T (6–8 mL/kg) Pplat <30 cm H ₂ O

Key: PCV = pressure-controlled ventilation
 PC-IRV = pressure-controlled, inverse-ratio ventilation
 PEEP = positive end-expiratory pressure
 Pplat = inspiratory plateau pressure
 V_T = tidal volume
 V_I = inspiratory flow rate
 f = respiratory rate

Table 12-9. Monitoring mechanical ventilation.

Variable or Ventilator Setting	Clinical Significance
Measured \dot{V}_E	Is patient breathing more than set V_T and f ? Weaning may be feasible if $\dot{V}_E < 12$ L/min. High \dot{V}_E relative to P_{aCO_2} means high V_D/V_T or increased metabolic rate.
Peak airway pressure	High pressure at a given tidal volume suggests high airway resistance and/or low respiratory system compliance.
Inspiratory plateau pressure (see text)	High pressure suggests low respiratory system compliance.
F_{iO_2}	Combined with P_{aO_2} , indicates efficiency of oxygenation. Use F_{iO_2} to calculate $P(A-a)O_2$ or P_{aO_2}/F_{iO_2} ratio.
Respiratory rate	During IMV, spontaneous rate and tidal volume indicate contribution of patient to total minute ventilation. During assisted ventilation, rate higher than set rate indicates patient has degree of respiratory drive.
Tidal volume	During pressure-support ventilation, comparison of V_T and support pressure assesses patient's contribution to total ventilation.
Intrinsic PEEP present?	See mechanical ventilator management of patients with respiratory failure from COPD. Useful in determining if gas exchange is compromised by dynamic hyperinflation.

Monitoring the Patient on Mechanical Ventilation

The patient-ventilator system warrants careful monitoring. The patient's normal homeostatic and feedback mechanisms are no longer completely functioning, and extremes of inflation, arterial blood gases, and effects on hemodynamics are likely without the usual constraints. Some important monitoring principles and guidelines are included in Chapter 8.

Monitoring of mechanical ventilation can be divided into two categories. First, respiratory therapy departments and ICUs have established monitoring standards for patients on mechanical ventilation. These usually include hourly—or more frequent—measurement and documentation of peak and plateau airway pressure, minute ventilation, oxygen saturation by pulse oximetry, endotracheal tube cuff pressure, and volume, tidal volume, and respiratory rate. The ventilator settings are charted, including mode, set tidal volume and rate, inspired concentration of oxygen, PEEP, and alarm settings

and limits. Clinicians should review these data, and the data should be studied carefully if patients deteriorate, have difficulty with discontinuation of mechanical ventilation, develop new gas-exchange problems, or show changes on chest x-rays.

A second category of mechanical ventilator monitoring involves slightly more sophisticated measurements and calculations, and these are recommended for certain clinical situations. Two simple measurements are PEEP_i and inspiratory plateau pressure. PEEP_i (auto-PEEP) can be measured automatically by some ventilators; in others, expiratory port occlusion (see below) is used. PEEP_i determination is useful in patients with COPD exacerbation and asthma. Inspiratory plateau pressure should be compared with peak airway pressure. Respiratory system pressure-volume (PV) curves have been recommended by some investigators, especially in Europe, to determine optimal PEEP settings and in limiting tidal volume in ARDS patients. Despite important experimental information derived from PV curves, their clinical use has not become routine for a variety of technical reasons and problems of interpretation. Finally, esophageal pressure measurements during mechanical ventilation would provide important information about PEEP_i, chest wall compared with lung compliance changes, and work of breathing. Once again, these measurements are not often made in the ICU.

Complications

Some of the complications of mechanical ventilation are listed in Table 12-10. These can be divided into two categories: (1) complications and adverse effects of positive-pressure ventilation and (2) complications of having a mechanical

Table 12-10. Complications of mechanical ventilation.

Complications of artificial airway

Complications of positive-pressure ventilation

- Pneumothorax
- Pneumomediastinum
- Parenchymal barotrauma (lung injury)
- Decreased cardiac output
- Increased intracranial pressure
- Impaired ability to monitor or interpret intrathoracic vascular pressures (pulmonary artery catheter)
- Altered gas exchange (worsening of \dot{V}/\dot{Q} mismatching)

Complications of artificial ventilation

- Hypoventilation
- Hyperventilation
- Apnea
- Oxygen toxicity
- Mechanical or electrical failure or disconnection of ventilator
- Increased risk of nosocomial pneumonia
- Accidental thermal or chemical burns to airway
- Aspiration and ventilator associated pneumonia
- Psychologic dependence on ventilator

substitute for the natural ventilatory system. Because the vast majority of mechanically ventilated patients have endotracheal tubes or tracheostomy tubes, airway complications also must be considered under this heading.

A. Barotrauma—Barotrauma is a misnomer because it is now understood that lung injury occurs because of excessive and repeated stretching of the lungs regardless of the pressure. Therefore, a patient with very stiff or noncompliant lungs may require high pressures to ventilate, but because the lungs are not particularly stretched, barotrauma is uncommon. On the other hand, a patient with very compliant lungs, such as are seen with bullous emphysema, requires very low pressures to overstretch the lungs. This type of patient is at high risk of barotrauma despite low pressure because of the large volume changes. Barotrauma might more properly be called *volume trauma*. Current recommendations to choose smaller tidal volumes when mechanically ventilating patients with asthma, COPD, and ARDS have been associated with a reduced incidence of lung injury.

PPV is associated with several forms of barotrauma to the lungs. Most often appreciated is explosive barotrauma, in which inspired gas under positive pressure ruptures an area of lung or airway. Air initially escapes into the interstitial spaces of the lungs and tracks along bronchovascular bundles toward the mediastinum. Therefore, at first the patient may have interstitial emphysema, which may be seen as thin air density lines against a background of lung consolidation. Subsequently, the patient may develop evidence of air surrounding mediastinal structures (pneumomediastinum). If the air separates the lungs and pleura from the inner surface of the chest wall, an extrapleural pneumothorax can form. A pneumothorax can evolve another way through rupture of the lung directly into the space separating the visceral and parietal pleural surfaces. PPV, especially combined with PEEP, has been associated with explosive barotrauma, including interstitial emphysema and pneumothorax, but debate continues about the relative contributions of underlying lung disease and PPV. It is likely that both acute lung injury and chronic lung disease increase the risk of barotrauma.

A more important and more common subtle form of barotrauma is suggested by evidence that PPV and PEEP are associated with parenchymal lung injury, leading to more severe gas-exchange abnormalities and permanent histologic damage. Mechanical ventilation and PEEP in ARDS may damage the lungs in somewhat the same way supportive care for neonatal respiratory distress contributes to bronchopulmonary dysplasia. These considerations have led to recommendations that airway pressure and tidal volume should be limited. In experimental animals, both the combination of low PEEP (0 cm H₂O) and high tidal volume (39 mL/kg) and the combination of high PEEP (15 cm H₂O) and low tidal volume (7 mL/kg) caused pulmonary edema. Other animal and human data indicate that inflammatory cytokines are generated and persist when larger tidal volume are used. Current recommendations to use tidal volumes of between

6 and 8 mL/kg of ideal weight are based on a decreased likelihood of barotrauma, decreased lung injury, and improved patient outcomes.

B. Decreased Cardiac Output—Patients started on positive-pressure mechanical ventilation not infrequently become hypotensive, and this is largely because PPV can reduce cardiac output. In normal subjects, negative pressure during spontaneous inspiration provides an additional impetus to systemic venous return by exerting negative pressure on the intrathoracic venae cavae, the right atrium, and the right ventricle. Pulmonary vascular resistance falls during inspiration, improved emptying of the right ventricle.

On the other hand, PPV may have several adverse effects on cardiac output. First, positive pressure (rather than negative pressure) during inspiration interferes with systemic venous return. Second, inflation of the lungs with positive pressure increases pulmonary vascular resistance and impedes right ventricular emptying. Third, PPV and PEEP may decrease left ventricular compliance by stiffening the intraventricular septum because of increased volume of the right ventricle. There is little evidence, however, for a negative inotropic effect of PPV. For several reasons, left ventricular afterload decreases during PPV, potentially improving left ventricular function and ejection fraction. It is important to distinguish effects on cardiac output from effects on cardiac function; PPV may improve cardiac function in some patients while reducing cardiac output in others. Mechanical ventilation often benefits patients with myocardial dysfunction, especially of the left ventricle.

Patients who become hypotensive or show evidence of decreased cardiac output while on PPV should be assessed for volume depletion, administration of vasoactive drugs (including opioid analgesics and sedatives), excessively high tidal volume or airway pressure, and PEEPi, as well as other systemic causes of hemodynamic compromise. A trial of intravenous fluids is sometimes warranted while ventilator adjustments are considered.

C. Other Complications—Inadvertent hypoventilation and hyperventilation are not uncommon because mechanical ventilators do not respond automatically to changes in PaCO₂. Appropriate ventilation may not be delivered because of machine malfunction; disconnection from the patient, electrical power, O₂, or compressed air; operator error; or obstruction of the ventilator circuit. A rare reported complication is injury from overheating of the humidifier used to warm and humidify inspired gas.

Ventilator circuits and humidifiers may become colonized with pathogenic bacteria or fungi. Nosocomial pneumonia is an important complication of mechanical ventilation (ventilator-associated pneumonia [VAP]). In a study of 264 patients admitted to a medical-surgical ICU who required mechanical ventilation for more than 48 hours, 22% developed bacterial pneumonia. Gram-negative bacilli were identified in 63% and *Staphylococcus aureus* in 23%. Forty-two percent of those with pneumonia died, compared

with 37% who did not develop nosocomial pneumonia. Although this difference in mortality rate was not statistically significant, VAP did increase the time spent in the ICU. The diagnosis of VAP is very difficult. Presence or absence of fever, leukocytosis, or purulent sputum are not sensitive or specific for VAP. The combination of new infiltrates plus two of fever, leukocytosis, or purulent sputum has a likelihood ratio of 2.8. The absence of new infiltrates lowers the likelihood of VAP (likelihood ratio = 0.35). Some investigators have recommended that patients undergo invasive diagnostic testing using fiberoptic bronchoscopy (eg, protected brush catheters with quantitative bacterial cultures); others suggest that these data do not improve diagnostic accuracy. Decreasing the frequency of ventilator circuit changes is associated with fewer episodes of nosocomial pneumonia. Attention to careful suctioning, frequent draining of condensate in the ventilator circuit, judicious use of antibiotics (including shorter courses), and avoiding prolonged mechanical ventilation decrease the risk of VAP.

Discontinuation of Mechanical Ventilation (“Weaning”)

Mechanical ventilation can be discontinued easily and safely in the majority of patients, that is, those who do not have severe lung disease or neuromuscular weakness or who are electively placed on mechanical ventilation for surgery. In other patients—especially those with lung disease—mechanical ventilation usually must be discontinued with careful monitoring using a variety of techniques. A gradual reduction in ventilatory support has led to the use of the term *weaning* from the mechanical ventilator as the patient resumes spontaneous ventilation, but there is growing evidence that many patients in the ICU do not need slow withdrawal of mechanical ventilation. Discontinuation of mechanical ventilation should be distinguished from discontinuation of endotracheal intubation or tracheostomy. Although the terms *intubation* and *ventilation* are often used synonymously, there are some patients in whom intubation is necessary but mechanical ventilation is not (eg, those with upper airway obstruction).

In many ICUs, discontinuation of mechanical ventilation is facilitated by protocols directing physicians, nurses, and respiratory therapists. These evidence-based protocols have been successful in decreasing duration of mechanical ventilation and maximizing patient understanding and comfort during the process. However, not all studies demonstrate that such protocols are necessary.

A. Physiologic Assessment—For mechanical ventilation to be discontinued, the patient must have a sustained ventilatory capacity that equals or exceeds the ventilatory requirement. For most patients who fail, the ventilatory requirement (ie, how much minute ventilation is needed to maintain PaCO_2) is high relative to ventilatory capacity (how much minute ventilation the patient is capable of providing

Table 12-11. Factors contributing to difficult weaning: Increased ventilatory requirement or decreased ventilatory capacity.

Increased Ventilatory Requirement	Decreased Sustained Ventilatory Capacity
Fever	Respiratory muscle fatigue
Infection	Hypokalemia
Increased ventilatory drive	Hypophosphatemia
Metabolic acidosis	Decreased ventilatory drive
Excessive hyperalimantation (especially with carbohydrate?)	Bronchospasm
Liver disease	Airway secretions
	Decreased lung or chest wall compliance
	Neuromuscular weakness
	Malnutrition
	Small endotracheal tube
	Increased resistance of endotracheal tube or ventilator circuit

without assistance)(Table 12-11). The ventilatory requirement is a function of the metabolic rate (CO_2 production), the set point for PaCO_2 , and the efficiency of lung gas exchange (dead space:tidal volume ratio). Ventilatory capacity is determined primarily by the interaction of ventilatory drive, respiratory system mechanics, and inspiratory muscle strength and endurance.

Disuse of respiratory muscles leads to atrophy, earlier and easier fatigue, and possibly discoordination. In patients with increased airway resistance or decreased lung or chest wall compliance, respiratory muscles must generate relatively greater pressure for a given tidal volume. Often these patients have an increased ventilatory requirement and, therefore, an increased pressure-time product—an index of muscle work and potential for fatigue. Factors associated with decreased muscle strength and endurance include electrolyte abnormalities (eg, hypokalemia and hypophosphatemia), critical illness polymyopathy and polyneuropathy, high-dose corticosteroid therapy, malnutrition, and recent use of nondepolarizing muscle relaxants.

B. Predicting Successful Weaning—The underlying disease that caused a need for mechanical ventilation must be corrected first. The patient should have adequate gas exchange, as evidenced by an only moderate supplemental oxygen requirement ($\text{PaO}_2/\text{FIO}_2 > 200$), PEEP of less than 5–8 cm H_2O , and VD/VT of less than 0.50. The ventilatory requirement is generally the minute ventilation (\dot{V}_E) provided during mechanical ventilation. If gas exchange and the metabolic rate do not change, the patient will have to provide this amount of \dot{V}_E to maintain PaCO_2 at the preweaning level. Weaning is usually unsuccessful when the \dot{V}_E requirement is greater than 10–12 L/min, or about twice the resting \dot{V}_E in normal adults. Adequate ventilatory capacity is encouraged by ensuring normal plasma electrolytes (especially phosphorus,

magnesium, and potassium), discontinuing sedatives, and minimizing abnormal lung mechanics by treatment with bronchodilators and suitable patient positioning.

Ventilatory capacity is assessed using a variety of *weaning parameters*, some of which are shown in Table 12–12. Vital capacity, negative inspiratory pressure, spontaneous \dot{V}_E measured for 1 minute, and maximum voluntary ventilation measured for 8–10 seconds estimate short-term ventilatory capacity. These variables have excellent predictive value in patients recovering from short-term general anesthesia, but their predictive value is only marginal in patients with acute or chronic lung diseases. This is largely because these parameters assess only ventilatory capacity and do not take into account the ventilatory requirement and work of breathing. In one study in which 58% of patients were weaned successfully, the following variables were found to be most closely correlated with success: days of mechanical ventilation before the weaning trial, respiratory frequency:tidal volume ratio, maximal inspiratory pressure, maximal expiratory pressure, and vital capacity. There were important differences between groups with COPD, neurologic respiratory failure, and other causes of respiratory failure; positive predictive values for successful weaning ranged from 74–94%.

Indices that combine estimates of ventilatory requirement, work of breathing, and ventilatory capacity may be useful. For example, a spontaneous respiratory rate:tidal volume ratio (f/V_T) of less than 100/min/L may predict successful weaning because it is an index of requirement and capacity. This ratio, termed the *rapid shallow breathing index*, proved to have greater sensitivity and specificity than other variables for prediction of weaning. However, a report of 52 patients undergoing weaning from mechanical ventilation indicated that 12 of 13 patients with a f/V_T of more than 105/min/L were weaned successfully, whereas only one patient who failed extubation had a ratio that high. One interpretation is that very low f/V_T ratios have a high positive

predictive value for successful weaning, whereas very high ratios predict unsuccessful weaning well. On the other hand, ratios of between 70 and 110/min/L are less useful.

Nevertheless, current predictors and clinical judgment of successful weaning are poor. Because of this, a clinical trial of patients who have marginal or low likelihoods of successful weaning may be indicated. In an important study, all patients using mechanical ventilation had a daily spontaneous breathing trial unless contraindicated (eg, apnea, hypopnea, severe hypoxemia, or high oxygen or minute ventilation requirements). Surprisingly, a number of patients were discontinued successfully from mechanical ventilation who would not have been predicted to do so by their clinicians. In fact, patients who tolerate a spontaneous breathing trial of 30–120 minutes should be considered for immediate extubation in the absence of contraindications.

C. Weaning Methods—Patients who are easily weaned from mechanical ventilation are easily weaned regardless of the specific method used. Those who are difficult to wean for any reason are difficult no matter which method is used. An explanation of the weaning procedure, including descriptions of possible discomfort and an assurance of close monitoring, should be provided to the patient before weaning is started.

Once mechanical ventilatory support is being withdrawn, slowly or rapidly, signs that should lead to restarting mechanical ventilation or slowing the process include tachypnea, tachycardia (HR >120 beats/min), hypotension, severe anxiety, hypoxemia, respiratory acidosis (pH <7.30), arrhythmias, chest pain, or other signs of hemodynamic compromise. A study of a small number of patients showed that a fall in gastric intramural pH, suggesting tissue ischemia, was found in patients who failed weaning, whereas those who were successful had no change in gastric intramural pH. In any patient who has difficulty being weaned from mechanical ventilation, reassessment of ventilatory requirements and ventilatory capacity is indicated.

There are no conclusive studies demonstrating superiority of any weaning method for patients with difficulty having mechanical ventilation discontinued. Recent studies, however, suggest that spontaneous breathing trials followed by extubation in suitable patients reduces length of ICU stay and duration of mechanical ventilation. Although attractive, noninvasive PPV in those with postextubated respiratory distress has not been shown to benefit these patients. Evidence that intermittent mandatory ventilation helps in difficult patients is lacking.

1. T TUBE—The ventilator circuit is disconnected from the endotracheal tube, and humidified oxygen is supplied by a tube connected across the endotracheal tube connection (T tube) while the patient breathes spontaneously. The patient is observed carefully for signs of respiratory failure, discomfort, severe dyspnea, or other intolerance.

If the T tube is used for a spontaneous breathing trial and the patient tolerates the procedure for 30–120 minutes, then

Table 12–12. Some variables used to predict success during weaning from mechanical ventilation.

Ventilatory capacity

\dot{V}_E (on ventilator) <10 L/min and \dot{V}_E (spontaneous) = \dot{V}_E (on ventilator)
 V_T >5 mL/kg; VC >10–15 mL/kg
 Spontaneous f <25/min
 Maximum negative inspiratory pressure <–25 cm H₂O
 Maximal voluntary ventilation (MVV) >2 × \dot{V}_E (ventilator)

Ventilatory requirement

P_{aO_2} >60 mm Hg with F_{iO_2} <0.50
 V_D/V_T <0.50

Combined indices

$\frac{f \text{ breaths/min}}{V_T(L)}$ <100 breaths/min/L

Successful 30-minute spontaneous breathing trial

the patient can be extubated. Otherwise, the duration of T-tube sessions is increased depending on the patient's response. In between sessions, the patient is reconnected to the mechanical ventilator in the assist-control mode. In some patients, a T-tube session may be as short as 5–10 minutes at first, with very gradual lengthening. The sessions may be repeated two to four times daily depending on patient tolerance. It is important to strike a balance between excessive respiratory muscle fatigue during the sessions and adequate time for the patient to assume some of the work of breathing.

A variation of the T-tube weaning method uses the ventilator circuit and ventilator to provide the air-oxygen mixture during spontaneous breathing rather than a separate T tube. This method allows for monitoring and warning of low spontaneous tidal volume. However, some ventilator circuits during spontaneous ventilation require much more patient effort than the conventional T tube. Some mechanical ventilators provide gas mixtures to spontaneously breathing patients with minimal work and effort by using continuous flow or bypass circuits.

2. INTERMITTENT MANDATORY VENTILATION (IMV)—This mode was described earlier. The number of mechanical ventilator breaths each minute is decreased gradually over hours or days while the patient provides a progressively increasing share of the breaths taken each minute. The IMV mode in some mechanical ventilators requires that the patient do excessive work during the spontaneous breaths, and for this reason, patients may tire easily. Despite encouraging data when IMV was first used in the 1970s, there is no evidence that IMV facilitates weaning in patients with lung disease or in those who are difficult to wean. IMV has the advantage of providing good monitoring of the patient during weaning, with breath-by-breath spontaneous tidal volume and rate displayed by most ventilators.

3. PRESSURE-SUPPORT VENTILATION—The theoretic advantages of PSV were outlined earlier. During weaning by this technique, the pressure-support pressure is chosen initially to achieve a tidal volume of 6–8 mL/kg and a respiratory rate less than about 20 breaths/min. Pressure-support pressure then is decreased gradually until the patient's own tidal volume without pressure support is adequate. Mechanical ventilation usually can be discontinued when the pressure support is less than 7–10 cm H₂O.

When it is desired to rest the inspiratory muscles temporarily, either pressure-support pressure can be increased until tidal volume reaches the desired level with little or no patient effort or using conventional mechanical ventilation. A few studies comparing PSV to T-tube weaning and IMV have been completed, and T-tube weaning and PSV are similarly more successful than IMV weaning. It is likely that PSV and T-tube weaning will both be useful depending on patient selection and clinician preference.

4. NONINVASIVE POSITIVE-PRESSURE VENTILATION—Noninvasive positive-pressure ventilation has potential benefits

in the weaning process after the patient is extubated. Some studies have suggested that patients who are marginal weaning candidates (eg, those with COPD with high ventilatory requirements or low ventilatory capacity) may be extubated successfully with the assistance of face-mask noninvasive positive-pressure ventilation. The advantages might be decreased duration of intubation, fewer complications, and shorter hospital stays. Other studies have found that patients who have failed weaning or extubation might be temporarily supported using noninvasive positive-pressure ventilation rather than reintubation. Recent studies have not shown particular benefit in selected and unselected patients. Further studies are necessary to determine the precise role and outcome of noninvasive positive-pressure ventilation in weaning. If used, however, candidates should be selected carefully and monitored closely.

5. OTHER METHODS—Facilities that specialize in management and weaning of long-term ventilator-dependent patients may be a less costly alternative than the ICU in selected patients. A number of specialized centers have reported considerable success in weaning patients after very prolonged mechanical ventilation.

ACUTE RESPIRATORY FAILURE FROM SPECIFIC DISORDERS

▶ Neuromuscular Disorders

ESSENTIALS OF DIAGNOSIS

- ▶ May present with decreased ventilation owing to respiratory muscle weakness (usually high respiratory rate with low tidal volume) or decreased ventilatory drive (low respiratory rate and tidal volume).
- ▶ PaCO₂ >50 mm Hg.
- ▶ VC <55% of predicted or less than 1500 mL may be associated with hypercapnia.
- ▶ Neuromuscular disorders often lead to atelectasis, aspiration, pneumonia, hypoxemia, and poor cough reflex.
- ▶ Suspect respiratory muscle weakness in all patients with neuromuscular weakness; general muscle strength does not always correlate with respiratory function.

General Considerations

Respiratory failure from neuromuscular diseases results from respiratory muscle weakness or abnormal control of ventilation. Muscle weakness or paralysis can result from disease in any part of the nervous system involved with motor activity. Problems with control of ventilation are seen in diseases that affect the O₂ and CO₂ chemoreceptors, their connections to the CNS, or the integrative and autonomic parts of the brain stem, primarily the medulla.

In addition to respiratory failure, neuromuscular disease can be associated with a number of other respiratory manifestations (Table 12–13). For critically ill patients, complications of nonneurologic diseases and treatment may include neuromuscular weakness (eg, electrolyte abnormalities, corticosteroid myopathy, hypothyroidism, and peripheral neuropathy) and depressed ventilatory drive (eg, sedatives and opioid analgesics).

Table 12–13. Respiratory complications of neuromuscular disease.

Hypercapnic respiratory failure
Hypoxemia
Pneumonia
Aspiration of gastric contents
Pulmonary edema
Abnormal ventilatory pattern
Upper airway obstruction
Atelectasis
Respiratory alkalosis
Pulmonary embolism

Pathophysiology

Respiratory failure in neuromuscular disease is due to weakness of the intercostal muscles and the diaphragm. However, other factors contribute to abnormal gas exchange (Table 12–14). Acute weakness of inspiratory and expiratory muscles results in a rapidly progressive decrease in vital capacity and alveolar hypoventilation with hypoxemia. In most cases, the mechanical properties of the chest wall are altered, but the lungs are normal unless complications occur. On the other hand, chronic neuromuscular disease may alter the lungs and chest wall. Other factors that contribute to differences in the presentation of respiratory failure include the age of the patient at onset of disease, the distribution of muscle weakness, a chronic or relapsing course, and the presence of underlying lung or heart disease.

A. Normal Respiratory Muscles—Respiratory muscles include the diaphragm, the intercostal muscles, muscles in the neck that can generate additional respiratory effort, and muscles of the abdominal wall. Other muscles play a key part in ventilation, including muscles in the upper airway and the smooth muscles of the lower airways. Respiratory muscles can be divided into inspiratory and expiratory muscles, although some are used during both parts of the respiratory cycle. The

Table 12–14. Physiologic consequences of neuromuscular disease.

Decreased lung volumes
Alveolar hypoventilation
Decreased lung compliance
Increased chest wall compliance (acute weakness)
Decreased chest wall compliance (chronic spastic paralysis)
Abnormal abdominal wall mechanics
Ventilation-perfusion maldistribution
Atelectasis
Impaired cough effectiveness

diaphragm generates negative intrathoracic pressure during contraction by pulling downward toward the abdomen. However, if abdominal wall muscles contract simultaneously with the diaphragm, the net effect is rather to pull the lower margins of the rib cage upward and outward, thereby expanding the thoracic volume. Muscles in the neck assist inspiratory efforts, especially when the work of breathing is increased, high ventilation is needed, the lungs are hyperinflated, or the diaphragm becomes fatigued. These accessory muscles include the sternocleidomastoids and scalenes.

Exhalation is usually passive, but normal subjects can increase expiratory flow by contracting expiratory muscles and generating higher positive intrathoracic pressures. Even passive exhalation depends on respiratory muscles, however, because passive expiratory flow is proportionate primarily to airway caliber and lung elastic recoil; both these factors are maximized at high lung volume, which requires good inspiratory muscle strength to achieve.

B. Lung Volumes in Neuromuscular Disorders—Vital capacity (VC) and inspiratory capacity (IC) are diminished because of decreased ability to expand the lungs and chest wall against passive inward recoil of those structures. While decreased IC contributes to decreased total lung capacity (TLC), the other component of TLC is the functional residual capacity (FRC), often considered to be determined by the passive balance between inward recoil of the lung and outward recoil of the chest wall at end expiration. But FRC does change with the onset of neuromuscular weakness. For example, normal volunteers given submaximal doses of muscle relaxants had about a 10% decrease in VC and TLC, but FRC decreased about 20% as a result of decreased stiffness of the chest wall. In patients with myasthenia gravis given pyridostigmine, an increase in FRC correlating with an increase in respiratory muscle strength was found. A study of stable patients with moderate respiratory muscle weakness found that VC averaged about 50% of predicted from height and age, TLC about 67% of predicted, and FRC about 79% of predicted.

In chronic neuromuscular disease, both altered chest wall compliance and reduced lung compliance contribute further to decreased FRC. Chest wall compliance in patients with spinal cord injury and spastic paralysis of chest wall muscles may be only 70% of normal. Small tidal volumes reduce lung compliance, adversely affecting surfactant distribution and perhaps stiffening and shortening lung fibrous and elastic tissues from chronically reduced lung expansion.

C. Inadequate Cough—Inadequate cough, with retention of secretions and increased tendency to pneumonia and atelectasis, is the most common and important problem seen in patients with neuromuscular weakness. Coughs are most effective in removing secretions from airways if large shear forces are generated by high-velocity gas movement in the airways. In normal individuals, coughs are initiated at high lung volumes, depend on vigorous contraction of expiratory muscles to compress airways and generate high positive intrathoracic pressures, and are released explosively. The

patient with neuromuscular weakness cannot produce effective cough if these three components are compromised.

The combination of low lung volume, impaired cough, and accumulation of secretions leads to atelectasis. At low lung volumes, alveoli are strongly influenced by surface forces generated at the interface between the alveolar gas and the wetted surface of the alveoli. This surface tension increases the tendency of the alveoli to collapse. Airway secretions also contribute to atelectasis by obstructing inward airflow and allowing alveolar gas to be absorbed into the blood.

D. Abnormal Control of Ventilation—As described earlier, alveolar ventilation in normal individuals is adjusted to regulate PaCO₂. Hypoxemia also stimulates respiration but does not play an active role in normal individuals at sea level. Neurologic disorders that affect the central or peripheral chemoreceptors, the integrative centers in the brain stem, or the primary outputs to the respiratory muscles (phrenic nerves) may lead to inappropriate ventilation for the metabolic requirements of the patient. Both hypoventilation and hyperventilation may be seen depending on the site of the neurologic problem.

Clinical Features

Symptoms, signs, and laboratory findings depend on the type of neuromuscular disorder leading to respiratory failure (Table 12–15). Common to all forms of respiratory failure in neuromuscular diseases are hypoxemia, hypercapnia, atelectasis, poor cough, and risk of development of pneumonia and other complications. Deep venous thrombosis and pulmonary embolism are common in immobilized patients. Occasionally, patients who have difficulty in weaning from mechanical ventilation are found to have an unsuspected primary or secondary neuromuscular disorder.

A. Disorders of Ventilatory Control—Impaired ventilatory control owing to a primary neurologic disorder is a relatively unusual cause of respiratory failure. Patients present with low respiratory rate and tidal volume, fluctuating uncoordinated breathing patterns, or markedly periodic breathing. Diseases that affect the medullary centers, including poliomyelitis and cerebrovascular disease, as well as depression by CNS drugs or hypothyroidism, can suppress the respiratory rhythm and output from the autonomic nervous system. In patients with impaired ventilatory control, clinical findings are related primarily to the effects of respiratory failure on gas exchange in addition to the consequences of the underlying disease. If CNS depression from opioid or sedative drugs is present, patients often will be lethargic or comatose. Other manifestations of autonomic dysfunction such as hypertension or hypotension and bradycardia or tachycardia can be seen in medullary infarction. Furthermore, infarction or ischemia of the medulla often results in characteristic effects on other neurologic pathways, including motor and sensory long tracts. A largely reversible disorder of ventilatory control may be seen in patients who have intermittent and transient hypoxemia, such as seen in those with severe sleep-disordered breathing or obstructive sleep apnea syndrome.

Table 12–15. Neuromuscular diseases associated with respiratory failure.

Medullary center injury or depression

Poliomyelitis
Cerebral vascular disease
Hypothyroidism
Narcotic and sedative drug overdosage

Primary muscle diseases

Muscular dystrophy
Myotonic dystrophy
Polymyositis, dermatomyositis
Drugs: corticosteroids
Hypokalemia, hypophosphatemia
Critical illness myopathy

Peripheral nerve diseases

Peripheral neuropathies
Guillain-Barré syndrome
Vasculitis
Diabetes
Vitamin deficiency
Toxin exposure
Infection
Infiltrative diseases
Critical illness polyneuropathy

Neuromuscular junction diseases

Myasthenia gravis and cholinergic crisis
Botulism
Tick paralysis
Drugs: paralyzing agents, aminoglycosides

Spinal cord injury and disease

Trauma
Poliomyelitis
Amyotrophic lateral sclerosis
Malignancy
Paraspinous or parameningeal abscess

Diaphragmatic paralysis

Cerebral cortical diseases

Stroke
Extrapyramidal disorders
Neurogenic pulmonary edema

B. Neuromuscular Weakness—Respiratory failure from neuromuscular diseases that leave ventilatory control mechanisms intact usually presents with low tidal volume and, because of the response to hypoxemia, hypercapnia, and lung and chest wall mechanoreceptors, increased respiratory frequency. There are some differences between the clinical pictures depending on the particular disorder.

1. MUSCLE DISEASE—Primary muscle diseases can be congenital or acquired. All can result in respiratory failure when severe, including the congenital muscular dystrophies, inflammatory muscle disorders such as polymyositis and dermatomyositis, drug-induced muscle weakness from such agents as corticosteroids, and muscle weakness caused by electrolyte and metabolic disturbances, including

hypokalemia, hypophosphatemia, hypothyroidism, hyperthyroidism, and chronic renal failure. Muscle weakness may not affect all muscle groups equally. Proximal muscles may be more severely affected in some muscular dystrophies, and even when respiratory failure is developing, there may be poor correlation between the strength of the extremity muscles and that of the respiratory muscles. Myotonic dystrophy, a rare disorder presenting with weakness and myotonic phenomena including impaired muscular relaxation, imposes the additional burden of a stiff chest wall and increased work of breathing.

The myopathic effects of corticosteroids can exacerbate the effects of the underlying disease for which the drug is administered, and corticosteroid-induced weakness in patients with asthma or interstitial pneumonitis can contribute substantially to respiratory impairment. A syndrome associated with use of neuromuscular junction blocking agents and corticosteroids can cause weakness and failure to wean from mechanical ventilation. In some of these patients, both evidence of myopathic changes on muscle biopsy and neuropathic changes evidenced by nerve conduction studies have been found. Hypokalemia and hypophosphatemia also may precipitate respiratory failure in ICU patients. Myxedema is associated with muscle weakness and elevated plasma creatine kinase. Muscle weakness seen in thyroid disease is generally correlated with the severity of thyroid disease and corrects with treatment.

Patients with a variety of critical illnesses can develop a syndrome called *critical illness myopathy*. This disorder has been associated with critical illness polyneuropathy but may occur alone. Clinically, these patients develop muscle weakness during treatment for serious illness, although no specific cause of muscle injury can be identified. Histopathologic changes may include variation in muscle fiber size, fiber atrophy, angulated fibers, fatty degeneration, fibrosis, and single-fiber necrosis, but there are no inflammatory changes. There are structural differences between patients who receive corticosteroids and those whose muscles are affected by some combination of cytokines and myotoxic substances. Common predisposing conditions include ARDS, pneumonia, liver and lung transplantation (possibly related to corticosteroids), liver failure, and acidosis. Because of common predisposing conditions, critical illness polyneuropathy should be distinguished from this syndrome. Both are associated with difficulty in weaning from mechanical ventilation and sometimes are not suspected until this stage of respiratory failure.

Primary muscle disorders often can be distinguished from peripheral neuropathy by the absence of sensory findings and by electromyography.

2. PERIPHERAL NEUROPATHIES—Peripheral nervous system disorders can be divided into those that affect the neuromuscular junction and those that affect the peripheral nerves. Peripheral neuropathies, although seen in many disorders such as vasculitis, diabetes mellitus, vitamin deficiencies,

toxin exposure (eg, lead), infections, and infiltrative diseases, cause respiratory failure only rarely. For ICU patients, the most important disorders are acute polyradiculoneuritis (Guillain-Barré syndrome) and critical illness polyneuropathy. Guillain-Barré syndrome is a demyelinating disease that is seen most often several weeks after nonspecific viral or other infectious illnesses, although the primary illness may be asymptomatic or difficult to pinpoint. Some variants have a strong association with prior *Campylobacter jejuni* infection. Clinical findings include ascending paralysis and sensory involvement initially of the lower extremities. In patients whose disease progresses over the course of about 2–4 weeks, involvement of the respiratory muscles, upper extremities, and trunk may contribute to respiratory failure. Autonomic instability may further complicate diagnosis and management. Variants of Guillain-Barré syndrome may have different patterns of involvement, making diagnosis more difficult. About 5% of Guillain-Barré syndrome patients initially have ataxia, ophthalmoplegia, and areflexia with less striking extremity weakness (Miller-Fisher variant). Other variants have purely motor or sensory involvement only.

Critical illness polyneuropathy is associated with sepsis and multiple-organ failure. Manifestations include muscle weakness and wasting and findings suggestive of peripheral neuropathy. Patients have flaccid weakness and loss of deep tendon reflexes. There is no evidence that metabolic or nutritional factors or inflammation play a major role. The histologic appearance of primary axonal degeneration and denervation is consistent with widespread primary nerve injury. It has been speculated that the association with failure of other organ systems indicates that peripheral neuropathy is another marker of severe systemic illness. Critical illness polyneuropathy is associated with respiratory failure and difficulty in weaning from mechanical ventilation. As many as 70% of patients with sepsis and multiple-organ failure have primary axonal degeneration of motor and sensory fibers, and 30% have difficulty in weaning from mechanical ventilation, limb muscle weakness, or diminished muscle reflexes. Electrophysiologic studies show reduction or absence of muscle and sensory action potentials, but slowing of nerve conduction or nerve conduction blocks is absent. Clinically, patients with critical illness polyneuropathy should be evaluated for botulism, Guillain-Barré syndrome, prolonged effects of muscle relaxants, and critical illness myopathy. Some investigators do not make a distinction between critical illness polyneuropathy and myopathy; the disorders are part of a continuum of associated complications of critical illness.

3. NEUROMUSCULAR JUNCTION DISORDERS—Neuromuscular junction disorders include myasthenia gravis, an immunologic disease caused by antibodies to acetylcholine receptors; botulism, in which a specific neurotoxin produced by *Clostridium botulinum* is ingested; and drug-induced disorders, including pharmacologic blockade of the neuromuscular junction by paralyzing agents or inadvertent blockade by aminoglycosides and other drugs. Myasthenia gravis

occasionally has gone unrecognized until it was severe enough to present with respiratory failure. Botulism should be suspected if there is descending paralysis and an appropriate clinical history. On occasion, botulism results from toxin produced by organisms infecting a wound, often in association with parenteral drug abuse. Weakness or difficulty in weaning in ICU patients should prompt a review of medications that can affect the neuromuscular junction. Rarely, these include calcium channel blockers, quinidine, procainamide, and lithium.

4. SPINAL CORD DISORDERS—Acute cervical spinal cord injury resulting in quadriplegia may cause near-total respiratory muscle paralysis if above the C3 level, but some function of neck muscles still may be present. If injury is below C3–4, diaphragmatic activity may be preserved, but respiratory failure may develop. In this setting, rib cage movement may be paradoxical, with inspiratory effort causing the chest wall to move inward because of flaccid paralysis of intercostal muscles. The mechanical efficiency of the diaphragm is also diminished as a result of flaccid paralysis of abdominal wall muscles, and cough effectiveness is greatly reduced. With time, the chest wall and abdominal wall become less compliant as muscles become spastic. In some patients, these changes may allow spontaneous efforts to become sufficient to maintain ventilation.

Other spinal cord diseases presenting with respiratory failure include poliomyelitis and amyotrophic lateral sclerosis. Poliomyelitis has a variable prognosis, with both weakness and inability to protect the upper airway contributing to potential respiratory failure. Amyotrophic lateral sclerosis is progressive, and respiratory failure is inevitable and irreversible.

5. DIAPHRAGMATIC PARALYSIS—Diaphragmatic paralysis from bilateral phrenic nerve injury or disease is rare. Vital capacity is usually less than 50% of predicted and worsens when supine. The abdominal wall moves paradoxically inward during inspiration, increasing the work of breathing and making ventilation particularly inefficient for the other muscles of inspiration. Unilateral diaphragmatic paralysis is often well tolerated unless there is underlying lung disease or a requirement for increased work of breathing or minute ventilation during illness.

C. Diseases of the Cerebral Cortex—Patients with strokes have upper motor neuron paralysis but rarely present with primary respiratory failure. However, respiratory problems are the most common complications of stroke, including aspiration and lung infection owing to generalized weakness, immobility, and aspiration. More recently, the respiratory complications of extrapyramidal disorders such as Parkinson's disease have become appreciated. The increased stiffness of the chest wall increases the work of breathing, and there are increased respiratory complications from immobilization. Isolated closed head injury of any kind requiring mechanical ventilation is commonly associated

with pneumonia. In one study, 41% of these patients developed pneumonia and had a longer ICU stay compared with those without pneumonia.

A rare complication of cerebral injury is neurogenic pulmonary edema, seen in association with head injury, stroke, status epilepticus, and cerebral hypoxia. Although it can be indistinguishable from other forms of pulmonary edema, neurogenic pulmonary edema may appear and disappear rapidly despite causing severe gas-exchange disturbances. The mechanism of neurogenic pulmonary edema is unknown but may be related to extreme changes in pulmonary vascular tone in response to autonomic stimuli. Both increased lung epithelial permeability and increased regional lung hydrostatic pressures cause pulmonary edema.

Among critically ill patients, abnormal neurologic status is a major factor leading to prolonged mechanical ventilation, with reduced level of consciousness the most common cause. However, the underlying neurologic problem is more likely a systemic illness (eg, drug toxicity or metabolic encephalopathy) rather than a primary CNS disease.

D. Laboratory Findings—Hypoxemia is common, and a PaO_2 of less than 70 mm Hg on room air is likely. Hypercapnia with acute respiratory acidosis is the key marker of respiratory failure owing to neuromuscular weakness or decreased ventilatory drive. Other laboratory findings are not particularly useful, but abnormal plasma electrolytes, including decreased potassium, magnesium, calcium, and phosphorus, may contribute to muscle dysfunction. In patients with unexplained neuromuscular weakness, elevated plasma creatine kinase suggests myopathy or myositis. Thyroid function tests may be useful even if the patient lacks the usual signs of hypothyroidism or hyperthyroidism. Diagnosis of specific neuromuscular disorders may be helped by electromyography, nerve conduction studies, or nerve biopsy.

E. Imaging Studies—Complications of neuromuscular diseases may be seen on chest x-ray. Atelectasis is a common finding—either as macroatelectasis, with focal linear, rounded, or other opacities visible on chest x-ray or evidence of segmental, lobar, or other collapse, or in some cases with no chest x-ray findings but only hypoxemia and an increased P(A-a)O_2 . In one study, 95% of patients with neuromuscular disease requiring mechanical ventilation had atelectasis at some time, most often as lobar atelectasis in the dependent lungs. Aspiration pneumonia is another common respiratory complication of neuromuscular diseases. Although dependent areas of the lungs are involved most often, new alveolar or interstitial infiltrates anywhere in the lungs suggest pneumonia.

When assessing neurologic disorders associated with respiratory failure, CT scanning is not often useful in evaluating the brain stem and has variable usefulness for spinal cord abnormalities. MRI is highly effective for imaging these areas, but patients cannot undergo MRI while being supported with mechanical ventilation.

F. Assessing Respiratory Muscle Strength—Prediction of respiratory failure in these disorders involves assessment of

respiratory muscle strength. Adequate respiratory muscle function requires both inspiratory and expiratory strength, but neither maximum inspiratory pressure nor expiratory pressure strongly correlates with general muscle strength. In patients with polymyositis or other proximal muscle myopathies presenting with generalized weakness, mean maximum inspiratory and expiratory airway pressures averaged about 50% of normal in one study, whereas at the same time the average of maximum inspiratory and maximum expiratory pressures were less than 70% of predicted in about two-thirds of patients. PaCO_2 was inversely correlated with both respiratory muscle strength and VC expressed as a percentage of predicted. Hypercapnia was especially likely when VC was less than 55% of predicted. In a study of patients with Guillain-Barré syndrome, one-half of patients developed respiratory failure. These had a mean VC when intubation was required of about 15 mL/kg compared with more than 40 mL/kg for nonintubated patients.

In patients with progressive neuromuscular weakness who are at risk of respiratory failure, a reasonable approach is to follow VC daily or more often if necessary. If VC falls below about 20 mL/kg, is less than 55% of predicted, or decreases below 1500 mL in an adult, respiratory failure should be anticipated and arterial blood gases measured. Intubation and mechanical ventilation (or noninvasive ventilation if rapid reversal is expected) may be necessary if there is progressive hypercapnia. Although some investigators recommend using the mean or sum of maximum inspiratory and expiratory pressures rather than VC measurements, VC is usually obtained more easily in the ICU.

Treatment

In most cases, treatment of respiratory failure owing to neuromuscular disease is supportive, including airway protection and mechanical ventilation. The exceptions are the few diseases for which specific treatment is available, including electrolyte abnormalities, myasthenia gravis, botulism, thyroid disease, and corticosteroid myopathy. It is essential to prevent respiratory complications when possible and to recognize and treat them promptly when they occur.

A. General Care—Patients with neuromuscular disorders should have attention to airway protection, including examination of the swallowing mechanism and gag reflex, alteration of diet if necessary, careful feeding, and attention to body positioning. Feeding by mouth or by enteral feeding tubes should be monitored closely, especially because some neuromuscular diseases can affect gastric emptying and intestinal motility. In all neuromuscular disorders—even when stable—respiratory failure can be precipitated by stress from conditions such as pulmonary or other infections, concurrent illness such as heart failure, major surgery, medications, or electrolyte disturbances. General measures such as prophylaxis for gastritis and prevention of deep venous thrombosis should be instituted.

Prevention of atelectasis by mechanical means is controversial. Incentive spirometry is not as helpful in patients with

neuromuscular weakness as in those with normal strength. Intermittent positive-pressure breathing (IPPB) seems attractive as a way of overcoming low lung volume during tidal breathing. However, results of studies have been mixed. Continuous positive airway pressure (CPAP) and bilevel noninvasive positive-pressure ventilation also have been tried without clear success. Some studies have shown that rotational therapy using special beds is helpful in decreasing atelectasis and pneumonia in immobile patients.

B. Treatment of Respiratory Failure—Treatment of respiratory failure in patients with neuromuscular disease includes airway maintenance, oxygen, bronchodilators if necessary, and use of incentive spirometry to avoid atelectasis. Respiratory failure is usually of the hypercapnic variety unless there is atelectasis or consolidation from pneumonia. Mechanical ventilation is often necessary to perform the work of breathing in the patient with muscle weakness who develops hypercapnia.

If respiratory drive is inadequate, the assist-control mode is used with volume-preset ventilation. There is little rationale for IMV or pressure-control ventilation, and pressure-support ventilation cannot be used unless the patient can initiate and sustain inspiratory efforts. Lung compliance and resistance are normal in the absence of secondary pulmonary complications. Unless and until ventilation-perfusion maldistribution develops, high concentrations of supplemental oxygen are not needed. As in patients with obstructive or interstitial lung disease, tidal volumes should be limited to 6–8 mL/kg of ideal body weight. PEEP may be quite helpful in decreasing atelectasis and for reducing the sense of dyspnea in some patients.

Patients with specific neuromuscular diseases may present with different needs. If respiratory muscle weakness is the primary problem but ventilatory control is intact, pressure-support ventilation may be suitable. In some disorders, it may be desirable to rest the respiratory muscles entirely. The assist mode does not “rest” inspiratory muscles as much as the control mode—that is, if the patient initiates the breath, the inspiratory muscles continue to contract throughout inspiration, whereas if the ventilator initiates the breath, inspiration is completely passive on the patient’s part. Pressure-support ventilation, although the inspiratory muscles are not completely rested, may have potential advantages of allowing some work to be done but with less effort.

In some patients, positive-pressure ventilation is needed only for some part of the day eg, (at night), and the patient can breathe well for long periods of time. Tracheostomy may be necessary to attach the ventilator at night, or noninvasive ventilation may be tried for intermittent use.

▶ Thoracic Wall Disorders

ESSENTIALS OF DIAGNOSIS

- ▶ Chest wall anatomic deformity, chest wall stiffness, or severe obesity.
- ▶ Massive ascites, late-stage pregnancy, recent abdominal or thoracic surgery, thoracic and abdominal trauma, and large abdominal or pelvic masses sometimes may present with respiratory failure.
- ▶ $Paco_2 > 50$ mm Hg, usually with hypoxemia.
- ▶ Low tidal volume; usually increased respiratory frequency.
- ▶ Primary lung disease absent but secondary complications frequent.

General Considerations

Thoracic wall abnormalities other than those owing to neuromuscular disease are relatively rare causes of respiratory failure. However, acquired and congenital abnormalities may result in distortion of the chest wall, mechanical disadvantage of the respiratory muscles, increased work of breathing, or limitation of chest wall expansion. Patients usually have chronic respiratory failure with hypoxemia, hypercapnia, and cor pulmonale but also may present with acute deterioration or exacerbations. The most common chronic disorders leading to respiratory failure are severe obesity of the chest wall and abdomen, kyphoscoliosis and scoliosis, and ankylosing spondylitis. Massive ascites, late-stage pregnancy, recent abdominal or thoracic surgery and trauma, and myotonic dystrophy may cause respiratory failure in a similar manner.

Pathophysiology

Thoracic cage abnormalities restrict lung expansion. Vital capacity and total lung capacity are decreased. Functional residual capacity (FRC) is usually decreased except in most patients with spondylitis. Because of overall reduction in lung volumes, FEV_1 is also usually low, but the ratio of FEV_1

to VC is normal in the absence of obstructive lung disease. Respiratory failure results from a combination of increased work of breathing and ventilation-perfusion maldistribution owing to restriction of expansion of the lungs and chest wall. The mechanics of the chest wall and the diaphragm are altered in ways unique to the type of disorder and the location of the abnormalities.

A. Chest Wall Deformity—Scoliosis and kyphosis may be idiopathic or due to poliomyelitis, tuberculosis, or other identifiable causes. Patients with scoliosis have an inverse relationship between the severity of scoliotic deformity and the compliance of the thoracic cage. Those who develop respiratory failure have the most severe thoracic deformity and lowest chest wall compliance. Patients with scoliosis breathe at low tidal volumes, presumably to minimize the work of breathing. Kyphosis alone rarely is associated with respiratory failure, but when seen together with scoliosis, it may contribute to increased work of breathing and other abnormalities.

Ankylosing spondylitis limits rib cage expansion, and patients tend to breathe primarily by diaphragmatic movement as the thoracic cage becomes increasingly immobile. The contribution of thoracic cage expansion to tidal breathing falls as minute ventilation increases. The position of the thoracic cage at end expiration often becomes fixed at a volume larger than in normal subjects. The chest wall therefore exerts a greater than normal outward pull on the lungs, resulting in a normal or increased FRC despite low VC and TLC.

A flail chest results from severe blunt trauma outside the hospital but occasionally from cardiopulmonary resuscitation. The *flail* is the paradoxical inward movement of the chest wall during inspiration, making ventilation inefficient and worsening respiratory mechanics. Chest pain and underlying lung contusions contribute to respiratory failure.

B. Obesity

1. SEVERE OBESITY—Severe obesity—in particular, predominantly central or truncal obesity—puts a heavy mechanical burden on the chest wall and the diaphragm during inspiration. Increased weight causes the end-expiratory position of the chest wall and diaphragm to be more inward than normal. Thus the amount of gas that can be further expired from the end-expiratory position (expiratory reserve volume [ERV]) is reduced. On the other hand, the inspiratory capacity—the maximal amount of gas that can be inspired from the resting end-expiratory point—is normal or increased, at least in young obese adults with no underlying diseases. The work of breathing is increased, especially when minute ventilation increases. The larger mass of the chest wall and abdominal wall must be accelerated at each breath, and additional energy is expended to move them during tidal breathing. Small tidal volumes are usually selected by these patients, and the ability to increase minute ventilation can be limited and associated with severe dyspnea. It is likely that obesity associated with more peripheral distribution of added adipose tissue (eg, buttocks and extremities) has less effect on respiratory function, but this has not been studied.

Obese patients are more prone to develop obstructive sleep apnea because of a greater redundant soft tissue in the upper airway, potentiating airway obstruction during sleep-associated relaxation of upper airway muscles. A syndrome of obesity-hypoventilation has been described. The mechanism of this central hypoventilation is unclear but is probably associated with increased work of breathing, decreased responsiveness of the respiratory center, and chronic hypoxemia. These patients have daytime hypercapnia from depressed chemoresponsiveness, increased work of breathing, and abnormal pulmonary function. Patients with obesity-hypertension syndrome often have pulmonary hypertension and cor pulmonale.

C. Limitation of Diaphragmatic Excursion—Patients with massive ascites, late stage of pregnancy, recent abdominal or thoracic surgery or trauma, severe hepatomegaly, or large pelvic or abdominal tumors may present occasionally with respiratory problems. Most often they have basilar atelectasis, low tidal volumes, and mild hypoxemia. If diaphragmatic excursion is severely limited, these patients may develop hypercapnia. The underlying condition may contribute to additional problems. For example, patients with liver disease, ascites, or tumors also may have pleural effusions, further compromising lung function. Those with recent surgery or trauma may be unable or unwilling to take deep inspirations because of pain.

D. Gas Exchange and Pulmonary Hypertension—Patients with all types of chest wall abnormalities may have ventilation-perfusion maldistribution contributing to hypoxemia and hypercapnia. In obesity and limited diaphragmatic excursion, this finding has been attributed primarily to atelectasis at the bases of the lungs because of elevation of the diaphragm and low FRC. This is supported by observations that obese subjects have better gas exchange when standing than when supine and improvement in hypoxemia and reduced $P_{(A-a)O_2}$ during exercise. Patients with ascites and abdominal tumors would be expected to be similar. In scoliosis and spondylitis, regional differences in ventilation can be explained by differences in expansion owing to local chest wall stiffness in spondylitis or asymmetric deformity in scoliosis.

The combination of chronic hypoxemia and respiratory acidosis along with anatomic deformity of pulmonary vessels explains the pulmonary hypertension and cor pulmonale seen in some patients with severe chest wall abnormalities. For reasons that are not clear, cor pulmonale is seen more often in chronic respiratory failure from scoliosis, sometimes in the absence of severe gas-exchange abnormalities; it may be related to anatomic deformity or arrested development of pulmonary vessels.

Clinical Features

Some patients with thoracic wall abnormalities have chronic respiratory failure with chronic hypoxemia and hypercapnia.

Decompensation leading to acute respiratory failure may be due to further abrupt worsening of the chest wall disease, development of a lung complication such as pneumonia or bronchospasm, or additional metabolic requirements imposed by surgical stress, infection, or other disease. The clinical history may reveal the cause of thoracic deformity, such as prior poliomyelitis or other disease, thoracic wall surgery or injury, tuberculosis of the spine, or surgery for pulmonary tuberculosis.

A. Symptoms and Signs—Dyspnea at rest and on exertion are common complaints, but some patients complain only of fatigue and weakness. Patients present usually with rapid, shallow tidal breathing unless there is a disorder of ventilatory control suggesting central hypoventilation. Physical examination can show obvious chest wall deformity or decreased range of motion of the chest wall or diaphragm, but the degree of abnormality may not be easily determined from examination alone. Wheezing, rhonchi, or stridor may be evidence of superimposed obstructive airway disease such as asthma, but kinking of large central and upper airways in scoliosis may be the cause. Other signs are due to complications such as pneumonia, left-sided heart failure, atelectasis, and pleural effusions. Findings of right-sided heart failure, such as peripheral edema, elevated central venous pressure, and hepatic congestion, generally indicate chronic respiratory failure.

The likelihood of respiratory failure resulting from obesity is not well correlated with the degree of obesity. Lung volumes do not decrease routinely in proportion to excess weight, and no marker of obesity such as weight/height² (body mass index) predicts respiratory failure. For example, in otherwise normal subjects who are more than 160% of ideal weight, lung volumes and flows are usually found to be normal. Such normal lung function may not persist, however, as these patients age, and the decline in lung function with advancing age may be accelerated compared with nonobese subjects. In addition, obesity is associated with hypertension and cardiovascular disease, which themselves may contribute to decreased respiratory function. Central hypoventilation in obesity (obesity-hypoventilation syndrome) further dissociates the degree of obesity from the severity of hypercapnia, as does the high prevalence of basilar atelectasis causing hypoxemia.

Patients with ascites from liver disease and pregnancy frequently have increased ventilatory drive, probably because of hormonal changes. The severity of respiratory impairment from decreased diaphragmatic excursion is highly unpredictable, but most of the patients have some degree of hypoxemia and only rarely develop hypercapnia.

B. Laboratory Findings—Respiratory failure results from insufficient minute ventilation to maintain CO₂ homeostasis. With mild thoracic wall disorders, patients often can maintain normal PaCO₂ and PaO₂. As the disorder progresses, work of breathing increases. Compensation in the form of increased PaCO₂ in exchange for decreased minute ventilation

then occurs, resulting in chronic respiratory acidosis. The chronicity of respiratory failure can be confirmed by finding an elevated plasma bicarbonate level.

C. Imaging Studies—The likelihood of respiratory failure correlates with the severity of the deformity in scoliosis. Severe thoracic scoliosis is generally considered when the angle of spinal curvature exceeds 70 degrees, as measured on an x-ray film. This angle is measured as the angle between lines drawn perpendicularly to the longitudinal axis of two vertebral bodies, one above and one below the area of maximum deformity. The angle is 0 degrees in the absence of scoliosis and increases with increasing scoliosis. As many as 50% of patients with an angle greater than 80 degrees may be considered at risk for respiratory failure. An angle of 100 degrees seems to be associated with dyspnea on exertion and an angle greater than 120 degrees with alveolar hypoventilation.

Treatment

Care of the patient with respiratory failure from thoracic wall disorders is largely supportive. There is considerable reported success with noninvasive positive-pressure ventilation (NIPPV) in these patients, but most of these data are in stable patients requiring ventilation at night and intermittently during the day. There is less experience with acute respiratory failure, but NIPPV should be considered in order to avoid endotracheal intubation. The benefits of NIPPV often persist, likely because of improvements in respiratory muscle function and improved respiratory gas exchange. Mechanical ventilation is initiated if the patient requires additional ventilatory support to overcome increased metabolic requirements or during an acute exacerbation owing to infection or surgery. If concomitant central hypoventilation contributes to respiratory failure, patients often will respond after several days of correction of hypoxemia and respiratory acidosis by demonstrating greatly improved respiratory drive. Respiratory stimulant drugs such as progesterone and almitrine are not helpful. Patients with limited diaphragmatic excursion are approached according to the type of problem. Those with severe ascites may benefit from large-volume paracentesis or other efforts to decrease the volume of ascites. Pain management is critical in patients following abdominal or thoracic surgery or trauma.

Treatment of flail chest depends on the severity of injury. Pain management and monitoring may be adequate. If respiratory failure develops, mechanical ventilation may be necessary until chest wall mechanics recover. Only in rare cases is surgical repair indicated, including prolonged recovery, deeper injuries to thoracic structures, and extensive injuries.

Patients with right-sided heart failure from cor pulmonale may have peripheral edema and hepatic congestion, but vigorous diuresis is not usually indicated and may be harmful. Patients with pulmonary hypertension may be sensitive to preload reduction and rapid decrease of intravascular volume. However, spontaneous diuresis as a response to improved oxygenation is a good sign. Patients with coexisting

left-sided heart failure may benefit from diuresis and decreased pulmonary edema.

The outlook for patients who present with respiratory failure from chest wall disorders is surprisingly favorable. In many cases, one or more precipitating factors can be identified and corrected. Other patients will respond with improved gas exchange after a short period of supplemental oxygen or mechanical ventilation. While there is little chance of improving the underlying pathophysiology in severe scoliosis or severe ankylosing spondylitis, weight reduction and treatment of obstructive sleep apnea in obesity can be highly effective.

▶ Chronic Obstructive Pulmonary Disease

ESSENTIALS OF DIAGNOSIS

- ▶ Chronic bronchitis or emphysema.
- ▶ Increased dyspnea and cough; decreased exercise tolerance.
- ▶ COPD exacerbation: one or more of increased sputum volume, increased sputum purulence, and/or worsening dyspnea.
- ▶ Respiratory muscle fatigue.
- ▶ Worsening hypoxemia/hypercapnia; new onset or worsening of hypercapnia.

General Considerations

Chronic obstructive pulmonary disease (COPD) is the most common respiratory disorder leading to respiratory failure in adults. Although asthma and cystic fibrosis are chronic obstructive diseases, COPD is usually considered to include

chronic bronchitis and emphysema. Most patients with COPD have chronic respiratory failure, many with hypoxemia (some requiring home oxygen supplementation), a lesser proportion with chronic hypercapnia. Acute respiratory failure in COPD develops both in patients with and those without chronic respiratory failure. Although precipitated most often by exacerbation of airway obstruction from infection and increased sputum production, an important factor leading to acute respiratory failure is inspiratory muscle fatigue. Patients with COPD, because they have limited ventilatory reserve, may have acute respiratory failure when they have a nonrespiratory infection, heart failure, or diabetes or after major surgery.

COPD patients typically have acute exacerbations several times per year, but only some require hospitalization and ICU admission. When admitted to the ICU, however, mortality is high, and recovery is slow.

A. Definition—Chronic bronchitis and emphysema have in common limitation of airflow caused by obstruction of intrathoracic airways, and airway obstruction is more marked during expiration. Chronic bronchitis is characterized by increased sputum production, chronic inflammation of the airways, hypertrophy of airway smooth muscles, increased number and size of airway mucus glands, and thickening of airway connective tissue. Patients with chronic bronchitis often have a history of cigarette smoking leading to hypertrophy of mucus glands. Chronic bacterial infection also plays a role.

Emphysema is characterized by destruction of alveoli and other tissues beyond terminal bronchioles. Decreased expiratory airflow in pure emphysema is not due to primary disease of the airways but results from decreased elastic recoil of the destroyed lung parenchyma. During expiration, decreased lung elastic recoil lowers the distending pressure holding the airways open and leads to increased airway resistance. The pathogenesis of emphysema is not known. In a very small proportion of patients, deficiency of α_1 -antitrypsin has been identified, and these patients are thought to have destruction of lung elastic and connective tissue by unopposed action of leukocyte elastase. The mechanism of lung parenchymal destruction in the majority is unknown. Cigarette smoking, as well as some occupational exposures, is associated with development of emphysema. Many patients with emphysema have clinical features of chronic bronchitis.

B. Bacterial Infection and Sputum Changes—Acute respiratory failure in COPD occurs with worsening airway obstruction. Sputum production increases, and the characteristics of the sputum are altered in response to bacterial infection. Increased sputum and difficulty clearing sputum may provoke bronchospasm. Bacterial infection also may follow viral or *Mycoplasma* infection. Some of the evidence for the role of bacteria in causing exacerbation of COPD comes from serologic testing, but the most convincing data has been the demonstration of the beneficial effects of antibiotics in preventing exacerbation, shortening the course of acute deterioration, and decreasing the need for hospitalization.

Bacteria colonize the trachea and bronchi of COPD patients—even when stable—whereas normal subjects do not have organisms in these sites. The most commonly found organisms from tracheal aspirates have been *Haemophilus influenzae* and *Streptococcus pneumoniae*, found in 30–60% of COPD patients, and during acute exacerbations, there may be an increase in the numbers of these bacteria. Other bacterial pathogens, including *Moraxella catarrhalis*, are suspected of being important causes of COPD exacerbation, but other bacteria capable of causing pneumonia, such as gram-negative aerobic bacilli, anaerobes, and staphylococci, do not play a major role in exacerbation of COPD. There is debate about whether the type and number of bacteria change significantly during an exacerbation. A recent study indicates that bacterial subtypes change during exacerbations even though the same species are present chronically and during exacerbation. Since bacteria quantity and quality are only slightly different, the host's response is an important feature of acute exacerbation. The number of inflammatory cells and the amount of other sputum components change during acute exacerbation. Sputum becomes thicker, more viscous, and more adherent to mucosal surfaces. A change from white to green or yellow reflects increased amounts of myeloperoxidase in neutrophils. Protein, cellular and bacterial debris, and cellular DNA are responsible for mechanical changes in sputum. Disruption and inefficiency of the normal mucociliary clearance mechanisms results, with further worsening of airway obstruction.

C. Bronchospasm and Respiratory Failure—

Bronchospasm is not a primary cause of airway obstruction in chronic bronchitis or emphysema as it is in asthma, but increased bronchomotor tone and airway smooth muscle contraction are present. In COPD, much of the airway smooth muscle contraction is mediated through the parasympathetic nervous system via the vagus nerve. Local irritation of the tracheobronchial mucosa from sputum, bacteria, and other debris stimulates the parasympathetic nervous system by way of vagal afferent pathways. Vagal efferent fibers in the vagus nerve stimulate increased airway smooth muscle contraction and increased airway resistance. Patients with COPD frequently have a heightened response to methacholine inhalation challenge, although not usually as marked as patients with asthma.

D. Lung Mechanics and Respiratory Muscles—As COPD patients develop increased airway resistance from secretions and bronchoconstriction, the work of breathing increases, and the distribution of ventilation becomes more nonuniform. Ventilation requires increased respiratory muscle exertion. Several factors may prevent the patient with COPD from maintaining adequate ventilation during exacerbation. First, because of the increase in airway resistance, patients with severe COPD are unable to maintain expiratory flow. To keep minute ventilation constant, patients then must either increase expiratory time by increasing inspiratory flow rate (shortening inspiratory time) or breath at a relatively higher

lung volume (with respect to TLC). Breathing at higher lung volumes is helpful because airway resistance is less. Second, the work of breathing increases. Increased airway resistance is the major component of increased work, but hyperinflation displaces the tidal volume to a higher and flatter portion of the respiratory system's pressure-volume curve, resulting in increased elastic work of breathing as well. Third, although increased resistance is largely expiratory, it is the inspiratory muscles that compensate by generating faster inspiratory flow. The inspiratory muscles are disadvantaged by the decreased lung compliance accompanying hyperinflation. When the increased force needed exceeds the capacity of the inspiratory muscles, muscle fatigue ensues, and acute respiratory failure results from inability to maintain minute ventilation. Malnutrition, corticosteroids, hypophosphatemia, hypokalemia, and other factors predispose patients to respiratory muscle fatigue.

E. Impaired Lung Gas Exchange—Patients with COPD have maldistribution of ventilation and perfusion even when stable, and gas exchange worsens during acute exacerbations of disease. Hypoxemia generally is responsive to oxygen therapy, but because of the increased V_D/V_T , hypercapnia may develop if patients are unable to sustain higher than normal minute ventilation.

F. Control of Ventilation—There has been considerable focus on the contribution of reduced ventilatory drive in acute respiratory failure in COPD, but this is not important in most patients, who appear to have normal or increased ventilatory drive. Chronic hypercapnia is found in many but not all patients with COPD; it is more common in chronic bronchitis compared with emphysema. Severity of COPD is not the major determinant of hypercapnia; decreased ventilatory response to CO_2 in family members of hypercapnic COPD patients suggests that familial factors play a role.

In COPD patients with acute respiratory failure, the combination of severe hypoxemia, high $Paco_2$, and low pH depresses central chemoreceptor-mediated ventilatory drive. Hypoxic stimulation of the carotid bodies is relatively more preserved as a chemical stimulus for ventilation, and when arterial hypoxemia is corrected by administration of supplemental oxygen, ventilatory drive may be suppressed, and the patient's minute ventilation falls. This mechanism has been challenged by evidence suggesting that oxygen administration does not further depress minute ventilation acutely. Several studies have shown that breathing pattern and minute ventilation do not change appreciably after oxygen is given in the majority of COPD patients with acute exacerbations. Despite these data, high concentrations of oxygen should be given cautiously to COPD patients with hypercapnia or suspected hypercapnia (see below). Furthermore, because ventilation-perfusion mismatching is the largest contributor to hypoxemia, COPD patients generally will achieve adequate Pao_2 with only minimal supplemental oxygen.

Clinical Features

Features that warrant particular concern are listed in Table 12–16. These findings suggest impending worsening of respiratory failure requiring close monitoring and potential need for endotracheal intubation and mechanical ventilation. Long-term use of corticosteroids, greater PaCO₂, and advanced age are associated with higher mortality during COPD exacerbation.

A history of chronic sputum production along with chronic cough, shortness of breath, a history of cigarette smoking, features of airway obstruction on pulmonary function tests, and lack of evidence of left-sided heart failure will identify most patients with chronic bronchitis. The diagnosis of emphysema is made from an obstructive pattern on pulmonary function testing, decreased diffusing capacity for carbon monoxide, hyperinflation and abnormal lucency of lung fields on chest x-ray, and dyspnea. Cough and sputum production are not primary features of emphysema, but these may develop. The initial presentation of COPD is rarely acute respiratory failure, and it is highly likely that the patient will have had some symptoms of COPD even if a previous diagnosis has not been made. These symptoms usually include exertional dyspnea and chronic cough.

A. Symptoms and Signs—With acute respiratory failure, COPD patients often will have a variable history of increasing symptoms lasting hours to days; these may include low-grade fever, malaise, or upper respiratory symptoms leading to increased dyspnea, cough, inability to clear sputum from the airways, and decreased exercise tolerance. Some will report that home oxygen and bronchodilator drugs are less effective despite increased frequency and intensity of use. Sleeplessness because of dyspnea, sometimes for days, is a

common complaint, and patients may state that they are unable to breathe when recumbent. On occasion, COPD exacerbations may present with evidence of severe right-sided heart failure manifested by peripheral edema and ascites. A retrospective case-control study of patients admitted to an ICU with COPD exacerbation found that they had lower body weight, greater rate of deterioration of lung function, worse arterial blood gases and plasma bicarbonate, and larger right ventricular diameter than those not requiring ICU admission. Numerous studies have confirmed a high prevalence of malnutrition in COPD patients (40–60%), and this is more marked in those who required mechanical ventilation for exacerbation of disease (74%) compared with those who did not need mechanical ventilation (43%).

The amount of sputum increases, but patients may be unable to cough up the sputum adequately. Sputum may change from white or clear to green or yellow and usually becomes thicker, more viscous and adherent, and produces longer strands. Blood-streaked sputum reflects increased airway inflammation, but hemoptysis should raise concern about other processes as well.

Features of COPD can be found along with signs of acute respiratory failure. Increased anteroposterior diameter of the chest gives the appearance of a barrel chest, and on examination, the hemidiaphragms are low and flat and move little even when the patient is stable. Clubbing and hypertrophic osteoarthropathy indicate severe chronic lung disease. Breath sounds are often difficult to hear, and low-pitched sonorous rhonchi rather than higher-pitched musical wheezes are more common than in asthmatics. Especially in emphysema, but also in any patient with severe obstruction, breath sounds may be nearly inaudible. Signs of lung consolidation (pneumonia), decreased breath sounds with dullness to percussion (pleural effusions), and decreased breath sounds with hyperresonance to percussion (pneumothorax) are important in searching for contributing causes of acute decompensation. Especially in patients who have had prior tracheostomy or endotracheal intubation, acute respiratory failure could be due to upper airway obstruction. These patients may have loud stridor heard best over the trachea during inspiratory efforts. Hypercapnic patients may be somnolent, stuporous, or comatose. Hypercapnia may be associated with asterixis.

It is essential to look for features on examination suggesting impending worsening of ventilatory function. These include use of accessory muscles of respiration (sternocleidomastoid contraction), intercostal retraction, and paradoxical abdominal wall motion (inward displacement of the anterior abdominal wall during inspiration)—all of which indicate high inspiratory work of breathing or impending inspiratory muscle fatigue. Patients who are unable to breathe while supine usually brace their arms on a table or the arms of a chair to facilitate inspiration using accessory muscles (ie, “tripoding”). On the other hand, while important, peripheral edema, hepatomegaly, ascites, a parasternal lift, and other features of right ventricular hypertrophy or cor pulmonale are not reliable predictors of severity of acute respiratory failure.

Table 12–16. Findings suggesting severe exacerbation of COPD.

Clinical	
	Pneumonia
	Pneumothorax
	Left ventricular failure
	History of requiring mechanical ventilation
	Nocturnal desaturation or apnea
	Concurrent infection, renal insufficiency
	Poor response to bronchodilators
	Poor nutritional status
	Paradoxical abdominal wall movement
	Use of accessory muscles of respiration
	Pulsus paradoxus
	Severe pulmonary hypertension or cor pulmonale
Physiologic	
	pH <7.25 with Pco ₂ >60 mm Hg
	Pao ₂ <50 mm Hg
	Respiratory muscle fatigue

B. Laboratory Findings—Hypercapnia ($\text{PaCO}_2 > 45$ mm Hg) with acute respiratory acidosis is seen often. In those who have chronically elevated PaCO_2 , plasma bicarbonate is high, and the pH may be only mildly reduced. Therefore, the severity of acute hypercapnic respiratory failure is indicated by how low the pH is, not the degree of elevation of PaCO_2 . Any patient with a pH less than 7.30 should be considered to have severe acute hypercapnia.

Hypoxemia is due to both hypoventilation and \dot{V}/\dot{Q} mismatching. Erythrocytosis, if present, indicates chronic hypoxemia. Electrolyte abnormalities may include hyponatremia caused by the syndrome of inappropriate antidiuretic hormone and hypokalemia, especially in those receiving chronic corticosteroids or aggressive β -adrenergic agonist therapy. Malnutrition contributing to respiratory failure is observed commonly, and biochemical markers of decreased nutritional status such as low plasma albumin, prealbumin, and retinol-binding protein are present.

Sputum Gram stain and cultures are often obtained, but the results of these tests rarely guide therapy. On the other hand, there is considerable interest in “biomarkers” as predictors of COPD exacerbation and response to therapy. C-reactive protein may indicate inflammation, and elevated procalcitonin has been associated with response to antibiotics. It remains to be proven if such markers will indicate, for example, whether a patient should get corticosteroids or antibiotics.

C. Electrocardiography—The ECG may show right ventricular hypertrophy and low QRS voltages.

D. Imaging Studies—Chest x-ray findings range from essentially normal with a few increased linear bronchovascular markings and mild hyperinflation to severe hyperinflation with localized or diffuse bullae and cysts. The diaphragm is low and flat, especially as seen on lateral views, and there are often enlarged retrosternal and retrocardiac spaces. The chest x-ray should be reviewed carefully, looking for pneumonia, pneumothorax, pleural effusions, evidence of pulmonary hypertension, evidence of left-sided heart failure, and atelectasis. About 16–21% of chest x-rays show significant abnormalities in patients with COPD exacerbations.

E. Spirometry—Pulmonary function tests are rarely needed to diagnose obstructive lung disease during acute exacerbation. Peak flow measurements and FEV_1 may be useful, however, in assessing the response to therapy and prognosis, but there are few data supporting routine use.

Differential Diagnosis

The differential diagnosis of respiratory failure from COPD includes asthma with acute exacerbation, upper airway obstruction, and left ventricular failure. Peripheral edema, weight gain, hepatomegaly, and other features of fluid overload may be due to cor pulmonale or left-sided heart failure. Hyperinflation of the lungs on chest x-ray often makes the heart look smaller; some clinicians advise that a normal-sized heart be considered a

sign of cardiomegaly in COPD. Pulmonary embolism is seen in COPD patients with increased frequency.

Treatment

Treatment of acute respiratory failure in COPD is supportive until the reason for exacerbation of airway obstruction is eliminated. Oxygen is usually needed for hypoxemia. Bronchodilators, corticosteroids, and antibiotics address airway obstruction and acute infection, but because of the importance of inspiratory muscle fatigue, the major therapeutic decision is when to start mechanical ventilation because the respiratory muscles are no longer able to maintain adequate ventilation.

A. Oxygen—Hypoxemia has several effects in COPD. Aside from the systemic effects of tissue hypoxia, hypoxemia is a respiratory stimulant that may be counterproductive. If patients increase respiratory frequency, expiratory time shortens, and further adverse hyperinflation ensues. Increased ventilatory drive generates an increased inspiratory flow rate and contributes to respiratory muscle fatigue.

Hypoxemia is due almost entirely to ventilation-perfusion mismatching. Therefore, small increases in inspired O_2 concentration usually lead to acceptable increases in PaO_2 . The target PaO_2 is greater than 60 mm Hg or an O_2 saturation of more than 90%. An increase in FiO_2 to 0.24–0.35 is usually sufficient, and this can be provided by a Venturi-type mask or by nasal cannula (1–4 L/min). Oxygen therapy has been associated with worsening of hypercapnia and respiratory acidosis in occasional patients, and this has been attributed to loss of hypoxic drive with administration of O_2 . While this particular mechanism has been questioned, caution in giving excessive O_2 is advised. However, caution must be balanced with the very real danger of hypoxia if arterial O_2 saturation remains less than 90%. Patients with COPD and hypoxemia ($\text{PaO}_2 < 55$ mm Hg), when they are ready for discharge, are candidates for home oxygen therapy. When given for 18–24 hours per day, long-term home oxygen improves prognosis.

B. β -Adrenergic Agonists—Clinical response to these agents when given by aerosol is almost always achieved, although not usually as marked a response as in asthmatics. Because COPD patients are generally older and have more concurrent medical problems than asthmatics, side effects of hypokalemia, myocardial stimulation, tremor, effects on blood pressure, and drug interactions may be more significant. Therefore, in COPD patients, the drugs may be given in lower dosage and less often than in asthma. Oral β -adrenergic agonists are of lesser value and may limit the amount of aerosolized drug that can be given. Long-acting β -adrenergic agonists do not have a role in acute exacerbation.

C. Anticholinergics—Anticholinergic bronchodilators have become the primary therapy for chronic stable COPD and are used in conjunction with β -adrenergic agonists during acute exacerbations despite little data supporting combined

use. Ipratropium bromide, in well-tolerated doses, is superior to usual doses of β -adrenergic agents in stable COPD, and a combination of modest doses of ipratropium, theophylline, and albuterol was better than ipratropium alone. Surprisingly, there is little evidence comparing the use of ipratropium with other bronchodilators during acute exacerbations. Nevertheless, because of the high level of safety of ipratropium and its potential as a bronchodilator in COPD, it should be included in all pharmacologic regimens for management of COPD exacerbations. Effective doses can be as much as two or three times the dose usually recommended, but this is so because this drug is very well tolerated with few, if any, side effects. Ipratropium is available in MDIs and in a solution for nebulization. Each puff from the MDI provides 18 μg ipratropium inhaled solution; an effective starting dosage for stable COPD is two to four puffs every 6 hours. If the solution for nebulization is used, a roughly equivalent dosage of 500 μg is nebulized for inhalation every 6 hours. Because the effectiveness in acute exacerbation is not clear, both increased dosage and increased frequency may be necessary. Response to treatments should be monitored closely. A fixed-dose MDI containing a combination of albuterol and ipratropium is available; this is likely more suitable for chronic stable COPD patients.

D. Methylxanthines—Theophylline has a long history of use in COPD, but the degree of bronchodilation from theophylline has been called into question. Theophylline increases the rate and force of contraction of skeletal muscle and increases the force that can be generated by fatigued respiratory muscles. Myocardial effects, including increased contractility, may be beneficial. Theophylline has other effects unrelated to bronchodilator action, including evidence for immune modulation, alterations in calcium flux, diuretic action, and central respiratory stimulation. In acute exacerbation of COPD, one controlled trial found no further improvement when aminophylline was added to a standard treatment regimen that included inhaled β -adrenergic agonists and corticosteroids. These studies, plus the narrow therapeutic range for theophylline coupled with its dangerous toxic effects, have decreased its use as a primary bronchodilator. Theophylline should be used carefully in COPD patients and only when maximum therapy with other bronchodilators proves inadequate. Advanced age, heart disease, liver disease, and concomitant drugs (including some antibiotics such as erythromycin and fluoroquinolones) decrease theophylline clearance. Severe COPD by itself may be a factor increasing the incidence of theophylline toxicity. Moderate therapeutic levels of theophylline should be sought—10–12 $\mu\text{g}/\text{mL}$ —in most patients. Theophylline toxicity must be considered in patients with unexplained tachycardia, arrhythmias, hypokalemia, or GI or CNS symptoms.

E. Corticosteroids—Corticosteroids have an undisputed role in management of acute exacerbation of asthma, and data support their use in COPD patients as well. In one controlled study during acute exacerbation of COPD, slightly more

rapid improvement was seen in patients given methylprednisolone compared with placebo. Several recent studies of systemic corticosteroids in acute exacerbation of COPD found improvement in lung function, decreased symptoms, and better outcome. Subsequent exacerbations were not affected, as would be expected.

Severe acute exacerbations of COPD should be treated with corticosteroids, but it is likely that some subgroups will benefit more than others. These might include those with predominant bronchospasm and those with increased numbers of blood or sputum eosinophils. The optimal dose and duration of corticosteroid treatment in COPD exacerbation are unknown, and complications from these drugs in COPD patients is high. Therefore, somewhat smaller doses and earlier withdrawal of corticosteroids have been recommended. However, in the largest controlled trial of COPD patients, methylprednisolone was given 125 mg every 6 hours for 3 days, followed by daily oral prednisone 60, 40, and 20 mg for 4 days each. These patients improved more rapidly than with placebo and were similar to a group that was given an 8-week course of corticosteroids.

Although there are little data supporting rapid withdrawal, metabolic complications from corticosteroids (eg, hyperglycemia and hypokalemia) and corticosteroid myopathy may be avoided.

F. Antibiotics—Antibiotics are given routinely for acute exacerbations of COPD, although benefit has not been clearly established in all patients. The goals of treatment are to shorten the duration of exacerbation and decrease the degree of severity in those with little pulmonary reserve. Long-term goals of prolonging time between exacerbations, slowing progression, and modifying bacterial flora may or may not be achieved. A large randomized trial found that patients who had all three of increased volume of sputum, increased dyspnea, and increased purulence of sputum were the most likely to improve with antibiotic therapy. Patients without these changes are statistically more likely to have viral infection and not improve with antibiotics.

Broad-spectrum drugs are usually used, aimed at *H. influenzae*, *S. pneumoniae*, and other organisms commonly found in sputum of COPD patients. However, one guideline has recommended selecting the type of antibiotic based on age, number of exacerbations, and lung function. Simple chronic bronchitis (age <65, fewer than four exacerbations per year, and mild impairment in lung function) should have therapy directed against *H. influenzae*, *S. pneumoniae*, and *M. catarrhalis*. Those with complicated chronic bronchitis (age >65, more exacerbations, and poorer lung function) may have other gram-negative bacilli involved, and therapy should be broadened accordingly.

Because of the emergence of β -lactamase-producing *Haemophilus* and *M. catarrhalis*, second-generation cephalosporins, amoxicillin-clavulanic acid, extended-spectrum macrolides, and trimethoprim-sulfamethoxazole are now often prescribed for simple chronic bronchitis

exacerbation. For complicated exacerbations, second- or third-generation cephalosporins or fluoroquinolones may be more efficacious. The clinical significance of penicillin-resistant *S. pneumoniae* is unknown in patients with COPD. Comparison studies often do not clearly support the efficacy of one agent over another, and cost, availability, and drug toxicity are important factors. Individual agents all have their advantages and disadvantages.

Antibiotics previously used may be ineffective. Erythromycin is not active against *Haemophilus*, and ampicillin and amoxicillin are destroyed by β -lactamases and have no activity against atypical bacteria. Extended-spectrum macrolides (eg, azithromycin and clarithromycin) are effective against common organisms in COPD exacerbations, as are fluoroquinolones such as levofloxacin. Clinicians at each hospital and ICU should be aware of local bacterial sensitivities, the frequency of resistance, and local efforts to reduce development of resistant organisms (eg, restricted use of antibiotics).

In patients with COPD who are found to have pneumonia, antibiotic therapy should be intensified. Use of agents with particular efficacy against *S. pneumoniae*, aerobic gram-negative bacilli, *M. pneumoniae*, and *Legionella pneumophila* should be considered, and intravenous antibiotics probably are indicated at least initially until the patient has shown clinical response.

G. Mechanical Ventilation—Patients with COPD and acute respiratory failure who require mechanical ventilation either have very severe obstruction or encounter fatigue of respiratory muscles and inability to maintain adequate minute ventilation. Hypercapnia and respiratory acidosis are the most common reasons for starting mechanical ventilation; hypoxemia is not often the primary problem and usually can be treated satisfactorily by supplemental oxygen alone. Although mechanical ventilation is frequently administered to patients with acute exacerbations of COPD, a subset of patients has been identified that has a poorer prognosis. These patients are more likely to have pulmonary infiltrates on chest radiographs, lower plasma albumin, and lower baseline lung function. In several studies, mortality from acute exacerbation of COPD requiring mechanical ventilation ranges from 30–50%.

1. VOLUME-PRESET VENTILATION—The volume-preset (volume-cycled) mode is used most often in COPD patients and generally is well tolerated. Because of increased resistance in intrathoracic airways, exhalation of the tidal volume is prolonged in COPD. Thus sufficient expiratory time during mechanical ventilation must be allowed to avoid “air trapping,” or hyperinflation. Tidal volume generally is limited to 6–8 mL/kg; inspiratory time is kept relatively short by choosing high inspiratory flow (at least 1 L/s, often 1.25–1.5 L/s), and expiratory time is kept relatively long by a slow respiratory rate. The I:E ratio should be at least 1:3 and preferably more (1:4–5). If patients have chronic hypoventilation with compensatory elevation of plasma bicarbonate, minute ventilation should be chosen to avoid causing acute alkalemia

by not correcting PaCO₂ to normal. High concentrations of supplemental oxygen during mechanical ventilation rarely are required, and most patients have a satisfactory PaO₂ when the inspired O₂ fraction is 0.3–0.5. A need for higher inspired oxygen concentrations suggests atelectasis or consolidation rather than airway obstruction alone.

An inspiratory plateau pressure (see above) greater than 30 cm H₂O is likely to be associated with barotrauma and hyperinflation; pressures greater than this should be avoided by prolonging expiratory time as much as possible. As in asthmatics, lower tidal volume (6–8 mL/kg) during mechanical ventilation is recommended to decrease barotrauma and other complications. PaCO₂ is allowed to rise, if necessary (permissive hypercapnia), as long as pH remains above 7.25–7.30. Smaller tidal volume also has a beneficial effect by reducing intrinsic PEEP.

Increased peak airway pressure (rather than inspiratory plateau pressure) should prompt an examination of the patient for pneumothorax, bronchospasm, or airway obstruction with mucus or foreign body rather than hyperinflation.

If patients are able to contribute some efforts to ventilation, the pressure-support mode may be useful. With this mode, patients can choose the rate and depth of breathing while having some of the inspiratory work of breathing taken on by the mechanical ventilator. This mode may be particularly helpful during weaning. The pressure-controlled mode should not be used in COPD exacerbations because the inspiratory flow rate, tidal volume, and I:E ratio cannot be maintained consistently.

2. INTRINSIC PEEP—In any situation in which a high ventilatory requirement or severe airway obstruction is present, expiration may not be completed by the onset of the next inspiration. Because expiratory flow persisting up to end exhalation indicates that there is a positive-pressure gradient between alveoli and atmosphere at end expiration, alveolar PEEP must be present. PEEP generated in this way is termed *intrinsic PEEP* (PEEP_i) or *auto-PEEP*. The most accurate method of estimating the magnitude of PEEP_i is to use an esophageal balloon connected to a pressure transducer to measure intrathoracic pressure. The change in intrathoracic pressure between end exhalation and the onset of inspiratory gas flow into the lungs is approximately equal to the PEEP_i (provided that there is minimal or no active expiratory muscle contraction at end exhalation). For clinical purposes, another method is to occlude the expiratory port of the ventilator circuit just at the end of expiration. An increase in pressure displayed on the ventilator manometer indicates the presence and degree of PEEP_i (Figure 12–6). This method may underestimate the degree of PEEP_i in patients with severe obstruction, especially those with heterogeneous distribution of increased resistance.

High levels of PEEP_i adversely affect lung compliance, work of breathing, and cardiovascular function and dominate gas exchange by affecting distribution of ventilation.

▲ Figure 12-6. Demonstration of intrinsic PEEP in a patient with obstructive lung disease. In the top figure, increased airway resistance slows expiratory airflow so that the lung is still emptying until the start of the next inspiration. Alveolar pressure at end expiration is positive (+10 cm H₂O in this example). Because of the high downstream resistance, a large pressure drop occurs before the pressure manometer site, and manometer pressure reads 0 cm H₂O despite positive alveolar pressure. If, however—as shown in the bottom figure—at end expiration, the expiratory port is occluded, stopping flow, pressure equalizes throughout the system. The manometer now reads a positive pressure that approximates intrinsic PEEP. Some mechanical ventilators can make this measurement automatically. In patients with very heterogeneous distribution of airway resistances and compliances, the occlusion method may underestimate the level of intrinsic PEEP.

COPD patients who develop PEEPi while undergoing mechanical ventilation may have worsening of hypoxemia and hypercapnia. In this common clinical scenario, PaCO₂ can paradoxically worsen when minute ventilation is increased, leading to rapid deterioration. Lowering respiratory frequency and tidal volume instead in this situation improve gas exchange, reducing PaCO₂. Clinicians should be aware of this potential problem and act accordingly.

Another effect of inadvertent PEEPi is an increase in the work of breathing when assisted mechanical ventilation is used. In this mode, the ventilator initiates inspiratory flow when it senses negative pressure in the circuit, but if alveolar end-expiratory pressure is positive, inspiratory muscle contraction will not immediately generate pressure that is negative with respect to atmospheric pressure. Thus additional work

of breathing is performed by the patient. Some investigators have added PEEP (extrinsic PEEP) to the ventilator circuit in this situation to change the absolute pressure at which the ventilator initiates inspiratory flow. Ideally, the small amount of PEEP reduces the work of breathing but does not worsen hyperinflation. The use of PEEP in this situation is debated, but the usual recommended amounts of extrinsic PEEP are small (75–85% of estimated PEEPi) and probably do not cause adverse effects if monitored carefully.

3. NONINVASIVE VENTILATION—In the last several years, studies have shown a striking benefit of noninvasive positive-pressure ventilation (NIPPV) for acute respiratory failure in selected patients with COPD. Theoretically, the use of a face mask or nasal interface can provide positive-pressure ventilation to the patient without endotracheal intubation. In selected patients, only short-term support may be needed until the reversible problem leading to exacerbation can be corrected. A further attraction is obviation of the need for prolonged weaning after intubation and conventional mechanical ventilation. Some studies have used NIPPV on a continuous basis for 24–48 hours or more; in other studies, patients are placed on NIPPV for 8–20 h/day with interspersed spontaneous breathing periods. Patients who are poor candidates for NIPPV include those with apnea, concurrent unstable medical problems, swallowing dysfunction, impaired cough, poor fit of the mask, and upper airway narrowing or those unable to cooperate fully.

For COPD exacerbations, several forms of NIPPV have been used. First, low levels of continuous positive airway pressure (CPAP) alone have been given. CPAP theoretically acts by reducing the work of breathing in patients who have developed PEEPi and hyperinflation. Other patients have been administered bilevel positive pressure, with a small expiratory pressure (3–5 cm H₂O) and a time-cycled or patient-initiated larger inspiratory pressure (8–15 cm H₂O). In this mode, the expiratory pressure acts to overcome PEEPi, while the inspiratory pressure support provides assistance during inspiration without providing enough pressure to deliver the entire tidal volume.

Success of NIPPV is measured by rate of subsequent endotracheal intubation, improvement in arterial blood gases, and mortality. Success rates of 40–60% have been reported, but most studies have been on selected patients who are cooperative, do not have excessive airway secretions, and who can tolerate a face mask or nasal interface. In a meta-analysis of NIPPV trials, there was an 11% reduction in deaths and a 28% reduction in endotracheal intubations. Surprisingly, NIPPV was most beneficial in the most severe patients (pH <7.30 or more than 10% mortality in control group). Decreased respiratory infections is another benefit of NIPPV compared with endotracheal intubation.

H. Respiratory Stimulants and Depressants—In the past, acute respiratory failure in COPD was considered to be partly due to insufficient ventilatory drive, and respiratory stimulant drugs were administered. Increasing ventilatory

drive makes little sense if respiratory muscle fatigue and hyperinflation are exacerbated by stimulants, so stimulants should be used rarely. Acetazolamide, a carbonic anhydrase inhibitor, is given occasionally to enhance excretion of bicarbonate accumulated as compensation for hypercapnia, but its indications are not clear. It should be considered only in patients in whom the precipitating factors have been reversed and there is obvious “metabolic alkalosis” as a consequence of compensation for chronic respiratory acidosis. Most patients who benefit from acetazolamide will have known chronic hypercapnia and a known steady-state plasma bicarbonate target.

Respiratory depressant drugs, including sedatives and opioids, should be avoided in COPD exacerbations while patients are breathing spontaneously. These drugs are useful, however, in patients during mechanical ventilation. On occasion, muscle relaxants are essential to avoid hyperinflation.

I. Other Therapy—A guideline developed following an extensive critical review of the literature recently concluded that there was no benefit from chest physiotherapy and mucolytic medications in patients with COPD exacerbation.

▶ Acute Respiratory Distress Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Appropriate clinical situation.
- ▶ Refractory hypoxemia (hypoxemia that responds poorly to increased inspired oxygen concentration).
- ▶ Bilateral, diffuse pulmonary infiltrates.
- ▶ Absence of clinical evidence of hydrostatic or cardiogenic pulmonary edema.

General Considerations

Acute respiratory distress syndrome (ARDS) is a disorder of severe hypoxemic respiratory failure that occurs in association with a variety of critical situations including trauma, aspiration, shock, and pulmonary and extrapulmonary infection. Other terms used to describe this syndrome are more descriptive of its pathophysiology, such as *noncardiogenic* or *exudative pulmonary edema with acute lung injury*. ARDS deserves considerable attention because of its high mortality rate and the interest it has aroused in the mechanism of acute lung damage from apparently different causes. Because of superficial similarity to neonatal respiratory distress syndrome, ARDS formerly had been “adult” respiratory distress syndrome. However, consistent with the original definition and recommendations of consensus conferences, ARDS should be understood to mean “acute” respiratory distress syndrome.

Although the term ARDS was first used in 1967, it is not a new disease. Well-documented descriptions of hypoxemic respiratory failure after severe trauma were reported during World War II, and there were even earlier reports of pulmonary edema associated with severe infection. The last 40 years have shown a remarkable increase in recognition of this syndrome, and there is general agreement that the outcome from ARDS remains relatively poor. Nevertheless, very encouraging prognostic information seems to reflect improved understanding of the pathophysiology and response to therapy of ARDS.

The major change in the management of ARDS has been the recognition that a low-tidal-volume strategy (6–8 mL/kg of ideal weight) decreases mortality. This important finding, the only proven treatment, has a strong basis in pathophysiology and has markedly changed the treatment of this disorder.

Definition

ARDS is a clinical syndrome resulting from the severe end of the spectrum of acute lung injury (ALI). In ALI, variable amounts of inflammation, disruption of normal lung architecture by tissue destruction and repair processes, and increased lung permeability to capillary fluids are seen. By definition, ALI does not result from elevated left atrial or pulmonary capillary pressure (although elevated pressures may be found coincident to the lung injury). Both the lung injury and ARDS evolve over hours to days rather than weeks to months.

ARDS includes clinical features, radiographic findings, and physiologic derangements, and the association with one of many clinical situations. Table 12–17 lists criteria for ARDS. Older criteria required lung compliance measurement to establish increased lung stiffness, pulmonary artery wedge pressure measurement to exclude cardiogenic pulmonary edema, and the presence of a known clinical disorder likely to cause lung injury. The North American–European Consensus Committee statement requires only refractory hypoxemia ($\text{PaO}_2/\text{FiO}_2 < 200$ regardless of PEEP), diffuse pulmonary infiltrates on chest roentgenogram, and absence of clinical features suggestive of heart failure. These criteria have a very high degree of concordance with other definitions. It should be emphasized

that criteria for ARDS are designed primarily to facilitate comparison of patients in research studies. On the basis of appropriate clinical judgment, an individual patient may be diagnosed as having ARDS and treated accordingly without meeting all criteria.

ARDS is often distinguished from *acute lung injury* (ALI), a somewhat confusing term because it is used frequently to indicate a similar syndrome with less severe hypoxemia ($\text{PaO}_2/\text{FiO}_2 > 200$) for purposes of clinical studies and prognosis.

Pathophysiology

ARDS results from a combination of ALI, pulmonary edema from increased permeability of the alveolar epithelium (non-cardiogenic pulmonary edema), and fibroproliferation with collagen deposition.

A. Acute Lung Injury—One of the intriguing aspects of ARDS is the variety of clinical situations associated with ALI, both direct and indirect. Lungs can be injured directly from severe bacterial, viral, or other infectious pneumonia; aspiration of gastric contents; near-drowning; inhalation of toxic gases, such as smoke, chemicals, or poison gas; or blunt trauma to the lungs. Other disorders cause indirect lung injury, such as bacterial or fungal sepsis, severe nonthoracic trauma, fat embolism after orthopedic injury, pancreatitis, hemodynamic shock, and drugs; these probably damage the lung through circulating mediators.

ARDS occupies the severe end of a spectrum of lung injury seen in many clinical contexts, with the histologic hallmark of diffuse alveolar damage as the common feature of inflammatory, toxic, infectious, or other processes that injure the lung parenchyma. Diffuse alveolar damage consists of disruption of normal alveolar architecture, replacement of type I with type II alveolar epithelial cells, damage to pulmonary capillaries, increased collagen deposition, exudative pulmonary edema, and a variable amount and variety of inflammatory cells. Evidence of both ongoing acute and chronic processes may be found. Diffuse alveolar damage is seen in other clinical situations, such as cytotoxic drug exposure or as a complication of severe pulmonary infections, or may be idiopathic.

An approximate time course for diffuse alveolar damage in ARDS has been proposed. Early in the course (1–7 days), lung injury is coincident with exudative pulmonary edema, variable inflammation, platelet-fibrin thrombi, and disappearance of type I alveolar epithelial cells. This is followed by a proliferative phase (days 7–21) in which there is type II alveolar cell proliferation and the beginning of organization and fibrosis (see below). Findings in the later fibrotic phase may be indistinguishable from the various forms of idiopathic interstitial pneumonitis, especially idiopathic pulmonary fibrosis.

In ARDS, every potential mediator that could lead to diffuse alveolar damage has been implicated, including neutrophils

Table 12–17. Criteria for diagnosis of acute respiratory distress syndrome.

Refractory hypoxemia $\text{PaO}_2/\text{FiO}_2 < 200$
Diffuse bilateral pulmonary infiltrates (<7 days old)
Absence of heart disease PA wedge < 18 mm Hg or No evidence of left ventricular failure

and lymphocytes and their cytokines, prostaglandins, leukotrienes, platelets, coagulation factors, adhesion molecules, and immunoglobulins, as well as exogenous substances such as endotoxin and other products of bacteria and fungi. Endogenous cell products have received the most attention—some as mediators of injury, such as oxygen radicals and proteolytic and elastolytic enzymes, but others as amplifiers of inflammation and injury, such as interleukins, platelet-activating factor, complement, and other substances that are chemotactic, bronchoreactive, or vasoreactive. These may be active in the early, middle, or late phases of lung injury. A role for injury from oxygen radicals is supported by the finding of reduced alveolar fluid glutathione in patients with ARDS. The coagulation system has been suggested by some investigators as having a central role in lung injury, perhaps by linking intravascular events to direct injury to the endothelium and by activation of inflammatory sequences. Elevated plasma levels of tumor necrosis factor (TNF) are found in some patients with ARDS but also in those with sepsis and other systemic disorders. A potent cytokine, TNF has a variety of systemic effects, some of which could cause or potentiate lung damage. The finding of several elevated cytokines in ARDS suggests the possibility of common regulatory factors being involved. One factor, NF- κ B, regulates production of TNF, interleukin 1 (IL-1), IL-6, and IL-8. This hypothesis is attractive because of the frequent association of IL-6, TNF, and IL-8 with lung injury. More recently, ARDS has been linked to toll-like receptors (TLRs), which respond to a variety of substances to trigger a vast cytokine response. TLRs are responsible for innate immunity; this could explain the common finding of ALI in response to the range of inciting factors.

A key role for polymorphonuclear leukocytes in lung injury is supported by finding neutrophils in large numbers in the lungs of ARDS patients. Furthermore, neutrophils are primed to release potentially toxic substances from their granules, neutrophil chemotactic factors and activators are increased, and in some animal models, lung injury is attenuated after neutrophil depletion. For example, neutrophil-activating protein/interleukin-8 (NAP-1/IL-8) has been found in high concentrations in alveolar fluid, and there was a correlation with the number of neutrophils. High concentrations of NAP-1/IL-8 also were associated with poor clinical outcome. On the other hand, neutropenic cancer patients may develop ARDS indistinguishable from that observed in nonneutropenic patients, and diffuse alveolar damage in some animal models does not require the presence of neutrophils. Levels of both cytokines and modulators of cytokine function are highly variable in ARDS, and it is clear that cytokines taken individually or as patterns of response are not able to predict development or prognosis of ARDS. In parallel with the diversity of clinical conditions associated with diffuse alveolar damage and ALI, it is highly likely that different conditions in different patients explain why consistent findings cannot be identified. While this makes a single common causative mechanism unlikely, this hypothesis helps to

explain why so many conditions can result in very similar histologic and physiologic features. Nevertheless, there is now ample evidence that persistent elevation of inflammatory cytokines in blood or alveolar fluid is associated with poor outcome in ARDS in all forms of this disorder.

Patients may develop secondary bacterial or fungal pneumonia during the course of ARDS, further confusing the picture. Administration of high concentrations of inspired oxygen contributes to lung injury, and high airway pressure and relatively high tidal volume during mechanical ventilation are closely linked to worsening pulmonary edema and fibrosis. On the other hand, higher oxygen requirements and airway pressures may simply indicate more severe underlying disease.

B. Noncardiogenic Pulmonary Edema—Normal lungs are kept very dry to permit efficient gas exchange, and the structure and activity of the lungs maintain only a small amount of fluid in the lungs. Normal lungs have tight junctions between alveolar epithelial cells, an extensive lymphatic system, low hydrostatic pressure in the pulmonary capillaries, and other mechanisms to avoid pulmonary edema. Thus, lung injury from any number of insults can promote pulmonary edema by damaging these mechanisms.

Pulmonary edema is a major clinical manifestation of ARDS, and the pulmonary edema fluid contains a high concentration of protein. This is in marked contrast to pulmonary edema owing to elevated pulmonary venous pressure (hydrostatic pulmonary edema) or to decreased plasma albumin concentration (hypo-oncotic pulmonary edema), in which the edema fluid is a low-protein transudate. ARDS also has been called *exudative* or *noncardiogenic pulmonary edema*, reflecting the increased permeability of the injured lung to water, solute, and protein. Exudative pulmonary edema forms in the absence of elevated pulmonary artery wedge pressure, and the ratio of edema fluid protein to plasma protein is high. Edema fluid accumulates both in the pulmonary interstitium and in the alveoli, and because of potential fluid pathways, lung lymphatics and bronchovascular spaces (surrounding the bronchioles, bronchi, and pulmonary arteries) may become engorged. Pulmonary edema removal by the pulmonary circulation and lymphatics, including active transport of solute and water, is severely impaired because of the ALI. In a minority of ARDS patients, the pulmonary epithelium is able to resolve pulmonary edema during the first 12 hours. This probably reflects relatively preserved epithelial cells that might increase solute and water transport in response to β -adrenergic agonists. These and other drugs are currently being studied.

C. Chronic Lung Injury—Diffuse alveolar damage seen in ARDS may follow several courses, including resolving entirely with little or no evidence of chronic damage after weeks or months. However, other patients develop mild to severe pulmonary fibrosis. One of the most interesting findings in ARDS is evidence of very early deposition of type III collagen (procollagen III peptide in alveolar fluid) in the lung, sometimes within 24 hours of the onset of diffuse

alveolar damage. Evidence for early fibrosis has been associated with poor prognosis, stressing the potentially inappropriate role of remodeling and repair in late lung injury. These findings have challenged the time course of ALI, with irreversible fibrosis occurring much sooner than in earlier proposed models. Attraction and activation of fibroblasts may be mediated by various substances such as platelet-activating factor that are increased in blood and pulmonary edema fluid. Oxygen toxicity may play a role, especially if patients require very high inspired oxygen to treat hypoxemia. Another potential contributor to chronic lung damage is recognized to be overdistention of the lungs by high tidal volume, high PEEP, or high airway pressure.

In chronic lung injury, variable amounts of collagen are laid down into the alveolar and interstitial spaces with distortion and disruption of the normal lung parenchyma, resulting in restrictive lung disease, reduced exercise capacity, and hypoxemia. Histologic findings may be indistinguishable from idiopathic pulmonary fibrosis. Particularly sensitive findings are the PaO_2 and P(A-a)O_2 during exercise. Recent data show that survivors with more severe early ARDS had worse late-stage pulmonary function than those with less severe acute disease. Lung function as assessed by spirometry, total lung capacity, and diffusing capacity for carbon monoxide averaged about 80% of predicted in these survivors. The greatest degree of improvement was seen in the first 3 months, and there was little additional improvement between 6 months and 1 year.

The relationship of collagen deposition, severity of lung injury, and outcome provides some possibilities for intervention. These include potential inhibition of chemotactic or activating factors for fibroblasts, removal of some forms of collagen during tissue repair phases, and limitation of lung injury by controlling inflammation, oxygen toxicity, and ventilator-induced lung injury.

D. Physiologic Manifestations

1. REFRACTORY HYPOXEMIA—Hypoxemia in ARDS is due to right-to-left shunt and \dot{V}/\dot{Q} mismatching resulting from atelectasis and filling of alveolar spaces with edema fluid. \dot{V}/\dot{Q} mismatching also may result from nonuniform changes in airway resistance, decreases in regional lung compliance, and primary and secondary alterations of lung blood flow. Hypoxemia usually is severe and not corrected even when the patient is given high concentrations of inspired O_2 , termed *refractory hypoxemia* (Figure 12-7). As part of the definition of ARDS, the ratio of PaO_2 to FiO_2 is less than 200.

As shown by CT scanning, the majority of lung in ARDS is completely airless, with small proportions either normally inflated or collapsed with potential for recruitment. These findings suggest that right-to-left shunting plays the major role in refractory hypoxemia, whereas the use of PEEP walks a fine line between recruitment of atelectatic lung and overdistention of normal lung.

▲ **Figure 12-7.** Lines showing PaO_2 versus FiO_2 for various constant-shunt fractions (\dot{Q}_s/\dot{Q}_T) between 0% and 30%. Superimposed are typical responses in patients with ARDS (lines *a* and *b*). Line *b* shows severe hypoxemia with a response suggesting severe right-to-left shunt as the primary mechanism of hypoxemia. Line *a* demonstrates severe hypoxemia but with PaO_2 increasing more rapidly with increasing FiO_2 than with pure right-to-left shunt. The mechanism of hypoxemia is probably severe ventilation-perfusion mismatching.

2. ALTERED STATIC LUNG MECHANICS—Lung compliance is severely decreased and airway resistance mildly increased in ARDS. Decreased lung compliance results from a combination of interstitial pulmonary edema, collapse of lung units, airway obstruction, and inactivation of alveolar surfactant. Ineffective surfactant in ARDS may be due to reduced pool sizes, alteration in surfactant proteins, altered metabolism, or inactivation by plasma proteins, oxygen radicals, or phospholipases exuding into the alveolar spaces. In later stages, lung compliance is reduced because of accumulation of collagen.

Studies correlating regional radiographic lung volume change and inflation pressure show that disease involvement in ARDS is much less uniform than formerly thought. This finding has resulted in a major change in understanding of ARDS. Most lung regions are extensively involved and completely airless, some participate variably in gas exchange, and other uninvolved regions accept the bulk of ventilation. These latter regions have normal specific lung compliance, indicating that the primary cause of decreased overall lung

compliance is overdilatation of these small uninvolved regions of the lung rather than uniform stiffening of the entire lung. This finding has major implications for how patients with ARDS should be mechanically ventilated, notably the use of a low-tidal-volume strategy.

The pressure-volume (PV) curve of the lungs in ARDS is shifted downward and rightward (Figure 12-8). The lungs require greater pressure to inflate, and the work of breathing is increased. An increase in lung compliance may indicate improvement of the disease or recruitment of atelectatic lung, especially with the application of PEEP. Some investigators have noticed that the respiratory system compliance curve, which considers both lung and chest wall mechanics, is altered in ARDS. Patients with nonpulmonary causes of ARDS (eg, abdominal sepsis, trauma, or postoperative) had greater response to PEEP, suggesting that the “pulmonary ARDS” patients (mostly those with pneumonia) had more severe and less recruitable lung consolidation, whereas the nonpulmonary ARDS patients had more atelectasis.

The shape of the PV curve has been stressed by some clinicians. The curve has been divided into sections, including a flat initial increase in volume with increasing pressure, a lower inflection point after which compliance (slope) increases, an upper inflection point, and then another region of low compliance (flat slope). The regions of the PV curve

▲ **Figure 12-8.** Hypothetical respiratory system pressure-volume curves for a patient with ARDS showing a flatter than normal relationship (decreased respiratory system compliance, $C_{rs} = V_T/\Delta P_1$). With addition of PEEP, a shift to a more compliant curve may occur such that $C_{rs} = V_T/(\Delta P_2 - PEEP)$ increases. The change in compliance may represent recruitment of poorly ventilated or nonventilated lung units with application of PEEP and may be correlated with improved oxygenation and gas exchange.

may have implications for adjusting PEEP (see below) and limiting tidal volume.

3. INCREASED AIRWAY RESISTANCE—Increased airway resistance is described in ARDS patients, probably owing to edema in the bronchovascular spaces surrounding the bronchi, but there may be inflammatory mediators that induce bronchoconstriction. Another cause may be the normal increase in airway resistance in areas of decreased pulmonary perfusion in response to ventilation-perfusion mismatching. The increased airway resistance, as much as sixfold compared with normal individuals, contributes to higher airway pressure and work of breathing. In one study, increased resistance correlated positively with both peak airway pressure and the severity of gas-exchange abnormality.

E. Multiple-Organ-System Failure—Although often viewed as a primary lung disorder, ARDS is clearly associated with multiple-organ-system dysfunction and failure. Subtle evidence of organ-system dysfunction is very common in both survivors and nonsurvivors of ARDS, and renal failure, liver failure, CNS failure, heart failure, thrombocytopenia, and GI bleeding and malabsorption contribute to mortality and morbidity. In fact, of those who die with ARDS, respiratory failure has been estimated to be the primary cause in as few as 16%. Sepsis and nonrespiratory failure accounted for the remainder.

The cause of multiple-organ-system failure in ARDS remains poorly understood. There are three major theories. First, some investigators believe that the same systemic process that damages the lungs injures other organs as well; ARDS is simply the most obvious and earliest manifestation. For example, one study found that ARDS patients had increased urinary myoglobin and β_2 -microglobulin during development of pulmonary edema, and there was a correlation between pulmonary edema and the amount of these proteins in the urine. This mechanism of multiple-organ-system failure may be particularly likely in patients with sepsis and shock. Circulating factors such as endogenous cytokines or endotoxin are likely mediators of multiple-organ-system failure in this hypothesis.

Another hypothesis is that hypoxemia and inadequate O_2 delivery are the causes of multiple-organ-system failure. Some studies of ARDS patients suggest that tissue oxygen consumption depends on systemic oxygen delivery even when oxygen delivery is normal or elevated. Thus a small decrease in oxygen delivery can cause oxygen consumption to fall, resulting in tissue hypoxia and potential organ damage. Studies undertaken to test the hypothesis that increasing oxygen delivery will raise oxygen consumption, however, have not shown improved outcomes.

A final consideration in multiple-organ-system failure is the effects of therapy of ARDS. Positive-pressure ventilation and PEEP are important parts of the supportive care of ARDS, but these can have adverse effects on cardiac output and oxygen delivery. Invasive monitoring, artificial airways, and other devices increase risk of infection and sepsis. This theory is attractive because mortality in ARDS, while still

high, is less often related to respiratory failure than to nonrespiratory organ dysfunction and sepsis. Recent clinical studies provide circumstantial support for this theory. For example, use of a low-tidal-volume strategy reduces mortality in ARDS patients by close to 25%. Because there was no difference in the degree of obvious barotrauma, a beneficial effect on nonrespiratory organ system function might be one explanation.

Clinical Features

A. Predisposing Conditions—More than 100 clinical situations have been associated with development of ARDS. Prospective studies have helped to identify the most common conditions, and 60–80% of cases of ARDS can be accounted for by sepsis, trauma, diffuse pulmonary infection, and aspiration of gastric contents, with other conditions being much less frequent (Table 12–18).

The overall attack rate of ARDS is relatively low. In one study, only 8% of patients at risk with any of the nine most frequently associated predisposing conditions developed ARDS, although the incidences ranged from 6–50% for individual risks. In those with multiple predisposing conditions, the incidence of ARDS increases substantially, with an average incidence of 42% for two or more risks for ARDS compared with 19% for those with a single risk in one study—although 41% of patients with sepsis alone developed ARDS.

Table 12–18. Some predisposing conditions associated with ARDS.

Infection
Pneumonia: bacteria, fungi, viruses, <i>Pneumocystis jirovecii</i>
<i>Nonpulmonary:</i> Sepsis from gram-negative bacilli, staphylococci, other gram-positive cocci, <i>Candida</i>
Aspiration of gastric contents
Trauma
Thoracic: lung contusion
Nonthoracic
Hemorrhagic shock
Head trauma
Burns
Blunt abdominal trauma and pancreatitis
Orthopedic: fat embolism syndrome, severe fracture
Other conditions
Drugs: opiate or salicylate overdose
Pancreatitis
Toxic: smoke or gas inhalation
Amniotic fluid embolism
Central nervous system pulmonary edema
Near-drowning
Multiple transfusions of blood and blood products
Collagen-vascular disease, including vasculitis and pulmonary hemorrhage

1. SEPSIS—Sepsis is present in as many as 50% of ARDS patients. In medical patients, sepsis is the most common ARDS association; in trauma patients, sepsis is the most common association in ARDS developing 48 hours or more after admission. A distinction sometimes can be made between pneumonia leading to ARDS and infection from a nonlung site leading to ARDS. In severe pneumonia, gas-exchange abnormalities and chest x-ray features of ARDS are sometimes seen prior to or in the absence of other characteristics of systemic infection, suggesting that much of the lung injury is due to the infectious agent and local response to infection within the lung. Pathogens include bacteria, mycobacteria, fungi, viruses, *Pneumocystis jirovecii*, and rickettsiae. On the other hand, a nonpulmonary primary site of infection is often identified in ARDS patients, including the GI tract, urinary tract, heart, or soft tissues. Although gram-negative enteric bacilli are encountered most often, ARDS can result from systemic infection with any bacterial, viral, or fungal pathogen. Sepsis is of particular interest because it appears that circulating mediators, including interleukins and other responses to infection, are largely responsible for ARDS, hypotension, and multiple-organ-system failure, in addition to the microbial organisms themselves. Sepsis complicated by ARDS has a higher mortality, especially if the source of infection cannot be identified and treated readily.

2. ASPIRATION OF GASTRIC CONTENTS—Aspiration of gastric contents is defined as an observed aspiration during intubation or witnessed vomiting in a patient with impaired airway protective mechanisms. Although acidic gastric fluid is thought to be the primary cause of lung injury and ARDS, studies support a contributory role for bacteria, partially digested food particles, gastric enzymes, and other noxious substances. Neutralization of gastric acid prior to aspiration does not prevent or moderate ALI. Other syndromes of aspiration, including necrotizing pleuropulmonary infection and lung abscess, can lead to ARDS if there is severe lung injury response or sepsis. Aspiration of gastric contents is particularly common in patients of advanced age, those who have neurologic diseases resulting in paralysis or impaired swallowing, or those who have advanced organ-system failure. In other ICU patients, including surgical and obstetric patients, aspiration potential is increased by sedatives, muscle relaxants, general anesthesia, and local anesthesia to the pharynx and larynx; during endotracheal intubation; during enteral feeding; and in diabetics or others with impaired GI motility. In a sizable number of patients, aspiration of gastric contents can only be presumed because predisposing factors are absent and there is no observed aspiration event.

3. TRAUMA—Trauma is a common predisposing condition to ARDS, but the precise mechanism is uncertain. Direct trauma to the thoracic wall may result in lung contusion, with hemorrhage into the lung causing abnormal gas exchange, atelectasis, and further lung injury.

Nonthoracic trauma is also associated with an increased incidence of ARDS. In some of these patients, lung injury

results from fat embolism syndrome, a disorder seen in fractures of long bones, or pancreatitis from blunt or sharp abdominal trauma. In others, the risk of ARDS correlates with hypotension and shock and with the amount of blood and blood products transfused, suggesting that the nature and extent of trauma may have something to do with the development of ARDS. Hypotension and shock release inflammatory cytokines, and tissue damage liberates a variety of products that could result in lung injury. Although the number of blood transfusions administered seems to correlate with the development of ARDS, the requirement for transfusions is usually closely tied to the severity of trauma. Any patient, however, who receives blood products has a risk of lung injury owing to transfusion-related acute lung injury (TRALI). While other mechanisms are present, TRALI is primarily thought to be mediated by antibodies in donor plasma reacting with recipient leukocytes. Blood products from multiparous donors have an increased risk of causing TRALI.

4. RISK MODIFIERS—Cigarette smoking is associated with increased likelihood of permeability pulmonary edema and alveolar hemorrhage. With similar acute risk for ARDS, a higher proportion of chronic alcoholics will develop ARDS. Although risk balancing is difficult, elderly patients seem to be at somewhat higher risk of developing ARDS, and outcome has been reported to be poorer. Some studies have shown that ARDS mortality is higher in men.

B. Symptoms and Signs—Patients have severe dyspnea and respiratory distress. Findings include features of hypoxemia, such as cyanosis, tachycardia, and tachypnea, but rales and wheezes are the only features on chest examination, and these are often surprisingly mild. Although the lungs are filled with fluid, sputum production is rare, except in those with bacterial pneumonia. Evidence of the underlying problem leading to ARDS may be found, including fever, hypotension, trauma, or findings of organ-system dysfunction. Features of congestive heart failure are notably absent. Early in ARDS, symptoms and signs are limited to the lungs. If multiple-organ-system failure develops, then features of hepatic, renal, or CNS failure may become evident.

C. Laboratory Findings—A key feature of ARDS is refractory hypoxemia. PaO_2 is severely reduced even when the patient is given supplemental oxygen. Even 100% O_2 may not raise PaO_2 above 60–100 mm Hg. Arterial pH may be high, normal, or low depending on the success of the patient in maintaining PaCO_2 with severe lung disease and the presence of hypotension and metabolic acidosis.

Other laboratory findings reflect the clinical condition leading to ARDS and the multiple-organ-system dysfunction seen as a consequence of this disorder. Renal and hepatic failure and electrolyte disturbances are frequent complications.

D. Imaging Studies—At disease onset, the chest x-ray shows diffuse bilateral infiltrates consistent with pulmonary edema. The infiltrates range from patchy reticular to dense consolidation. Unless there is coexisting heart disease, cardiomegaly

is absent, and there is a lack of the central perihilar prominence of edema seen in congestive heart failure. In fact, some have pointed out that ARDS is associated with predominantly peripheral distribution of infiltrates. Nevertheless, distinguishing cardiogenic from noncardiogenic pulmonary edema is never perfect. In patients with severe pneumonia leading to ARDS, there may be focal densities in addition to diffuse pulmonary edema. In later stages of ARDS, the original dense opacification may change to a pattern of reticular densities consistent with the proliferative and fibrotic stages of lung injury. While chest x-rays usually suggest diffuse involvement, marked nonhomogeneity of lung involvement is seen on chest CT scans. Chest x-rays are essential in monitoring patients for complications of ARDS, including barotrauma. Early evidence of air leaking into the lung interstitium sometimes may be found as linear low-density streaks of air surrounding bronchovascular bundles. Occasionally, this finding is seen as a rounded lucent area surrounding a pulmonary artery and bronchus. Air subsequently may track inward to the mediastinum (pneumomediastinum) or into the pleural space (pneumothorax).

Differential Diagnosis

Cardiogenic pulmonary edema is the most important disorder to be distinguished from ARDS (Table 12–19) because treatment is often different. This may be particularly difficult when ARDS is seen in conjunction with fluid overload or concomitantly with congestive heart failure. Septic shock may confound this distinction because circulating endotoxin or cytokines may exert myocardial depressant activity.

Table 12–19. Distinguishing cardiogenic from noncardiogenic pulmonary edema.

Cardiogenic	Noncardiogenic (ARDS)
Prior history of heart disease	Absence of heart disease
Third heart sound	No third heart sound
Cardiomegaly	Normal-sized heart
Central distribution of infiltrates	Peripheral distribution of infiltrates
Widening of vascular pedicle (increased width of mediastinum at level of azygos vein)	Normal width of vascular pedicle
Elevated pulmonary artery wedge pressure	Normal or low pulmonary artery wedge pressure
Positive fluid balance	Negative fluid balance

Treatment

Treatment of ARDS centers on management of severe hypoxemia, correction of the underlying disease that led to ARDS, and supportive care to prevent complications. Four major treatment principles have evolved. First, almost all types of therapy shown to benefit patients with ARDS—including oxygen, PEEP, and positive-pressure ventilation—have potentially severe adverse effects. Second, although ARDS is often considered primarily respiratory failure, multiple nonpulmonary organ-system failure and infection are the major causes of death in ARDS. Third, careful management of mechanical ventilation, especially tidal volume, is associated with fewer complications and is the only treatment demonstrated to improve survival. Finally, prognosis is especially poor if the underlying process is not identified or is poorly treated.

A. Oxygen—Treatment of hypoxemia in ARDS is begun almost always using 100% oxygen ($FiO_2 = 1.0$), and the concentration of O_2 is reduced with the goal of maintaining a PaO_2 greater than 60 mm Hg (arterial O_2 saturation about 90%). PaO_2 increases only slightly with administration of increasing concentrations of inspired oxygen (refractory hypoxemia), even when 100% O_2 is given, indicating right-to-left shunt or severe \dot{V}/\dot{Q} mismatching. A very few patients can be managed using a nonrebreathing oxygen mask, but most patients will be given oxygen via mechanical ventilation because they are unable to tolerate the increased work of breathing without mechanical support. The typical response to administration of O_2 in ARDS is shown in Figure 12–7, and examining the changes in venous admixture as O_2 and other therapy are given can be helpful. The FiO_2 should be lowered as soon as possible to less than 0.5 to reduce the risk of lung damage from oxygen toxicity. In most patients, lowering FiO_2 is helped by using PEEP or other mechanical ventilation methods to improve lung gas exchange. Because both PEEP and high FiO_2 both have the potential for complications, a compromise between high FiO_2 and high PEEP often must be chosen.

B. Positive End-Expiratory Pressure—PEEP includes both positive end-expiratory pressure provided with mechanical ventilation and continuous positive airway pressure (CPAP) given to spontaneously breathing patients. During exhalation without PEEP, alveolar pressure is higher than atmospheric pressure, providing a pressure gradient, until equilibrium is reached. When PEEP is applied, a pneumatic valve terminates exhalation when the pressure in the system decreases to a value set by the clinician. This PEEP is termed *extrinsic PEEP*. The effective PEEP is the sum of extrinsic and intrinsic PEEP (PEEPi).

1. MECHANISM—The mechanism of action of PEEP is not known, but PEEP probably works by counteracting the tendency of alveoli to collapse in the face of pulmonary edema, low lung volume, and loss of surfactant. Current understanding of ARDS suggests that a majority of lung (although highly

variable) is completely atelectatic, whereas smaller proportions are normally aerated or partially collapsed. PEEP “recruits” some proportion of partially collapsed areas, improving of gas exchange to these areas of low \dot{V}/\dot{Q} matching. PEEP does not decrease the rate of pulmonary edema formation nor speed the rate of water reabsorption. It is also unlikely that PEEP is able to open completely collapsed alveoli. Some investigators have found that PEEP may affect the distribution of pulmonary artery blood flow away from poorly ventilated areas and toward better-ventilated regions, resulting in improved arterial oxygenation. Finally, some studies have indicated that PEEP may have a beneficial effect on the amount or nature of lung injury.

If partially collapsed alveoli are recruited by PEEP to participate in gas exchange, each tidal volume will be delivered into a larger number of lung units. Lung compliance should increase as PEEP is added, and the increase in compliance should parallel improvement in arterial oxygenation (see Figure 12–8). On the other hand, if PEEP simply distended alveoli that are already participating in tidal gas exchange, then lung compliance would remain constant or, if the lung units become overdistended, lung compliance would decrease. An upward shift in the position of the pressure-volume curve indicates recruitment of lung units; movement along the original pressure-volume curve suggests that no recruitment occurred and that gas exchange will not be improved.

2. PEEP AND THE PV CURVE—In patients with early acute-phase ARDS, the pressure-volume curve (Figure 12–9) is flat at lung volumes near the end-expiratory volume. In this region, compliance is abnormally low. As airway pressure is raised—for example, during a tidal volume breath given with positive-pressure ventilation—many patients will demonstrate a region of steeper slope or higher compliance. In theory, this region of higher compliance can only be explained by recruitment of additional lung units. These units must have been completely collapsed previously, but open when the airway pressure exceeds the units’ critical opening pressures. The changeover point between low-compliance and higher-compliance regions on the PV curve has been called the *lower inflection point*. In theory, PEEP should be set just above the lower inflection point to indicate recruitment.

Some investigators also have recommended giving sufficient PEEP to prevent the patient breathing in the region crossing the lower inflection point. At lung volumes near the end-expiratory volume, alveoli are highly prone to collapse. As the tidal volume is administered, alveoli are repeatedly exposed to large shear stress as they change from completely closed to completely open. This may lead to damage in the small airways and bronchioles leading to the atelectatic lung units. Lung injury may be moderated if sufficient PEEP is given to raise the end-expiratory lung volume high enough to prevent cyclic lung unit collapse (above the lower inflection point).

On the other hand, selecting an optimal PEEP value using the lower inflection point remains controversial for several reasons. First, some patients with ARDS have PV curves that

▲ Figure 12-9. Hypothetical PV curves shown for normal individuals and ARDS patients. Regions on the ARDS PV curve include (1) a region of low compliance at low lung volume—with a lower inflection point; (2) a region with a steeper slope showing higher compliance—with an upper inflection point; and (3) a region with a flatter slope (poorly compliant). In theory, PEEP might be chosen to be above the lower inflection point to maximize recruitment and minimize shear stress on the lungs. Tidal volume should be adjusted to stay within region (2) to avoid overdistention. This concept has been challenged because of evidence that recruitment occurs throughout the PV curve and is not restricted to the area around the lower inflection point. See text.

have no inflection point and no region of increasing compliance. This has been associated with later stages of ARDS during which lung units are poorly or not recruited even at higher lung volume, and improvement of PaO_2 in response to PEEP is generally poor. Second, some ARDS patients whose respiratory PV curves have been partitioned into lung and chest wall PV curves show no inflection point on the lung PV curve but only on the chest wall PV curve. This finding challenges the singular notion of lung recruitment with PEEP. Next, the lower inflection point in ARDS patients may be as high as 15–18 cm H_2O , or considerably higher than many clinicians believe is necessary. It is likely that a more modest level of PEEP in conjunction with a low-tidal-volume strategy will have the most physiologic and clinical benefit. Finally, some workers have not found that the linear segment of the PV curve is associated with constant increase in compliance, implying that the lower inflection point is not sharply defined.

3. ADVERSE EFFECTS—Adverse effects of PEEP include reduced cardiac output that, in turn, decreases systemic oxygen delivery. There have been several postulated mechanisms of decreased cardiac output from PEEP, including, among others, (1) decreased systemic venous return, (2) impaired ventricular performance, (3) increased pulmonary vascular resistance, and (4) decreased left ventricular compliance. It is important to distinguish between decreased cardiac output and decreased cardiac function, however, because positive-pressure ventilation and PEEP can support ventricular function, especially in severe pump failure and cardiogenic shock. Decreased cardiac output lowers systemic oxygen delivery, the product of cardiac output and arterial oxygen content.

PEEP has been associated with barotrauma, including pneumothorax and lung injury, and with exacerbation of pulmonary edema, interstitial fibrosis, and inflammation. Debate continues about whether the underlying lung disease that led to the use of PEEP contributes to barotrauma or whether barotrauma is solely related to PEEP. It is clear that the degree of lung distention rather than the level of PEEP or airway pressure is the important variable. In animal studies, high end-inspiratory lung volumes were reached using either low PEEP and high tidal volume or high PEEP and low tidal volume. Both groups showed evidence of barotrauma. The relationship of PEEP to barotrauma is clearly linked to tidal volume, and the low-tidal-volume strategy will influence the incidence of lung injury from PEEP.

Patients in whom PEEP is poorly tolerated have hypotension, tachycardia, and decreased cardiac output as the earliest manifestations. Hemodynamic intolerance may be signs of volume depletion, severe pulmonary hypertension, or ventricular dysfunction. A pulmonary artery catheter may be helpful, and volume expansion or vasopressor drugs may be necessary. In other patients, PEEP may improve PaO_2 only slightly, suggesting that they have few recruitable lung units. PEEP is generally contraindicated in very asymmetric or localized lung disease with hypoxemia.

PEEP may paradoxically worsen PaO_2 in ARDS patients with a patent foramen ovale. In 39 patients with ARDS given PEEP of 10 cm H_2O , mean P(A-a)O_2 improved, and only 7 patients had an increase in shunt fraction, but in 7 patients with patent foramen ovale, 6 had an increase in shunt fraction and little or no reduction in P(A-a)O_2 . Failure to improve oxygenation with PEEP was likely due to increased right-to-left shunting of blood through the foramen ovale, owing to an increase in pulmonary vascular resistance mediated by PEEP.

4. APPLICATION OF PEEP—In patients with ARDS, many clinicians prefer to give oxygen at FiO_2 1.0 initially and then to decrease FiO_2 as long as adequate PaO_2 and O_2 saturation are maintained. To do this, PEEP is titrated upward starting at 5 cm H_2O . One strategy is to use the lowest predetermined combination of PEEP and FiO_2 (Table 12-20), with a clear target for PaO_2 and O_2 saturation. Higher PEEP levels have

Table 12–20. Lower tidal volume strategy for ARDS.

Step 1: Calculate predicted body weight (PBW) in kg.	$0.91 \times (\text{height, cm} - 152.4) + 50$ (for men) or 45.5 (for women).			
Step 2: Set ventilatory mode (volume-cycled assist/control) and tidal volume.	a. Initial tidal volume = 6 mL/kg PBW (if already set higher, then lower 1 mL/kg/h). b. Measure inspiratory plateau pressure (Pplat) with 0.5 s pause every 4 hours and after every change in PEEP or tidal volume. c. Adjust tidal volume based on inspiratory plateau pressure. If Plat >30 cm H ₂ O, decrease tidal volume to 4–5 mL/kg. If Pplat <25 cm H ₂ O and tidal volume <6 mL/kg, increase tidal volume by 1 mL/kg.			
Step 3: Adjust respiratory rate.	a. Initial respiratory rate to maintain same minute ventilation. b. Adjust to keep pH 7.30–7.45. c. Do not exceed rate >35/min or increase rate if PaCO ₂ <25 mm Hg.			
Step 4: Adjust FiO ₂ and PEEP (cm H ₂ O) to maintain Pao ₂ 55–80 mm Hg using only these combinations. Minimize both FiO ₂ and PEEP.	FiO ₂	PEEP	FiO ₂	PEEP
	0.3–0.4	5	0.7	10, 12, 14
	0.4	8	0.8	14
	0.5	8, 10	0.9	16, 18
	0.6	10	1.0	18, 20, 22, 24
Step 5: Manage acidosis or alkalosis as needed.	pH <7.30, increase rate (see Step 3) pH <7.30 and rate = 35, consider bicarbonate administration pH <7.15, consider increase in tidal volume (even if limited in Step 2) pH >7.45 and no patient triggering, decrease rate (keep >6/min)			

Modified from The Acute Respiratory Distress Syndrome Network. Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. *N Engl J Med* 2000;342:1301–8.

not shown benefit, although studies of high versus low PEEP have shown variable results. As described earlier, to avoid the lowest lung volume range at which additional stress-induced lung injury may occur, a minimum PEEP of 5 cm H₂O probably should be given, but the minimum PEEP defined by the lower inflection point may be substantially higher in some patients. Recently, it has been suggested that the level of PEEP could best be set by measuring the percentage of recruitable lung. This avoids excessive PEEP in “nonrecruitable” patients but requires CT scanning of the lungs while inflated to different pressures.

PEEP should be adjusted incrementally, with close monitoring of respiratory mechanics (especially inspiratory plateau pressure), arterial blood gases, and hemodynamic variables. An initial PEEP of 5 cm H₂O is almost always well tolerated, but blood pressure, heart rate, and pulse oximetry should be checked immediately before and after the addition. If the patient is stable, allow 10–20 minutes before arterial blood gases and cardiac output are determined. If desired goals are not met, PEEP is increased using selected combinations of PEEP and oxygen concentration. In some patients, changes in PaO₂ may not occur until several hours after PEEP is changed. These patients cannot be easily identified, but clinicians should be aware that changes in blood gases and hemodynamics may occur both immediately and long after a change is made in PEEP.

The goal of PEEP is to facilitate oxygen transfer across the lungs without impairing systemic oxygen delivery. In most patients, this is achieved by using the lowest PEEP consistent with adequate arterial O₂ saturation (>90%). For some time, the concept of “best PEEP” has been promoted, variously described as the PEEP level applied to an individual patient with ARDS that results in the best balance between tissue oxygenation and adverse effects. Most now agree that the optimal PEEP is the least that achieves predetermined objectives of patient management rather than some theoretically ideal value. Thus PEEP should be titrated until PaO₂, arterial oxygen content, and oxygen delivery increase to acceptable levels as long as adverse effects are minimized. In practice, most clinicians prefer PEEP levels between 5 and 12 cm H₂O and rarely exceed this range because of fear of barotrauma and decreased cardiac output. Although respiratory system PV curves can be determined, most clinicians adjust PEEP using a combination of response of arterial blood gases, hypothetical maximum and minimum PEEP values, and hemodynamic response.

C. Mechanical Ventilation

1. LOW-TIDAL-VOLUME STRATEGY—The most important development in the management of ARDS is that mechanical ventilation with lower tidal volume than previously used is associated with improved clinical outcome. This

has been termed a *low-tidal-volume* or *lung-protective strategy*. In animals, overdistention of lung regions causes increased epithelial permeability and a histologic picture of diffuse alveolar damage. In a multicenter study of ARDS, mortality decreased from 39% (12 mL/kg of predicted body weight) to 31% in a group whose tidal volume was set at 6 mL/kg of predicted body weight. Even smaller tidal volumes were used if inspiratory plateau pressure remained greater than 30 cm H₂O. A protocol for adjusting the mechanical ventilation using a low-tidal-volume strategy is summarized in Table 12–20. Reducing tidal volume is associated with little or no change in the dead space:tidal volume ratio and may result in improved O₂ delivery. Because lung injury is associated with excessive inspiratory lung volume, higher levels of PEEP may be safer if tidal volume is limited. Studies have shown little or no adverse effects of low tidal volume as long as PEEP is given, but PaCO₂ may increase as minute ventilation is decreased with the lower tidal volume. Low-tidal-volume ventilation with elevated PaCO₂ has been termed *permissive hypercapnia*. Acute respiratory acidosis with permissive hypercapnia

was surprisingly well tolerated in several clinical trials. However, there may be more subtle effects of respiratory acidosis on nonpulmonary system function, including renal and neurologic, that are not yet appreciated.

There is not yet agreement on the mechanism of improved clinical outcome with a low-tidal-volume strategy. No differences in pneumothorax (explosive barotrauma) are reported, but there have been small differences in the rate of nonpulmonary organ dysfunction. An attractive hypothesis is that ALI is worsened by lung overdistention, and low tidal volume moderates this “ventilator-associated lung injury.” For example, the levels of a variety of proinflammatory cytokines in blood and alveolar fluid are lower in ARDS patients treated with low tidal volumes. It is likely that the severe regional heterogeneity of lung involvement is important because overdistention would predominate in the most compliant portions of the lungs (Figure 12–10).

Interestingly, there are data supporting the hypothesis that a tidal volume of 6 mL/kg designed to reach a target of a plateau pressure of less than 30 cm H₂O may not be the final answer. Data suggest that outcome appears to continue to

▲ Figure 12–10. Schematic illustrating heterogeneity of lung injury in ARDS and effect on respiratory system compliance for the same tidal volume (ΔV) in all three examples. **A.** Normal lungs with uniformly normal compliance. A representative PV curve is shown with a small ΔP change as the tidal volume is delivered (ΔV). **B.** Uniformly decreased compliance of the lungs. The flatter slope of the PV curve results in a larger ΔP required to deliver the same tidal volume (ΔV). **C.** ARDS is now recognized to have nonuniform lung involvement, and the decreased respiratory system compliance arises from collapse of the majority of lung units and overdistention of remaining normal units. The same tidal volume is delivered to a smaller region of normal lung so that ΔP is large for the same ΔV . The overall compliance shown in **C** ($\Delta V / \Delta P$) is the same as in **B**.

improve as tidal volume or targeted plateau pressure decreases. This likely would mean that some patients would benefit from a tidal volume of less than 6 mL/kg, although not all would require this. Further randomized trials are needed.

2. VOLUME-PRESET VENTILATION—Most ARDS patients are ventilated using conventional volume-preset (volume-cycled) positive-pressure ventilators. The major studies using low tidal volume for ARDS used this mode. Initial tidal volume is set at 6 mL/kg of ideal body weight, and peak inspiratory flow rate is generally at least 1–1.2 L/s owing to the high demand for inspiratory flow. Adjustments in tidal volume depend on the level of the inspiratory plateau pressure (P_{plat}), as shown in Table 12–20. PEEP is given as necessary for refractory hypoxemia and in order to lower the FIO_2 using a set of predetermined values for each variable.

Volume-preset ventilation using a high peak flow and a descending inspiratory flow pattern may have characteristics similar to those of pressure-controlled ventilation (PCV). In theory, these settings may improve distribution of ventilation to poorly ventilated lung regions, improving hypoxemia with smaller increases in PEEP or FIO_2 .

3. PRESSURE-CONTROLLED VENTILATION—Pressure-controlled ventilation (PCV) might seem like a very attractive option in the management of ARDS, largely because a preset maximum positive airway pressure cannot be exceeded. However, this feature does not automatically provide the same benefit as a low-tidal-volume strategy unless the maximum pressure is adjusted to also limit tidal volume. On the other hand, PCV does have the theoretical advantage of providing maximum inspiratory flow at the beginning of the inspired breath. In some patients, distribution of ventilation may be enhanced, especially to the most poorly ventilated lung regions.

A few studies have shown that PCV compared with conventional volume-preset ventilation results in increased PaO_2 , decreased mean and peak airway pressures, and less impairment of cardiac output. Other studies have shown no appreciable differences. Careful adjustment of inspiratory time is needed to optimize tidal volume and minute ventilation. PCV with pressure limited to 30–40 cm H_2O might be considered in ARDS patients with severe hypoxemia unresponsive to PEEP with conventional volume-preset ventilation or in those who require excessively high airway pressures or PEEP with conventional ventilation.

Similarly, airway pressure-release ventilation (APRV; see above) has some attractive features for ventilatory support in ARDS. Lung recruitment might be improved because of the higher mean airway pressure, and there may be reduced stress-relaxation lung injury. No studies, however, have demonstrated improved outcome in ARDS with APRV compared with more conventional modes. For refractory hypoxemia, a trial of APRV might be useful and could be used in comparison to IRV, prone ventilation, and maximum-lung-recruitment strategies.

4. INVERSE-RATIO VENTILATION—In ARDS patients with refractory hypoxemia, inverse-ratio ventilation (IRV) has been used. In contrast to conventional ventilation, inspiratory time is made longer than expiratory time by decreasing the inspiratory flow rate, holding inspiration for a preset time before allowing for exhalation, or, if a time-cycled ventilator is used, directly increasing inspiratory time. How IRV might improve oxygenation is not clear. Inspired gas may be distributed more evenly because of the longer inspiratory time. The shortened expiratory time, on the other hand, may cause dynamic hyperinflation, raising end-expiratory volume and improving gas exchange in a manner similar to intrinsic PEEP.

There have been no controlled clinical trials demonstrating improved outcome with IRV. This method should be reserved for the rare patient with refractory hypoxemia unresponsive to PEEP and oxygen therapy. Current understanding of IRV suggests that there is nothing intrinsically different about a I:E ratio greater than 1:1. Rather, the gas-exchange effects of I:E ratio vary continually.

When initiated, an I:E ratio of 1:1 should be tried, and blood pressure, heart rate, and pulse oximetry should be monitored closely. If needed, I:E ratio can be further altered to 1.5:1, 2:1, or more. It is unusual for I:E ratios of greater than 3:1 or 4:1 to improve gas exchange.

Increased time spent during inspiration and dynamic hyperinflation can cause severely reduced cardiac output and hypotension. Prolonged inspiratory time may be very uncomfortable to the patient, and sedation or muscle relaxants are always needed. Monitoring of IRV is complex because I:E ratio, peak airway pressure, and PEEP do not adequately reflect all the essential parameters and because the pattern of inspiratory pressure and flow in IRV differs depending on how IRV is produced. Monitoring mean airway pressure has been suggested, but this value does not correlate with gas exchange or hemodynamic compromise in IRV.

5. OTHER MODES OF MECHANICAL VENTILATION—Lung-protective strategies are the basis for several other modes of mechanical ventilation. Carrying low tidal volume to extreme is extracorporeal membrane oxygenation and CO_2 removal, in which the lungs receive no ventilation at all. Clinical trials have been unable to demonstrate improved clinical outcomes from this practice. High-frequency oscillation has been used for more than 20 years. With this method, very small tidal volumes (1–2 mL/kg or less) at respiratory rates as high as several hundred per minute are administered by an oscillating membrane. High-frequency oscillation has been successful in neonatal respiratory distress, but scaling up to larger patients has not been uniformly feasible. Gas exchange often can be maintained or improved, but no difference in clinical outcome has been demonstrated. Another lung-protective method is tracheal gas insufflation, in which a 4–6 L/min flow of fresh gas is provided into a small catheter placed in the lower trachea. The effect is to reduce the apparent

dead space and achieve improved gas exchange with lower tidal volume and pressure. As such, it may be an adjunct to low-tidal-volume methods.

A more radical method of ventilation is partial liquid ventilation (PLV), in which the lungs are filled with a perfluorocarbon, a substance in which oxygen is highly soluble. Conventional volume-preset ventilation is used, but gas movement through the lungs is almost entirely by diffusion. PLV has the potential advantages of overcoming loss of surfactant, recruiting lung units without increased airway pressure, and avoiding further lung injury. Multiple randomized trials of PLV have failed to show improved outcome.

D. Supportive Care—Patients with ARDS often require prolonged mechanical ventilation and long duration of stay in the ICU, putting them at risk for complications of ICU monitoring and therapy, infection, and prolonged bed rest. Attention must be paid to maintaining nutrition, preventing deep venous thrombosis and GI bleeding, and preventing other complications. However, recognizing that deaths in patients with ARDS often result from infection and nonrespiratory system failure, supportive care focuses especially on minimizing cardiovascular compromise and preventing infection.

E. Treatment and Prevention of Infection—Infection is a major prognostic factor in ARDS, either as the primary cause of ARDS or secondarily as a cause of death. In one study, the mortality rate was 78% in patients who developed ARDS during bacteremia and 60% in those who develop nosocomial pneumonia. In another study, infection was absent in two-thirds of survivors but present in two-thirds of nonsurvivors. The major infection sites were the lungs or pleura, the abdomen, soft tissues, and other locations, and about 5% had multiple sites of infection. Gram-negative bacilli made up 57% of 177 isolates causing infection in ARDS in one series, whereas gram-positive cocci were found in 36% and other organisms in 7%. Among pneumonias, gram-negative organisms were found in 58% and were related to endotracheal intubation and prolonged need for ventilatory support. The finding of gram-negative pathogens in ARDS patients with pneumonia assumes particular importance because those patients had only a 12% survival rate despite appropriate in vitro sensitivity of bacteria to administered antibiotics, whereas patients with ARDS associated with gram-negative bacillary abdominal infections had a 59% survival rate.

Sepsis or severe pneumonia should be suspected as the cause of ARDS in all patients unless a highly likely alternative is present. A primary infection site may be easily identified, but in doubtful cases, occult lung and abdominal sources must be investigated. Antibiotics should be selected on the basis of clinical findings and epidemiologic data. Some important considerations include the likelihood of gram-negative bacilli, staphylococci, and candidemia in hospitalized

patients; previous antibiotic use; the possibility of infection with anaerobic organisms; immunologic competence of the patient; gastric antacid administration; and other host and local ICU factors. Ventilator-associated pneumonia is a common complication of ARDS with prolonged mechanical ventilation. The diagnosis is difficult to confirm, but new or changing infiltrates, fever, purulent sputum, and worsening gas exchange are usually to make the diagnosis.

F. Pharmacologic Therapy—There are at present no established pharmacologic therapies for ARDS. Many studies have attempted to intervene in the early stages of ALI by interruption of cytokine pathways (eg, antagonists and receptor antagonists), inhibition of endotoxin (eg, monoclonal antibodies), reduction of nonspecific inflammation (eg, corticosteroids and prostaglandin and leukotriene inhibitors), and prevention of oxidant damage (eg, antioxidants such as acetylcysteine, vitamin C, and superoxide dismutase). None has proved to be successful.

Nitric oxide is a potent endogenous vasodilator. When given by inhalation in low concentration, it selectively dilates pulmonary vessels in well-ventilated regions of the lung, and it is rapidly inactivated before reaching the systemic circulation. Clinical trials have shown improvement in gas exchange probably because of improved distribution of pulmonary perfusion. No large study has concluded that nitric oxide improves clinical outcome.

Diuretics such as furosemide should be given to ARDS patients who show evidence of volume overload and are judged to have adequate systemic intravascular volume. Diuretics should be used judiciously to avoid volume depletion and compromise of right and left ventricular filling. ARDS patients often have increased airway resistance, so inhaled β -adrenergic agonists may be helpful as bronchodilators. These drugs also stimulate sodium and water transport by alveolar epithelial cells, perhaps helping to resolve pulmonary edema.

Corticosteroids have been attractive in ARDS because of potential roles for cytokine- and inflammation-mediated lung injury, and these drugs are potent anti-inflammatory agents. However, a large study found no difference in overall mortality despite some improvement in gas exchange in patients with ARDS for at least 7 days given large doses of corticosteroids. The role of nonsteroidal anti-inflammatory drugs, antioxidants, and other drugs such as ketoconazole and pentoxifylline remains unclear despite small studies showing potential benefit. Synthetic surfactants of different types and components have been the subject of several studies in ARDS. In most, gas exchange improves, at least transiently, but survival is not improved.

Prognosis

In the first description of the syndrome of ARDS, 12 patients were described, of whom 7 died. Despite improvement in care, the mortality rate has changed only slightly. Nevertheless, recent studies have been encouraging. In one

study from Seattle, mortality was 50–60% in the mid-1980s but fell to 30–40% in the late 1990s. The large National Institutes of Health (NIH)–sponsored trial using low tidal volumes reported mortality of 30–40%.

A. Respiratory Failure and Outcome—Previously, patients with ARDS often died early in the course of the disease from intractable hypoxemic respiratory failure. Hypoxemia could not be corrected adequately by administration of high concentrations of oxygen, and survival was often less than 3 days after onset. Accordingly, treatment focused on reversing hypoxemia with positive end-expiratory pressure, changes in ventilator management, and extracorporeal membrane oxygenation. Despite significantly improved hypoxemia, these measures have had little or no effect on outcome. One retrospective study found that unmatched patients who did not receive PEEP had no higher mortality than those who were given PEEP, although the PEEP group died later in their course. Other studies indicate that the severity of respiratory failure at the onset of ARDS correlates poorly with mortality rate. In another analysis, the number of neutrophils and lack of acidosis were associated with survival, whereas the severity of respiratory failure and lung mechanics, response to PEEP, wedge pressure, blood pressure, and cardiac output were not predictive. On the other hand, a few studies do find a correlation between outcome and severity of respiratory failure, but more closely with initial response to therapy. That is, those patients who have a marked improvement in oxygenation with initial therapy (oxygen and PEEP) at 24 hours do significantly better than those with a poorer response. More recently, high dead space:tidal volume ratio has been shown to correlate with poor outcome in ARDS.

B. Nonrespiratory Organ Failure and Outcome—In one study, death associated with ARDS was due to irreversible respiratory failure in only 16%, and most of these died in the first 3 days. In contrast, of the deaths in this series, most were due to sepsis, with others resulting from cardiac, CNS, and hepatic failure. In another study, multiple-organ-system dysfunction was found in almost all patients with sepsis and ARDS but much less frequently in those with ARDS who showed no evidence of infection. The kidneys were the most commonly affected nonpulmonary organ in ARDS, with renal failure developing and contributing to morbidity and mortality data in 30–50%. In a European multicenter report, the overall ARDS mortality rate was 59%, but death occurred in 38% of cases of ARDS following trauma and 68% of those with intraabdominal sepsis. Probably because of decreased organ-system reserve, patients over age 70 in this report had a mortality rate of 82%. A study of the importance of multiple-organ-system failure in ARDS found that nonsurvivors had more severe thrombocytopenia than survivors, as well as lower blood pH, more liver dysfunction, and higher plasma creatinine concentrations.

Current Controversies and Unresolved Issues

A. Fluid Management—Whether intravascular volume should be reduced in ARDS remains a controversial issue. Because of increased lung permeability, pulmonary edema is maintained at pulmonary capillary hydrostatic pressures that are normal or low. It is argued that resolution of pulmonary edema would be facilitated by lowering microvascular hydrostatic pressure with diuretics and fluid restriction. On the other hand, there is concern about oxygen delivery to the tissues in the face of intravascular volume depletion. Positive-pressure ventilation and PEEP reduce cardiac output and oxygen delivery, and cardiac output is maintained by ensuring adequate intravascular fluid volume. Sepsis and shock, major factors in ARDS, often require massive fluid administration because of hypotension and decreased tissue perfusion. These factors suggest that volume expansion may be needed and that diuretics and negative fluid balance should be avoided.

Retrospective evidence indicates that net negative fluid balance is desirable in ARDS. Reduction of pulmonary microvascular pressure decreases lung water despite severe lung injury, and cumulative net negative fluid balance and weight loss are significantly higher in survivors compared with nonsurvivors of ARDS. These trials have the problem of self-selecting patients with better prognoses, but they nonetheless suggest that fluid balance may be an important determinant of outcome. In one study, better survival in ARDS was found in those who had at least a 25% reduction in pulmonary capillary wedge pressure compared with those who did not. Survivors of ARDS had lower wedge pressures and body weights compared with nonsurvivors, and the mean number of days of mechanical ventilation and days of ICU care were less in those who gained less than 1 L of fluid over the first 36 hours. There was no detrimental effect on nonpulmonary organ system function despite low fluid intake.

Two prospective studies shed light on this problem. In one, a more “conservative” strategy of fluid replacement was compared with a more liberal one. Using central venous pressure (CVP) or pulmonary artery wedge pressure (PAWP) for guidance, as well as urine output and mean arterial pressure, ALI patients were managed according to protocols. Over the first 7 days, there was a very small negative cumulative fluid balance for the conservative protocol; the liberal protocol resulted in a mean positive fluid balance of nearly 7000 mL. There was no difference in 60-day mortality, but the conservative strategy resulted in shorter duration of mechanical ventilation and duration of ICU stay. There were no additional complications.

In the other study, randomization of ALI patients to insertion and use of a pulmonary artery catheter or central venous catheter showed no difference in 60-day survival or organ dysfunction. There were more arrhythmias seen with the pulmonary artery catheter, but no differences in incidence of renal failure or use of vasopressors, diuretics, or dialysis.

B. Periodic Lung Recruitment—The PV curve of the lungs, both in normal individuals and in those with ARDS, shows hysteresis, or a different curve during inflation and deflation. Because the inflation limb requires higher pressures at the same lung volume than the deflation limb, a relatively high transpulmonary pressure may be needed initially to “open” lung units. For subsequent breaths, the pressure needed for inflation is considerably smaller. This finding has led to the recommendation for periodic “recruitment maneuvers” superimposed on conventional ventilatory techniques.

One kind of recruitment maneuver consists of increasing airway pressure to 30–45 cm H₂O and holding pressure constant for 30 seconds or more while ventilator cycling is inhibited. This can be done by using the continuous positive airway pressure (CPAP) mode, with the patient heavily sedated or paralyzed. Successful recruitment is marked by a subsequent increase in lung compliance (lower inspiratory plateau pressure at the same tidal volume) and lower oxygen requirements. The frequency, magnitude, safety, and clinical benefit of aggressive lung recruitment are not established. These maneuvers might be considered in patients with refractory hypoxemia, but routine use is not supported by current evidence.

C. Prone Positioning—A number of investigators have advocated placing the ARDS patient into the prone position. Several studies have demonstrated improvement in PaO₂ in 50–75% of patients turned from supine to prone, with some patients having prolonged benefit. The mechanism of prone positioning appears to be the smaller volume of lung that is compressed by the abdominal contents and heart in the prone position and by more uniform lung ventilation. Hypoxemia is more likely to improve during early-stage ARDS with pulmonary edema than after significant fibrosis develops. Because the prone position may allow adequate gas exchange with lower values of PEEP, tidal volume, and FiO₂, this technique also might be considered a lung-protective strategy.

Recent studies vary the daily duration of prone positioning, use changes in PaCO₂ to predict benefit, and compare prone position with PEEP and recruitment maneuvers. While there is general agreement that PaO₂ increases, current evidence does not support a survival benefit.

D. Routine Use of PV Curves—PV curves have been recommended for determining optimal PEEP and tidal volume levels to avoid ventilator-associated lung injury. There is no doubt that careful PV curve analysis has been instrumental in enhancing our understanding of lung and chest wall mechanics in ARDS, but routine use is not practical for a combination of technical and clinical reasons. Of interest, some investigators have shown that current recommendations for minimal PEEP, optimal tidal volume, and target plateau pressure match very well with data derived from PV curves.

► Obstructive Sleep Apnea & Obesity-Hypoventilation Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Excessive daytime somnolence with evidence of upper airway obstruction during sleep (obstructive sleep apnea syndrome).
- ▶ Impaired ventilatory response to CO_2 and hypoxemia (obesity-hypoventilation syndrome).
- ▶ May have right-sided heart failure with cor pulmonale, hypertension, and left ventricular dysfunction.

General Considerations

The obstructive sleep apnea-hypopnea syndrome is a common condition affecting 5% of adult men and approximately half that number of women. This syndrome is closely associated with snoring and is characterized by repeated episodes of upper airway collapse during sleep with resulting acute hypercapnia, hypoxemia, sleep disruption, hemodynamic alterations, and impairment of daytime functioning. Severely affected individuals may develop respiratory failure and be admitted to the ICU with marked hypercapnia, polycythemia, altered mental status, and pulmonary hypertension with cor pulmonale. Alternatively, obstructive sleep apnea may be observed in ICU patients admitted for other indications (eg, unstable angina pectoris or cardiogenic pulmonary edema); in such cases, the recognition and treatment of the sleep-disordered breathing may be a critical component of the overall ICU therapy. It should be noted, however, that most patients with obstructive sleep apnea do not have daytime hypoventilation and therefore do not have respiratory failure in the usual sense.

A. Normal Breathing during Sleep—For the purpose of this chapter, sleep may be separated into two main types, rapid eye movement (REM) sleep and non-rapid eye movement (NREM) sleep, which differ considerably in their effects on breathing and on upper airway resistance. Although REM and NREM sleep stages alternate throughout the night, the majority of REM sleep is normally concentrated during the latter half of the sleep period.

In normal awake individuals, the control of breathing is influenced not only by chemical and mechanical stimuli but also by inputs from higher cortical centers. With the transition to sleep (usually light NREM sleep), volitional influences are lost, and in addition, the responsiveness of the central respiratory center to increasing PaCO_2 is blunted relative to the awake state. Upper airway caliber is also reduced owing to both gravitational effects related to the supine position and a decrease in the tonic activity of upper airway dilator muscles, which, during wakefulness, prevent inspiratory narrowing owing to negative intrairway pressures. The net

effects of these changes in ventilatory drive and airway caliber are a slight increase in inspiratory upper airway resistance and mild hypoventilation ($\text{PaCO}_2 = 42\text{--}44$ mm Hg at sea level) relative to the awake state.

During REM sleep, respirations are irregular, and ventilation appears to be, in part, under the control of behavioral processes activated during this dreaming state. Ventilatory responsiveness to chemical stimuli is markedly reduced, and there is a profound suppression of skeletal muscle tone, including the intercostal muscles and other accessory muscles of respiration, but excluding the diaphragm and extraocular muscles. Although brief central apneas and hypopneas can result in transient mild arterial oxygen desaturations, these are clinically unimportant in normal individuals.

B. Obstructive Sleep Apnea Syndrome—In contrast to mild narrowing of the upper airway found in normal persons, an exaggerated response is seen in obstructive sleep apnea syndrome, with episodic partial (hypopnea) or complete (apnea) obstruction of the upper airway during sleep. These events may last from 10–90 seconds and are terminated by an arousal from sleep, resulting in sleep fragmentation. The site of obstruction can occur at any point along the airway above the level of the glottis, and often more than one site is involved. A strong association of obstructive sleep apnea with obesity in men suggests that small upper airway caliber is an important predisposing factor, although obstructive sleep apnea is found in nonobese individuals as well. Other potential factors include adenotonsillar hypertrophy or other anatomic abnormalities, increased collapsibility of the upper airway, inflammation or edema of these structures, and abnormal neural reflexes. The degree of respiratory drive plays a role, as does the amount of nasal airway resistance; both these factors tend to increase the amount of intraluminal negative pressure and, thereby, the tendency to collapse the pharyngeal airway during inspiration.

Patients with obstructive sleep apnea syndrome tend to experience most of their problems during the wake-to-sleep transition (when ventilatory control is relatively unstable) and during REM sleep (when respiratory muscle hypotonia and chemical insensitivity combine to produce frequent and prolonged apneas). Because the threshold for arousal is relatively low during lighter NREM sleep (stages 1 and 2), patients with obstructive sleep apnea may alternate between these sleep stages and wakefulness throughout the entire night and never reach the more restorative deeper NREM stages 3 or 4. For similar reasons, REM sleep is also typically fragmented and reduced in quantity. While the severity of daytime sleepiness generally correlates with the frequency of obstructive breathing events, some patients may have minimal sleepiness despite severe disruption of breathing during sleep (defined as more than 30 apneas or hypopneas per hour).

Hemodynamic abnormalities during sleep are common in patients with obstructive sleep apnea. Hypoxemia and high levels of circulating catecholamines contribute to both increased systemic and pulmonary vascular resistance. Blood

pressure peaks immediately after an arousal occurs after an obstructive event, when a sudden increase in cardiac output meets these high vascular resistances. The markedly negative intrathoracic pressures during obstructed inspiratory efforts raise the transmural myocardial pressure, further increasing both right and left ventricular afterload. In addition to apnea-related fluctuations in blood pressure, obstructive sleep apnea increases the risk of daytime hypertension. This effect has been shown to be independent of obesity, age, and gender and is thought to be related to a “resetting” of the carotid baroreceptors as a result of repeated hypoxemia and repetitive bursts of catecholamines with each obstructive event that remodels vascular tone. Left ventricular hypertrophy is common in patients with obstructive sleep apnea, and left ventricular diastolic dysfunction (more often than systolic abnormalities) may result in cardiogenic pulmonary edema in these patients. Increased myocardial oxygen requirements combined with apnea-related hypoxemia can precipitate myocardial ischemia and present as nocturnal angina in patients with underlying coronary artery disease. Cardiac arrhythmias, including bradycardias and pauses up to 13 seconds during apneas and ventricular ectopy associated with severe desaturation, may be seen in the most severe cases.

Obstructive sleep apnea also has been strongly associated with coronary artery disease and stroke, although a direct causal relationship has yet to be definitively demonstrated. Suggested pathophysiologic mechanisms include the hemodynamic abnormalities described earlier, as well as increases in platelet activation and plasma fibrinogen that have been reported in patients with untreated obstructive sleep apnea.

C. Obesity-Hypoventilation Syndrome—Obesity-hypoventilation syndrome is an uncommon condition in which usually morbidly obese individuals develop hypercapnic respiratory failure from a combination of depressed response to CO_2 and hypoxia, increased work of breathing, and possibly abnormal heart and lung function. Obesity-hypoventilation syndrome has a variable relationship to obstructive sleep apnea perhaps because of the association of each with obesity, but most obesity-hypoventilation syndrome patients have some degree of obstructive sleep apnea. Obesity-hypoventilation patients have daytime hypercapnia and decreased responsiveness to hypercapnia, in contrast to the majority of obstructive sleep apnea patients, who, while awake, maintain normal PaCO_2 and have a normal ventilatory response to CO_2 . Patients with obesity-hypoventilation syndrome often have pulmonary hypertension leading to cor pulmonale.

Clinical Features

A. Symptoms and Signs—Patients with obstructive sleep apnea may complain of daytime hypersomnolence, a history of heavy snoring, awaking gasping for breath, and unrefreshing sleep. Bed partners, if available, often provide more reliable information and will describe repeated periods of apnea terminated by loud snorts and gasping. Systemic hypertension

is common. These patients may be seen occasionally in the ICU for severe nocturnal hypoxemia, arrhythmias, cardiac ischemia, heart failure, or altered mental status. Patients with obesity-hypoventilation syndrome often have severe right- and left-sided heart failure with dyspnea and pulmonary and peripheral edema.

On examination of the obstructive sleep apnea patient, periodic breathing may be noted during sleep. Unlike the Cheyne-Stokes breathing pattern seen in severe heart failure, however, the patient with obstructive sleep apnea will have little or no airflow despite the increasing respiratory efforts. After a time varying from seconds to minutes, the patient arouses, may awaken briefly, and opens the airway to the accompaniment of snoring and upper respiratory noises. During the apnea, the patient may demonstrate use of accessory muscles, intercostal retractions and paradoxical inspiratory chest wall movements, and movement of the neck toward the thoracic inlet during inspiratory maneuvers. These findings are characteristic of obstruction of the upper airway while respiratory efforts are being made. Pulsus paradoxus is not uncommon during apneic events.

Those with respiratory failure associated with obstructive sleep apnea or those with obesity-hypoventilation syndrome may have acute respiratory acidosis, which may be severe enough to cause lethargy or coma. Other patients may seek medical attention primarily for severe peripheral edema and massive weight gain because of right ventricular failure from pulmonary hypertension. Dyspnea or wheezing suggests a component of obstructive lung disease or pulmonary edema. Most, but not all, patients with severe sleep apnea will show evidence of daytime hypersomnolence.

B. Laboratory Findings—Most patients with obstructive sleep apnea have few abnormal laboratory findings when awake. Erythrocytosis is unusual in obstructive sleep apnea alone and suggests superimposed obesity-hypoventilation or other causes of sustained hypoxemia. In patients seen in the ICU who present with respiratory failure, hypercapnia and hypoxemia are seen. Chronic CO_2 retention leads to a compensatory elevation of plasma bicarbonate. Electrocardiography may show evidence of left-sided or biventricular hypertrophy, tachycardia or bradycardia in association with apneic events, and, rarely, ventricular ectopy. The chest x-ray may confirm cardiomegaly, pulmonary edema from left ventricular failure, or enlarged pulmonary arteries in patients with pulmonary hypertension. Patients with obesity-hypoventilation syndrome have abnormally low ventilatory response to CO_2 and hypoxia.

C. Confirmatory Testing—Traditionally, confirmation of obstructive sleep apnea has been made by polysomnography. Measurements made during sleep demonstrate episodic upper airway obstruction by showing periods of absence of airflow despite evidence of inspiratory effort. Arterial hypoxemia or O_2 desaturation proves that obstruction is causing significant gas-exchange abnormalities. In the sleep laboratory, the number, nature, severity, and duration of sleep-disordered breathing events (ie, apneas and hypopneas)

are carefully measured and counted. Other measurements include electroencephalography and electrocardiography. Portable cardiorespiratory recorders (four to six channels including, at a minimum, airflow, respiratory effort, saturation, and heart rate) are better suited for use in the ICU and generally provide the information needed to guide treatment. In some critically ill patients, diagnostic testing may not be feasible, and a presumptive diagnosis of obstructive sleep apnea may have to be made prior to confirmatory testing. In these patients, direct observation of the sleeping patient and pulse oximetry trends demonstrating an episodic (sawtooth) pattern of desaturations in the ICU can be used to initiate and titrate therapy.

Differential Diagnosis

Obstructive sleep apnea syndrome may coexist with other lung diseases. Both obstructive sleep apnea and COPD are common in men, and these diseases complicate each other. Severe cardiomyopathy and CNS disease may present with periodic breathing, dyspnea, and hypersomnolence. Obesity is associated with hypoxemia from atelectasis. Weight gain, edema, heart failure, and hypoventilation may be seen with hypoventilation. Thyroid function should be determined in all patients considered to have obesity-hypoventilation syndrome.

Treatment

A. Mild Obstructive Sleep Apnea—Patients with mild obstructive sleep apnea are unlikely to be seen in the ICU for this problem alone, but this syndrome is common and may be seen in those admitted with other diseases. In these patients, apneic episodes occur relatively infrequently during sleep onset and REM sleep, and daytime hypercapnia is not a problem. Treatment is directed at weight reduction, abstinence from alcohol and cigarette use, treatment of nasal disease (if present), and avoidance of a supine body position during sleep. Nocturnal nasal CPAP can be used if necessary. Additional treatment options include mouthpieces that displace the mandible anteriorly during sleep (thereby pulling the tongue away from the posterior pharyngeal wall), and rarely, pharyngeal surgery. Successful management should result in reduced daytime somnolence and improvement of such neuropsychiatric symptoms.

B. Severe Obstructive Sleep Apnea—Severe obstructive sleep apnea may require aggressive relief of nocturnal upper airway obstruction. Tracheostomy is very effective because of unequivocal reversal of upper airway obstruction, but this is very rarely required.

1. Nasal CPAP—Nasal continuous positive airway pressure (CPAP) has become the treatment of choice for this disorder. By providing positive pressure to the collapsible portion of the upper airway during sleep, nasal CPAP effectively prevents airway obstruction during inspiration.

Nasal CPAP is generally provided by a blower attached to flexible tubing leading to a small mask placed over the nose or small soft nasal prongs. A sufficient continuous flow of air is blown into the system, and via a controllable vent, continuous positive pressure of up to 20 cm H₂O can be maintained. The appropriate level of nasal CPAP is best determined during polysomnography; however, rough approximations may be made in the ICU by direct observation of the patient during sleep, with upward titration of pressure until apneas, snoring, and desaturations are eliminated. Newer “autotitrating” devices that adjust pressure based on the shape of the inspiratory flow profile also can help to identify optimal pressures. Most patients in whom it is tried, at least for the short term, tolerate nasal CPAP, but not all patients can be managed successfully in this way. For those unable to tolerate the required continuous pressures, bilevel nasal ventilation may be more comfortable and effective while allowing a high inspiratory and a lower expiratory pressure level.

Nasal CPAP has a variable role in patients with obstructive sleep apnea who present with respiratory failure to the ICU. In many, nasal CPAP is sufficient to restore and maintain upper airway patency and normalize gas exchange during sleep. These patients probably have only mild respiratory center depression from hypoxemia and hypercapnia. Some patients are improved by the combination of nasal CPAP and oxygen. On the other hand, some obstructive sleep apnea patients with respiratory failure have little immediate response to nasal CPAP, which suggests that upper airway obstruction is no longer the only factor. In these patients, nasal CPAP can be tried, but if satisfactory results are not obtained quickly, more definitive efforts at restoring ventilation and oxygenation must be made using mechanical ventilation.

Effective treatment with nasal CPAP is often accompanied by a “rebound” of sleep, which gradually returns to more normal quantities over several days. A spontaneous diuresis is also seen commonly and is the result of a reduction in hypoxia-induced pulmonary vasoconstriction and a lowering of left ventricular afterload. Hypertension may improve or even resolve with effective nasal CPAP therapy.

2. OXYGEN—Oxygen, alone or given in combination with noninvasive positive-pressure ventilation, is given to correct hypoxemia in the setting of respiratory failure with obstructive sleep apnea. Hypoxemia is a serious complication of this syndrome, with potential for arrhythmias, altered mental status, and further deterioration of ventilatory drive. However, oxygen therapy alone typically prolongs apnea duration, resulting in worsening hypercapnia and respiratory acidosis.

In patients with acute respiratory failure, however, hypoxemia is often very severe and may cause hypoxic inhibition of central respiratory neural output and marked hypoxia of the brain, heart, and other organs. The goal is to raise PaO₂ to at least 60 mm Hg for at least several days. Oxygen should be given with careful monitoring of mental status, vital signs, respiratory rate, and arterial blood gases. Increased hypercapnia indicating

worsening of respiratory failure with oxygen administration should suggest the need for initiating or increasing ventilatory support rather than discontinuing oxygen.

3. OTHER TREATMENT—Endotracheal intubation or tracheostomy is highly effective. In patients with localized obstruction owing to adenotonsillar hypertrophy or nasal polyps, surgical excision may be curative but should not be done until the patient has been stabilized medically. Other surgical treatments (including uvulopalatopharyngoplasty and mandibular osteotomy with hyoid suspension) have even less of a role in the actual setting because these procedures tend only to reduce the severity of the obstruction, and the results are difficult to predict. Diuretic administration may be helpful if elimination of obstructive breathing events and desaturations is insufficient to induce a spontaneous diuresis. Pulmonary edema is often the result of left ventricular diastolic dysfunction, and β -blockers may be more effective than afterload-reducing medications. There is no role for respiratory stimulants or carbonic anhydrase inhibitors in the treatment of obstructive sleep apnea syndrome. The use of sedative-hypnotic agents is contraindicated in these patients because they suppress the arousal response and therefore tend to lengthen apneas and cause more severe O_2 desaturations.

C. Obesity-Hypoventilation Syndrome—These patients often benefit from diuresis in response to oxygen and diuretics. Because of coexisting obstructive sleep apnea, maintenance of upper airway patency is essential. Mechanical ventilation may be necessary. Left ventricular failure is treated with diuretics with β -blockers or afterload reduction added as indicated clinically based on estimates or objective measures of left ventricular function.

Mechanical ventilation should not be withheld until gas exchange becomes severely abnormal. More often, mechanical ventilation is required as a temporizing measure while oxygen and other treatment correct the acute physiologic derangement. Mechanical ventilation is sometimes necessary so that oxygen can be given safely in patients who have decreased ventilatory drive. After a few days of improved PaO_2 , many patients will have improved ventilatory drive and marked attenuation of hypercapnia. Patients often will regain significant ventilatory responsiveness to CO_2 .

Some patients can be ventilated successfully using noninvasive nasal ventilation with bilevel positive-pressure

ventilation. This procedure requires careful monitoring and observation because minute ventilation and airway patency cannot be guaranteed as with conventional mechanical ventilation using an endotracheal tube. Bilevel positive-pressure ventilation is much like inspiratory pressure-support ventilation, with increased pressure maintained at a preset level throughout inspiration. Although backup rates can be added (similar to pressure-controlled IMV), they generally add little to spontaneous ventilation in these patients owing to the limited ability of inspiratory pressure applied noninvasively to counteract forces produced by the weight of the chest and abdomen.

Medroxyprogesterone acetate may have a beneficial effect in patients with chronic obesity-hypoventilation syndrome, but its usefulness in acute respiratory failure is unclear. In the long term, weight loss is of substantial benefit because studies have shown that even a 10% reduction in weight can improve gas-exchange derangements.

Renal Failure

Andre A. Kaplan, MD

▶ Acute Renal Failure

Acute renal failure can be defined as a precipitous impairment of kidney function without regard to etiology or mechanism. It can occur as a result of many causes, but clinical findings, complications, and some forms of treatment are the same in all cases. The causes can be divided into three main groups: *prerenal*, resulting from rapidly reversible renal hypoperfusion; *postrenal*, owing to obstruction to urine flow; and *intrinsic*, owing to lesions directly involving the renal parenchyma. In most patients, intrinsic renal failure can be considered a diagnosis of exclusion once pre- and postrenal causes are eliminated.

Clinical Features

Investigations useful in determining the cause and severity of acute renal failure are listed in [Table 13–1](#).

A. History—Noting the time of onset of renal problems helps to differentiate between acute renal failure and the natural progression of chronic renal disease. The most common causes of chronic renal failure are diabetes, hypertension, chronic glomerulonephritis, and polycystic kidney disease. The patient's drug history should seek to identify medications known to cause renal dysfunction, including nonsteroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, and antibiotics ([Table 13–2](#)). Exposure to hydrocarbons (carbon tetrachloride), ethylene glycol (antifreeze), or radiologic contrast agents also can cause acute renal failure.

B. Symptoms and Signs—Acute renal failure is rarely associated with flank pain or dysuria, exceptions being conditions characterized by severe renal inflammation, crystalluria, acute obstruction, intrarenal hemorrhage, and arterial embolization. Most of the symptoms associated with acute renal failure are the result of renal dysfunction. Salt and water overload, resulting in edema, hypertension, and pulmonary congestion, is most often the result of inadequate

diuresis. Manifestations associated with acute retention of uremic toxins include anorexia, nausea, hiccupping, vomiting, hematemesis, impaired hemostasis, neuromuscular irritability, asterixis, lethargy, coma, and seizures. Conditions seen more often after prolonged uremia include pruritus, pericarditis, and anemia. Spontaneous bone fractures owing to secondary hyperparathyroidism and altered vitamin D metabolism are *not* associated with acute renal failure, and their presence argues strongly for chronic uremia as the cause. Hyperkalemia owing to impaired renal excretion can cause cardiac arrhythmias. Uremic acidosis may elicit Kussmaul respirations.

Evaluation of intravascular volume status and degree of hydration should include measurement of orthostatic blood pressure and heart rate, assessment of mucosal hydration and skin turgor, and inspection for the presence or absence of edema (peripheral and sacral), jugular venous distention, pulsus paradoxus, cardiac rubs or gallops, pulmonary rales, or effusions and ascites. Equally informative are signs of associated morbidity, including those of congestive heart failure, cirrhosis, or systemic vasculitis.

C. Laboratory Findings—

1. SERUM CREATININE AND GLOMERULAR FILTRATION RATE—

Creatinine is made in the muscle and released into the circulation at a rate of 15–25 mg/kg per day for a middle-aged man and 10–20 mg/kg per day for a middle-aged woman. Under conditions of severe muscle damage (rhabdomyolysis), leakage of creatinine into the serum can exceed the preceding estimates. Creatinine is excreted primarily by glomerular filtration, with only a small percentage (10%) secreted by the tubules and virtually none reabsorbed. The normal glomerular filtration rate (GFR) must be reduced by about half before there is a substantial increase in serum creatinine levels (>1 mg/dL). As a result, serum creatinine is not a reliable guide to modest decreases in renal function. In contrast, preexisting increases in serum creatinine support the diagnosis of chronic renal disease.

Table 13-1. Renal assessment.

History
Physical examination
Serum chemistries Urea, creatinine, electrolytes, abnormal serologic tests (see text)
Urine chemistries Na, FE _{Na} , urea, FE _{urea} , creatinine 24-hour clearance: creatinine, urea, protein
Urinalysis Dipstick determinations Microscopy Sulfosalicylic acid
Urine culture/Gram stain
Hemodynamic monitoring
Ultrasound imaging
Radiography KUB, IVP, tomography, CT scan, MRI
Invasive radiography Renal arteriography (selective, digital subtraction) Retrograde pyelography Percutaneous antegrade pyelography
Nuclear scanning Split function studies and renal flow (DTPA, MAG-3) Gallium scan
Renal biopsy

When creatinine levels are relatively stable over several days, a crude estimate of the prevailing GFR can be made using the following formula:

$$\text{GFR} = \frac{[140 - \text{age}][\text{wt (kg)}]}{72 \times \text{Serum creatinine (mg/dL)}}$$

The result (in mL/min) is multiplied by 0.85 for a female.

This calculation is useful in providing a quick estimate of renal function but is potentially misleading if there are subsequent changes in the serum creatinine level. In order to validate the calculation, a 24-hour urine collection for creatinine is required.

During bouts of severe renal failure, serum creatinine increases by 1–2 mg/dL per day. More rapid increases in serum creatinine suggest rhabdomyolysis. Spurious increases in serum creatinine can occur without declines in GFR when certain cephalosporins or ketones (acetoacetate) interfere with the colorimetric reaction used for its identification. Likewise, cimetidine and trimethoprim-sulfamethoxazole can compete for tubular secretion and result in increases in serum creatinine unrelated to decreased GFR.

2. UREA—Urea is the major nitrogen-containing metabolite of protein catabolism and is excreted primarily by the kidneys. Normally, 35–50% of filtered urea is reabsorbed by the tubules. Under conditions of decreased renal blood flow,

Table 13-2. Drugs associated with acute renal failure.

Drug	Mechanism of Nephrotoxicity
Antimicrobial Agents	
Abacavir	AIN
Acyclovir	Crystalluria
Aminoglycosides	ATN; electrolyte-wasting
Amphotericin B	ATN; electrolyte-wasting, renal tubular acidosis
Cephalosporins	AIN, spurious increased creatinine
Cidofovir	ARF
Ciprofloxacin	AIN
Dapsone	ATN
Foscarnet	ATN, electrolyte-wasting, hypocalcemia
Ganciclovir	ARF
Indinavir	Nephrolithiasis, crystalluria, pyuria, obstruction
Meropenem	ARF
Penicillins	AIN
Pentamidine	ATN
Polymyxin B	ATN (may occur when given orally)
Quinolones	AIN?
Rifampin	AIN
Sulfadiazine	ARF, crystalluria
Sulfamethoxazole	AIN, crystals, decreased creatinine secretion
Sulfisoxazole	Crystalluria
Valacyclovir	ARF
Immunosuppressive Agents	
Cisplatin	ATN, HUS, Glomerular capillary thrombosis
Cyclosporine	Intrarenal vasoconstriction
Daclizumab	ATN, renal dysfunction?
Ifosfamide	ARF
Interferon	Prerenal azotemia? ATN?
Interleukin-2	Shock-like syndrome, prerenal azotemia
Methotrexate	Crystalluria (high-dose IV)
Mitomycin	HUS
Tacrolimus	Intrarenal vasoconstriction
Diuretics	
All	Prerenal azotemia
Mannitol	Osmotic nephrosis

(continued)

Table 13-2. Drugs associated with acute renal failure. (continued)

Drug	Mechanism of Nephrotoxicity
Antihypertensives	
ACE inhibitors	Hemodynamic compromise (most common with bilateral renal artery stenosis), AIN
Angiotensin receptor blockers	Hemodynamic compromise (most common with bilateral renal artery stenosis)
Anti-Inflammatory Drugs	
Celecoxib	AIN
Diclofenac	AIN
Fenoprofen	AIN, nephrotic syndrome
Ibuprofen	AIN
Indomethacin	AIN, nephrotic syndrome
Ketorolac	AIN
Nabumetone	AIN
Naproxen	AIN, nephrotic syndrome
NSAIDs (all)	Prerenal azotemia (especially in CHF, cirrhosis, nephrosis, chronic renal failure, volume depletion), ATN
Rofecoxib	AIN
Sulindac	AIN, nephrotic syndrome
Tolmetin	AIN
Antiplatelet Agents	
Clopidogrel	HUS
Ticlopidine	Nephrotic syndrome, HUS
Miscellaneous Agents	
Allopurinol	AIN
Cimetidine	AIN, decreased creatinine secretion
Disopyramide	Obstructive uropathy
Intravenous immune globulin	Prerenal azotemia with filtration failure due to hyperoncotic plasma
Lithium	AIN
Omeprazole	AIN
Phenindione	AIN
Phenytoin	AIN
Ranitidine	AIN
Radiocontrast Agents	
All	ATN (especially with volume depletion or advanced diabetic nephropathy)

Key: ACE = angiotension-converting enzyme, AIN = allergic interstitial nephritis, ATN = acute tubular necrosis, CHF = congestive heart failure, HUS = hemolytic uremic syndrome, NSAID = nonsteroidal anti-inflammatory drug. (See Table 13-6.)

tubular reabsorption of urea can increase to 90% or more. Since creatinine is not reabsorbed, serum urea increases more rapidly than serum creatinine under these conditions, as seen in prerenal renal failure. In general, when measured as blood urea nitrogen (BUN) in milligrams per deciliter, the normal ratio of BUN to serum creatinine is 10:1. If it rises to levels of 20:1 or more, one should suspect prerenal azotemia. In addition to variations in renal handling, blood urea concentrations are also subject to the state of protein catabolism. Thus 6 g of protein yields approximately 1 g of urea nitrogen. Under most clinical conditions, there is a direct relationship between the amount of protein ingested and urea nitrogen production. Under conditions of stress, inadequate caloric intake, or corticosteroid administration, endogenous protein catabolism results in enhanced urea production. GI hemorrhage and the resulting absorption of blood proteins—approximately 200 g of protein in 1 L of whole blood—also can increase urea production.

3. PLASMA ELECTROLYTES—Abnormalities of plasma sodium, potassium, bicarbonate, calcium, magnesium, and phosphate are common in acute renal failure, and their determination and monitoring are an integral part of the diagnosis and management of acute renal failure.

4. SEROLOGIC MARKERS—A search for abnormal serologic markers, such as various autoantibodies, is part of the basic workup of immunologically mediated renal disease, including glomerulonephritis.

5. URINE ELECTROLYTES—Evaluation of random urine samples provides quick information about the current state of renal function. The fractional excretion of sodium (FE_{Na}) is the best means of differentiating between prerenal azotemia and acute tubular necrosis and can be calculated as follows:

$$FE_{Na} = \frac{\text{urine Na (meq/L)}}{\text{urine Cr (mg/dL)}} \times \frac{\text{serum Cr (mg/dL)}}{\text{serum Na (meq/L)}}$$

In the context of oliguria (urine output <500 mL/day), a FE_{Na} of less than 1% is most commonly associated with prerenal azotemia, but it also may be seen with acute glomerulonephritis. Under similar oliguric conditions, a FE_{Na} of greater than 1% is probably related to acute tubular necrosis. Unfortunately, the potential usefulness of this test is often lost if diuretics are given prior to collection of the urine sample.

The fractional excretion of urea (FE_{urea}) also can be useful and is similarly calculated as follows:

$$FE_{urea} = \frac{\text{urine Ur (mg/dL)}}{\text{urine Cr (mg/dL)}} \times \frac{\text{serum Cr (mg/dL)}}{\text{serum Ur (mg/dL)}}$$

Normal values in well-hydrated individuals are between 50% and 65%. Values below 35% are most compatible with renal hypoperfusion and are not affected by loop diuretics

such as furosemide. A markedly diminished FE_{urea} cannot distinguish between a rapidly reversible prerenal azotemia and more definitive ischemic damage, such as occurs in acute tubular necrosis. Nonetheless, values below 35% are very useful in identifying renal hypoperfusion in patients taking diuretics, as is most often the case in decompensated congestive heart failure. Osmotic diuresis resulting from administration of mannitol or acetazolamide or from diabetic ketoacidosis increases the fractional excretion of urea despite the existence of volume depletion.

Twenty-four hour urine collections for determinations of creatinine, urea, and protein are the most reliable means of assessing renal function and determining nitrogen balance. Creatinine or urea clearance can be calculated as follows:

$$\begin{aligned} &\text{Creatinine clearance (mL/min)} \\ &= \frac{\text{urine Cr (mg/dL)} \times \text{urine volume (mL/min)}}{\text{serum Cr (mg/dL)}} \end{aligned}$$

$$\begin{aligned} &\text{Urea clearance (mL/min)} \\ &= \frac{\text{urine Urea (mg/dL)} \times \text{urine volume (mL/min)}}{\text{serum Urea (mg/dL)}} \end{aligned}$$

When serum levels of creatinine or urea are increasing rapidly, the mean of the pre- and postcollection values is used in the denominator. Timed collections less than 24 hours are reasonably accurate for creatinine but are less useful for assessing proteinuria or urea production.

Modest amounts of proteinuria (<1 g/day) are common in many forms of acute renal failure, but proteinuria in the nephrotic range (>3.5 g/day) is most often related to glomerular disease, except when associated with low-molecular-weight proteins such as Bence Jones protein in multiple myeloma. Urine protein electrophoresis performed on a 24-hour urine collection will distinguish between these two disorders.

6. URINALYSIS—Routine urinalysis consists of rapid dipstick tests and microscopic examination. Dipstick determinations measure pH and can reveal the presence of hemoglobin (positive for intact red blood cells, free hemoglobin, and myoglobin), protein, glucose, and ketones. Microscopic analysis can suggest infection (white blood cells, white blood cell casts, and bacteria), nephritis (red and white blood cells, with or without cellular casts), or nephrosis (granular casts or oval fat bodies). Red blood cell casts are associated most commonly with glomerulonephritis but may be seen occasionally with other types of acute glomerular injury such as cholesterol emboli or with malignant hypertension. White blood cell casts are seen most often with infectious pyelonephritis, but when associated with sterile urine, they may be a sign of immunologically mediated interstitial nephritis. Tubular epithelial cells can be found with interstitial nephritis or acute tubular necrosis. When associated with muddy-brown casts, acute tubular necrosis is a more likely diagnosis. Eosinophiluria, demonstrable on smears of urine

sediment stained with Wright's or Hansel's stain, can occur in drug-induced allergic interstitial nephritis.

The urine dipstick test for protein is most sensitive for albumin, whereas sulfosalicylic acid added to the urine causes precipitation of all proteins. When the urine dipstick is negative or only modestly positive for protein and the sulfosalicylic acid precipitation is markedly positive, Bence Jones proteinuria should be suspected.

Urine culture and Gram staining should be performed on any urine containing white blood cells. Sterile pyuria is often a sign of drug-induced interstitial nephritis, but renal tuberculosis also should be considered.

7. ASSESSMENT OF INTRAVASCULAR VOLUME—Central venous pressure monitoring can be accomplished with subclavian, internal jugular, or femoral catheterization. A low central venous pressure is most compatible with decreased intravascular volume; elevated central venous pressure may be secondary to intravascular expansion or pulmonary hypertension. When the volume status is unclear in the context of dyspnea, elevated levels of B-type natriuretic peptide (BNP) may help to identify an element of heart failure that would support a diagnosis of intravascular volume overload. Pulmonary artery catheterization is the most reliable means of assessing optimal fluid status by determination of cardiac output and left ventricular filling pressure but usually is not necessary.

8. RENAL BIOPSY—Renal biopsy is most often helpful when inflammatory nephritis (ie, glomerulonephritis, allergic interstitial nephritis, etc.) is suspected. However, in patients suspected of having acute tubular necrosis in whom renal failure fails to resolve in 6–8 weeks, renal biopsy may be indicated to diagnose irreversible causes of renal failure (eg, cholesterol emboli, cortical necrosis, etc.).

D. Imaging Studies—Renal *ultrasound* provides an accurate means of measuring renal size (small kidneys are evidence of chronic renal disease) and determining the existence of hydronephrosis. Because potentially nephrotoxic contrast agents are not required, ultrasound has become the first choice in the evaluation of ureteral obstruction. In rare cases, tumor infiltration or retroperitoneal or perirenal fibrosis may inhibit the expansion of the renal pelvis, thus yielding a falsely negative result.

The plain *abdominal x-ray* can demonstrate the presence of radiopaque kidney stones but is often more valuable in evaluation of associated disease processes. *Intravenous pyelography* (IVP) most reliably identifies the site of renal obstruction, provided that creatinine levels are not excessively elevated (≤ 4 mg/dL). *Retrograde pyelography* can image both the ureters and the bladder. *Percutaneous pyelography* can determine the site of renal obstruction when retrograde pyelography is unsuccessful. *CT scanning* can evaluate the site of obstruction (extrinsic versus intrinsic obstruction) and assess for associated morbidity. Selective *renal angiography with digital subtraction* is the best way to assess the renal vasculature for stenosis or hemorrhagic leak.

The potential for radiocontrast nephrotoxicity always should be considered. Risk factors include volume depletion, low cardiac output, preexisting renal disease, large contrast load or multiple exposures to contrast agents, a history of contrast-induced acute renal failure, multiple myeloma, and most significantly, advanced diabetic nephropathy. Patients with diabetic nephropathy and creatinine levels above 4 mg/dL have a 90% probability of developing some degree of renal dysfunction. In some of these patients, renal failure may be irreversible. Patients at increased risk should be well hydrated prior to and immediately after exposure to radiocontrast dyes, and every effort should be made to limit the amount of contrast material administered. The newer low-osmolality agents may be preferable. Other means of minimizing the risk of contrast-induced renal damage include oral administration of the antioxidant acetylcysteine and infusion of sodium bicarbonate.

Radionuclide scanning provides the only noninvasive means of assessing the relative percentage of renal function from each kidney (split function studies). Renal blood flow can be assessed with diethylenetriamine pentaacetic acid (DTPA), which is excreted by glomerular filtration and may demonstrate renal vascular stenosis. Repeat examination after administration of captopril increases this test's sensitivity. Gallium scans can identify any type of renal inflammation and are most valuable in assessing unilateral lesions or identifying a renal origin of pyuria. Gallium scans also may be positive in patients with nephrosis. Technetium-99m mercaptoacetyltriglycine (MAG3) is both filtered and secreted and is the radionuclide imaging agent of choice for patients with substantial renal failure.

MRI is not yet widely employed in the evaluation of acute renal failure, but it may be of value in the diagnosis of renal vein thrombosis. Gadolinium-enhanced magnetic resonance angiography (MRA) is an accurate means for assessing renal artery stenosis without the risks of catheterization or the contrast material used for percutaneous angiography.

Complications

The complications of acute renal failure are listed in [Table 13-3](#). Cardiovascular problems are most often due to fluid overload and electrolyte abnormalities. Pericarditis is probably the result of retained uremic toxins. Insufficient erythropoietin may cause decreased red blood cell production and anemia, but this mechanism is seen more commonly in patients with chronic renal failure. In contrast, platelet dysfunction, clinically diagnosed on the basis of prolonged bleeding time, is a common consequence of acute renal failure. Infections represent an important cause of morbidity and death in acute renal failure—especially urinary tract infections, which are particularly difficult to eradicate because of inadequate urine concentrations of antibiotics. Electrolyte and acid-base abnormalities are common, the

Table 13-3. Acute renal failure—Common complications.

Fluid overload

- Pulmonary edema
- Anasarca

Pericarditis

Electrolyte disorders

- Hyperkalemia
- Hyperphosphatemia
- Hypocalcemia (rarely, hypercalcemia)
- Hypermagnesemia

Metabolic acidosis

Neurologic disorders

- Altered sensorium
- Peripheral neuropathy
- Seizures

Others

- Anorexia, nausea, vomiting
- Platelet dysfunction
- Anemia

most serious being hyperkalemia. Hypoglycemia may result from decreased renal catabolism of exogenously administered insulin. Neurologic abnormalities include somnolence, coma, and convulsions and are often compelling indications for initiation of dialysis. GI hemorrhage in acute renal failure is due to the combination of uremic coagulopathy and gastritis, but in chronic renal failure, arteriovenous malformations are the most common causes.

▶ Prerenal Renal Failure

ESSENTIALS OF DIAGNOSIS

- ▶ BUN:creatinine ratio >20:1.
- ▶ Decreased urine output (unless renal losses are primary).
- ▶ $FE_{Na} < 1\%$ and/or $FE_{urea} < 35\%$.
- ▶ Urine sediment may show a few granular casts but absence of inflammatory cells and red and white blood cell casts.
- ▶ No evidence of urinary tract obstruction.

General Considerations

Prerenal azotemia is defined as a state of renal hypoperfusion that can be rapidly reversed with proper management. All causes of renal hypoperfusion stimulate renal autoregulatory mechanisms that function to maintain glomerular filtration despite decreasing renal blood flow. Central in this response is the balance between vasoconstricting angiotensin II and vasodilating renal prostaglandins. Angiotensin II causes vasoconstriction of both the afferent and the efferent glomerular arterioles, but resistance in the efferent arteriole rises more. As a result, glomerular hydrostatic pressure increases, filtration fraction rises, and unfilterable serum proteins are concentrated. The resulting increase in efferent arteriolar oncotic pressure stimulates water and urea reabsorption from the proximal tubule, thus decreasing the fractional excretion of urea and increasing the BUN:creatinine ratio. Furthermore, angiotensin II acts directly on the proximal tubule to stimulate sodium reabsorption, thus decreasing the fractional excretion of sodium.

The causes of prerenal failure can be classified as shown in Table 13–4. A decrease in cardiac output can be the result of primary cardiac disease or insufficient end-diastolic filling pressures. Volume depletion can occur along obvious routes such as the GI or urinary system, via surgical drains, or via more occult mechanisms, including diaphoresis and retroperitoneal hemorrhage. Redistribution of fluid out of the intravascular space with insufficient circulating volume can occur with hypoalbuminemia, vasodilatory shock with capillary leak (sepsis), or intraabdominal accumulation (eg, peritonitis, ascites, and pancreatitis). Crush injury with massive tissue damage can cause sufficient localized edema to result in intravascular depletion. Rarely, overzealous administration of vasodilators decreases effective circulating volume and can mimic endogenous causes of vasodilatory shock.

Intrarenal vasoconstriction can be mediated by several mechanisms, including an imbalance between vasoconstrictive angiotensin II and vasodilating prostaglandins (most often seen when prostaglandin synthetase inhibitors are

Table 13–4. Causes of prerenal renal failure.

Decreased cardiac output

- Myocardial infarction
- Cardiomyopathy
- Pericarditis (constrictive or cardiac tamponade)
- Arrhythmias
- Valvular dysfunction
- Pulmonary embolus
- Pulmonary hypertension
- Mechanical ventilation (especially with PEEP)
- Trauma

Extracellular volume depletion

- Dehydration
- GI losses (vomiting, NG suction, diarrhea, ostomy output)
- Renal losses (diuretics, osmotic diuresis, nonoliguric ATN, adrenal insufficiency)
- Peritoneal losses (surgical drains)
- Skin losses (burns, diaphoresis)
- Hemorrhage (gastrointestinal, intra- and retroperitoneal)

Redistribution of fluid

- Hypoalbuminemia (nephrosis, cirrhosis, malnutrition)
- Vasodilatory shock (sepsis, hepatic failure)
- Peritonitis
- Pancreatitis
- Crush injury
- Ascites
- Vasodilators

Primary intrarenal vasoconstriction

- NSAIDs (prostaglandin inhibition)
- Hepatorenal syndrome
- Preeclampsia
- Malignant hypertension
- Scleroderma
- Cyclosporine

Renovascular obstruction

- Renal artery (intravascular stenosis, embolus, laceration, thrombus)
- Renal vein (intravascular thrombosis, tumor infiltration, extravascular compression)

given to patients with nephrosis, cirrhosis, congestive heart failure, preexisting renal disease, or volume depletion). Renal artery stenosis, preeclampsia, malignant hypertension, scleroderma with severe hypertension and renal failure, and intravenous cyclosporine may be associated with intrarenal vasoconstriction mediated by angiotensin II or endothelin. Finally, obstruction to blood flow to or from the kidney can result from renal artery stenosis or emboli to the renal arteries, related to valvular heart disease, or in patients with atrial or ventricular mural thrombi; can occur from valvular heart disease or arrhythmias; or can occur as a complication of percutaneous renal angioplasty. Renal vein thrombosis in adults is seen most often in the context of nephrotic syndrome and is considered to be the result of its associated hypercoagulable state.

Clinical Features

A. Symptoms and Signs—Patients may present with a history of excessive fluid losses from diarrhea, high urine output, or sweating, and this may be compounded by low fluid intake. They may complain of lightheadedness or syncope and may have tachycardia, hypotension, and diaphoresis. Often, postural decrease in blood pressure and increase in heart rate are present in patients with significant volume depletion. Although prerenal azotemia is associated most commonly with volume depletion, patients with congestive heart failure, systemic vasodilation, or hypoalbuminemia may have substantial peripheral edema yet still have insufficient cardiac output or intravascular volume to maintain adequate renal perfusion. Conversely, a severely hypoalbuminemic patient who appears euvoletic is likely to be intravascularly depleted.

Thromboembolic diseases, including renal artery embolization and renal vein thrombosis, decrease renal perfusion but are distinct in their symptomatology and diagnostic workup. Renal artery embolization is most often associated with cardiac valvular disease and can present with nausea, vomiting, flank pain, and hematuria.

Renal vein thrombosis in adults is most often associated with nephrotic syndrome, but it also may result from extrinsic compression by tumor. Acute thrombosis can present with flank pain, hematuria, and increased proteinuria and may be misdiagnosed as a kidney stone. Chronic thrombosis may be asymptomatic except for an ipsilateral varicocele when the thrombosis is in the left renal vein.

B. Laboratory Findings—Considering these varying clinical presentations, evaluation of serum and urine chemistries is required to confirm the diagnosis. Although both serum creatinine and urea nitrogen increase, low tubular flow results in increased reabsorption of urea. Therefore, the serum BUN:creatinine ratio increases usually to greater than 20:1, and the FE_{urea} is less than 35%. Because renal tubular function is normal in early prerenal azotemia, avid sodium reabsorption in the face of volume depletion causes FE_{Na} to be very low, usually less than 1%. Urinary sediment is usually normal except for the finding of a few granular casts; white blood cells and red and white blood cell casts are absent.

C. Imaging Studies—The diagnosis of thromboembolic disease may be suspected with the demonstration of decreased function on IVP or absent flow on radionuclide scan. The definitive diagnosis and a judgment about the advisability of operation are best arrived at by renal angiography (the presence of collateral circulation suggests a better surgical outcome). Renal venography is the most definitive diagnostic test for renal vein thrombosis but risks dislodging the thrombus, with resulting pulmonary embolization. Digital subtraction renal angiography with evaluation of the venous phase, CT scan, and MRI are safer alternatives.

Treatment

Prerenal azotemia caused by volume depletion should be treated by correction of decreased extracellular fluid volume. Most often, normal saline is given intravenously in an amount sufficient to replete volume, but in some patients, blood or colloid solutions are needed. The total volume of replacement should be estimated in most cases as 10–25% of extracellular fluid volume (ie, 2–4 L), but the amount actually given should be carefully titrated by monitoring urine output, blood pressure, and heart rate. Elderly patients and those with heart failure should be given fluid cautiously, usually with central venous pressure or pulmonary artery pressure monitoring. Fluid replacement also should take into account continued losses from the GI tract and other sources of fluid loss.

Prerenal azotemia associated with cardiac failure usually responds to standard drugs and procedures for improving cardiac output, including loop diuretics, vasodilators, inotropic agents, and oxygen. Low-dose dopamine (<5 µg/kg per minute) has become a popular means of initiating diuresis in resistant cases. However, its use is unsupported by large randomized studies. Potential secondary effects include tachycardia and ischemia. Heart failure and prerenal azotemia associated with substantial fluid overload also may respond to infusions of nesiritide, with or without diuretics. This approach has shown a remarkable success in allowing for aggressive diuresis without worsening of renal perfusion. If diuresis is associated with increasing BUN, ACE inhibitors may be beneficial in decreasing renal resistance. When successful, this approach yields an increase in the fractional excretion of urea, which can be followed on a daily basis and used as a guide to further treatment. The management of pericarditis, arrhythmias, pulmonary emboli, and pulmonary hypertension is discussed elsewhere. One should note that positive end-expiratory pressure for treatment of respiratory failure can spuriously elevate pulmonary wedge pressure, thus making it a misleading measure of intravascular volume.

Volume repletion should be tailored to the patient's cardiopulmonary reserve. The hypoalbuminemic states associated with cirrhosis or malnutrition can be corrected with intravenous albumin, but worsening of associated ascites may occur in a third of patients. In contrast, albumin infusions are futile in patients with ongoing nephrotic syndrome.

Treatment of vasodilatory shock often requires a combination of fluids and vasoconstrictors. Crush injury represents a particular case where intravascular volume depletion combines with the potential nephrotoxicity of myoglobin to yield a toxic acute tubular necrosis. Proper prevention of myoglobin nephrotoxicity can be accomplished with aggressive intravascular volume expansion (see below).

Primary intrarenal vasoconstriction by prostaglandin synthetase inhibitors reverses spontaneously after cessation of these drugs. Prevention of hepatorenal syndrome involves restoration of intravascular volume despite increasing ascites

or edema (see below). Preeclamptic renal failure must be treated by delivery or termination of pregnancy. Malignant hypertension and renal crises associated with scleroderma can be treated successfully with ACE inhibitors. Patients with refractory hypertension may require nitroprusside, but prolonged use of this agent in renal failure may predispose to thiocyanate toxicity. Intrarenal vasoconstriction resulting from high doses of intravenous cyclosporine is reversed by decreasing or discontinuing the drug.

Renal artery stenosis can be treated by percutaneous angioplasty or surgery. Massive renal artery embolization resulting from cardiac sources can be managed with anticoagulation and thrombolytic therapy but may require operative management. Renal vein thrombosis is treated with long-term anticoagulation with heparin and warfarin but may respond to either intravenous or intraarterial thrombolytic therapy.

▶ Postrenal Renal Failure

ESSENTIALS OF DIAGNOSIS

- ▶ Dilated renal pelvis on ultrasound.
- ▶ Enlarged, palpable bladder (if obstruction to bladder outflow).

General Considerations

Demonstrable changes in renal function occur only if both kidneys are involved or if there is preexisting kidney disease involving the contralateral kidney. It is important to keep in mind that obstruction to urine flow decreases tubular sensitivity to antidiuretic hormone, leading to nephrogenic diabetes insipidus. Thus the presence of a high urine volume does not rule out the possibility of partial obstruction.

Table 13-5. Causes of postrenal renal failure.

Ureteral obstruction (bilateral or unilateral single kidney)

Extrinsic

- Tumors (endometrial, cervix, lymphoma, metastatic)
- Retroperitoneal fibrosis or hemorrhage
- Accidental surgical ligation

Intrinsic

- Stones, blood clots, sloughed papillae (papillary necrosis), tumors (transitional cell, etc.)

Bladder or urethral obstruction

- Prostatic hypertrophy or tumor
- Bladder carcinoma
- Uterine prolapse
- Stones, blood clots, sloughed papillae
- Neurogenic bladder (functional or iatrogenic)
- Obstructed Foley catheter

Obstruction to urine flow can occur anywhere along the urinary tract and may be secondary to extrinsic compression or intrinsic blockage (Table 13–5). Causes include tumors, stones, blood clots, and sloughed renal papillae—the result of papillary necrosis, a condition known to occur with analgesic abuse, diabetes, recurrent infections, and sickle cell anemia. Although sloughed renal papillae usually cause unilateral obstruction, blockage of the bladder neck can cause bilateral obstruction and acute-onset oliguria. In men, the most common cause of postrenal renal failure is prostatic hypertrophy.

Clinical Features

A. Symptoms and Signs—Obstruction to urine flow resulting in renal failure may be accompanied by symptoms and signs related to unilateral ureteral obstruction or urethral or bladder obstruction. Occasionally, obstruction is not associated with any symptoms or signs.

Acute ureteral obstruction may be painful, with the patient complaining of severe flank and midback pain, especially when caused by renal stones or blood clots. Examination may indicate localized tenderness, especially to percussion. Urethral obstruction, especially in prostatic hypertrophy, will cause bladder distention and inability to urinate. Although urine output is very often low or absent, partial obstruction may cause renal failure without oliguria or anuria.

B. Laboratory Findings—Elevated serum creatinine and BUN are indicative of renal insufficiency, and serum electrolytes reflect the severity of renal failure. In patients with renal stones or blood clots, hematuria without red blood cell casts is a prominent feature, but ureteral or urethral obstruction from extrinsic compression such as tumors will not be associated with abnormal urinary sediment.

C. Imaging Studies—The existence of postrenal obstruction, regardless of the site or cause, almost always can be determined by renal ultrasound examination. In rare cases, however, tumor infiltration of the renal parenchyma or perirenal fibrosis may inhibit dilation of the renal pelvis and yield a falsely negative ultrasound examination. Minimal or absent caliceal dilation also may occur during the first few hours after an acute obstruction. Radiologic procedures requiring potentially nephrotoxic radiocontrast agents are most helpful in determining the site and nature of the obstruction. IVP is employed most often in the context of suspected kidney stone, but imaging is poor if serum creatinine levels are elevated. Retrograde pyelography performed through a cystoscope avoids intravenous contrast administration and offers a direct view of the bladder and the possibility of a corrective urologic procedure. Percutaneous pyelography demonstrates the site of obstruction and offers rapid relief of obstruction if the catheter is left in situ. CT scans and MRI are most helpful for determining the extrinsic or intrinsic nature of the obstruction. Radionuclide scanning can be valuable in cases of suspected obstruction when dilation of the renal pelvis can be identified, but the severity of the blockage is in doubt.

Treatment

Acute ureteral obstruction with a kidney stone or sloughed papillae is most often managed with aggressive hydration and control of pain. Treatment of other causes of ureteral obstruction, such as tumors, depends on the location and extent of obstruction and may require surgical relief of the obstruction. Percutaneous nephrostomy is a reasonable alternative for short-term correction of obstruction of the kidney. Bladder obstruction or dysfunction can be treated initially with insertion of a Foley catheter, but in some patients this may be difficult to perform without special urologic instruments. An infected, obstructed kidney is a medical emergency that cannot be managed adequately with antibiotic therapy alone. Rapid relief of obstruction is essential.

Klahr S: Urinary tract obstruction. *Semin Nephrol* 2001;21:133–45. [PMID: 11245776]

O'Neill WC: B-mode sonography in acute renal failure. *Nephron Clin Pract* 2006;103:C19–23. [PMID: 16543751]

► Intrinsic Renal Failure

Intrinsic renal failure is often a diagnosis of exclusion after prerenal and postrenal causes have been eliminated or treated. Cases of intrinsic acute renal failure can be categorized as follows (Table 13–6): (1) those involving the glomeruli (glomerulonephritis), (2) those involving the interstitium (interstitial nephritis), (3) those leading to microcapillary or glomerular occlusion, (4) acute tubular necrosis, and (5) cortical necrosis.

Table 13–6. Causes of intrinsic acute renal failure.

Acute glomerulonephritis

Postinfectious: streptococcal, bacteria, hepatitis B, HIV, visceral abscess

Systemic vasculitides: systemic lupus erythematosus, Wegener's granulomatosis, polyarteritis nodosa, Henoch-Schönlein purpura, IgA nephritis, Goodpasture's syndrome

Membranoproliferative glomerulonephritis

Idiopathic

Acute interstitial nephritis

Drugs: penicillins, NSAIDs, ACE inhibitors, allopurinol, cimetidine, H₂ blockers, proton pump inhibitors

Infectious: streptococcal infections, diphtheria, leptospirosis

Metabolic: hyperuricemia, nephrocalcinosis

Poisons: ethylene glycol (calcium oxalate)

Autoimmune disease: systemic lupus erythematosus, cryoglobulinemia

Microcapillary/glomerular occlusion

Thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, disseminated intravascular coagulation, cryoglobulinemia, cholesterol emboli

Acute tubular necrosis

Drugs: aminoglycosides, cisplatin, amphotericin B

Ischemia

Septic shock

Intratubular obstruction: rhabdomyolysis, hemolysis, multiple myeloma, uric acid, calcium oxalate

Poisons: radiopaque contrast media, carbon tetrachloride, ethylene glycol, heavy metals

Cortical necrosis

Key: ACE = angiotensin-converting enzyme; NSAID = nonsteroidal anti-inflammatory drug

1. Glomerulonephritis

ESSENTIALS OF DIAGNOSIS

- Nephritic urine sediment with red blood cells, white blood cells, and red blood cell casts.
- Proteinuria (variable, sometimes in nephrotic range: ≥ 3.5 g/day).
- Kidney size normal or increased; no evidence of obstruction.
- Hypertension (variable).
- Evidence for immunologic disease: antinuclear antibodies, antistreptolysin O, cryoglobulins, antineutrophil cytoplasmic antibodies (ANCA), anti-glomerular basement membrane (anti-GBM) antibodies, IgA levels, hepatitis B antigen, hepatitis C antibody, HIV, decreased C3 and C4.
- Renal biopsy to confirm diagnosis.

General Considerations

Table 13–6 lists several glomerulonephritides that are most commonly associated with acute renal failure. Most—perhaps all—are immunologically mediated as a result of recent or ongoing infections, systemic vasculitis, or idiosyncratic autoimmune reactions. Histologic evaluation is most often positive for immune deposits in varying locations within the glomerular structures. In pauci-immune glomerulonephritis, such as is found with Wegener's granulomatosis or polyarteritis, no immune deposits are found, but the presence of antineutrophil cytoplasmic antibodies (ANCA) may stimulate leukocytes to release their enzymes, thus mediating an intraglomerular inflammatory reaction.

Clinical Features

A. Symptoms and Signs—Patients with acute glomerulonephritis may present with edema (especially in periorbital distribution), hypertension, fatigue, and possibly pulmonary congestion. They may note smoky, rust-colored, or grossly bloody urine. These findings are common to glomerulonephritis owing to any cause. Other clinical features reflect the underlying disease causing glomerulonephritis. Postinfectious glomerulonephritis presents about 10 days after acute infection, usually a streptococcal pharyngitis or skin infection. Symptoms and signs of systemic vasculitis are highly variable and depend on the distribution of involvement and the size of the vessels involved. They may include arthralgias and arthritis, fever, rash, myalgias and muscle tenderness, hypertension, abdominal pain, nausea, vomiting, diarrhea, headache, and other features that are manifestations of organ system involvement, including the heart, GI tract, kidneys, CNS, peripheral nerves, lungs, pleura, and pericardium. In some situations, the clinical presentation may strongly suggest a given diagnosis, such as one of the pulmonary-renal syndromes.

B. Laboratory Findings—The most compelling finding suggestive of acute glomerulonephritis is the presence of red blood cell casts in the urine. These casts are the result of leakage of red blood cells past damaged glomeruli into the tubular lumen, and they must be carefully distinguished from granular pigmented casts. The absence of red blood cell casts does not rule out the diagnosis of glomerulonephritis, however, and they are found occasionally in other disorders such as acute interstitial nephritis and cholesterol emboli. Other urinary abnormalities include varying degrees of proteinuria and pyuria in the absence of urinary infection. A history of symptoms suggestive of systemic vasculitis can be confirmed by serologic testing, including antinuclear antibodies, anti-GBM antibodies, IgA levels, antistreptolysin O antibodies, cryoglobulins, ANCA, antibodies and markers for hepatitis B, hepatitis C, and HIV, and decreased levels of the third and fourth components of complement (C3 and C4).

Since therapy of glomerulonephritis often entails long-term risk, renal biopsy usually should be performed to confirm the diagnosis.

Treatment

Most cases of acute glomerulonephritis are treated with aggressive immunosuppressive medications, including high-dose corticosteroids and cyclophosphamide. Recent reports suggest that mycophenolate mofetil may be an effective alternative to cyclophosphamide in some cases. Since therapy is likely to be prolonged, with the possibility of substantial morbidity, consultation with a nephrologist is strongly suggested prior to initiation of treatment. On the other hand, poststreptococcal glomerulonephritis is treated with supportive therapy alone, including prevention of fluid overload and control of hypertension.

Glomerulonephritis associated with infective endocarditis responds to appropriate antibiotics. Goodpasture's syndrome and cryoglobulinemia often require plasma exchange. ANCA-positive glomerulonephritis commonly requires treatment with cyclophosphamide. Patients presenting with dialysis-requiring renal failure also may benefit from plasma exchange.

2. Acute Interstitial Nephritis

ESSENTIALS OF DIAGNOSIS

Interstitial nephritis:

- ▶ History of drug sensitivity, infection, or toxin ingestion.
- ▶ Flank pain (occasionally).
- ▶ Kidney size normal or increased.

Allergic interstitial nephritis:

- ▶ Fever, rash, peripheral blood eosinophilia.
- ▶ Sterile pyuria, hematuria, white blood cell casts, tubular epithelial cells, eosinophiluria.
- ▶ Positive renal gallium scan with prolonged renal uptake.

General Considerations

Several drugs are capable of eliciting an autoimmune attack on the renal interstitium, resulting in allergic interstitial nephritis (see Table 13–2). Direct invasion by infection is less common. Acute urate nephropathy results from the intratubular precipitation of uric acid and is most often associated with the chemotherapeutic treatment of large lymphomas or leukemias, with serum levels of uric acid often above 20 mg/dL. The metabolism of ethylene glycol, ingested accidentally or deliberately, results in calcium oxalate deposition within the interstitium and may result in irreversible

renal damage. Autoimmune diseases such as systemic lupus erythematosus or cryoglobulinemia may cause a “pure” interstitial nephritis but more often present with concomitant glomerular disease.

Clinical Features

A. Symptoms and Signs—Drug-induced allergic interstitial nephritis is often associated with a history of drug hypersensitivity and classically presents with a triad of fever, rash, and peripheral blood eosinophilia. Unfortunately, the triad is complete in only one-third of patients. The rash is usually symmetric and widespread, appears suddenly, and is usually not pruritic. In the case of NSAID toxicity, nephrotic syndrome with glomerular involvement may be present in addition to evidence of interstitial involvement.

B. Laboratory Findings—Further evidence for interstitial nephritis includes sterile pyuria, white blood cell casts, and occasionally, eosinophiluria. Hematuria and varying degrees of proteinuria usually are present as well. Infectious causes of interstitial nephritis can be identified by blood or urine cultures. Acute urate nephropathy should be anticipated whenever aggressive chemotherapy is initiated in a patient with a large lymphoma or acute leukemia. In these patients, serum uric acid is often above 20 mg/dL, and urinalysis reveals flat, rhomboid crystals of uric acid or needle-shaped crystals of sodium urate. Autoimmune diseases are best identified by finding serologic evidence of specific diseases.

C. Imaging Studies—A gallium scan positive for prolonged renal uptake (>72 hours) supports the diagnosis of allergic interstitial nephritis.

Treatment

Drug-induced acute interstitial nephritis usually reverses spontaneously after cessation of the offending agent, but patients may benefit from a course of corticosteroids if renal failure is severe or prolonged. In anticipation of aggressive chemotherapy for lymphomas or leukemias, the risks of acute urate nephropathy can be greatly reduced by pretreatment with allopurinol and forced alkaline diuresis designed to keep urine pH \geq 7.0. Alkalinization of the urine can be accomplished by administration of 5% dextrose in water to which approximately 100–150 meq/L of sodium bicarbonate has been added. Acetazolamide may be added to stimulate bicarbonate excretion.

Infectious causes of interstitial nephritis are treated with antibiotics selected for urinary tract bacterial pathogens and adjusted on the basis of urine and blood cultures. Ethylene glycol-induced renal failure may require hemodialysis.

Taber SS, Mueller BA: Drug-associated renal dysfunction. *Crit Care Clin* 2006;22:357–74. [PMID 16678005]

3. Microcapillary & Glomerular Occlusion

ESSENTIALS OF DIAGNOSIS

- ▶ Hematuria.
- ▶ Proteinuria (variable).
- ▶ Thrombotic thrombocytopenic purpura–hemolytic uremic syndrome and disseminated intravascular coagulation: thrombocytopenia and microangiopathic hemolytic anemia.
- ▶ Cryoglobulinemia: cryoglobulin present in serum, purpura (variable), and hypertension (variable).
- ▶ Cholesterol embolization: hypertension, signs of peripheral vascular occlusive disease (claudication), skin discoloration (livedo reticularis, purple toes), eosinophilia, and a history of recent intraaortic catheterization.

General Considerations

These disorders have in common obstruction of the various parts of the renal circulation or glomerular vascular pole. Thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), and disseminated intravascular coagulation (DIC) have the potential to deposit thrombi of fibrin and platelets in the glomerular capillary lumen. Cryoglobulins can precipitate in glomerular capillaries but also may cause an immunologically mediated glomerulonephritis. Microscopic cholesterol emboli may occur spontaneously in patients with severe atherosclerotic disease but are seen most often after catheterization of the aorta for diagnostic purposes. Cholesterol emboli are of varying size and may block intrarenal arteries, preglomerular arterioles, or the vascular pole of the glomerulus.

Clinical Features

A. TTP and HUS—Thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) can be suspected when severe thrombocytopenia is associated with microangiopathic hemolytic anemia in the presence of normal prothrombin time and partial thromboplastin time. Symptoms include jaundice, renal disease, and varied neurologic manifestations.

B. DIC—Disseminated intravascular coagulation (DIC) is often associated with sepsis and is diagnosed by a combination of thrombocytopenia, increased fibrin split products, elevated D-dimers, and elevated prothrombin time and partial thromboplastin time. Owing to the ongoing coagulopathy, renal biopsies are performed only rarely in these diseases.

C. Cryoglobulinemia—Cryoglobulinemia is often associated with purpura and hypertension and is confirmed by identification of serum cryoglobulins. It has now been

established that many cases of cryoglobulinemia are associated with hepatitis C infection.

D. Cholesterol Embolization—A syndrome of microvascular embolization with livedo reticularis, purple toes, signs of peripheral vascular disease, and occasionally eosinophilia will lead to a suspicion of cholesterol embolization. Renal biopsy, however, is the only confirmatory test.

Treatment

TTP requires aggressive plasma exchange with fresh-frozen plasma. HUS may respond to intravenous immune globulin or plasma exchange. DIC is best treated by management of the inciting cause. Cryoglobulinemia may respond to immunosuppressive therapy or plasma exchange. If there is an associated hepatitis C infection, long-term management may include interferon. Renal failure associated with cholesterol embolization is irreversible. However, on occasion, renal failure from cholesterol emboli may be associated with an element of acute tubular necrosis owing to vascular occlusion. In these patients, some improvement may occur. On theoretical grounds, anticoagulation is contraindicated because it may be a precipitating factor.

4. Acute Tubular Necrosis

ESSENTIALS OF DIAGNOSIS

- ▶ History of exposure to nephrotoxic drugs or hypotension.
- ▶ Oliguria in ischemic ATN but absence of oliguria in toxic ATN.
- ▶ $FE_{Na} > 1\%$.
- ▶ Urinalysis: tubular epithelial cells, red blood cells, and “muddy brown” casts.

General Considerations

The most common form of hospital-acquired intrinsic acute renal failure is referred to as *acute tubular necrosis* (ATN). This designation is somewhat misleading because in many cases there is more tubular dysfunction than necrosis. In general, the pathogenesis involves direct toxicity to the tubular epithelium, resulting in inability to reabsorb glomerular filtrate properly and massive sodium wasting, intrarenal vasoconstriction, and tubular blockage with necrotic cellular debris and proteinaceous material. The most common causes are ischemia, exogenous toxins including drugs (see Table 13–2) and radiocontrast agents, and endogenous toxins such as myoglobin, hemoglobin, light chains of immunoglobulins, or crystals (see Table 13–6). Any cause of prerenal azotemia (see Table 13–4), if sufficiently severe or prolonged, can cause ischemic tubular damage and lead to this disorder. Furthermore, all conditions of renal hypoperfusion increase the likelihood of toxicity from exogenous or endogenous toxins. In many cases, a combination of noxious stimuli can be identified.

Clinical Features

Ischemic ATN is encountered most often after an identifiable episode of hemodynamic compromise or after prolonged ischemia during aortic surgery. The presentation is that of acute onset of oliguria with an FE_{Na} greater than 1% and a urine rich with cellular and proteinaceous debris, including red blood cells, white blood cells, tubular epithelial cells, and “muddy brown” casts. In this setting, correction of identifiable prerenal factors and a renal ultrasound examination excluding obstruction are often sufficient to make the diagnosis on clinical grounds, and renal biopsy usually is reserved for patients in whom renal failure is abnormally prolonged (6–8 weeks).

ATN from toxic causes is often nonoliguric, and the urine sediment may be unremarkable. A history of toxin exposure (eg, aminoglycosides, radiocontrast agents, etc.) and the exclusion of prerenal and postrenal causes are often sufficient for a clinical diagnosis. Urinalysis with dipstick positive for blood in the absence of identifiable red blood cells is suggestive of rhabdomyolysis or hemolysis.

Treatment

Although several experimental treatments have been designed to enhance recovery (eg, antiendothelin antibodies, ATP, $MgCl_2$, thyroxine, growth factors, etc.), none are currently applied in clinical practice. Experimentally, infusions of atrial natriuretic peptide have been shown to increase creatinine clearance and decrease the need for dialysis, but currently available treatment strategies are limited to prevention and management. Preventive measures include ensuring adequate hydration when nephrotoxic agents are unavoidable (eg, radiocontrast agents or necessary nephrotoxic antibiotics) and proper dosing of nephrotoxic drugs with special

attention to changing renal function and daily measurements of toxic drug levels. Recent evidence suggests that pretreatment with acetylcysteine or infusions of sodium bicarbonate may help to prevent contrast-induced nephropathy.

In the early stages of oliguric ATN, a short course of mannitol or furosemide may decrease the tendency toward tubular obstruction. Mannitol has the theoretical advantage of stimulating an osmotic diuresis originating in the proximal tubule, with the possibility of increasing tubular flow throughout the nephron. Unfortunately, when mannitol is given without resulting diuresis, it may precipitate intravascular volume expansion, which may be poorly tolerated. If diuresis is not established after 24 hours of treatment with furosemide or mannitol, further attempts at diuretic therapy will be futile and potentially harmful.

5. Cortical Necrosis

Cortical necrosis is the result of severe and prolonged renal hypoperfusion and has been most often associated with the hemodynamic catastrophes of pregnancy, including eclampsia, abruptio placentae, and postpartum hemorrhage. The diagnosis is usually suspected when an episode of acute renal failure fails to resolve in 6–8 weeks. Renal biopsy is often required for definitive diagnosis. Renal damage is irreversible.

▶ Common Syndromes Associated with Acute Renal Failure

1. Pigment Nephropathy: Rhabdomyolysis & Hemolysis

ESSENTIALS OF DIAGNOSIS

- ▶ Urine dipstick positive for heme in the absence of red blood cells.
- ▶ Rhabdomyolysis: elevated creatine kinase and aldolase; decreased BUN:creatinine ratio.
- ▶ Hemolysis: elevated serum-free hemoglobin, decreased haptoglobin, elevated lactate dehydrogenase (LDH).

General Considerations

Rhabdomyolysis is commonly associated with acute renal failure, especially in the context of traumatic crush injury. Hemolysis is usually more insidious and less likely to cause renal failure except when severe, such as with major transfusion incompatibilities.

In the case of rhabdomyolysis, intravascular volume depletion promotes intratubular precipitation of myoglobin and is probably the most important comorbid factor in the initiation of nephrotoxicity. Hemoglobin-related toxicity seems to be enhanced by the presence of fragmented red blood cell membranes. Several etiologic factors in the development of rhabdomyolysis and hemolysis are listed in [Table 13–7](#).

Clinical Features

A. Symptoms and Signs—Patients may note dark-colored red or brown urine. Symptoms and signs in rhabdomyolysis may be due to crush injury and other associated trauma and may be focal or diffuse. However, patients with rhabdomyolysis owing to inflammatory muscle disorders such as polymyositis may complain of muscle pain, tenderness, and weakness. Patients with hemolysis-induced renal failure will have symptoms related to severe anemia. Other clinical findings are due to renal failure and associated complications.

Table 13–7. Causes of pigment nephropathy: hemolysis and rhabdomyolysis.

Rhabdomyolysis

Physical trauma: crush injury, heat stress, electrocution, exercise, hypothermia, malignant hyperthermia, neuroleptic malignant syndrome
 Anoxic injury: arterial occlusion, seizures, tetanus, compartment syndrome
 Metabolic: hypokalemia, hypophosphatemia, diabetic ketoacidosis, myxedema, carnitine deficiency, hereditary muscle enzyme deficiency
 Infections: influenza-like viral infections, gas gangrene, pyomyositis
 Inflammation: polymyositis, dermatomyositis
 Poisons and toxins: ethanol, amphetamine, cocaine, snake and spider venom.

Hemolysis

Transfusion reactions
 Drug toxicities: quinine sulfate, hydralazine, etc.
 Poisons and toxins: benzene, aniline, fava beans, snake and spider venom, etc.
 Mechanical trauma: valvular prosthesis, extracorporeal circulation, march hemoglobinuria
 Enzyme deficiencies: glucose-6-phosphate dehydrogenase deficiency
 Osmotic stress: intoxication with hypotonic fluids as seen in drowning, transurethral prostatectomy, incorrect priming of extracorporeal circulation
 Infections: malaria
 Autoimmune: drugs, systemic lupus erythematosus

B. Laboratory Findings—In the absence of detectable red blood cells in the urine, a urinalysis dipstick positive for heme is virtually diagnostic of hemoglobinuria or myoglobinuria. Similarly, a highly positive heme reaction (3+ or 4+) in the face of minimal hematuria (3–5 red cells/high-power field [hpf]) is equally suspicious. Since myoglobin is sufficiently small to be filtered, patients with myoglobinuria have brown urine, but the serum is clear. In contrast, hemoglobinuria also may produce a dark brown urine, but the spun serum sample is pink because haptoglobin-bound hemoglobin is a complex that is too large to be filtered. Further confirmation of the diagnosis is seen in serum chemistry values. Rhabdomyolysis is associated with elevated creatine kinase (CK) and other muscle-derived enzymes released into the circulation, including aspartate aminotransferase (AST), lactate dehydrogenase (LDH), and aldolase. Of these, aldolase is specific for muscle damage. Occasionally, creatinine released from damaged muscle leads to an abnormally low BUN:creatinine ratio (<10:1). Severe hemolysis capable of producing renal failure is usually associated with detectable free hemoglobin levels above 25 mg/dL and a marked decrease in free haptoglobin. As with rhabdomyolysis, elevated LDH and AST may be present; thus these abnormalities do not permit distinction between the two disorders.

C. Imaging Studies—Imaging studies are not helpful in diagnosis of pigment nephropathy other than in evaluating the extent of injury in patients with traumatic rhabdomyolysis. In patients with serious trauma with renal failure, however, injury to the kidneys, ureters, bladder, or urethra should be considered, and ultrasound, CT scan, or IVP may be helpful in distinguishing direct injury from rhabdomyolysis.

Treatment

The single most important therapeutic maneuver is to restore circulating volume rapidly and initiate diuresis. If oliguria is present, a single dose of mannitol, 12.5 g intravenously, can be given to promote diuresis. If successful, mannitol can be continued as a 5% infusion. Alternatively, furosemide, 40–200 mg intravenously, can be given and repeated every 6 hours if necessary. Forced diuresis with aggressive hydration should strive for a urine output of at least 100 mL/h and should be maintained until levels of creatine kinase or haptoglobin begin to normalize. Alkalinization of the urine is recommended by some, but there is no definitive evidence that it is necessary.

Rhabdomyolysis is commonly associated with several potentially troublesome electrolyte disorders. Hypocalcemia may be seen early, probably as a consequence of precipitation of calcium salts owing to associated hyperphosphatemia. Despite extremely low levels of serum calcium, tetany is uncommon, perhaps owing to the associated acidosis. Severe hyperuricemia also may be encountered. Hyperkalemia, sometimes extremely difficult to control, may be encountered with both rhabdomyolysis and hemolysis. In contrast,

crush victims who have received early and vigorous fluid resuscitation and who present with polyuria may develop hypokalemia. Hypercalcemia during the recovery phase may be the result of calcium release from healing muscle and an increase in 1-25 dihydroxyvitamin D.

2. Pulmonary Renal Syndromes

Any type of acute renal failure can present with fluid overload and pulmonary edema, but there are several conditions in which simultaneous involvement of both lung and kidneys is a common presentation or an intrinsic part of the basic pathogenesis (Table 13–8). Of these, two are of particular importance because their rapid identification and subsequent treatment can be lifesaving: Goodpasture's syndrome and paraquat intoxication.

Goodpasture's Syndrome

Goodpasture's syndrome is an autoimmune disease characterized by the formation of anti-GBM antibodies that attack

Table 13–8. Pulmonary-renal syndromes causing acute renal failure.

Disease	Renal Involvement
Goodpasture's syndrome	RPGN
Wegener's granulomatosis	RPGN
Systemic lupus erythematosus	RPGN
Churg-Strauss syndrome	RPGN
Sarcoidosis	Interstitial nephritis
Scleroderma	Hypertensive renal crisis
Pulmonary embolism	Prerenal azotemia
Pneumonia	Prerenal azotemia
Poisons (paraquat)	Acute tubular necrosis
Congestive heart failure	Prerenal azotemia
Adult respiratory distress syndrome	Acute tubular necrosis, prerenal azotemia

Key: RPGN = rapidly progressive glomerulonephritis; ATN = acute tubular necrosis

both the pulmonary capillary and the glomerulus. The classic clinical presentation is that of a young male smoker with signs of acute glomerulonephritis (ie, hematuria, proteinuria, and red blood cell casts) and hemoptysis associated with bilateral pulmonary infiltrates. Iron deficiency anemia is also a frequent finding.

The diagnosis of Goodpasture's syndrome can be made by detecting serum levels of anti-GBM antibodies or by linear immunofluorescence of the GBM on renal biopsy. Unfortunately, availability of these confirmatory tests may be delayed, and rapid initiation of treatment often depends on a high degree of suspicion. Early initiation of treatment is essential because therapeutic success in reversing renal failure is rare if the therapy is started after the onset of oliguria. Aside from smoking, genetic predisposition and hydrocarbon exposure have been identified as associated risk factors.

Both life-threatening hemoptysis and rapidly progressive renal failure can be treated successfully with a combination of corticosteroids, cyclophosphamide, and 2 weeks of daily plasma exchange.

Paraquat Poisoning

Paraquat is a herbicide used in concentrated solutions. Ingestion is highly corrosive for the oral and esophageal mucosa, and net absorption results in pulmonary edema and anuria. Effective treatment involves gastric lavage and aggressive use of charcoal adsorbents. Daily treatments with charcoal hemoperfusion or high-efficiency hemodialysis may be helpful in lowering paraquat levels. There is also reason to believe that low oxygen tension may limit lung injury. Consultation with a poison control expert should be sought. Web site information can be obtained from the national pesticide information network at <http://ace.orst.edu/info/nptn/>

Van Vleet TR, Schnellmann RG: Toxic nephropathy: Environmental chemicals. *Semin Nephrol* 2003;23:500–8. [PMID: 13680539]

3. Hepatorenal Syndrome

Conditions associated with combined hepatic and renal failure include infections (eg, sepsis, hepatitis, and leptospirosis), drug toxicity (eg, acetaminophen, allopurinol, rifampin, and methoxyflurane), poisons (eg, rodenticide and carbon tetrachloride), and autoimmune disorders (eg, systemic lupus erythematosus, vasculitis, and cryoglobulinemia). More common, however, is prerenal azotemia associated with cirrhosis. Patients presenting with this combination often have signs of advanced liver disease, hypoalbuminemia, and ascites. Under these conditions, if prerenal azotemia

becomes unresponsive to intravascular volume replacement, a diagnosis of *hepatorenal syndrome* becomes appropriate. This syndrome is a condition of severe renal vasoconstriction presenting with extremely low urinary sodium (<10 meq/L), decreased FE_{urea} (<20%), an extremely high urine:plasma creatinine ratio, and a relatively unimpressive urine sediment showing bile-pigmented casts.

Until recently, hepatorenal syndrome was considered to be almost universally fatal, rendering preventive measures as the most important management option. Most patients with hepatorenal syndrome develop the problem during hospitalization. GI hemorrhage, bacterial peritonitis, and the overzealous use of diuretics to control ascites all have been shown to be associated with the precipitation of the hepatorenal syndrome. Thus it is crucial that all patients presenting with liver disease and prerenal azotemia receive aggressive volume repletion. In many cases, pulmonary edema and ascites may be limiting factors in repletion; central venous pressure or pulmonary artery catheterization may be required to adequately judge how much fluid can be administered safely. With increasing central venous pressure, there also will be the increased risk of variceal hemorrhage. In patients with peripheral edema associated with hypoalbuminemia, albumin infusions can successfully mobilize fluid into the intravascular space, but ascites formation increases in approximately one-third of patients. In the same vein, high-volume paracentesis should be performed in conjunction with intravenous albumin infusions to minimize the tendency for intravascular volume depletion.

Successful reversal of well-established hepatorenal syndrome is rare, but several new treatment strategies appear to offer some success. The combined use of midodrine (an α_1 -adrenergic agonist) and octreotide (a somatostatin analogue) may improve renal hemodynamics and subsequent survival. The use of vasopressin analogues in conjunction with albumin infusions also may improve renal perfusion, but there is also the risk of ischemia. Interestingly, since the hepatorenal syndrome is a result of a severe renal vasoconstriction, the renal parenchyma may remain intact, and liver transplantation has been associated with return of renal function. Recently, there have been reports in Europe of successful treatment of hepatorenal syndrome with albumin-based dialysis (molecular adsorbent recycling system [MARS]).

4. Renal Failure in AIDS

Acute renal failure occurs in more than 50% of hospitalized patients with AIDS. The combination of volume depletion, nephrotoxic medications, and sepsis accounts for most cases (Table 13–9), but most AIDS patients presenting with acute renal failure can recover renal function and be discharged from the hospital.

Intravascular volume depletion can result from poor fluid intake, fever, and GI disturbances or may be secondary to hypoalbuminemia owing to nephrotic syndrome or malnutrition. Enlarged periaortic lymph nodes can obstruct lower extremity venous return, resulting in severe leg edema but insufficient central venous pressure. Careful attention to restoring intravascular volume not only reverses prerenal azotemia but also will serve to reduce substantially the risk of nephrotoxicity associated with medications and radiocontrast agents. In many cases of drug-induced renal failure, renal function may return rapidly after termination of exposure to the drug, such as can be seen with NSAIDs and the crystalluria associated with indinavir and acyclovir. In other cases, a full-blown syndrome of acute tubular necrosis may develop; this disorder may require dialytic therapy before recovery.

A renal syndrome that seems to be unique to patients with AIDS is rapidly progressive focal segmental

glomerulosclerosis. This syndrome is most common in patients of African descent and is associated with nephrotic-range proteinuria (>3 g/day), enlarged, hyperechogenic kidneys on renal ultrasound, and—in contrast to focal segmental glomerulosclerosis in the non-AIDS population—normotension. Progression of this type of renal disease can be explosive, reaching a stage of irreversible renal failure in weeks or months. Recent experience, however, suggests that the new highly active antiretroviral therapy (HAART) regimens can slow the progression of this type of AIDS nephropathy.

Standard precautions during hemodialysis are employed to limit transmission of HIV and hepatitis B. In addition, HIV has been identified in peritoneal dialysate from patients with AIDS, and this effluent should be handled with appropriate precautions.

5. Renal Failure in the Renal Transplant Recipient

Acute renal failure in the transplant recipient can be arbitrarily defined as being early (<10 days after transplantation) or late (>10 days). In the early period, acute renal failure may be due to ischemic acute tubular necrosis of the transplanted graft, acute or hyperacute immunologic rejection, or technical problems related to the surgery (eg, obstruction, leak, or infection of the renal artery or vein or of the ureter). Acute drug toxicity from cyclosporine can present as prerenal azotemia associated with hypertension and is encountered most often with relatively elevated intravenous dosing.

Acute renal failure in the late period may be the result of acute rejection, cyclosporine toxicity, ureteral obstruction, renal artery stenosis, or recurrence of the original renal disease. Acute rejection may present with fever, graft tenderness, and swelling where the kidney is implanted into the iliac fossa, but concurrent immunosuppressive therapy with steroids or cyclosporine may mask these signs. If the history, physical examination, and imaging studies (ie, ultrasound and nuclear flow scans) cannot distinguish the cause of renal failure, renal biopsy may be required. In any event, prompt and continued consultations with the patient's transplant surgeon and nephrologist are essential to proper management.

The intensivist is often in a position to identify potential organ donors. Acceptable donors for renal transplantation

Table 13–9. Causes of acute renal failure associated with AIDS.

Prerenal azotemia

Volume depletion, hypoalbuminemia, NSAIDs

Acute tubular necrosis

Pentamidine, amphotericin B, aminoglycosides, foscarnet, acyclovir, radiocontrast agents, sepsis, shock

Allergic interstitial nephritis

Trimethoprim-sulfamethoxazole, phenytoin

Rapidly progressive focal segmental glomerulosclerosis

Obstructive uropathy

Sulfadiazine-related crystalluria, lymphoma, retroperitoneal fibrosis

Nephrolithiasis

Indinavir-induced crystalluria

Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome

Renal edema

Hypoalbuminemia with massive proteinuria

Multiple myeloma

Acute glomerulonephritis

are aged 6 months to 60 years with no identifiable renal disease, no active infection, and no malignancy (except brain tumors). Physicians working in the ICU should familiarize themselves with local laws and policies regarding the procurement of organs and the criteria for brain death.

NONDIALYTIC THERAPY FOR ACUTE RENAL FAILURE

► Fluid Balance

Achieving the appropriate fluid balance in the setting of an ICU involves two potentially conflicting goals: providing sufficient volume to ensure adequate renal perfusion and avoiding volume overload with resulting pulmonary congestion. In some patients, when decreased renal perfusion is suspected in the context of pulmonary compromise, only a pulmonary artery catheter will yield sufficient information to guide appropriate therapy. Optimal fluid management for acute renal failure can be divided arbitrarily into three periods: (1) the prevention phase, during the initial onset of oliguria, (2) the oliguric phase, once renal failure is well established, and (3) the recuperative phase, often heralded by relative polyuria. Not all episodes of acute renal failure pass through each of these phases, but a discussion of their management is a useful guide to overall treatment goals.

Prevention Phase

On initial presentation, the onset of oliguria should call for prompt evaluation of the type of renal dysfunction. If volume depletion is suspected, rapid restoration of circulating volume may prevent ischemic damage. Restoration of adequate circulating volume can be achieved by administration of crystalloid or colloid. If simple fluid repletion is required, normal saline usually suffices. In the context of hypoalbuminemia and edema, intravenous albumin can serve to draw excess extravascular fluid into the circulation.

If oliguria persists despite adequate fluid replacement and acute tubular necrosis is suspected, a short trial of diuretic therapy may offer some benefit in limiting renal damage. A single intravenous 12.5-g dose of mannitol may initiate diuresis and has the theoretical advantage of limiting epithelial cell swelling and intratubular precipitation of cellular debris. If initially unsuccessful, further mannitol administration is potentially harmful in that it may lead to poorly

tolerated intravascular expansion. Alternatively, furosemide may be given intravenously at a dose of 200 mg (1-hour infusions are preferable to more rapid injection) and may be repeated safely within 6 hours. Dosages above 1 g/day have been associated with ototoxicity. If, despite the preceding maneuvers, oliguria persists more than 24 hours, diuretics should be discontinued, and the physician should be prepared to manage a potentially prolonged period of oliguria.

Oliguric Phase

The oliguric phase of acute renal failure may persist for several weeks. During this period, especially in the critical care setting, the patient may require enormous amounts of intravenous fluids, including hyperalimentation, vasopressors, and antibiotics. Every effort should be made to minimize the volume of these infusions. Continuous infusions of vasopressors should be maximally concentrated, and antibiotics should be given in minimum volumes of fluid. When given in adequate amounts, parenteral hyperalimentation always requires 1–2 L/day. Thus enteral alimentation is always preferred when possible.

Proper maintenance of fluid balance requires careful attention to all avenues of fluid intake and output, including surgical drains, nasogastric suction, and diarrhea. Normal insensible losses can equal 1000 mL/day but can increase substantially in the presence of fever, burns, or exfoliative dermatitis. Increased minute ventilation enhances water loss from the lungs even if the inspired gas is humidified. On the other hand, metabolism of carbohydrate and fat yields approximately 500 mL/day of metabolically produced water. Thus, unless insensible losses are increased, an anuric patient requires only 500 mL/day of water. Finally, despite meticulous monitoring of fluid input and output, there can be no substitute for daily weight measurements.

Recuperative Phase

In many patients with acute renal failure, the oliguric phase is followed by a period of relative polyuria, heralding the beginning of tubular recuperation. During this period, serum urea nitrogen and creatinine may remain elevated, and renal dysfunction persists. One must bear in mind that the urine produced is not appropriately concentrated and that reabsorption of sodium and other ions is inadequate. During this phase, it is the goal of management to replace lost volume and electrolytes. Urinary sodium and potassium should be measured and replaced in appropriate amounts. Abnormalities of magnesium, calcium, and phosphate also should be anticipated.

Monitoring Fluid Balance

In the presence of active pulmonary disease such as pneumonia, acute respiratory distress syndrome (ARDS), or pulmonary edema and suspected prerenal azotemia, aggressive fluid replacement may worsen pulmonary gas exchange.

Furthermore, in patients with vasodilatory shock or hypalbuminemia, substantial edema may be present, and still the patient has insufficient circulating volume. In these settings, intravascular pressure monitoring becomes invaluable. Although central venous pressure can be monitored easily via subclavian, internal jugular, or femoral vein catheterization, a more definitive assessment of optimal cardiac filling pressures can be obtained with pulmonary artery catheterization. This is because central venous pressure can be increased by pulmonary hypertension or central venous thrombosis or occlusion even in a volume-depleted patient. Similarly, positive-pressure ventilation and, especially, positive end-expiratory pressure may elevate pulmonary capillary wedge pressure spuriously.

► Acid-Base Balance

Uremic acidosis occurs as a result of the slow accumulation of phosphates and sulfates and is related to protein catabolism. Approximately 1 meq acid is retained for every gram of protein catabolism. Thus a 70-g protein diet yields approximately 70 meq acid, which, when distributed into the total body water compartment, consumes approximately 2 meq bicarbonate per liter per day. Replacement of this amount of bicarbonate is relatively easy and can be in the form of intravenous sodium bicarbonate, orally administered sodium or potassium citrate, or as acetate in hyperalimentation solution (1 meq acetate converts to 1 meq bicarbonate plus some energy). The patient's tolerance for the associated sodium and potassium load should be considered.

Patients with prolonged uremia may present with a substantial buffer deficit (serum bicarbonate <15 meq/L), Kussmaul respirations, and associated hypocalcemia. In this situation, bicarbonate replacement relieves the dyspnea by correction of acidosis, but the rapid increase in serum pH may precipitate tetany. Under these conditions, after determination of serum calcium and phosphate, it may be prudent to administer 1 ampule of calcium gluconate after the first 50–100 meq of bicarbonate. However, if phosphate levels are particularly elevated, there is a theoretical risk of metastatic calcifications with calcium administration.

Lactic acidosis is potentially a more difficult problem. In the presence of insufficient tissue oxygenation, lactic acid production can exceed 50 meq/h. This amount of acid lowers serum bicarbonate at a rate of 1–2 meq/L per hour. In the face of oliguria, replacement of this amount of bicarbonate would risk intravascular fluid overload and hypernatremia and may require dialytic therapy. Therefore, in lactic acidosis, an aggressive effort to restore adequate tissue perfusion is the mainstay of treatment.

Metabolic alkalosis is an uncommon complication of acute renal failure, but it may occur as a result of massive losses from gastric suctioning. Decreasing net acid loss can be achieved by raising gastric pH with H_2 blockers such as cimetidine or ranitidine or with proton pump inhibitors such as omeprazole or lansoprazole. If these efforts fail, acid

can be given carefully as arginine hydrochloride or dilute hydrochloric acid. These treatments can produce severe life-threatening hyperkalemia and must be given with vigilant monitoring of potassium levels.

► Electrolytes

Sodium

Sodium balance in acute renal failure is maintained by evaluation and matching of sodium losses. Urinary losses are best measured with 24-hour collections but can be reasonably assessed by random sampling and multiplication of sodium concentration by the day's total urine volume. After diuretic administration, urinary sodium will be increased for several hours and may not reflect a constant excretion rate. GI losses must be either measured (eg, nasogastric suction) or estimated (eg, diarrhea)(Table 13–10).

In oliguric renal failure, hyponatremia is the most common electrolyte abnormality and is almost always the result of excessive free water administration. Since most fluid losses are lower in sodium when compared with serum (see Table 13–10), a reasonable initial approach is to add 50 meq sodium to each liter of infused fluid, most notably the hyperalimentation fluid. Daily monitoring of serum sodium allows for readjustment of water and sodium administered as necessary.

Potassium

Hyperkalemia is the most serious electrolyte abnormality associated with acute renal failure. Cardiotoxicity, however, does not correlate strictly with the measured serum potassium and may be encouraged by acidosis, serum calcium concentration, and medications. The most rapid and reliable means for assessing cardiotoxicity is to obtain an ECG, which may show hyperkalemia in the form of peaked T waves, a prolonged PR interval, diminished to absent P waves, widening of the QRS complex, prolongation of the QT interval,

Table 13–10. Sodium content: intake and output.

Sodium Content of Intravenous Infusion Fluids	Sodium Content of Body Fluids
1 g Na^+ = 43 meq Na^+	Gastric fluid = 30–90 meq Na^+ per liter
1 g NaCl = 17 meq Na^+	Diarrhea = 50–110 meq Na^+ per liter
1 L of 0.9% NaCl = 154 meq Na^+	Small bowel ostomy = 70–150 meq Na^+ per liter
1 L of 0.45% NaCl = 77 meq Na^+	Biliary drainage = 120–170 meq Na^+ per liter
1 L of Ringer's lactate = 130 meq Na^+	Sweat = 20–100 meq Na^+ per liter
50 mL of 7.5% $NaHCO_3$ = 44 meq Na^+	

and ultimately, a sine wave pattern. Immediate management requires medications designed to stabilize the myocardial membrane and promote intracellular movement of potassium. Infusion of calcium, bicarbonate, and insulin with glucose temporarily improves the electrocardiographic abnormalities. Definitive procedures for removing potassium should be initiated as soon as possible.

In oliguric patients unresponsive to diuretic therapy, exchange resins of sodium polystyrene sulfonate are the most efficient means of extracorporeal potassium removal. Administration can be either orally or by retention enema for at least 30 minutes (orally: 50 g resin in 150 mL 20% sorbitol; by enema: 50 g resin in 200 mL tap water to avoid sorbitol-induced colonic irritation). These doses can be repeated every hour as necessary. Each potassium ion removed will be exchanged for a sodium ion—a situation that may be poorly tolerated in the hypernatremic or fluid-overloaded patient. In addition, to avoid the possibility of forming intraluminal concretions, sodium polystyrene sulfonate never should be given concurrently with aluminum hydroxide (used as a phosphate binder or antacid). When these measures are poorly tolerated because of fluid overload or hypernatremia—or when the GI tract is not available for use—dialytic therapy should be considered.

Maintaining potassium balance requires evaluation of renal and extrarenal losses (Table 13–11). A normal diet contains approximately 70–100 meq potassium per day, and dietary potassium restriction to 2 g (50 meq) per day is reasonable for patients with oliguric renal failure.

Calcium

Hypocalcemia often accompanies chronic renal failure and is the result of hyperphosphatemia and altered vitamin D metabolism. In acute renal failure, hypocalcemia may be associated with the hyperphosphatemic phase of rhabdomyolysis or may occur during administration of the antiviral agent foscarnet. Hypercalcemia is seen in multiple myeloma

or hyperparathyroidism. Urinary calcium losses are minimal during acute renal failure. Frank tetany is rare and is usually the result of overly aggressive correction of acidosis. Since hypoalbuminemia and acid-base disturbances are common in the critically ill patient, ionized calcium levels, when available, are preferred to total serum calcium.

Magnesium

Magnesium excretion is limited during renal failure, and magnesium-containing antacids such as Maalox and Mylanta should be avoided. Magnesium wasting may occur with amphotericin- or cisplatin-induced renal failure or during the polyuric recuperative phase of acute tubular necrosis.

Phosphate

Hyperphosphatemia results from insufficient renal excretion and secondary hyperparathyroidism. Avoiding hyperphosphatemia limits the risk of metastatic calcifications and helps to maintain normal levels of ionized calcium. Diets should be limited to 800 mg/day of phosphorus, but even at this level, oral phosphate binders are required to limit GI absorption. When serum phosphorus exceeds 6 mg/dL, aluminum hydroxide antacid can be given at a dosage of 30 mL with each meal and at night. Sevelamer at a dose of 800–1600 mg with each meal also can be used as an effective phosphate binder and has the advantage of not presenting the potential for aluminum toxicity or the constipation associated with aluminum hydroxide.

When levels are controlled below 6 mg/dL, calcium carbonate at 500 mg with each meal or calcium acetate at 667 mg with each meal can be initiated. Intravenous hyperalimentation should be prepared without phosphate until levels are normalized. However, once normal phosphorus levels are reached, intravenous hyperalimentation solutions should contain approximately 100–250 mg phosphorus per day (5–10 meq sodium or potassium phosphate). In the presence of renal failure, hypophosphatemia is almost always the result of prolonged parenteral nutrition devoid of phosphate.

Table 13–11. Potassium content: intake and output.

Intake
2 g K ⁺ in diet = 50 meq
Output
Gastric fluid = 4–12 meq K ⁺ /L
Abdominal drainage = approximately the serum level
Diarrhea = 10–30 meq K ⁺ /L
Sorbitol-induced diarrhea = 30–40 meq K ⁺ /L
Sodium polystyrene sulfonate (Kayexalate) = 1 meq K ⁺ /g of retained absorbent per hour
Urine = 5–150 meq K ⁺ /L
Peritoneal dialysis (2 L/h), CAVH (1 L/h) = 5–10 meq K ⁺ /h*
Hemodialysis = 40–60 meq K ⁺ /h*

*Assuming serum [K⁺] = 5 meq/L.

Key: CAVH = continuous arteriovenous hemofiltration

► Nutrition

Nitrogen Balance

Several studies have suggested that appropriate nutritional support can promote renal recovery and improve overall survival in patients with acute renal failure. Unfortunately, there is often conflict between giving adequate protein replacement while at the same time limiting the production of nitrogenous wastes. Under ideal conditions, an adequate diet should include 1 g/kg per day of protein and 35–40 kcal/kg per day of carbohydrates and fats. There is no definitive evidence that diets with substantially more than 1.2 g/kg per day of protein enhance survival rates or reduce morbidity,

with the possible exception of the patient with extensive burns. Overly aggressive protein feeding (>2 g/kg per day) is unwarranted and can lead to abnormally high amino acid levels and an unnecessary increase in retained nitrogen wastes. In the very stable patient with minimal net negative nitrogen balance (<5 g/day), protein intake can be limited to 0.6 g/kg per day. In the nonoliguric patient, this may reduce the need for dialysis, but careful attention to nitrogen balance is required.

Nitrogen balance can be evaluated easily by measuring the rate of urea production, commonly referred to as the *urea nitrogen appearance* (UNA). The daily UNA can be measured by obtaining a 24-hour urine for urea nitrogen measurement and evaluating the change in BUN occurring at the beginning and end of the 24-hour collection. The UNA then can be calculated using the following formula:

$$\text{UNA (g/day)} = \frac{\text{BUN}_2 - \text{BUN}_1}{100} \times \text{total body water} + \text{UUN}$$

where UNA equals the daily urea nitrogen appearance in grams per day, BUN₁ and BUN₂ are the levels of blood urea nitrogen in milligrams per deciliter at the beginning and end of the 24-hour urine collection, total body water in liters is estimated as 60% of lean body mass plus the amount of any extra edema fluid, and UUN is the urine urea nitrogen expressed as grams per day.

Under conditions of nitrogen balance, UNA depends on protein ingestion and can be calculated as follows:

$$\text{UNA (g/day)} = \frac{\text{Protein intake (g/day)}}{6.25} - \text{Nonurea nitrogen (g/day)}$$

It is assumed that every 6.25 g of protein contains 1 g of nitrogen and that the production of nonurea nitrogen is 30 mg/day per kilogram of lean body mass. The minimum amount of urea clearance required to remove a given amount of UNA can be calculated using the following formula:

$$\text{Urea clearance (L/day)} = \frac{\text{UNA (g/day)}}{\text{BUN (mg/dL)}} \times 100$$

When the preceding formulas are used, a 70-kg patient receiving 1 g/kg per day of protein will receive 11 g nitrogen (70 g ÷ 6.25). On balance, approximately 2 g nitrogen will become nitrogenous wastes other than urea; the remaining 9 g will form urea.

On the other hand, many patients with acute renal failure present with a degree of hypercatabolism. Under these conditions, urea production is greatly enhanced owing to the catabolism of endogenous proteins, and UNA can greatly

exceed that predicted from exogenous protein administration alone. For example, under conditions of severe stress, endogenous protein breakdown can generate 30 g or more of urea nitrogen per day, representing the catabolism of approximately 200 g protein. In addition to enhanced proteolysis accompanying hypercatabolism, increased urea production is often the result of GI bleeding, with the ultimate breakdown and absorption of the blood and its proteins. There are approximately 200 g protein per liter of whole blood.

Treatment of endogenous hypercatabolism and the negative nitrogen balance that results is controversial. Although adequate nutrition is essential, it is often not sufficient to match the ongoing catabolism. Several studies have demonstrated that increased protein catabolism associated with stress is mediated by hormones (eg, glucagon, catecholamines, and cortisol) and cytokines (eg, interleukins, tumor necrosis factor, etc.). For this reason, overly aggressive protein administration is not only futile but yields unnecessary amounts of nitrogenous waste, thereby increasing the need for dialysis therapy. Until specific therapy for cytokine neutralization is available, the most successful strategy will be to administer the majority of needed calories in the form of carbohydrates, thus allowing for the maximum administration of "anticatabolic" insulin.

Calories

Adequate caloric intake is essential to minimize negative nitrogen balance and to improve overall survival. In the critically ill patient with acute renal failure, approximately 35 kcal/kg per day is a reasonable goal. Hyperglycemia resulting from administration of large amounts of carbohydrate can be managed with insulin.

Vitamins and Trace Elements

There is no evidence that patients with acute renal failure have unique requirements for either vitamins or trace elements. Thus daily minimum requirements should be adequate. Once dialysis is initiated, replacement of water-soluble vitamins should be assured. In most situations, a standard multivitamin preparation suffices with the possible exception of folic acid, which should be replaced at a dosage of at least 1 mg/day.

DIALYTIC THERAPY FOR THE CRITICALLY ILL PATIENT

Renal replacement therapy can provide homeostasis of fluid, electrolyte, acid-base, and nitrogen balance. Consequently, the initiation of renal replacement therapy should be considered whenever any of these factors cannot be controlled with other therapy. At present, three types of renal replacement treatment are available for the patient with acute renal failure: intermittent hemodialysis, peritoneal dialysis, and continuous renal replacement therapy (CRRT) (Table 13–12). The particular therapy chosen is often dictated by the patient's condition (eg, massive fluid overload, hypercatabolism, or vascular instability) and associated morbid states (eg, respiratory compromise, hemorrhagic risks, or abdominal surgery). Aside from these needs, the patient's baseline requirements for fluid and solute removal depend on nutritional intake and residual renal function.

Using conventional techniques, machine-driven hemodialysis is best suited for the hemodynamically stable patient in whom solute balance is the major concern and rapid fluid removal is well tolerated. Peritoneal dialysis is preferred in the patient with significant hemorrhagic risk and in

whom vascular access is difficult to obtain. Continuous hemofiltration and its related techniques are best for providing fluid removal in the patient with vascular instability or massive fluid overload. Despite these generalizations, with appropriate technical modifications, adequate renal replacement therapy can be provided by any of these methods.

► Indications for Dialytic Therapy

Fluid Overload

Poorly tolerated volume overload is the most evident indication for initiating renal replacement therapy. In general, the need to relieve pulmonary vascular congestion is the most pressing issue. It should be noted that even massive amounts of peripheral edema may be appropriate for the patient's condition (ie, hypoalbuminemia or vasodilatory shock), and fluid removal may cause intravascular volume depletion, hampering the return of endogenous renal function. When hypotension is associated with edema and apparent pulmonary congestion, pulmonary artery catheter monitoring can be invaluable in determining the amount of fluid that can be removed safely.

Table 13–12. Renal replacement therapies: urea clearance and protein losses.

Treatment	Prescription	Time-Averaged			
		Urea Clearance			Protein Loss
		mL/min	L/day	L/week	g/day*
Hemodialysis†	3 × 4 h/week	14.3	21	144	6
	7 × 4 h/week	33.3	48	336	15
Peritoneal dialysis	2 L/h	26.7	24	168	30
CAPD	2 L/6 h‡	6.9	10	70	10
CAVH	14 L/day	9.7	14	98	15
CAVHD	1–2 L/h	19–35	29–51	189–357	11
CVVH	1–3 L/h	17–50	24–72	168–504	18–36
CVVHD	1–3 L/h	19–52	27–75	189–525	18–36

*Includes amino acids and peptides. Published data have been adjusted to account for increased porosity of currently available dialyzers.

†Assumes average urea clearance of 200 mL/min.

‡Assumes 3 L/d net filtrate.

Key: CAPD = chronic ambulatory peritoneal dialysis

CAVH = continuous arteriovenous hemofiltration

CAVHD = continuous arteriovenous hemodialysis

CVVH = continuous venovenous hemofiltration

CVVHD = continuous venovenous hemodialysis/hemodiafiltration

Modified from Kaplan AA: Dialysis and other extracorporeal therapy for acute renal failure. In: *Current Therapy in Nephrology and Hypertension*, 4th ed. Glasscock RJ (editor). Mosby, 1998. Copyright 1998 Elsevier.

In the hemodynamically stable patient, intermittent hemodialysis can provide the most rapid removal of fluid by easily removing 1–2 L of fluid per hour by ultrafiltration. In patients with vascular instability, one of the continuous therapies is more appropriate because modest rates of fluid removal can proceed steadily throughout the day. For example, peritoneal dialysis can provide for the gentle removal of the 2–3 L/day necessitated by intravenous medications and hyperalbuminemia. Excessive net fluid removal (>5–10 L/day), however, may lead to hypernatremia because fluid removed by peritoneal dialysis is hyponatric when compared with plasma. In patients presenting with massive fluid overload, continuous hemofiltration offers the best-tolerated treatment because the ultrafiltrate is isosmotic. A reasonable combination of treatments would employ several days of continuous hemofiltration to achieve normovolemia, followed by intermittent hemodialysis to provide maintenance therapy.

Electrolyte Abnormalities

Electrocardiographic changes caused by hyperkalemia should be treated initially with nondialytic therapy (eg, calcium, glucose, and insulin). The only renal replacement therapy capable of rapid potassium removal is machine-driven hemodialysis, providing clearance rates of 150–250 mL/min or more (see Table 13–11). Neither continuous hemofiltration nor peritoneal dialysis can achieve potassium clearance rates much above 20–40 mL/min, and both these continuous therapies are best reserved for normalization of modest levels of hyperkalemia or for maintaining potassium balance.

Toxic serum levels of calcium, magnesium, or phosphate are also most rapidly corrected with machine-driven hemodialysis. Once normal levels are achieved, any of the renal replacement therapies can maintain homeostasis if nutritional intake is limited and magnesium-containing phosphate binders are avoided. Renal replacement therapies using dialysate (ie, hemodialysis, peritoneal dialysis, or continuous hemodialysis) may contain calcium concentrations of 3.5 meq/L (1.75 mmol/L of ionized calcium) in the dialysate. Therefore, successful and rapid treatment of hypercalcemia requires lower dialysate calcium concentrations of 2.5 meq/L (1.25 mmol/L) or less. Severe hypophosphatemia may complicate all renal replacement therapies, especially in patients being maintained on intravenous hyperalbuminemia devoid of phosphate.

Acid-Base Abnormalities

Uremic acidosis rarely generates more than 50–100 mmol acid per day and can be easily corrected by any of the renal replacement techniques. Severe uremic acidosis is encountered most often as a presenting abnormality of unattended chronic renal failure. Under these conditions, hemodialysis can provide the most rapid correction of acidosis, but aggressive hemodialysis may precipitate a dysequilibrium syndrome. Despite associated hyperkalemia, the dialysate bath composition should include at least 2 mmol/L potassium because correction of acidosis causes a substantial lowering

of serum potassium concentration. Consideration also should be given to a relatively low-calcium bath (2.5 meq/L) because overly aggressive correction of long-standing hypocalcemia may precipitate nausea, vomiting, muscle cramping, and hypertension.

Lactic acid may be produced at rates of up to 50 mmol/h and usually is associated with severe hemodynamic instability. Although daily hemodialysis can provide adequate replacement of lost bicarbonate, the patient may be left with rapidly worsening acidosis during the interdialytic period. Continuous hemofiltration can provide continuous correction of acidosis and may be best for managing the fluid overload often associated with shock and its treatment. Replacement solutions containing 150 mmol/L bicarbonate can provide as much as 100 mmol/h of continuous buffer replacement, but required calcium replacement must be administered in a separate solution. Peritoneal dialysis, with exchanges at 2 L/h, can provide approximately 25 mmol buffer per hour. Dialytic solutions containing lactate should be avoided because conversion to bicarbonate may be slowed in patients with circulatory impairment.

Uremia

Although urea is not universally accepted as a uremic toxin, its levels are used most commonly to judge the degree of uremic toxicity. Several studies suggest that maintaining predialysis BUN at or below 120 mg/dL (43 mmol/L) is beneficial for overall survival, and it is no longer acceptable to tolerate excessively high urea levels prior to initiation of renal replacement therapy. There is good or better evidence to suggest that proper protein-calorie nutrition is also beneficial. Thus it is inappropriate to withhold adequate nutrition in order to avoid the associated increase in nitrogen and fluid intake. On empirical grounds, when pericarditis, encephalopathy, or hemorrhage is associated with BUN levels above 100 mg/dL, it is hard to argue that such symptoms are not at least partially the result of retained uremic toxins. With the preceding considerations in mind, it is reasonable to initiate renal replacement therapy when BUN is above 100 mg/dL (36 mmol/L). Nonetheless, if rapid return of renal function is anticipated (eg, in the presence of prerenal azotemia or obstructive uropathy), levels of 150 mg/dL (54 mmol/L) or more may be tolerated for a limited period.

Specific indications for dialytic therapy for complications of uremia include uremic encephalopathy, pericarditis, and uremic platelet dysfunction. Slowed mentation, somnolence, and convulsions are part of the uremic syndrome and are usually associated with other neuromuscular manifestations, including asterixis, myoclonus, and muscle twitching. In general, these symptoms respond within several days after the start of dialytic therapy.

Despite the existence of massive pericardial effusions, patients with uremic pericarditis may present with hypertension and pulmonary congestion. The treatment of uremic pericarditis often presents two distinct problems:

removal of fluid in the face of potentially compromised hemodynamics and definitive treatment of the pericardial inflammation. Initial rapid fluid removal with hemodialysis may be well tolerated, but as volume removal proceeds, intravascular pressures may become inadequate to maintain intracardiac filling, and severe hypotension may result. Thus normovolemia should be achieved with gentle fluid removal and anticipation of rapid declines in blood pressure. Although the toxins responsible for uremic pericarditis have not been identified, it has been shown empirically that aggressive solute removal can lead to resolution of pericarditis. Hemodialysis performed five times weekly is recommended, but means to limit anticoagulation should be employed in order to minimize the risk of hemopericardium. In patients with large pericardial effusions, early use of pericardiectomy may be recommended because aggressive hemodialysis may be associated with a high mortality rate. In one retrospective report, peritoneal dialysis was found to be superior to hemodialysis in avoiding the need for surgical drainage. Peritoneal dialysis also avoids the risk of anticoagulation.

Uremic platelet dysfunction is identified most often with prolongation of the bleeding time. In general, bleeding times will normalize along with lowering of serum urea. Acutely, rapid correction of platelet dysfunction can be achieved with infusions of desmopressin at a single dose of 0.3 µg/kg.

▶ Drug Dosing During Renal Replacement Therapy

Many renally excreted medications require dosage modification to account for the amount removed by a given renal replacement therapy. Unfortunately, most of the published data are of questionable accuracy as a result of variability between patients and the great differences in clearance rates achievable with each technique. Four factors govern the removability of a given drug: molecular weight, degree of protein binding, volume of distribution, and endogenous plasma clearance. In general, hemodialysis can offer the most rapid clearance rates for a low-molecular-weight drug (<500 kDa). Continuous hemofiltration—but not continuous hemodialysis—will efficiently remove drugs with molecular weights as high as 10,000 kDa or more. Peritoneal dialysis will eliminate drugs in the range of MW 500–10,000 kDa. Highly protein-bound medications are not substantially removed by any of the renal replacement techniques, with the possible exception of peritoneal dialysis. In addition, modifications of the major techniques may profoundly alter clearance rates because most of the published data were obtained with more conventional methodology. For example, it has been shown recently that the most modern “high flux” dialyzers can offer substantial removal of relatively high-molecular-weight drugs (>1500 kDa), thus greatly changing their dosing requirements as compared with previous recommendations.

Aronoff GR et al: *Drug Prescribing in Renal Failure: Dosing Guidelines for Adults*, 4th ed. New York: American College of Physicians, 1999.

▶ Stopping Dialysis

Owing to the availability of chronic dialysis, irreversibility of renal failure is not an acceptable indication for stopping treatment. Instead, the patient’s wishes and overall clinical status should be the only considerations in discontinuing therapy. In general, withholding of dialysis may be considered when there is evidence of irreversible vital organ failure or severe cerebral damage. Most forms of acute renal failure reverse within 8 weeks. If renal failure persists beyond this period, one should initiate plans for maintenance dialysis therapy.

▶ Specific Types of Renal Replacement Therapy in Acute Renal Failure

1. Hemodialysis

Intermittent hemodialysis is the most widely used technique for acute renal failure. The method of treatment chosen varies depending on the rate of generation of nitrogenous wastes and the patient’s tolerance for fluid overload. In general, 4-hour treatments performed three times weekly are sufficient to provide adequate replacement in the oliguric or anuric patient. Patients with significant residual renal function may require fewer treatments per week, especially if renal failure is nonoliguric. Conversely, the patient with severe hypercatabolism and poorly tolerated fluid overload may require daily treatments.

The major advantage of hemodialysis is its highly efficient solute removal, thus limiting treatment time and making the patient available for other procedures and treatments. Disadvantages include relatively rapid fluid removal, which may be poorly tolerated. Other disadvantages of hemodialysis involve the need for large-bore hemoaccess and anticoagulation of the extracorporeal circuit.

Effectiveness of Hemodialysis

Solute clearance and ultrafiltration rates are variable depending on the blood flows obtained and the dialyzers chosen. Most modern dialyzers provide 150–250 mL/min of urea clearance with blood flows between 200 and 300 mL/min. More rapid solute clearance can be obtained with the newer more porous filters, especially when operated at blood flows of up to 400 mL/min or more. Currently available dialyzers also can produce between 1 and 3 L of ultrafiltrate per hour, usually limited by the patient’s hemodynamic stability. A relatively gentler type of hemodialysis involves the prolongation of the treatment in a low-efficiency mode. These slow, low-efficiency dialysis (SLED) treatments are applied from 8–18 hours at a time and allow for less aggressive fluid

removal. “High flux” dialyzers provide the most rapid solute clearance, but their use requires dialysis equipment with volumetric control of fluid removal.

In general, urea removal during hemodialysis follows first-order kinetics and assumes that urea is distributed throughout total body water. Under normal operating conditions, a 4-hour dialysis will lower pretreatment urea levels by approximately 50–70%. Factors that may decrease treatment efficiency include inadequate blood flow to the dialyzer, access recirculation, and dialyzer clotting.

Vascular Access

Efficient hemodialysis requires blood flows of at least 200–300 mL/min and a relatively large-bore vascular access. In the acute setting, the most widely used method is the percutaneous cannulation of either the femoral or subclavian vein with double-lumen catheters. Regardless of placement site, the use of double-lumen catheters may allow a certain percentage of dialyzed blood leaving the efferent lumen to reenter the afferent lumen. This process is known as *recirculation* and may reach values of 50% or more, resulting in extremely inefficient dialysis treatment.

Percutaneous placement of a double-lumen catheter in the femoral vein is the most widely used method for achieving rapid access for hemodialysis. Extensive experience has shown this method to be safe and well tolerated despite the necessity for repeated punctures. A disadvantage is that the catheter limits the patient’s mobility, and an unresolved issue is the length of time a single catheter can be left in place safely. Ideally, the catheter should be removed after every procedure; however, this is often impractical or impossible. In any event, prolonged catheter placement should be avoided. When alternative access sites are unavailable, catheters may be replaced over a guidewire, and the removed catheter tip sent for culture. Careful attention to sterile technique during placement and meticulous care of the access site are essential. The most serious complications of femoral vein access are retroperitoneal hemorrhage and pulmonary embolism. Retroperitoneal hemorrhage may result from iliac vein rupture and has been associated with difficult guidewire placement. Pulmonary emboli are the result of catheter-related thrombi and are most apt to occur with catheters left in situ for prolonged periods. Other complications include hematomas, thrombophlebitis, arteriovenous fistulas, sepsis, and access-site infection.

Subclavian vein access allows for unhindered patient mobility, and catheters in the subclavian vein have been left in place safely for prolonged periods. The major disadvantage is the increased risk of life-threatening complications during placement. Radiologic evaluation for catheter placement is required prior to the first treatment. Sharp angulations of the distal catheter tip necessitate catheter repositioning to avoid vessel rupture. Massive hemothorax and pericardial tamponade are among the most serious complications. These complications can occur even after previously

successful treatments. Cardiac arrhythmias, thrombophlebitis, sepsis, air embolism, pneumothorax, and access-site infection are other complications. It has been demonstrated that prolonged cannulation can lead to significant subclavian vein stenosis, thus rendering the ipsilateral arm incapable of supporting subsequent permanent hemoaccess. Given this risk, use of this access site is to be avoided in patients for whom there is a high probability of permanent renal failure (eg, diabetic patients with preexisting renal dysfunction suffering from subsequent acute renal injury).

The right internal jugular vein offers an alternative to subclavian cannulation. A potential advantage of this method is that the catheter’s route is relatively straight, thus avoiding the sharp angulations associated with the subclavian route. Nonetheless, retrograde cannulation of the subclavian vein is possible, and radiologic evaluation of placement is required. A drawback to this technique is the relatively awkward placement and the difficulty of access-site care. “Tunneled” access to the internal jugular is becoming more popular and allows for much easier access-site care.

Anticoagulation

The need for anticoagulation can be the most significant disadvantage associated with hemodialysis. Several methods have been proposed for reducing hemorrhagic risks. Regional heparinization is performed by infusing heparin into the blood before it reaches the filter with continuous neutralization with protamine into the blood after the filter, but this procedure has fallen out of favor because of the “heparin rebound” effect, which may appear up to 10 hours after treatment.

Low-dose heparin (10–20 units/kg per hour) and bedside monitoring of coagulation status have been shown to be superior to regional heparinization in controlling hemorrhagic risks. Low-molecular-weight heparin has been proposed because of its limited effect on platelet function. Unfortunately, these low-molecular-weight fragments have a prolonged half-life (18 hours) and are not neutralized by protamine.

Citrate anticoagulation has been used successfully but requires careful attention to dialysate calcium concentration and may require substantial amounts of sodium and fluid infusions.

Because of their short half-life, prostacyclin and its derivatives have been used. Although employed successfully in stable patients, prostacyclin may be inappropriate for the critically ill. Aside from a considerable list of potentially troublesome secondary effects, including flushing, nausea, headache, and abdominal pain, the antiplatelet action of prostacyclin is still demonstrable up to 2 hours after cessation of infusion, and there is no known method for reversing the effect.

An increasingly popular approach is to completely avoid anticoagulation by using high blood flows and frequent saline flushes of the filter (200 mL every 20 minutes). The

new, more porous dialyzers have ultrafiltration capabilities that will easily remove the excess fluid administered.

Complications

Although hemodialysis is performed by specially trained nursing personnel and is directed by a nephrologist, complications may occur in the ICU setting when the intensivist is the first physician to evaluate the situation. During treatment, the most commonly encountered complication is hypotension. Other complications include cardiac arrhythmias, hypoxemia, hemorrhage, air embolism, pyrogenic reactions, and dysequilibrium syndromes.

A. Hypotension—Poorly tolerated fluid removal is the most obvious cause of hypotension, but several more subtle mechanisms may play a role in some patients. Relative intolerance to acetate can cause hypotension, and bicarbonate-based dialysates are now used commonly for any patient in whom vascular instability is considered a potential difficulty. The relative bioincompatibility of cuprophane- and cellulose-based membranes can, in rare cases, cause enhanced activation of complement and the acute onset of severe respiratory distress and hypotension resistant to volume replacement. This constellation of symptoms has been called the *first-use syndrome* and has been managed with intravenous aminophylline or subcutaneous epinephrine. Once a patient's susceptibility is established, the syndrome will occur at the initiation of every treatment with an unused dialyzer, usually within 15–20 minutes. Definitive management consists of switching to a more biocompatible membrane.

More recently, a similar anaphylactoid type syndrome has been described involving the use of polyacrylonitrile dialyzers (AN-69) in patients treated with angiotensin-converting enzyme (ACE) inhibitors. Regardless of the cause, symptomatic hypotension during dialysis should be treated initially by lowering the transmembrane pressure, decreasing blood flow, evaluating for cardiogenic causes, and administering normal saline, albumin, or hypertonic glucose. If significant wheezing is present, the first-use syndrome should be suspected.

B. Cardiac Arrhythmias—Several abnormalities increase the risk of cardiac arrhythmias during dialysis. Of these, the best-established is digitalis toxicity initiated by the rapid lowering of serum potassium levels. Many dialysate baths contain 2 mmol/L of potassium or less; dialysate baths containing 3.5 mmol/L of potassium have been shown to reduce the risk of digitalis toxicity. Other causes of arrhythmias include abnormalities of magnesium or calcium, hypoxia, pericarditis, myocardial infarction, acetate toxicity, and complications of subclavian catheterization.

C. Hypoxemia—The hemodialysis procedure can induce hypoxemia by at least two mechanisms. The more benign of these involves the loss of CO₂ through the dialyzer with subsequent decrease in respiratory drive. This complication occurs with acetate-buffered dialysate solutions, which are currently being replaced with bicarbonate-based solutions.

When this type of hypoxia does occur, it can be managed easily with supplemental oxygen. A more ominous cause involves the first-use syndrome (see above), with rapid activation of complement leading to leukoagglutination in the lung and severe bronchospasm. This presentation calls for termination of treatment and the potential need for aminophylline or epinephrine. Subsequent treatments must be performed with a more biocompatible membrane.

D. Hemorrhage—If serious hemorrhage occurs during dialysis, previously administered heparin should be neutralized with protamine. A rational starting dose would be 1 mg protamine for every 100 units heparin administered. If possible, protamine infusions should be limited to no more than 15 mg over 5 minutes to minimize the risk of anaphylactoid reactions. There is considerable individual variation in protamine requirements, and normalization of the partial thromboplastin time should be sought. There is also the possibility of a “heparin rebound” effect occurring up to 10 hours after successful neutralization.

E. Dialysis Dysequilibrium—This syndrome of headache, nausea, muscle irritability, obtundation, and delirium or seizures may be associated with rapid correction of severe uremia. To decrease the risk, short, gentle treatments (blood flows <200 mL/min) should be prescribed until BUN levels approach 100 mg/dL (36 mmol/L).

2. Peritoneal Dialysis

Peritoneal dialysis offers the best method of renal replacement for the patient in whom it is difficult or impossible to obtain adequate hemoaccess. In contrast, patients with recent abdominal surgery may be poor candidates owing to the risks of abdominal wound dehiscence and infection of recently implanted vascular grafts. In patients with previous abdominal surgery, intraperitoneal adhesions may limit dialysate distribution, thus causing decreased ultrafiltration and decreased solute removal. A major advantage of this technique is that no anticoagulation is required. Disadvantages include substantial protein loss

(see Table 13–12), risks of peritonitis, drainage difficulties, compromised pulmonary function owing to elevated diaphragms, hydrothorax, glucose and electrolyte abnormalities, and a relatively immobile patient.

Capabilities

Solute removal with this technique depends mostly on dialysate volume and how long the dialysate is allowed to stay in the peritoneal space before drainage (dwell time). A reasonably aggressive schedule incorporates 2-L exchanges every 2 hours. Assuming a 50% equilibration between serum and dialysate urea levels during a 2-hour dwell time, this schedule provides 12 L of urea clearance per day. A more modest schedule would be similar to that of chronic ambulatory peritoneal dialysis (CAPD), with 2-L exchanges every 4–6 hours. Assuming a 100% equilibration of urea after a 6-hour dwell time, four 2-L exchanges yield 8 L of urea clearance per day. Associated net filtration of approximately 2 L/day will add to these predicted values. Peritonitis hastens equilibration between serum and dialysate, thus yielding greater solute clearance during the more rapid exchange schedules.

Fluid removal depends directly on the concentration of glucose in the dialysate and the dwell times allowed. With 1.5% dextrose solution, a 2-L exchange performed every hour can extract 100–200 mL of fluid. A 4.25% solution provides 500 mL of filtrate per hour. Prolonging dwell times decreases net filtration rate because of an increasing equilibration of dialysate glucose with serum levels, thus decreasing the osmotic drive for fluid removal. The onset of peritonitis markedly limits ultrafiltration because of rapid absorption of dialysate glucose.

Access

There are two widely used methods for obtaining access to the peritoneal cavity. Bedside placement of a stiff Teflon catheter is the most rapid means of access. Complications include bowel perforation, bladder perforation, pericatheter

leakage, hemorrhage, and infection. Foley catheter placement to ensure bladder decompression prior to insertion is strongly recommended. A major drawback is that the patient must be bedridden, and drainage problems are not uncommon. Patients with previous abdominal surgery may have adhesions of bowel to the abdominal wall, thus increasing the risk of perforation. Bowel perforation sometimes may be managed successfully by repositioning the catheter and initiating empirical antibiotic therapy in the dialysate (Table 13–13). Abdominal wall infection should be considered a contraindication to catheter placement.

The surgical placement of a pliable Silastic catheter (Tenckhoff type) is the safest method of obtaining access. Drawbacks are catheter malposition, abdominal pain, and delays in catheter placement. When initiating treatment, low-volume exchanges may limit the risk of suture-line dehiscence.

Complications

The most common complication of peritoneal dialysis is failure to drain or insufficient drainage. Identification of the cause often can be aided by determining if the ability to infuse fluid through the catheter is maintained. If fluid infusion is obstructed, the catheter may suffer from intrinsic blockage, and an attempt at declotting may be appropriate with saline flushes or thrombolysis with urokinase or tissue plasminogen activator. If declotting is impossible, catheter replacement is necessary. A catheter that allows unimpeded fluid infusion but not outflow may be malpositioned or may be suffering from a “ball valve” effect caused by omentum wrapped around its pores. Initial management of this problem consists of having the patient move from side to side or be placed in the Trendelenburg position. On occasion, an enema may yield dramatic results. If these initial efforts fail, catheter position must be determined by radiographic technique and repositioned, either with an intracatheter guidewire or by surgical revision.

Table 13–13. Intraperitoneal doses of antibiotics for dialysis-related peritonitis.

Organism	Initial Dose (per 2 L)	Maintenance Dose (per 2 L)*
<i>Staphylococcus epidermidis</i>	Vancomycin 1 g Cefazolin 1 g	1 g every 5 days × 3 500 mg per exchange × 14 days
<i>Staphylococcus aureus</i>	Vancomycin 1 g	1 g every 5 days × 3
<i>Escherichia coli</i>	Ampicillin 500 mg	100 mg per exchange × 14 days
<i>Pseudomonas aeruginosa</i>	Gentamicin 70–100 mg	15 mg per exchange × 14 days

*Dosing appropriate for four exchanges per day.

Modified from Holley JL, Piraino BM: Complications of peritoneal dialysis: Diagnosis and management. *Semin Dialysis* 1990;3:245–48, with permission from Blackwell Publishing.

Peritonitis arises most often from contamination during bag exchanges, although intraperitoneal contamination also can occur as a result of intraabdominal disease. Clinical signs of peritonitis include abdominal pain, nausea, cloudy dialysate effluent, and loss of ultrafiltration (decreased fluid output per exchange). As opposed to spontaneously occurring peritonitis, peritoneal infection in the context of peritoneal dialysis may be managed successfully with intraperitoneal antibiotics (see Table 13–13). A reasonable diagnostic plan would include evaluation of white blood cell count in the effluent (with peritonitis, >100 granulocytes/ μL) and Gram staining and empirical treatment until the results of culture of the effluent are reported. Common antibiotic regimens are listed in Table 13–13. Treatment should be continued for at least 10 days. Fungal peritonitis most often requires removal of the catheter and is best treated with cessation of peritoneal dialysis.

In the immediate period after catheter placement, the dialysate effluent can be blood-tinged. The intraperitoneal administration of heparin (500–1000 units per 2-L bag) may limit the formation of fibrin clots but is unlikely to cause systemic anticoagulation. Open drainage systems are associated with a high rate of peritonitis, and a closed system, with bag-to-bag connections similar to those used in chronic ambulatory peritoneal dialysis, is preferred. Spent dialysate should be monitored daily for cell count. If granulocyte counts begin to increase above $100/\mu\text{L}$, empirical antibiotic therapy should be initiated pending culture results. Massive protein losses are associated with peritonitis but also may occur without infection (see Table 13–12). These losses should be measured, and protein intake should be adjusted upward. Substantial glucose absorption can lead to hyperglycemia and can be controlled with intraperitoneal insulin. A reasonable starting dose would be 5–10 units per 2-L dialysate bag.

3. Continuous Renal Replacement Therapy (CRRT)

The term *continuous renal replacement therapy* (CRRT) has been applied to a wide array of extracorporeal techniques for supporting the critically ill patient with acute renal failure. Originally proposed as a simple method of filtration powered by arteriovenous circuits and known as *continuous arteriovenous hemofiltration* (CAVH), filtrate outputs provided by a patient's unstable blood pressure were found to be inadequate for removing the large amounts of nitrogenous wastes associated with the hypercatabolic patient. In an attempt to

deal with this inadequacy, several technical modifications have been developed to enhance the efficiency of the treatment. These include the addition of a diffusive component to solute removal, known as *continuous arteriovenous hemodialysis* (CAVHD), and the development of specialized machines for providing continuous pumped filtration—allowing for a new set of extremely efficient techniques that do not require arterial access and that no longer depend on the variability of the patient's changing blood pressure—continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF).

The continuous therapies have several potential advantages over intermittent dialytic techniques. The most obvious is that the treatment is continuous, allowing for a constant readjustment of fluid and electrolyte therapy and the administration of large amounts of parenteral nutrition without the risk of interdialytic volume overload. Second among the advantages—at least for the hemofiltration-based treatments (ie, CAVH and CVVH)—is its convective mode of solute transport, known to increase middle-molecule clearance compared with diffusion-based dialytic techniques. When compared with peritoneal dialysis, CRRT is not contraindicated in patients with prior abdominal surgery and offers isovolumetric fluid removal without the risk of peritonitis. The major drawbacks are the need for continuous anticoagulation and that the patient must remain bedridden during the treatment.

Issues that arise when considering the application of CRRT include the amount of solute clearance required, the type of replacement fluid or dialysate to administer, the type of anticoagulation to be employed, the amount of nutrition to be infused, the amount of nutrients lost in the filtrate or dialysate, and the impact of the treatment on drug dosing, and the complications likely to be encountered. Each of these issues may have a substantial impact on outcome. For example, a recent study demonstrated that patients receiving filtration rates of 35 mL/kg per hour (approximately 2.5 L/h) had a significantly increased survival when compared with patients receiving filtration rates of 20 mL/kg per hour (approximately 1 L/h). One also must consider who is going to monitor the treatment and how these personnel are trained.

The following techniques for continuous renal replacement therapy are available. Each technique has advantages and disadvantages, and some are more practical or effective in patients with hypotension, those requiring large volume of fluid removal, or those needing dialysis as well as ultrafiltration.

Continuous Arteriovenous Hemofiltration (CAVH)

The standard CAVH circuit allows blood to flow from an arterial access through a tubing circuit to a low-resistance hemofilter and back to a venous access. Filtrate, which is relatively protein-free, is produced at a rate of several hundred

milliliters per hour and is collected into a bag connected to the ultrafiltrate port of the filter. In the postdilution mode, the replacement fluid is infused into the venous tubing. Continuous anticoagulation is administered through a pre-filter tubing connection.

Management of the circuit and maintenance of its patency are subject to a variety of procedural choices such as how often to rinse the system with saline, how often to change the filters and tubing, and how to achieve hemoaccess. These issues often depend on the clinical setting and the type of system components being employed. Owing to the need for arterial access and the inconsistent output provided by blood pressure-driven filtration, the popularity of CAVH has decreased, and this arteriovenous method is being replaced with blood pump-driven venovenous systems (see below).

Slow Continuous Ultrafiltration (SCUF)

Blood pressure-driven filtration is a means of providing continuous isosmotic fluid removal for aid in the management of oliguric patients. The circuit is similar to that of CAVH, but no replacement fluid is administered. Although insufficient for adequate solute removal, this technique has been found useful as a means of maintaining fluid balance in patients intolerant of aggressive fluid removal and in those with cardiodynamic instability such as may be seen during aortic balloon pumping or during open-heart surgery.

Continuous Arteriovenous Hemodialysis and Hemodiafiltration (CAVHD)

The circuit is essentially the same as that for CAVH but with the addition of a constant infusion of dialysate passing through the filtrate compartment of the filter. At the relatively slow blood flow rates encountered with an arteriovenous circuit, complete blood to dialysate equilibrium of urea is achieved, and clearance rates increase linearly with dialysate flow rates of up to 33.3 mL/min (2 L/h). Further increases in dialysate flow up to 4 L/h can yield urea clearances approaching 50 mL/min. In most clinical situations, the dialysate flow rate is set at 1 L/h, resulting in 17 mL/min of urea clearance by diffusion. The major advantage of this system is the enhanced solute clearance, which has allowed the technique to be applied to certain intoxications.

An interesting issue common to all the diffusion-based CRRT techniques (ie, CAVHD and CVVHD) is the amount of backfiltration that can occur. About 60% of the dialysate glucose is absorbed through the membrane. At the common flow rate of 1 L/h, a standard 1.5% dextrose-containing dialysate (such as is commonly used for peritoneal dialysis) produces a net glucose transfer averaging 120 mg/min (175 g/day), whereas a 4.25% solution yields approximately 415 mg/min (600 g/day). This amount of carbohydrate must be accounted for when considering the patient's nutritional and insulin requirements.

Continuous Venovenous Hemofiltration (CVVH)

This circuit requires a blood pump and an air detector and is often equipped with arterial and venous pressure monitors. Equipment especially designed for this treatment is available. This technique has the clear advantage of avoiding the potential complications of arterial access and is capable of providing a substantial amount of convection-based clearance. Common output rates are between 1 and 2 L/h, replaced with the appropriate replacement solution. Blood flow rates between 100 and 150 mL/min allow for a decreased tendency of filter clotting and limit the dosage requirements for anticoagulants.

Continuous Venovenous Hemodialysis or Hemodiafiltration (CVVHD/F)

The addition of a diffusive component to the CVVH system allows for the maximum clearance capabilities of any of the continuous therapies. The basic circuit resembles that of CVVH but allows a variable amount of dialysate to flow past the filtrate compartment of the filter as with CAVHD. The machines used are similar to those employed for CVVH.

Hemoaccess

The blood pressure-driven treatments (ie, CAVH and CAVHD) require large-bore arterial and venous access. The most widely used is the combined cannulation of the femoral artery and vein. Hemoaccess for pump-driven continuous therapies (ie, CVVH and CVVHD) does not require arterial catheterization and uses the same access as for machine-driven hemodialysis (see above).

Femoral artery and *femoral vein* cannulation is the most widely used method for obtaining an arteriovenous circuit. Adequate blood flows are best obtained with large-bore catheters (0.3-cm luminal diameter) with minimal taper and no sideholes. Standard hemodialysis catheters are often inadequate. Despite the apparent risk of arterial cannulation, the reported complication rate is low. The successful use of these catheters may be due to the common practice of restricting their insertion to the well-trained, experienced operator. Furthermore, access-site care is enhanced because of the constant monitoring of the filter circuit. Potential complications include retroperitoneal hemorrhage, vascular occlusion, sepsis, access-site infection, and hematomas.

Anticoagulation

The need for continuous anticoagulation is a major drawback to all methods of continuous therapy and has led to a high incidence of hemorrhagic complications. It may be helpful to use regional heparinization with the slow continuous postfilter infusion of protamine. Starting dosage is usually 10 units/kg per hour of heparin, with a neutralizing dose of protamine initially at 1 mg/h for every 100 units/h of heparin. Dosages should be adjusted to provide partial thromboplastin times of 150 seconds or more in the postheparin

circuit and approximately 50 seconds in the postprotamine circuit. After establishing required dosing, the partial thromboplastin time should be monitored three times daily to determine the need for further adjustments. In a patient with a severe preexisting coagulopathy, reasonable filter life may be achievable without any anticoagulation. The prefilter infusion of replacement fluid also may help to prolong filter life. Varying protocols for citrate anticoagulation have been proposed. These techniques have been shown to provide sufficient and safe anticoagulation, but alkalemia, hypernatremia, and the risk of systemic hypocalcemia must be addressed for each of the different protocols. Both prostacyclin and low-molecular-weight heparin have been tried, but their use retains the same drawbacks noted for hemodialysis— notably, prolonged duration of action with no method for rapid neutralization.

Predilution

The infusion of replacement fluid into the prefilter tubing segment of the circuit dilutes the intraplasmaic urea concentration and promotes the transfer of intraerythrocytic urea into the plasma compartment, where it is available for removal in the filtrate. The predilution technique also limits the hemoconcentration that occurs at the venous side of the hemofilter. The potential advantages of the predilution mode include enhanced urea clearance and the possibility of increasing filter patency by the prefilter dilution of hematocrit, clotting factors, and platelets. Disadvantages include the increased cost of replacement fluid and inability to estimate plasma electrolyte concentrations from analysis of the filtrate.

Replacement Fluids and Dialysate

All hemofiltration-based techniques (ie, CAVH and CVVH) require large volumes of sterile, pyrogen-free replacement fluid. A physiologic and relatively inexpensive formulation consists of two easily prepared solutions given in alternating fashion. The first solution is prepared by adding one 10-mL ampule of 10% calcium gluconate to 1 L of 0.9% NaCl. The second solution is prepared by adding 50 meq sodium bicarbonate to 1 L of 0.45% NaCl. When these two solutions are given alternately, the net result is an electrolyte solution containing sodium 141 meq/L, chloride 101 meq/L, bicarbonate 25 meq/L, and calcium 4 meq/L. Diffusion-based treatments (ie, CAVHD and CVVHD) require dialysate solutions with adequate buffering capacity. Common practice has been to employ peritoneal dialysis solutions, but several premixed solutions are now being marketed.

Careful attention to fluid balance is essential and can be aided by connecting the filtrate output to a volumetric pump or a balancing scale designed to match inputs and outputs. Regardless of the CRRT technique employed, volume outputs and inputs can easily attain 25–50 L/day or more. Thus even small percentage errors in fluid balance can lead to substantial changes in the patient's volume status. Evaluation with daily weights is essential.

CRITICAL ILLNESS IN PATIENTS WITH CHRONIC RENAL FAILURE

Patients receiving maintenance dialysis often require treatment in the ICU. Cardiac disease, GI hemorrhage, and infections are the most common comorbid conditions. Standard treatment options often must be modified for dialysis patients. Unresponsiveness to standard diuretic regimens means that fluid removal for pulmonary edema or severe hypertension calls for ultrafiltration by dialytic means. For upper GI hemorrhage, magnesium-containing antacids are best avoided, and H₂ blockers may require dosage adjustments. Antibiotic treatment actually may be facilitated in that antibiotics normally cleared by the kidney may have more prolonged therapeutic levels, and the nephrotoxicity of certain medications is no longer a major consideration.

In general, however, management of the patient on dialysis is similar to that of the patient with acute renal failure, with the exception of several special considerations as outlined below.

► Nutrition & Fluids

Fluid and Electrolyte Restrictions

Normal fluid restriction for a patient receiving maintenance hemodialysis (three times weekly) often depends on the patient's tolerance for aggressive fluid removal during each treatment. In general, fluid restriction should be 1–1.5 L/day and is dictated by the patient's tendency to develop hypertension or pulmonary congestion in the interdialysis period. A certain degree of pedal edema is tolerated as long as hypertension or pulmonary congestion is not present. A patient maintained on chronic ambulatory peritoneal dialysis often can tolerate a more liberal fluid restriction because dialysate glucose concentrations can be adjusted to achieve greater fluid removal on an ongoing basis. A restriction of 1.5–2 L/day of fluid intake is often well tolerated, and that amount is easily removed with the ongoing dialysis.

Nitrogen Balance and Caloric Requirements

Nitrogen balance studies in hemodialysis patients suggest that protein requirements are between 1 and 1.2 g/kg per day. The caloric requirement to maintain neutral nitrogen balance is

37 kcal/kg per day. Patients receiving chronic ambulatory peritoneal dialysis lose a substantial amount of protein in the dialysate (approximately 10 g/day), and their protein requirements approach 1.4 g/kg per day. Glucose absorption from the dialysate is substantial but depends on the dialysate glucose concentration and the length of the dialysate dwell time. A gross estimate of the absorbed glucose can be calculated by measuring the glucose concentration of the dialysate effluent and comparing this figure with the infused concentration.

▶ Vascular Access in Hemodialysis Patients

The hemodialysis patient's permanent vascular access is the life-line to adequate treatment, and these surgically implanted access sites must be treated with care. There are two commonly used means for creating a subcutaneous arteriovenous connection: surgical anastomosis of an artery and vein, often in the wrist (*primary* arteriovenous fistula), and placement of a polytetrafluoroethylene graft between artery and vein in the brachial fossa. The primary arteriovenous fistula is more resistant to infection and thrombosis, but it requires up to 6 weeks to mature, and its placement is surgically impossible in many patients with inadequate distal vasculature. Polytetrafluoroethylene grafts are available for use within 1–2 weeks but are more prone to infection and pseudoaneurysm formation. A properly functioning graft or fistula will have a palpable thrill and a bruit audible with a stethoscope. These findings should be checked daily. In general, the sites should not be used for routine venipuncture, and blood pressure readings should be taken on the contralateral arm. It is not uncommon for a prolonged period of hypotension to result in a thrombosed access. If an access site is found to be clotted (inaudible bruit), vascular surgical consultation should be sought immediately. In some cases, thrombolytic therapy with urokinase or tissue plasminogen activator may avoid the necessity for surgical revision. Angioplasty by interventional radiology also may be successful.

Infection of the vascular access route is the most common infectious complication in the hemodialysis population. Erythema and tenderness over the site are the most common signs; however, occult septicemia can result from an apparently unaffected site. Access-site infection should be suspected in all cases of systemic infection. Blood cultures from the access site are a reasonable first step in diagnosing infection. As opposed to other infections with implantable grafts, successful treatment without removal of the graft is possible with prolonged administration of antibiotics. Most antibiotic regimens for access-site infections include vancomycin because that agent is poorly dialyzable, and a single dose can maintain adequate serum levels for 3–5 days.

Venkat A, Kaufmann KR, Venkat K: Care of the end-stage renal disease patient on dialysis in the ED. *Am J Emerg Med* 2006;24:847–58. [PMID: 17098110]

▶ Chronic Ambulatory Peritoneal Dialysis Patients

Chronic ambulatory peritoneal dialysis (CAPD) commonly involves four 2-L exchanges per day. Net fluid removal depends on the rate of exchange and the dialysate glucose concentration (eg, 1.5%, 2.5%, or 4.25%). Peritoneal dialysis catheters are surgically placed Silastic tubing with direct connections to the intraperitoneal space. Strict sterility should be maintained whenever the connection between the catheter and the dialysate tubing is interrupted. Drainage problems are not uncommon and may respond to moving the catheter or turning the patient. On occasion, an enema may cause sufficient intraabdominal movement to produce adequate drainage. Standard intraperitoneal antibiotic therapy for peritonitis is outlined in Table 13–13.

▶ Renal Transplant Patients

The differential diagnosis of acute renal failure in the transplanted kidney was discussed earlier. Other commonly encountered problems in the transplant recipient include infections, GI complications, and hypertension.

Infections

Renal transplant patients require continuous immunosuppressive therapy that may include varying combinations of corticosteroids, azathioprine, cyclosporine, mycophenolate mofetil, and tacrolimus. The type of infection likely to occur as a result of the immunocompromised state has been noted to be somewhat bimodal in distribution. Whereas common bacterial pathogens, including streptococci, staphylococci, and gram-negative bacteria, seem to predominate in the immediate posttransplant period, common opportunistic infections with viral, protozoal, or fungal organisms seem to occur 1 month or more after surgery. It is important to note that the classic signs of infection, including fever, may be masked by the anti-inflammatory corticosteroids. In general, if a life-threatening infection is identified, it is often prudent to discontinue immunosuppressive medication temporarily despite the risk of graft rejection. In any event, close consultation with the patient's nephrologist or transplant surgeon is essential.

Gastrointestinal Complications

Peptic ulcer disease, colonic perforation, and pancreatitis are the most common GI complications in the renal transplant patient. Bleeding or perforation of a peptic ulcer carries a particularly high morbidity, and prophylactic use of H₂ antagonists, proton pump inhibitors, or antacids has been found to be effective. Colonic perforations are uncommon but are apt to be lethal if not identified quickly. Pancreatitis is believed to be a result of long-term use of corticosteroids, and severe sequelae including hemorrhagic pancreatitis and pseudocyst formation have been reported.

Hypertension

Hypertension can complicate up to 50% of all renal transplants. Possible causes include renal artery stenosis of the native or transplanted kidneys, allograft dysfunction, cyclosporine, and recurrence of the original renal disease. Renal artery stenosis of the grafted kidney may be treated successfully by percutaneous angioplasty. Cyclosporine-induced hypertension may result from the intrarenal vasoconstriction associated with endothelin and may respond to a decrease in dosage. In contrast, allograft dysfunction related to ongoing infection may require decreased immunosuppression.

Gastrointestinal Failure in the ICU

Gideon P. Naudé, MD

14

This chapter addresses the common causes that fall under the broad category of gastrointestinal (GI) failure. Pancreatitis, bowel obstruction, paralytic ileus, diarrhea, and malabsorption are discussed here. GI hemorrhage and specific GI diseases are presented in other chapters. For an overview of abdominal pathology, the reader is referred to Chapter 32, which discusses the acute abdomen.

▶ Pancreatitis

ESSENTIALS OF DIAGNOSIS

- ▶ Severe abdominal pain, usually radiating to the back.
- ▶ Nausea and vomiting.
- ▶ Hemodynamic and respiratory compromise in severe cases.
- ▶ Elevated serum levels of pancreatic enzymes.
- ▶ Pancreatic enlargements on CT scan.

General Considerations

Acute inflammation of the pancreas has a wide clinical spectrum from mild (eg, acute edematous pancreatitis) to very severe (eg, necrotizing pancreatitis). Most patients have a benign course, and recovery is uncomplicated. In approximately 30% of cases, the inflammatory process is aggressive and associated with a mortality rate that approaches 50%. In the latter group, management within the ICU is required. Aggressive early resuscitation may prevent the onset of lethal multisystem organ failure.

Acute pancreatitis is frequently precipitated by gallstone obstruction of the pancreatic duct. Although identification of a persisting stone within the common bile duct itself (choledocholithiasis) is unusual, careful straining of stools

identifies a gallstone in up to 90% of patients who have had an attack of pancreatitis within the preceding 10 days. Pathogenesis may be related to obstruction of the pancreatic duct during passage of the stone, which results in ductal hypertension and causes breakdown of intracellular compartmentalization, leading to zymogen activation.

In the United States, alcohol consumption is responsible for about 40% of cases of pancreatitis. Acute pancreatitis may occur at any time in the course of ongoing excessive consumption, although commonly the initial attack comes after several years of alcohol abuse. The initial episode may be followed by further attacks. The usual pattern is a severe first attack followed by subsequent attacks that are less dramatic, presumably because of the loss of active pancreatic tissue. Alcohol is the etiologic factor most commonly associated with chronic pancreatitis, and microscopic examination of the gland at first acute presentation often demonstrates evidence of chronicity, such as scarring and replacement of acinar elements with fibrous tissue. This may have implications for pancreatic endocrine function during subsequent acute attacks.

The mechanism of pancreatic damage by alcohol is incompletely understood and may be idiosyncratic. Alcohol has been shown to have ultrastructural effects on acinar cells. It also may cause spasm of the sphincter of Oddi, producing ductal hypertension.

Postoperative pancreatitis is seen most commonly following operations on the biliary tree. The onset of atypical pain or unexpected ileus following surgery raises the possibility of pancreatitis. Because postoperative pancreatitis often lacks the usual clinical features, early detection may be difficult. Acute pancreatitis following endoscopic retrograde cholangiopancreatography (ERCP) is seen in approximately 2% of cases and may be severe.

Acute pancreatitis may occur in conjunction with elevations of serum calcium, including transient hypercalcemic states that may occur with intravenous infusions. Other metabolic causes include hyperlipidemia, hypothermia, protein deficiency, and diabetes.

Drugs and toxins probably account for more cases of pancreatitis than is usually suspected. Common drugs include furosemide, azathioprine, estrogen-containing contraceptives, tetracyclines, and corticosteroids. Scorpion envenomation is a common cause in tropical environments such as the Caribbean.

Blunt trauma may be associated with acute pancreatitis, particularly if there is acute ductal obstruction caused by hematoma. More commonly, chronic pancreatitis, pseudocyst formation, or pancreatic fistulas result from blunt injury.

Pancreas divisum, ductal abnormalities, and pancreatic carcinoma all have been suggested as etiologic factors for acute pancreatitis. When pancreas divisum is present, the narrow opening of the minor papilla may obstruct the flow of pancreatic secretions. Unfortunately, sphincteroplasty of the minor ampulla has mixed results.

Less common causes of acute pancreatitis include infectious agents such as paramyxovirus (mumps), Epstein-Barr virus, *Mycoplasma* species, hepatitis virus, and ascaris, as well as autoimmune disorders, including systemic lupus erythematosus, necrotizing angitis, and thrombotic thrombocytopenic purpura. Recently, spinal surgery for scoliosis resulted in a 15% incidence of pancreatitis in children and young adults. In some patients, the etiologic factor is never discovered.

Pathophysiology

The pancreas produces a wide variety of digestive enzymes that have the potential for causing serious cellular and biologic disruption. Proteases such as trypsin, chymotrypsin, and elastase have been shown to activate proenzymes in the inflammatory and complement cascades. Lipases such as phospholipase A₂ can liberate phospholipid remnants. These particles perpetuate the inflammatory response and may have direct cellular toxicity. Normally, intrapancreatic enzyme control is achieved by secretion of inactive proenzymes (zymogens) and intracellular enzyme inhibitors and compartmentalization by storage of zymogens and enzyme activators in separate cytosol granules. Once the integrity of this protective process is breached, autodigestion initiates an inflammatory process that is self-sustaining.

Acinar damage quickly disrupts normal organ function, resulting in almost immediate cessation of exocrine secretion and alteration of endocrine secretion. For this reason, ongoing formation and leakage of pancreatic enzymes are probably only a minor factors in the perpetuation of acute pancreatitis following the initial insult. Factors contributing to progressive disease with severe inflammation and necrosis are unknown, but organ ischemia and infection are likely to be important.

Systemic toxicity and functional impairment of other organ systems are related to the release of inflammatory mediators such as interleukin-1 (IL-1), arachidonic acid metabolites, kinins, and tumor necrosis factor (TNF). There are profound changes in immune competence and

inappropriate activation of lymphocytes and polymorphonuclear neutrophils.

Clinical Features

Clinical evaluation of acute pancreatitis consists of confirmation of the diagnosis, estimation of severity, determination of prognosis, and identification of pancreatic necrosis.

A. Symptoms and Signs—Pain is the most constant symptom, although its nature and severity are variable. Radiation to the back is observed in 50% of patients, but no pattern can be considered typical. The intensity of the pain does not correlate with the degree of pancreatic inflammation. Occasionally, other clinical features such as vomiting are dominant. The diagnosis should be considered in all patients with abdominal pain of recent onset, especially if associated with physiologic compromise such as hypotension or hypoxia.

Various clinical signs have been described. Abdominal distention and tenderness are common, but peritonitis is rare. Abdominal findings do not indicate the severity of the retroperitoneal process. If the inflammatory process has extended beyond the pancreas, erythema around the flanks may occur. The classic signs of hemorrhagic pancreatitis—ecchymoses in the flank (Grey Turner's sign) or umbilicus (Cullen's sign)—are not commonly present.

Signs of respiratory compromise may indicate incipient respiratory failure. Tachypnea greater than 20 breaths/min and a limited chest expansion on inspiration are important. Clinical evidence of bilateral pleural effusion is found commonly in patients with severe pancreatic inflammation.

B. Laboratory Findings—Elevation of enzyme markers such as amylase and lipase traditionally was considered diagnostic, but the sensitivity and specificity of these tests generally are inferior to those of CT scan. A normal serum amylase level does not exclude the diagnosis, and enzyme elevation may be observed in a number of other conditions, including perforated or penetrating peptic ulcer, ruptured ectopic pregnancy, and bowel obstruction or infarction. Measurement of the renal clearance of amylase does not enhance the sensitivity of this variable.

C. Imaging Studies—Organ imaging has replaced serum biochemical analysis as the diagnostic modality of choice in acute pancreatitis. In all but the mildest cases, imaging the pancreas by CT scan or ultrasonography should be the initial investigation. Demonstration of organ enlargement confirms the diagnosis. Enzyme levels frequently return to normal within a few days, whereas pancreatic radiologic derangement persists for at least a week. Therefore, organ imaging is also valuable in the retrospective diagnosis of this condition. Very early in the disease, however, CT scan may be unhelpful because macroscopic changes may take hours to develop. During this brief period, measurement of enzyme markers is preferable.

The value of CT scan versus ultrasonography is debated. Actually, the procedures are complementary, and both

should be used. With the interference of bowel gas, examination of the retroperitoneum by ultrasonography is often limited initially. However, valuable information concerning the biliary tree may be obtained. CT scans have low sensitivity for the detection of gallstones but generally are superior to ultrasonography for the delineation of retroperitoneal disease processes.

D. Estimation of Severity and Determination of Prognosis

—Determination of the severity of acute pancreatitis based on clinical evaluation alone is accurate in only 35–40% of patients. A number of scoring methods have been devised for objective assessment of the severity and prediction of morbidity and mortality. These scoring techniques are useful in ensuring early institution of appropriate management and in tracking physiologic progress. However, sickness scoring systems are of limited use in making management decisions for individual patients. Their most valuable contribution in acute pancreatitis may be in assessment of new treatment strategies and evaluation of quality assurance.

Initial scoring systems for acute pancreatitis were developed prior to the widespread availability of CT scanning and are based on multiple clinical and biochemical parameters. They include Ranson's Early Prognostic Signs, Imrie's Prognostic Criteria, Simplified Prognostic Criteria, the Glasgow Criteria, and the APACHE II (Acute Physiology and Chronic Health Evaluation) scoring system. These systems have various drawbacks. Most are complex and difficult to remember, extensive data collection and computation are required, and lack of data on all parameters occurs frequently. Completed scores may not be available during initial management.

Ranson's method (Table 14-1) is the standard against which other scoring systems are judged. A score of less than 2 based on Ranson's criteria indicates mild disease with a good prognosis. A score greater than 6 correlates with a mortality rate of 20% and a complication rate of 80%. Imrie's system is a simplification of the original Ranson criteria and is popular in the Commonwealth countries. The Simplified Prognostic Criteria (SPC) with only four parameters is easier to remember. Two SPC signs are the equivalent of six or more Ranson signs. As a general guideline, all patients with more than three of Ranson's criteria or APACHE II scores greater than 8 should be managed in the ICU.

With the advent of routine organ imaging in acute pancreatitis, scoring systems based on the CT appearances of the primary disease process have been developed. These are at least as good predictors of severity and outcome as any of the physiologic scoring systems and have the advantage of immediate availability. Multiple scans may be necessary to ensure the accuracy of this technique because the CT appearance may change with time.

Another system, based on the quality and quantity of peritoneal fluid that can be recovered by lavage, also has been described. It has the disadvantage of requiring an invasive procedure and is not used widely except by clinicians who favor peritoneal lavage as a treatment measure in acute pancreatitis.

Table 14-1. Ranson's criteria of severity of acute pancreatitis.*

Criteria present initially

- Age >55 years
- White blood cell count >16,000/ μ L
- Blood glucose >200 mg/dL
- Serum LDH >350 IU/L
- AST (SGOT) >250 IU/L

Criteria developing during first 24 hours

- Hematocrit fall >10%
- BUN rise >8 mg/dL
- Serum Ca^{2+} <8 mg/dL
- Arterial Po_2 <60 mm Hg
- Base deficit >4 meq/L
- Estimated fluid sequestration >6000 mL

*Morbidity and mortality rates correlate with the number of criteria present. Mortality rates correlate as follows: 0–2 criteria present = 2%; 3 or 4 = 15%; 5 or 6 = 40%; 7 or 8 = 100%.

E. Identification of Pancreatic Necrosis—The most serious local complication of acute pancreatitis is pancreatic necrosis, which, if infection occurs and treatment is not provided, carries a 100% mortality rate. Following initial resuscitation, identification and delineation of this process are the primary aims of management because timely operation will reduce the mortality rate significantly.

Clinical signs include increasing pain and abdominal distention. Progressive physiologic derangement and increasing systemic toxicity are observed with necrosis. Physiologic monitoring by repeated objective scoring assessments may be useful to record progressive deterioration at this stage.

Identification and assessment of pancreatic necrosis are based on a combination of clinical appraisal, sickness scoring, measurement of serum factors, organ imaging, and fine-needle aspiration biopsy of the pancreas. Several serum factors can be correlated with pancreatic necrosis. Biochemical parameters include a fall in α_2 -macroglobulin and C3 and C4 complement factors and a rise in α_2 -antitrypsin, C-reactive protein, and pancreatic ribonuclease. These parameters lack absolute sensitivity and at best only complement other methods.

CT scanning is becoming established as the best means of assessment of pancreatic necrosis. Enhanced physiologic imaging using high-resolution contrast-enhanced scanning techniques increases the sensitivity and specificity of this technique and has been reported to clearly establish the presence and extent of pancreatic necrosis. The initial CT scan should be performed for diagnosis and estimation of disease severity. Repeated scanning is necessary in all but the mildest cases to monitor local progression of disease. Subsequent scans may be scheduled after 1 week if the clinical course gradually improves. Patients who fail to respond

after adequate initial resuscitation or show evidence of worsening clinical status require earlier evaluation and are candidates for scanning with dynamic vascular enhancement in an attempt to establish the presence and extent of the necrosis.

F. Needle Aspiration—Needle aspiration of pancreatic and peripancreatic collections under CT control is becoming accepted as a means of identification of superinfection. At least 40% of necrotic collections are found to be infected at the time of initial management. The most common organism is *Escherichia coli*, but a wide variety of gram-positive and gram-negative aerobic and anaerobic organisms (as single or mixed cultures) has been isolated. Aspiration culture results may be used as a guide to antibiotic selection.

G. Systemic Considerations—Respiratory failure is common in patients with moderate to severe acute pancreatitis. Indium-labeled leukocyte scintiscans demonstrate early margination of the leukocytes in the lungs. The quantitative deposition correlates with other prognostic indicators. This is identical to the pattern seen in sepsis-related acute respiratory distress syndrome (ARDS). Assessment of ventilation and gas exchange should be included in the initial evaluation. Patients may have clinical evidence of bilateral pleural effusions with or without evidence of underlying atelectasis. It is often useful to include a few CT images of the lung bases at the same time as the pancreatic scanning. Such lung sections clearly demonstrate the pulmonary involvement, which may be more significant than the chest x-ray suggests. In the more fulminant cases, the clinical picture is one of typical ARDS. A marked rise in liver aminotransferase (AST >1000 units/L) suggests the possibility of ischemic hepatitis. This diagnosis should be included in the differential in evaluation of a patient suspected of having gallstone pancreatitis and persistent choledocholithiasis. In its more severe form, ischemic hepatitis may be associated with other metabolic derangements, including a rise in bilirubin. Gradual recovery usually can be expected.

A low Glasgow Coma Score may be observed for several reasons in patients with severe acute pancreatitis. The use of sedation and opioids for pain relief may modify cerebral function, and catastrophic illness is often associated with acute organic brain syndrome. Pancreatic encephalopathy also has been described as a separate entity. It is attributed to the release of pancreatic lipases, but the evidence for this view is inconclusive. MRI demonstrates patchy white matter abnormalities that resemble the plaques seen in multiple sclerosis.

Treatment

Critical care of the patient with acute pancreatitis consists essentially of maintaining adequate perfusion and oxygen delivery to essential organs during resolution of the primary disease process. Early and aggressive resuscitation reduces the mortality rate by reducing the incidence of multisystem organ failure.

A. Fluid Resuscitation and Physiologic Monitoring—

The degree of intravascular fluid depletion is difficult to gauge accurately in patients with acute pancreatitis. Tissue fluid shifts related to systemic release of vasoactive toxins and severe retroperitoneal losses may be dramatic. As much as 10–20 L of replacement fluid may be required in the first 24 hours. Replacement by crystalloid is the fluid of choice. Colloid is used only in patients in whom the albumin is dangerously low. Depending on the clinical severity, blood transfusion should be considered when the hemoglobin is less than 10 g/dL. The use of fresh-frozen plasma for systemic deactivation of proteases has provided apparent benefit in empirical trials. Controlled studies, however, have failed to provide objective evidence of an improvement in outcome, and routine use of fresh-frozen plasma should await further evaluation.

As in any shock state, adequacy of fluid replacement is assessed by measurement of central venous or pulmonary arterial wedge pressure, aiming for values at least 10 mm Hg above the intrathoracic pressure. In patients in whom positive-pressure ventilation is being used, the systemic venous pressure or the pulmonary arterial wedge pressure should be at least 10 mm Hg higher than the ventilatory positive end-expiratory pressure.

The adequacy of fluid replacement can be further assessed by measurement of the response to repeated fluid challenges with 250–500 mL of balanced salt solution. If central filling pressures are sufficient, such challenges will be followed by a sustained rise in central venous pressure of 3–5 mm Hg. Once filling pressures are optimized, the increment in cardiac output in response to further fluid replacement is minimal, and the patient should be kept stable at this level.

Successful fluid resuscitation should be accompanied by improved peripheral perfusion, as indicated by limb temperature, peripheral pulse volume, arterial blood pressure, urinary output, and mixed venous oxygen. Low mixed venous oxygen tension ($P\bar{V}O_2 < 40$ mm Hg) indicates that the perfusion state is inadequate. If central filling pressures have been optimized, myocardial dysfunction should be suspected.

B. Inotropic Support—Echocardiographic evaluation is useful for differentiation of the hypovolemic state from the hypocontractile state. In the former, heart size is normal or less than normal, and there is evidence of vigorous wall motion. In the latter, there is usually discernible chamber enlargement and segmental or global hypokinesia.

If myocardial hypocontractility is diagnosed, inotropic support should be instituted. Strict guidelines for choice of inotropic agents are not available. In general, however, for patients in whom persistent hypotension dominates, an incrementally increased infusion of dopamine titrated against blood pressure is the preferred initial strategy. In situations where tissue perfusion remains poor despite adequate arterial pressures, inotropic agents without prominent α -adrenergic effects such as dobutamine may be preferable. Irrespective of the agent used, the clinical objective is

improvement of organ perfusion, and mixed venous oxygenation should be specifically evaluated rather than relying solely on monitoring of arterial blood pressure.

C. Respiratory Support—Patients with significant hypoxia ($\text{PaO}_2 < 60$ mm Hg) despite high inspired oxygen or clinical evidence of compromised ventilation (respiratory rate of > 30 breaths/min or dyskinetic breathing pattern) should be considered for early intubation and mechanical ventilatory support. Sedation, analgesia, and mechanical ventilation improve overall cardiopulmonary performance.

D. Renal Support—Impaired renal function—indicated by rising serum urea nitrogen and creatinine or oliguria with frank acute tubular necrosis—is seen often in severe acute pancreatitis. Early and adequate fluid replacement minimizes the risk, but renal function may continue to deteriorate despite adequate hemodynamic resuscitation. Low-dose dopamine may increase renal blood flow, minimizing the ischemic insult.

Fortunately, the prognosis for renal function is good, and in most cases temporary hemodialysis or hemofiltration will maintain adequate homeostasis until renal function returns.

Once acute tubular necrosis has become established, it is important to avoid secondary ischemic insults, which may result in acute cortical necrosis and permanent loss of renal function.

E. Nutrition—Acute pancreatitis is a hypermetabolic state similar to sepsis. Retroperitoneal edema may contribute to prolonged small bowel dysfunction and make enteral nutritional support impossible. This, along with ongoing negative nitrogen balance, mandates the institution of total parenteral nutrition. While early institution of total parenteral nutrition is theoretically desirable, these patients are variably intolerant of the high metabolic loads. The degree of insulin resistance is often extreme, with high-dose insulin infusions required to stabilize serum glucose levels at less than 150 mg/dL. Early institution of total parenteral nutrition is not critical, and in the hemodynamically unstable patient, delayed introduction is advised.

It has been proposed that hyperlipidemia may in itself stimulate the pancreas and help perpetuate the inflammatory process. For this reason, total parenteral nutrition regimens with reduced fat content have been advocated. There is, however, no objective evidence that patients with acute pancreatitis are adversely affected by customarily used lipid regimens, and the use of nutritional formulas low in lipids is a matter of personal choice.

Evidence of the benefit of total parenteral nutrition for modification of the disease process within the pancreas is not yet available. Nor is there real evidence to suggest the superiority of any particular regimen for the maintenance of basic nutrition.

Patients with acute pancreatitis do appear to have a heightened susceptibility to intravenous line infections, and meticulous care of catheters is required. Dedicated ports exclusively

for total parenteral nutrition infusions—with meticulous care during line changes—may help to reduce infection rates.

F. Other Modalities—Little can be done to substantially modify the inflammatory process within the pancreas. Various interventions have been proposed, but none has been shown to have substantial value. Steroids are not indicated. Inhibitors of pancreatic function such as glucagon and octreotide have been used without demonstrable benefit. Antiproteases such as aprotinin also have lacked obvious therapeutic effect and now have been largely abandoned.

The nature and extent of surgery depend on appraisal of the radiologic appearance of the pancreas and the physiologic status of the patient. Peritoneal lavage, manipulation of the biliary tree, and pancreatic procedures, as well as operative management of complications, all have a place in the operative management of severe acute pancreatitis. Optimal timing of any procedure is critical and is based largely on clinical judgment.

Once the patient with severe acute pancreatitis is resuscitated, efforts must be directed toward the detection and management of pancreatic necrosis. Dynamic contrast-enhanced CT scanning is the most accurate method for evaluating pancreatic ischemia and also can aid in planning operative treatment.

1. PERITONEAL AND RETROPERITONEAL LAVAGE—This relatively noninvasive procedure was first advocated in 1965 and was widely adopted thereafter. However, subsequent controlled trials and standardization of patient selection showed no significant difference in overall mortality rates. A more recent trial of therapeutic peritoneal lavage for 7 days reported a reduction in both the incidence and mortality rate of pancreatic sepsis in patients with severe acute pancreatitis. Some now advocate continuous lavage with 2-L exchanges performed every hour. A modified balanced salt solution is usually used.

Retroperitoneal lavage with aggressive irrigation has avoided surgery and treated sepsis in a significant number of patients.

2. BILIARY PROCEDURES—Overwhelming evidence of the association of choledocholithiasis with gallstone pancreatitis prompted evaluation of the role of removal of common bile duct stones in the management of acute pancreatitis. Up to 95% of patients with gallstone pancreatitis pass a gallstone in the feces during the course of the illness. Choledocholithiasis can be demonstrated in approximately 70% of these patients within the first 48 hours of presentation, with the rate of stone detection falling off rapidly thereafter.

Initial experience with urgent cholecystectomy or cholecystostomy with choledochostomy in acute pancreatitis demonstrated a 72% common duct stone retrieval rate and a 2% mortality rate. However, these results were difficult to replicate and were reported prior to the general use of scoring systems to standardize illness severity and prognosis in the management of patients with acute pancreatitis. Early

definitive surgery in the acute phase of acute pancreatitis carries unacceptable morbidity and mortality rates. However, results suggest that early ERCP and endoscopic sphincterotomy may have a favorable impact on survival in patients with severe disease. Patient selection for ERCP and the inherent risks and timing of this procedure in the very sick patient need to be considered prior to adoption of this policy. Ascending cholangitis in association with acute pancreatitis is ideally treated by ERCP and sphincterotomy. Most surgeons would advocate semielective cholecystectomy once the patient has recovered from the acute event—ideally, during the same hospital admission.

3. NECROSECTOMY—This operation, involving empirical debridement of devitalized pancreatic tissue, has gradually become the treatment of choice in patients with severe necrotizing pancreatitis. It has replaced formal pancreatic resection, which carries a persistently high mortality rate. The nonanatomic basis of this approach makes the outcome of surgery particularly dependent on optimal timing of operation. Clinically detectable separation of necrotic and viable tissue is best seen after 7 days, and patients in whom the initial operation can be delayed for as long as possible have an overall lower mortality rate. Minimal debridement should be planned if earlier operation is mandated by deteriorating condition of the patient.

In many cases, several operations are required for complete debridement because demarcation progresses over a period of time. Attempted resection of nondemarcated tissue to avoid multiple laparotomies is associated with increased morbidity and mortality rates. The use and placement of drains and the value of pancreatic bed lavage have lowered the mortality of this condition. Pancreatic fistulas should be managed by external drainage in the acute setting.

Management of the abdominal wall in the intervals between multiple, closely timed laparotomies is also a matter of choice for the surgeon. Vertical incisions with the use of zipper closure techniques or horizontal incisions with isolation of the supracolic compartment and an open wound have been advocated. If the abdomen is left open, paralysis of the patient is mandatory to prevent evisceration until early adhesions contain the abdominal contents.

Minimally invasive necrosectomy in the form of aggressive irrigation with fluoroscope-guided removal of tissue with forceps and snares can buy time as well as be the definitive procedure.

Standard laparoscopy with debridement of the retroperitoneum, cholecystectomy and splenectomy, endoscopic transgastric and transduodenal retroperitoneoscopy and debridement, and retroperitoneoscopy via either of the flanks are all being evaluated as procedures that can be performed on patients not fit for standard laparotomy.

4. ENTERIC FISTULAS—The massive retroperitoneal inflammation associated with acute pancreatitis may lead to vascular complications. These include thrombosis and aneurysm

formation, with the former being the most common. The middle colic vessels supplying the transverse colon are especially at risk, although gastric, duodenal, and small bowel fistulas also have been described. If necrosectomy is required, consideration should be given to examination of the transverse colon. If evidence of ischemia is present, elective terminal ileostomy at the time of first laparotomy may be valuable. Other enteric fistulas are investigated and managed in routine fashion. *One must be alert to this possibility to avoid dangerous delays in diagnosis.*

5. BLEEDING—Catastrophic bleeding is difficult to manage surgically because the inflamed pancreatic bed makes delineation of anatomy and accurate dissection hazardous. Embolization of the bleeding vessel by angiographic techniques is probably the treatment of choice. Bleeding from erosion into the splenic artery or other vessels may be life-threatening.

6. PANCREATIC ABSCESS—Pancreatic abscess occurs with delayed infection of limited pancreatic necrotic tissue that has progressed beyond demarcation to liquefaction and isolation. It is differentiated from infected necrosis by its delayed presentation (4–6 weeks). Abscesses are best diagnosed by CT scan. The value of percutaneous CT-guided catheter drainage in comparison with laparotomy has not been established.

7. PANCREATIC PSEUDOCYST—Pancreatic pseudocysts form by one of two mechanisms. Following acute pancreatitis, extravasation of pancreatic enzymes produces necrosis of surrounding tissues and forms a sterile collection of fluid that is not reabsorbed as the inflammatory process subsides. If the fluid collection becomes infected, a pancreatic abscess results. If not, the fluid is retained by the surrounding organs as a pseudocyst. The second mechanism typically follows trauma and is caused by ductal obstruction that leads to a retention cyst. Pseudocysts occur in about 2% of all cases of acute pancreatitis, and over 85% are singular. Pseudocyst formation presents several weeks after the episode of acute pancreatitis, making de novo presentation in the ICU somewhat uncommon. However, patients are frequently readmitted to a critical care facility when increased epigastric pain, fever, and amylase elevation occur after initial therapy for pancreatitis. Pain is the most common finding, but a few patients have a palpable mass, jaundice, or weight loss. A CT scan is the procedure of choice for establishing the diagnosis, although serial ultrasonography is useful for determining changes in the size of the pseudocyst. Infection, rupture, and hemorrhage are the major complications of pancreatic pseudocysts. Many resolve spontaneously, although internal drainage via cystoenterostomy may be required; endoscopic transgastric cystostomy is being evaluated. Critical care management is similar to that for acute pancreatitis, with particular requirements for parenteral nutritional support and treatment of infectious complications.

▶ Bowel Obstruction

ESSENTIALS OF DIAGNOSIS

- ▶ Colicky abdominal pain.
- ▶ Emesis.
- ▶ Dehydration.
- ▶ Peristaltic “tinkles and rushes” on abdominal auscultation.
- ▶ Air-fluid levels on abdominal x-ray.

General Considerations

Bowel obstructions are common among critically ill patients and may be the underlying reason for ICU admission or may develop as part of another disease process. Obstructions of the small bowel may be mechanical or paralytic. Mechanical obstructions occur when a physical impediment to the aboral progress of intestinal contents is present. Paralytic ileus (ie, functional obstruction) occurs when an underlying disease process interferes with normal peristalsis. Metabolic derangements, neurogenic causes, drug effects, and peritonitis are the most common causes of paralytic ileus. Mechanical obstruction can be divided into simple obstructions, involving only the bowel lumen, and strangulated obstructions, which impair blood supply and lead to necrosis of the intestinal wall. A simple obstruction takes place at just one location. When the bowel lumen is occluded in two or more locations, a closed-loop obstruction is created. Closed-loop obstructions are often associated with strangulation because blood supply may be compromised.

Adhesions from previous abdominal surgery are the most common cause of small bowel obstruction. Onset is usually insidious, with abdominal bloating and crampy abdominal pain. External hernias through the abdominal wall that become incarcerated are the second most common cause of small bowel obstruction. Internal hernias also can occur at the obturator foramen, through the diaphragm, or at the foramen epiploicum (Winslow). Defects caused by surgery, such as those adjacent to stomas, also are potential sites for the formation of internal hernias.

Neoplasms within or extrinsic to the small bowel may produce obstruction directly or by mass effect. Such tumors may serve as the lead point for an intussusception. Although rare in adults, intussusception may occur without a lesion serving as a lead point.

Volvulus is produced when mobile bowel rotates around a fixed point. This is frequently the consequence of congenital abnormalities or acquired adhesions. Obstruction typically occurs abruptly and leads to intestinal strangulation if not relieved quickly. Sigmoid and cecal volvulus of the colon is significantly more common than small bowel volvulus.

Other less common causes of small bowel obstruction include gallstone ileus, ingested foreign bodies, inflammatory bowel disease, stricture owing to radiation therapy, cystic fibrosis, and posttraumatic hematoma. Gallstone ileus occurs in patients with cholelithiasis who develop a fistula between the gallbladder and a loop of small bowel, typically the duodenum. As the gallstone progresses distally, it produces a pattern of intermittent small bowel obstruction at different levels, referred to as “tumbling” obstruction. Air in the biliary tree on abdominal x-ray is the key to the diagnosis.

When the small bowel is obstructed, distention with gas and fluid occurs proximally. Swallowed air is the major cause of distention. This is due to the high nitrogen content in room air, which is not well absorbed by the mucosa. Bacterial fermentation produces other gases as well, such as methane.

Inflammation leads to transudation of fluid from the extracellular space into the bowel lumen and peritoneal cavity. As the proximal lumen distends and fluid accumulates, the bidirectional flow of salt and water is disrupted, and secretion is enhanced. Other substances such as prostaglandins and endotoxins released by bacterial proliferation in the static lumen further the process. Fluid losses may be so severe that hypotension results and ultimately may lead to cardiovascular collapse unless recognized and treated expeditiously.

Vomiting usually accompanies small bowel obstruction and becomes progressively more feculent as the illness progresses. Peristaltic “rushes” are the auscultatory hallmark of this problem. Aspiration of vomitus may lead to severe pneumonia and respiratory distress. Respiration is adversely affected by abdominal distention and impaired diaphragmatic excursion.

Closed-loop obstruction is a feared consequence of complete mechanical obstruction. When it occurs, no outlet for the accumulated intraluminal contents exists, and perforation of the bowel may occur. Strangulation rarely results from progressive distention, although venous outflow becomes significantly impaired as the bowel and mesentery continue to distend. This ultimately results in intestinal gangrene and intraluminal bleeding. Free perforation occurs as a consequence of gangrene, releasing the highly toxic stagnant intraluminal mixture of bacterial products, live bacteria, necrotic tissue, and blood. There are no specific historical, physical, or laboratory findings that exclude the possibility of strangulation in complete small bowel obstruction, which occurs in approximately one-third of patients. The early appearance of shock, gross hematemesis, and profound leukocytosis suggests the presence of a strangulated obstruction.

Clinical Features

A. Symptoms and Signs—Obstruction of the proximal small bowel usually presents with vomiting. The extent of associated abdominal pain is variable and usually is described as intermittent or colicky with a crescendo-decrescendo pattern. When the obstruction is located in the middle or high small bowel (jejunum and proximal ileum), the pain may be more constant. As the site of involvement progresses distally, poorly localized crampy pain and abdominal distention become more common (Figure 14–1).

In the early stages of obstruction, vital signs are normal. As loss of fluid and electrolytes continues, dehydration occurs, manifested as tachycardia and postural hypotension. Body temperature is usually normal but may be mildly elevated. Abdominal distention is minimal or absent initially. It is more pronounced with distal obstruction and when more proximal lesions have been allowed to progress without decompression. Dilated loops of small bowel may be visible beneath the abdominal wall in thin patients. Characteristic peristaltic rushes, gurgles, and high-pitched tinkles may be audible and occur in synchrony with cramping pain. Rectal examination is usually normal. Abdominal wall hernias should be sought.

**High**

Frequent vomiting.
No distention. Intermittent
pain but not classic
crescendo type.

**Middle**

Moderate vomiting.
Moderate distention. Intermittent
pain (crescendo, colicky)
with pain-free intervals.

**Low**

Vomiting late, feculent.
Marked distention. Variable
pain; may not be classic
crescendo type.

▲ **Figure 14-1.** Small bowel obstruction. Variable manifestations of obstruction depend on the level of blockage of the small bowel. (Reproduced, with permission, from Way LW, Doherty GM (eds), *Current Surgical Diagnosis & Treatment*, 11th ed. New York: McGraw-Hill, 2002.)

B. Laboratory Findings—Early in the process, laboratory findings are normal. With progression, there is hemoconcentration, leukocytosis, and electrolyte abnormalities whose extent and nature depend in part on the level of obstruction present. Increases in serum amylase are common.

C. Imaging Studies—On plain abdominal films, a ladder-like pattern of dilated small bowel loops and air-fluid levels will be noted, particularly in distal obstruction. The colon may not contain gas. If a gallstone precipitated the event, it may be noted on the film, or air may be seen in the biliary tree. When strangulation and necrosis occur, loss of mucosal regularity, gas within the bowel wall, and “thumbprinting” of the bowel wall occur. On rare occasions, gas may be seen within the portal vein. Free air on an upright chest x-ray is highly suggestive of intestinal perforation.

Contrast studies are usually not required and should not be performed because of the risk of barium peritonitis if a perforation is present. However, in patients with high-grade partial obstructions who are poor surgical risks, administration of a dilute barium mixture through the nasogastric tube can

be used to determine whether a residual lumen is still present for the passage of gas and liquid contents.

Differential Diagnosis

Ileus is a prominent feature of the differential diagnosis. It can be caused by a number of intraabdominal and retroperitoneal processes, including intestinal ischemia, ureteral colic, pelvic fractures, and back injuries. It may occur after routine abdominal surgery. If paralytic ileus is present, the pain is usually not as severe and tends to be more constant.

Obstipation and abdominal distention characterize obstruction of the large intestine. Vomiting seldom occurs, and the pain is less colicky. The diagnosis is usually made on the basis of x-ray findings that show colonic dilation proximal to the point of obstruction.

Small bowel obstruction can be confused with acute gastroenteritis, acute appendicitis, and acute pancreatitis. Strangulating obstructions may be mimicked by acute pancreatitis, ischemic enteritis, or mesenteric vascular occlusion owing to venous thrombosis.

Paralytic ileus must be differentiated from mechanical obstruction. Radiographic findings usually show a more diffuse pattern of air-fluid levels without a distinct cutoff point. These patients may be very ill with other systemic diseases or may be apparently well with seemingly minor electrolyte abnormalities. Pseudo-obstruction is particularly common among patients with diabetes who are recovering from an episode of ketoacidosis or who have recently undergone intraabdominal surgery. Treatment of pseudo-obstruction is directed at the disease process causing the ileus. Metoclopramide may be helpful once the presence of mechanical obstruction has been excluded.

Treatment

A. Supportive Measures—Partial small bowel obstructions may be treated with intravenous hydration and nasogastric suction if the patient continues to pass stool and flatus. Fluid and electrolyte losses are corrected with balanced salt solutions. Isotonic solutions should be used to treat hemoconcentration. The extent of fluid resuscitation is best guided by urine output, although in elderly patients or those with cardiopulmonary disease, a pulmonary artery flotation catheter is advisable. If strangulation is suspected, broad-spectrum antibiotics should be administered promptly.

B. Surgery—Planning for surgery should be started concurrently with fluid and electrolyte therapy because the patient must be fully resuscitated before operation commences. Laparoscopy with lysis of the obstructing adhesion if the obstruction is due to a simple obstructing band or adhesion may be all that is required, or open surgery may be necessary if this cannot be performed laparoscopically. When closed-loop and strangulated obstructions are present, intestinal resection may be necessary. The major problem at surgery is distinguishing viable from necrotic bowel. In severe cases, patients may have to be returned to the operating room within 24–48 hours for a “second look” procedure to make certain that all remaining bowel is viable.

Prognosis

The mortality rate for simple obstruction is almost 2%. It increases to about 8% if strangulation is present and surgery is performed within 36 hours of presentation—and to 25% if operation is delayed beyond that point.

► Obstruction of the Large Bowel

ESSENTIALS OF DIAGNOSIS

- Constipation or obstipation.
- Abdominal distention and tenderness.
- Abdominal pain.
- Nausea and vomiting (late).
- Characteristic x-ray findings.

General Considerations

About 15% of intestinal obstructions involve the large bowel. The sigmoid colon is most commonly involved. When complete obstruction is present, carcinoma usually is the cause. Other causes include diverticular disease, volvulus, inflammatory disorders, benign tumors, and fecal impaction. Obstructive bands from adhesions and intussusception are rare causes of large bowel obstruction.

If obstruction occurs at the level of the cecum, the signs and symptoms will be similar to those of small bowel obstruction. With more distal colonic obstruction, physical findings will depend on the competence of the ileocecal valve. A form of closed-loop obstruction will occur if the colon cannot decompress itself in retrograde fashion through the ileocecal valve into the small bowel.

Colonic distention is a progressive process in which intraluminal pressures can reach very high levels that can impair the circulation and lead to gangrene and perforation.

Clinical Features

A. Symptoms and Signs—Patients typically complain of a deep-seated cramping pain referred to the hypogastrium. Lesions of fixed portions of the colon (ie, cecum, hepatic flexure, and splenic flexure) radiate anteriorly. Pain from obstruction of the sigmoid colon usually radiates to the left lower quadrant. Severe continuous pain suggests intestinal ischemia. When a progressive process is responsible, the obstruction may develop insidiously, although careful questioning often reveals signs of chronic disease such as a change in stool caliber, frequency of defecation, and dark or black feces.

The usual feature of complete obstruction is constipation or obstipation. Vomiting is a late finding and may not occur if the ileocecal valve does not allow contents to reflux back into the small intestine. Feculent vomiting is a late manifestation.

Abdominal distention with peristaltic waves radiating across the abdominal wall may be observed if the patient is thin. On auscultation, high-pitched metallic tinkling and associated rushes and gurgles can be heard. Localized tenderness or a nontender palpable mass may indicate a strangulated closed loop. Occult blood on rectal examination may be

due to carcinoma, whereas fresh blood is characteristic of diverticular disease and intussusception.

B. Endoscopy—Sigmoidoscopy and colonoscopy are often beneficial in establishing the diagnosis and may be therapeutic if sigmoid volvulus is present. Care must be exercised when advancing the endoscope to prevent accidental perforation of an attenuated colonic wall.

In strictures, dilatation and stenting can be therapeutic or allow bowel preparation before definitive surgery, making a diverting colostomy unnecessary. Fulguration of inoperable obstructing carcinomas can restore a lumen to palliate an inoperable lesion.

C. Imaging Studies—Plain abdominal x-rays reveal a distended colonic segment. With low sigmoid or rectal obstructions, the entire colon may be dilated. If the ileocecal valve is incompetent, retrograde decompression will cause distention of the terminal ileum.

The diagnosis is confirmed by barium enema. Water-soluble contrast medium should be used if strangulation or perforation is suspected. Barium is contraindicated in the presence of suspected colonic perforation.

Differential Diagnosis

It is important to differentiate small bowel obstruction from colonic obstruction. With the latter, onset is typically slower, and there is less pain. Vomiting is very unusual with colonic obstruction despite considerable abdominal distention. Plain abdominal x-rays are essential to the differential diagnosis, and adjunctive contrast studies are sometimes helpful.

Treatment

The primary goal of therapy is decompression of the obstructed segment and prevention of perforation. Operation is almost always required in cases of mechanical obstruction. The surgical procedure depends on the lesion present, the status of the patient, the extent of colonic dilatation, and whether there is evidence of perforation. In general, proximal diversion (colostomy) is required to decompress the dilated colon. Simultaneous or subsequent excision of the obstructing lesion is required before colonic continuity can be reestablished.

Prognosis

The prognosis depends on the age and general condition of the patient, as well as on the extent of vascular impairment of the bowel, the presence or absence of perforation, the cause of obstruction, and the promptness of surgical management. Mortality rates are about 20% overall. If the cecum perforates, a mortality rate of 40% can be expected. In the case of colonic obstruction secondary to carcinoma, the prognosis is worse.

▶ Adynamic (Paralytic) Ileus

ESSENTIALS OF DIAGNOSIS

- ▶ Continuous abdominal pain.
- ▶ Vomiting.
- ▶ Abdominal distention.
- ▶ Obstipation.
- ▶ Precipitating factor.
- ▶ Radiographic evidence of gas and fluid in the small or large bowel.

General Considerations

Adynamic ileus is often associated with neurogenic or muscular impairment of small or large bowel function. This may be due to a variety of causes such as alimentary tract surgery, a ruptured viscus, hemorrhage, pancreatitis, or peritonitis. Other causes include anoxic injury, anticholinergic medications, opioids, vertebral fractures, renal colic, injuries of the spinal cord, severe infections of either the thoracic or the abdominal cavity, uremia, diabetic coma, and electrolyte abnormalities.

Recent abdominal surgery is a principal cause of adynamic ileus among critical care patients. In the 24 hours following surgery, motility within the small bowel returns to normal, whereas gastric function will return after approximately 24 hours. The colon requires several days to regain normal motility. The pain associated with ileus is constant but not severe or colicky, as it is with mechanical obstruction. Mild abdominal tenderness is noted along with distention. If this is due to an intraperitoneal inflammatory process, signs and symptoms of that disorder are usually present. Plain films of the abdomen are extremely helpful.

Similar to paralytic ileus of the small bowel, pseudo-obstruction (Ogilvie's syndrome) of the colon may occur. This is a severe form of ileus that often arises in bedridden patients who have serious systemic illnesses. The abdomen is usually silent, and abdominal cramping is not present. Tenderness may be noted. Plain films show a dilated colon that may reach alarming proportions. The entire colon may

contain gas, but the distention is typically localized to the right colon with cutoff at the splenic flexure. Contrast studies may be required to prove the absence of obstruction, but instillation of radiopaque material must be stopped as soon as the dilated colon is reached. The risk of cecal perforation is very high in patients with pseudo-obstruction. Decompression of the colon should be attempted as quickly as possible using a fiberoptic colonoscope. Recurrence rates are as high as 20%. Initial colonoscopic decompression is successful in 90% of patients. Percutaneous cecostomy is reserved as an option for decompression if colonoscopy fails.

Clinical Features

A. Symptoms and Signs—Mild to moderate abdominal pain is usually present. It is continuous rather than colicky and is often associated with emesis, which may become feculent. Symptoms of the underlying condition also may be present, such as prostration from a ruptured viscus. Dehydration is usually present as a consequence of fluid translocation into distended loops of bowel. Massive abdominal distention and localized tenderness are common. Bowel sounds are absent or decreased.

B. Laboratory Findings—Hemoconcentration and electrolyte deficits occur with prolonged vomiting. Elevated serum amylase levels and leukocytosis are usually present.

C. Imaging Studies—The specific radiographic finding noted on flat-plate upright abdominal films is gas-filled loops of intestine. Air even may be present in the rectum. Air-fluid levels in the distended bowel are common. A contrast enema or barium swallow with subsequent small bowel “follow through” films may be helpful in differentiating adynamic ileus from mechanical obstruction.

Differential Diagnosis

Idiopathic pseudo-obstruction is usually seen in teenagers or young adults and is characterized by symptoms of small bowel obstruction that recur but never produce evidence of organic obstruction on x-ray. Treatment is with nasogastric intubation and suction. Intravenous fluids and parenteral nutrition are required. Occasionally, colonoscopic decompression or cecostomy is useful. The variant known as *chronic pseudo-obstruction* is associated with cramping abdominal pain, abdominal distention, and vomiting. There may be involvement of the esophagus, the stomach, the small bowel, the colon, or the urinary bladder. All or some of these patients have abnormal motility with sparing of some portions of the alimentary tract. Metoclopramide is often helpful. Avoiding narcotic analgesics may prevent an ileus. Use of thoracic epidural analgesia and postoperative local anesthetic wound devices will reduce the need for narcotics.

Treatment

A. Supportive Measures—Most cases of ileus in the postoperative period respond to restriction of oral intake and

nasogastric suction. Fluid and electrolyte replacement is essential.

B. Decompression—When colonic dilation is present, colonoscopy may be valuable. Use of a rectal tube was common practice at one time but now has been largely abandoned.

C. Surgery—If there is a failure of conservative therapy, surgery may be necessary. Operation is performed to decompress the bowel either by enterostomy or by cecostomy and to exclude mechanical obstruction. Bowel biopsy may be performed to identify neurogenic causes.

Prognosis

The initiating disorder often will dictate the prognosis. Adynamic ileus may resolve without specific therapy. Decompression usually helps to return bowel function to normal.

Current Controversies and Unresolved Issues

Recent studies have reported the use of new agents in the treatment of adynamic ileus. Itopride has shown some effect in postoperative ileus. Cisapride has been discontinued owing to side effects. Erythromycin was studied and showed no advantage when compared with placebo. Intravenous lidocaine also has been found to shorten the duration of paralytic ileus, presumably by suppressing inhibitory GI reflexes. Additional trials of all these agents are required before they can be either recommended or discredited.

DIARRHEA & MALABSORPTION

Critically ill patients often develop diarrhea from a number of causes, including overly aggressive enteral feeding, infectious diarrhea, and malabsorption. After GI resection, short gut syndromes and exocrine insufficiency may contribute. These common causes are discussed in the next several sections.

► Pancreatic Insufficiency

Following pancreatic surgery, pancreatectomy, or pancreatitis, pancreatic exocrine insufficiency can develop. Varying degrees of insufficiency may be present without overt symptoms. Following total pancreatectomy, malabsorption of 70% of dietary fat is common. However, in the face of a normal pancreatic remnant, some resections have little or no effect on fat absorption.

Patients with pancreatic insufficiency have increased fecal fat and decreased serum cholesterol. Steatorrhea manifests as frequent, bulky, light-colored stools. A loss of 90% of pancreatic exocrine function is required before such findings appear. If the patient retains 2–10% of normal pancreatic function, steatorrhea is mild to moderate. If less than 2% of normal function remains, steatorrhea is severe.

Pancreatic insufficiency affects fat absorption more than that of proteins or carbohydrates. Malabsorption secondary to fat loss or vitamin deficiency is rarely a problem. B vitamins, which are water-soluble, are absorbed through the small intestine. Fat-soluble vitamins depend on bile salt micelle formation for solubilization and do not require pancreatic enzymes for absorption. Vitamin B₁₂ deficiency occurs rarely but, when present, is an indication for exogenous enzyme replacement.

Diagnosis

A. Secretin or Cholecystokinin Test—The duodenum is intubated and pancreatic juice recovered after intravenous injection of synthetic or purified secretin or cholecystokinin. Optimally, pancreatic fluid bicarbonate should exceed 80 meq/L, and bicarbonate production should be greater than 15 meq every 30 minutes.

B. Pancreolauryl Test—A meal containing fluorescein dilaurate is ingested, and the subsequent urinary excretion of fluorescein is measured. Pancreatic esterase is responsible for the absorption and release of fluorescein. The test is both specific and sensitive and is the best modality for testing pancreatic exocrine function.

C. PABA Excretion (Bentiromide Test)—The synthetic peptide bentiromide is administered (1 g orally), and the urinary excretion of aromatic amines is measured. Patients with chronic pancreatitis excrete about 50% of the normal amount of the amines.

D. Fecal Fat (Balance) Measurement—A diet containing 75–100 g of fat—measured and given in the same amount each day—is ingested daily for 5 days. Excretion of less than 7% of the ingested fat is normal. Fat excretion of more than 25% of the total daily intake suggests significant steatorrhea.

Treatment

The diet should provide 3000–6000 kcal daily. Patients with steatorrhea may not have diarrhea. Dietary fat restriction is

intended primarily to control diarrhea. If a patient does have diarrhea and is restricted to 50 g fat, the daily allotment of fat should be increased until the diarrhea reappears.

Pancreatic enzyme replacement can be accomplished with exogenous extracts. With these formulations, 30,000–50,000 units of lipase can be distributed over several feedings during the day. If malabsorption does not improve with enzymes alone, the difficulty is usually due to destruction of the administered lipase by gastric acid. To alleviate this problem, an H₂-receptor–blocking agent is given and an enteric-coated lipase formulation provided. When lipase is administered in this form, the gastric pH is less likely to affect the enzyme.

Caloric supplementation may be given in the form of powder or as an oil containing medium-chain triglycerides (MCTs). The fatty acids are absorbed more readily in this preparation than when long-chain triglycerides are used. The MCT oil is associated with bloating, diarrhea, nausea and vomiting, and very poor patient acceptance.

► Lactase Deficiency

Lactase deficiency is a common problem among critically ill patients. The symptoms are variable and can range from minor abdominal bloating to distention, flatulence, and cramping pain. Some patients, however, have severe diarrhea in response to only a small amount of lactose. Although a lactose tolerance test is available, clinical suspicion and relation of the diarrhea to the time of refeeding usually suggest the diagnosis. Illnesses such as gastroenteritis may injure the microvilli and lead to a temporary lactase deficiency. Several congenital defects of disaccharidase have been described. Most patients will give a history of dietary problems with milk products, but the difficulties occasionally surface at times of physiologic stress. They include sucrose-isomaltose and glucose-galactose intolerance. Disaccharide deficiency secondary to short bowel syndrome, celiac disease, giardiasis, ulcerative colitis, cystic fibrosis, and postgastrectomy problems may be noted. In all cases, removal of lactose from the diet and use of a non-lactose-based enteral nutritional supplement usually solve the problem.

► Diarrhea

Diarrhea is defined as an increase in the fluidity, frequency, or quantity (>200 g/day) of bowel movements. Several

Table 14–2. Classification of diarrhea.**I. Diarrhea secondary to excessive fecal water:**

- A. Secretory diarrhea: Produced by excessive secretion by the mucosal cells of the intestine. Causes: cholera, toxigenic *E. coli* infections, Zollinger-Ellison syndrome, and VIPoma.
- B. Osmotic diarrhea: Produced by an excess of water-soluble molecules in the lumen of the bowel, which cause osmotic retention of intraluminal water. Causes: Abuse or surreptitious use of laxatives, administration of magnesium hydroxide, or undigested disaccharides.
- C. Exudative disease: Produced by intestinal loss of serum proteins, blood, mucus, or pus due to abnormal mucosal permeability.
- D. Accelerated transport: Impaired contact between intestinal chyme absorbing surface, which results in rapid transport. Common in short bowel syndromes.
- E. Motility disturbances: Causes: Amyloidosis, scleroderma, diabetes mellitus, and bacterial overgrowth.

II. Diarrhea not secondary to excessive fecal water:

- A. Small, frequent, and painful evacuations caused by partial obstruction of the left colon or rectum.

factors to be considered in the evaluation of diarrhea may influence the frequency or even the fluidity of bowel movements. Malabsorption or excessive secretion of water usually results in passage of stools that contain excess water and are therefore considered as diarrhea. The best index is daily stool weight. Therefore, one may have small-volume diarrhea, large-volume diarrhea, and other variants that depend on the content of blood, mucus, or exudate. The various types of diarrhea are listed in Table 14–2. Common causes of diarrhea among patients in an ICU include psychogenic disorders, drugs (especially antacids, antibiotics, and metoclopramide), intestinal infections, cholestatic syndromes (eg, hepatitis, bile duct obstruction, and steatorrhea), malabsorption (eg, short bowel syndrome and afferent loop syndrome), diabetic neuropathy, hyperthyroidism, and immunodeficiency.

Diagnosis

In general, diarrheal episodes are self-limiting, and diagnostic testing is not necessary. However, in patients with unexplained severe or chronic diarrhea, etiologic evaluation may become necessary. Review of the patient's chart, evaluation of drugs being used, and physical examination are often all that are needed to establish the cause. Examination of stool for polymorphonuclear cells and parasites and culture for

bacterial pathogens may be required. A sample for culture is best obtained with the sigmoidoscope. Rectal biopsy may be helpful and even necessary, especially when *Entamoeba histolytica* infection is suspected. Assays of stool for *Clostridium difficile* toxin are highly accurate and establish the diagnosis of pseudomembranous enterocolitis.

Treatment

Before specific therapy for diarrhea is begun, it is important to make certain that fluid losses have been replaced and electrolyte imbalances corrected. Malnutrition should be managed with parenteral nutrition.

Antidiarrheal agents should be used with great caution and attention to the patient's critical care history. The antidiarrheal agent used most commonly is bismuth subsalicylate. This can be given in liquid or tablet form. The usual dose is 30 mL up to eight times a day. Opioid analogs are also popular; the most frequently prescribed form is diphenoxylate with atropine, one tablet three or four times daily as needed. This drug is contraindicated in patients with jaundice or pseudomembranous or endotoxin colitis and must be used with caution in patients with advanced liver disease or those who are addiction-prone. Concurrent use of this medication with monoamine oxidase inhibitors may precipitate a hypertensive crisis. A secondary drug is loperamide, 4 mg initially and then 2 mg for each loose stool to a maximum dose of 16 mg/day. Loperamide is effective in both acute and chronic diarrhea. Opioids such as paregoric and codeine phosphate were popular in the past but have little role in critically ill patients.

Clonidine, when administered as a 1-mg patch, is useful in patients who have diabetes or cryptosporidiosis. Octreotide acetate is useful when diarrhea is due to carcinoid tumors, VIPoma, or AIDS. It is usually started at a dose of 50 µg subcutaneously once or twice daily. For carcinoid and VIPomas, the required dose may be higher but averages 300 µg/day in two to four divided doses.

Infections in the Critically Ill

15

Laurie Anne Chu, MD
Mallory D. Witt, MD

The management of infected critically ill patients is a challenge for ICU physicians and staff. Patients admitted with symptoms prior to hospitalization are considered to have community-acquired infections, and those who develop infection more than 48 hours following admission are considered to have hospital-acquired, or nosocomial, infections. Seriously ill patients presenting with fever must be quickly evaluated for possible infection because most are treatable. However, drug fever, hypersensitivity reaction, collagen-vascular disease, neoplastic disease, pulmonary embolism, trauma, burns, pancreatitis, hypothalamic dysfunction, and other noninfectious causes of fever must be considered in the differential diagnosis.

In contrast, some patients may appear to be stable but nonetheless have serious infections. Elderly patients, uremic patients, and patients with end-stage liver disease or those receiving corticosteroids often will fail to mount a significant febrile response even to serious infection. In addition, some infections are notorious for presenting with minimal symptoms—these include infective endocarditis, spontaneous bacterial peritonitis, intraabdominal abscess, endophthalmitis, and meningitis. In the absence of other symptoms and signs, fever in the asplenic patient, the neutropenic or immunosuppressed patient, the intravenous drug user or alcoholic, and the elderly patient requires a rapid and thorough diagnostic evaluation.

The infectious syndromes that may require direct admission and immediate therapy in the ICU—sepsis, community-acquired pneumonia, urosepsis, infective endocarditis, intraabdominal infections, and necrotizing soft tissue infections—will be described in the following sections. Special hosts such as patients with diabetes, asplenia or neutropenia patients, and corticosteroid-treated individuals will be discussed because they often have unique presentations and complications. Care of the HIV-infected patient is discussed in Chapter 27.

This chapter also will focus on other nosocomially acquired infections that are of great concern to the critical

care physician either because of a high mortality rate, diagnostic challenge, frequency of occurrence, contagiousness, or acquisition of antimicrobial resistance. Two unique disease entities—botulism and tetanus—also will be discussed in this chapter.

▶ Sepsis

ESSENTIALS OF DIAGNOSIS

- ▶ Wide spectrum of clinical findings ranging from fever, hypothermia, tachycardia, and tachypnea to profound shock and multiple-organ-system failure.
- ▶ Severe or complicated sepsis: lactic acidosis, acute respiratory distress syndrome (ARDS), acute renal failure, disseminated intravascular coagulation (DIC), shock, CNS dysfunction, or hepatobiliary disease.
- ▶ May present with altered mental status, unexplained hyperventilation, or tachycardia alone.
- ▶ Often an identifiable site of infection.
- ▶ Predisposing risk factors for infection: organ system failure, bed rest, invasive procedures, any antibiotic use, immunocompromised state.

General Considerations

To avoid ambiguity in interpreting the results of clinical trials and to facilitate communication among clinicians, it has been recommended that specific terminology be used when referring to sepsis and sepsis syndromes. The *systemic inflammatory response syndrome* (SIRS) is the body's response to various insults, both infectious and noninfectious. Patients with two or more of the following criteria are considered to have SIRS: (1) temperature greater than 38°C or less than 36°C, (2) heart rate greater than 90 beats/min, (3) respiratory

rate greater than 20 breaths/min, and (4) white blood cell count greater than 12,000 cells/ μ L, less than 4000 cells/ μ L, or more than 10% immature (band) forms. *Sepsis* is defined as the SIRS in response to infection. *Severe sepsis* is defined as sepsis associated with organ dysfunction. *Septic shock* is defined by the additional finding of refractory hypotension (ie, hypotension despite adequate fluid resuscitation). *Multiple-organ-system dysfunction syndrome* is defined as the presence of altered organ function such that homeostasis cannot be maintained without intervention. The vague terms *sepsis syndrome* and *septicemia* no longer should be used.

Sepsis, severe sepsis, and septic shock can be considered points on a continuum describing increasing severity of an individual patient's systemic response to infection. A prospective observational study demonstrated that among hospitalized patients meeting the criteria for SIRS, 26% subsequently developed sepsis, 18% developed severe sepsis, and 4% developed septic shock. The interval from SIRS to severe sepsis and septic shock was inversely correlated with the number of SIRS criteria met. The mortality rates of sepsis, severe sepsis, and septic shock were 16%, 20%, and 46%, respectively.

Sepsis and septic shock are encountered commonly in ICUs. Septic shock with multiple-organ-system failure is the most common cause of death in ICUs. There are currently over 750,000 new episodes of sepsis each year in the United States compared with 1979, when approximately 200,000 cases were reported. The greatest rise occurred in persons over 65 years of age, but increases have been noted in all age groups. This rising incidence is the result of more aggressive support of seriously ill patients, the care of more immunocompromised patients, use of more mechanical and invasive devices (eg, bladder catheters, endotracheal tubes, and intravascular catheters) in ICUs, increased longevity of patients with susceptibility to infection, and increasing prevalence of resistant organisms. Given the expanding use of invasive maneuvers in critically ill patients, it is likely that the number of cases will continue to rise. The mortality rate from sepsis ranges from 20–50% in published studies, with over 210,000 patients dying each year. The immediate cause of death is usually septic shock or multiple-organ-system failure.

Pathophysiology

The complex pathophysiology of sepsis is not completely understood. Sepsis begins with colonization and proliferation of microorganisms at a tissue site. Various host characteristics and organism virulence factors determine both invasiveness and subsequent intensity of the local inflammatory response. Replicating microorganisms release numerous exogenous enzymes and toxins that, in turn, trigger the release of endogenous mediators, resulting in both local and systemic inflammatory responses. The exogenous substances differ by type of microorganism. In the case of gram-negative bacilli, endotoxin (lipid A) contained in the outer cell membrane is the chief toxic substance that initiates the cascade of events clinically recognized as sepsis or septic shock. Endotoxin activates the complement cascade and Hageman factor,

leading to initiation of both coagulation and fibrinolysis. Prekallikrein is converted to kallikrein, resulting in the production of bradykinin, a mediator of hypotension.

Endotoxin, after binding with and activating macrophages, also initiates the production of numerous endogenous cytokines. The biologic effects of these mediators are amplified, causing host injury by way of endothelial inflammation, abnormalities in vascular tone, altered regulation of coagulation, and myocardial depression. Many of these endogenous mediators have been identified. Tumor necrosis factor, platelet-activating factor, interleukins, interferon, prostaglandins, thromboxane, leukotrienes, complement components C3a and C5a, and others factors have been shown to mediate and trigger the pathophysiologic events.

Tumor necrosis factor (TNF), probably the key endogenous mediator, acts on a variety of cells, stimulating production of other cytokines involved with sepsis and septic shock. Plasma TNF concentrations are elevated in both gram-negative and gram-positive sepsis. While endotoxin triggers TNF production in gram-negative sepsis, the stimulus for release of TNF in gram-positive sepsis is unknown. However, recent studies have shown that mediators other than endotoxin can induce TNF production, including IFN- α , prostaglandin E₂, immune complexes, and colony-stimulating factors.

Pathophysiologic factors in gram-positive bacterial sepsis are not clearly defined. In the case of *Staphylococcus aureus* strains that cause toxic shock syndrome, toxic shock syndrome toxin 1 (TSST-1) is the principal exogenous mediator. Some virulent strains of group A β -hemolytic streptococci produce similar toxins.

Microbiologic Etiology

Virtually any microorganism can cause sepsis or septic shock, including bacteria, viruses, protozoa, fungi, spirochetes, and rickettsiae. Bacteria remain the most common etiologic agent responsible for sepsis.

Gram-negative sepsis cannot be distinguished from gram-positive sepsis on the basis of clinical characteristics alone. However, certain epidemiologic, host, and clinical factors increase the likelihood of particular organisms. For example, *Escherichia coli* is the most frequently demonstrated etiologic agent of sepsis largely because the urinary tract is the most common source of infection. The incidence of infection caused by other gram-negative bacteria, staphylococci, streptococci, anaerobes, *Candida*, and other organisms is largely determined by epidemiologic and host factors that may be identified by a thorough history and physical examination.

Clinical Features

A. Symptoms and Signs of Sepsis—Sepsis can present with a spectrum of clinical features ranging from fever, tachycardia, and tachypnea to profound shock and multiple-organ-system (MOS) failure. The challenge to the critical care specialist is to make the diagnosis early in the course of the disease to increase the likelihood of a successful outcome.

Early in its course, the diagnosis of sepsis may not be obvious. Moreover, debilitated patients may not exhibit significant symptomatology at the onset of sepsis.

Implicit in the term *sepsis* is a documented site of infection along with systemic signs and symptoms of fever (or hypothermia), tachycardia, and tachypnea (Table 15–1). In more severe or complicated sepsis, there is also impaired organ system function, including lactic acidosis, ARDS, acute renal failure, DIC, CNS dysfunction, and shock. A systolic blood pressure of less than 90 mm Hg or a decrease from baseline of over 40 mm Hg signifies septic shock. Septic shock can be further subclassified into responsive and refractory shock states. Patients who do not respond to aggressive fluid resuscitation and who require dopamine at a rate of more than 6 µg/kg per minute (or other vasopressor agents) are considered to be in refractory shock, which confers a very poor prognosis.

Patients with clinical features of sepsis must be evaluated carefully, with particular attention paid to their immune status, clinical condition, and presence of specific epidemiologic factors. The main purpose of the physical examination in the septic patient is to identify the source of infection and to note the presence of shock. In particular, a search for a focus of infection that may require surgical drainage should be undertaken because these patients are unlikely to respond to antibiotics alone.

B. Laboratory Findings—Patients suspected of having sepsis should have relevant cultures obtained to document the infection and laboratory testing to identify metabolic or hematologic derangements. No single laboratory test is specific for sepsis. An elevated white blood cell count is nonspecific and cannot differentiate infection from inflammatory or

other pathologic states. However, an increase in immature polymorphonuclear white blood cells (*bands*) strongly suggests infection. Routine serum electrolytes, blood urea nitrogen, serum creatinine, and liver function tests may assist in determining the site of infection as well as identifying complications of sepsis such as acute renal failure or hepatobiliary dysfunction. Arterial blood gases, plasma lactate, and coagulation tests may demonstrate respiratory insufficiency, metabolic acidosis, and DIC, respectively.

Although most septic patients are intermittently bacteremic or fungemic, only 40% have a pathogen identified by blood cultures. Nevertheless, blood cultures should be obtained in every patient suspected of having sepsis. The laboratory may use special procedures and blood culture equipment to enhance growth and isolation of fungi, including *Candida*. Two sets of blood cultures, as well as urine, respiratory secretions, and wound exudates, for Gram staining and culture should be collected. If indicated by clinical findings, cerebrospinal fluid, pleural fluid, ascites fluid, and joint fluid should be analyzed as well.

C. Imaging Studies—A chest radiograph may serve to identify pneumonia or ARDS; other studies such as ultrasonography, CT scan, or MRI may be necessary to identify the site of infection.

Differential Diagnosis

Many clinical conditions can resemble sepsis, septic shock, and MOS dysfunction syndrome. Patients with severe burns, multiple trauma, severe hemorrhagic or necrotizing pancreatitis, pulmonary emboli, acute myocardial infarction, and various metabolic and hematologic abnormalities may have features that mimic sepsis and its complications.

Treatment

Despite modern therapy, the mortality rate in sepsis is still unacceptably high. However, the mortality rate can be reduced by early diagnosis and prompt initiation of appropriate therapy. A delay in therapy permits the pathophysiologic events in sepsis to proceed, with a concomitant increase in morbidity and mortality.

A. Supportive Care—Treatment of sepsis begins with oxygen and ventilatory support as needed. The PO₂ should be maintained above 60–65 mm Hg with oxygen delivered by cannula, mask, or respirator, if necessary.

The administration of intravenous fluids, either crystalloid or colloid, expands the intravascular volume to correct the relative deficit resulting from vasodilation owing to bacterial products or host responses. Administration of several liters of intravenous fluids is usually required over the first 2–6 hours. If cardiogenic pulmonary edema is a concern, pulmonary arterial catheterization and monitoring may assist in guiding appropriate fluid administration. Hypotension may persist despite fluid replacement because of very low systemic vascular resistance; in some patients, decreased myocardial contractility associated with sepsis may contribute. The goal of

Table 15–1. Definitions of stages of sepsis.

Stage	Characteristics
I	Systemic inflammatory response syndrome (SIRS). Two or more of the following: 1. Temperature >38°C or <36°C 2. Heart rate >90 per minute 3. Respiratory rate >20 per minute 4. White blood cell count >12,000/µL or <4000/µL or >10% bands
II	Sepsis SIRS plus a culture-documented infection
III	Severe sepsis Sepsis plus organ dysfunction (lactic acidosis, oliguria, hypoxemia, or acute alteration in mental status)
IV	Septic shock Severe sepsis plus hypoperfusion (despite fluid resuscitation)

initial resuscitation is to restore and maintain organ perfusion. Signs of adequate organ perfusion include central venous pressure of 8–12 mm Hg, mean arterial pressure of 65 mm Hg or greater, urine output of 0.5 mL/kg per hour or more, and central venous or mixed venous oxygen saturation of 70% or more. Vasopressor agents should be used to assist in attaining these goals. Norepinephrine is generally preferred over dopamine or other pressors. Patients not responding to norepinephrine may require the addition of phenylephrine or vasopressin. The use of vasopressin may allow a reduction in the dose of the other vasopressors, but this is controversial. Vasopressors are not effective when fluid replacement has been inadequate.

A coordinated approach to early treatment of sepsis is associated with reduced mortality. This “early goal-directed” therapy, targeted on the first 6 hours of care in the emergency department and ICU, focuses on adequate fluid replacement first (to achieve central venous pressure of 8–12 mm Hg) and then vasopressors as needed to maintain a mean arterial pressure of greater than 65 mm Hg. Oxygen delivery is assessed using central venous O₂ saturation, with a goal of greater than 70%. First, if the patient is anemic, packed red blood cells are transfused to a target hemoglobin of at least 10 g/dL. If central venous O₂ saturation remains less than 70%, then dobutamine is given.

B. Antibiotics—The next therapeutic challenge is choosing appropriate antibiotics. All available clinical, epidemiologic, and laboratory data should be considered in making this decision. Rarely is the causative microorganism known at the time treatment for sepsis is initiated, but if the source can be determined and/or if a Gram-stained specimen of infected material (eg, sputum, urine, or purulent drainage) can be examined, the long list of possible microorganisms often can be shortened. The following sections will provide a guide to initial antimicrobial selection depending on the potential source of infection. Importantly, intravenous antibiotics must be given without delay and at appropriate doses. Adjustments for age and renal and hepatic dysfunction are not required for the starting dose of antibiotics.

C. Surgical Drainage—Significant collections of purulent material must be drained and necrotic tissue excised in order to treat sepsis. Surgeons may be reluctant to operate because of the coexistence of acute renal failure, ARDS, or other organ system failure, but the pathophysiologic consequences of sepsis will tend to continue unless surgical drainage is performed.

D. Adjunctive Therapy—In the last several years, there has been renewed interest in using corticosteroids for sepsis and septic shock, with a large French trial showing improved survival with approximately physiologic replacement with hydrocortisone and fludrocortisone. The benefit was seen among patients who failed to increase plasma cortisol levels by more than 9 µg/mL in response to adrenocorticotropic hormone (ACTH). This was in contrast to pharmacologic doses of corticosteroids that, in the past, demonstrated no difference or an adverse effect. A recent large multicenter trial, however, demonstrated that physiologic replacement of

corticosteroids did not affect outcome, was associated with adverse effects, and did not show that the cortisol response to ACTH was helpful in identifying responders. It is recommended that corticosteroids be given only in severe sepsis if adrenal suppression is suspected (eg, recent administration of corticosteroids, etomidate, and other drugs) or if the patient fails to respond to fluids and vasoactive drugs.

A large trial comparing recombinant human activated protein C (drotrecogin-alfa [activated]) with placebo in patients with sepsis showed a statistically significant decrease in mortality in the treatment group. A major risk accompanying use of activated protein C is hemorrhage. In one study, 3.5% of patients receiving activated protein C had serious bleeding compared with 2.0% of those receiving placebo. Adjunctive treatment with activated protein C should be considered in patients with sepsis with severe organ compromise and the highest likelihood of death. The mechanism of action is unknown, but activated protein C may modulate coagulation and inflammation associated with severe sepsis.

▶ Community-Acquired Pneumonia

ESSENTIALS OF DIAGNOSIS

- ▶ Patients present with cough, fever, and occasionally pleuritic chest pain.
- ▶ Chest x-ray shows pulmonary infiltrates.
- ▶ Most common cause of community-acquired pneumonia is *Streptococcus pneumoniae*.

General Considerations

Community-acquired pneumonia accounts for a large number of hospitalizations each year and is the sixth leading cause of death in industrialized communities. Mortality ranges from 12–40%, the latter number reflecting the death rate in patients with community-acquired pneumonia requiring critical care. It is crucial for the physician to recognize the high-risk patient, to initiate diagnostic procedures, and to begin appropriate and prompt antimicrobial therapy.

A number of risk factors for community-acquired pneumonia have been identified and include increasing age, alcoholism, diabetes mellitus, malignancy, immunosuppression, institutionalization, and underlying cardiac, pulmonary, hepatic, renal, or neurologic disease. A meta-analysis evaluating outcomes of patients with community-acquired pneumonia revealed 11 statistically significant factors associated with mortality: male sex, diabetes mellitus, underlying neurologic or neoplastic disease, pleuritic chest pain, hypothermia, tachypnea, hypotension, leukopenia, multilobar infiltrates, and bacteremia. Increasing age and bacterial etiology of the infection were strongly associated with mortality as well. Patients with infections owing to *Pseudomonas aeruginosa*, *S. aureus*, and enteric gram-negative rods are at particularly high risk for increased morbidity and mortality.

Microbiologic Etiology

The most common organisms identified in community-acquired pneumonia requiring intensive care hospitalization are *S. pneumoniae*, *Legionella*, and *Haemophilus influenzae*, with *S. aureus* included in some series. *H. influenzae* usually occurs in persons with chronic obstructive pulmonary disease. *S. aureus* can cause severe pneumonia with disease acquired either by aspiration or by hematogenous spread. The former is seen in patients with decreased local host defenses (eg, after influenza, laryngectomy, bronchiectasis, or cystic fibrosis) or generalized decrease in immunity (eg, malnutrition or immunosuppression). Hematogenous disease typically is seen in injection drug abusers or patients with indwelling intravascular catheters. Recently, community-acquired methicillin-resistant *S. aureus* (CA-MRSA) has become an important pathogen. It should be suspected in any patient with gram-positive cocci in sputum and in patients with necrotizing pneumonia without suspected aspiration. Aerobic gram-negative rods such as *E. coli* and *Klebsiella* species are uncommonly implicated as pathogens in community-acquired pneumonia, but they can cause severe pulmonary disease in patients of advanced age with underlying illness who are colonized with these enteric organisms. Therefore, when enteric organisms are recovered from sputum samples, it can be difficult to tell if their presence is pathogenic or simply reflects colonization. *P. aeruginosa* traditionally has been considered a nosocomial pathogen, although it can cause severe community-acquired

pneumonia. The physician should consider this organism in a patient who has structural lung disease such as bronchiectasis, was hospitalized recently, has recently received or is currently receiving broad-spectrum antibiotics, or resides in a nursing home.

Atypical pathogens, especially *Legionella* species, can cause severe community-acquired pneumonia. More than half of such cases are caused by *L. pneumophila* subgroup 1. *Chlamydia pneumoniae* and *Mycoplasma pneumoniae* typically cause tracheobronchitis or mild pneumonia and only occasionally severe pneumonia.

Respiratory tract viruses are not commonly thought of as agents of community-acquired pneumonia. However, influenza virus, respiratory syncytial virus, adenovirus, and parainfluenza virus all have been associated with severe pneumonitis. In the appropriate host, varicella-zoster virus, cytomegalovirus, hantavirus, and coronavirus (the causative agent of severe acute respiratory distress syndrome [SARS]) should be considered.

In patients with episodes of altered level of consciousness caused by seizures, other neurologic diseases, and substance abuse, an aspiration syndrome should be considered. Aspiration of gastric contents can cause a chemical pneumonitis—with or without a polymicrobial pneumonia—that can lead to an anaerobic lung abscess if left untreated.

Other less common causes of community-acquired pneumonia include *Pneumocystis jiroveci* infection in the patient with risk factors for HIV infection or receiving long-term steroids or other immunosuppressive therapy. The physician should maintain a high level of suspicion for *Mycobacterium tuberculosis* in the appropriate host. In patients with a history of travel to the appropriate areas, endemic mycoses (eg, *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis*) should be considered. Infection with *Coxiella burnetii*, the etiologic agent of Q fever, can present with a community-acquired pneumonia in a patient with a history of exposure to infected cattle, sheep, goats, or parturient cats. *Chlamydophila psittaci* similarly should be considered if a history of exposure to psittacine birds is elicited. Despite aggressive diagnostic efforts, no etiologic agent is identified in over 50–60% of cases of community-acquired pneumonia.

Clinical Features

The diagnosis of community-acquired pneumonia and the choice of empirical antibiotics depends on results of a detailed history and physical examination of the patient, microbiologic analysis of sputum, and review of the chest radiograph.

A. Symptoms and Signs—Patients with severe community-acquired pneumonia may report fever, chills, cough (either dry or productive), dyspnea, and pleuritic chest pain. Nonspecific symptoms such as diarrhea, headache, myalgias, or nausea and vomiting are often present. On physical examination, the typical patient with severe community-acquired

pneumonia will have either fever or hypothermia accompanied by tachycardia, tachypnea, abnormal breath sounds, and possibly egophony or other evidence of lung consolidation. If a pleural effusion is present, the patient may have decreased breath sounds with dullness to percussion in the involved hemithorax. The physical examination may provide clues to guide empirical therapy. The presence of thrush or oral hairy leukoplakia may suggest underlying HIV infection. Poor dentition, caries, and gingival disease are often seen in patients with aspiration pneumonia. Bullous myringitis is seen occasionally with *M. pneumoniae* infection and also may occur in patients with viral infection. The finding of a new right-sided heart murmur should raise suspicion of right-sided endocarditis. The skin should be examined carefully for any lesions that suggest one of the endemic mycoses.

B. Laboratory Findings—Routine laboratory studies should be done, including a complete blood count; serum electrolytes, urea nitrogen, and creatinine determinations; arterial blood gas determinations; and chest x-ray. Because of their high degree of specificity, blood cultures should be obtained on all patients; 25% of patients with pneumococcal pneumonia will be bacteremic. Pleural fluid collections, when present, should be sampled to differentiate between a parapneumonic effusion and a complicated effusion or empyema, the latter of which would require definitive drainage. Pleural fluid should be submitted for Gram stain, culture, cell count, pH, total protein, and lactate dehydrogenase (LDH) concentration.

The Gram-stained smear of sputum may be the most immediately helpful tool in determining empirical antibiotic therapy. To ensure that an adequate specimen is obtained, the stain should have 10 or fewer squamous epithelial cells and more than 25 polymorphonuclear cells per high-power field. Table 15–2 provides a guide to the probable pathogen based on the Gram-stained smear of sputum (and other stains) that can be done in an expeditious fashion. *Legionella* urinary antigen is 80–95% sensitive for *L. pneumophila* group 1 and should be performed in appropriate patients.

Other more invasive methods of diagnosis are used in special situations or when patients fail to respond despite appropriate empirical therapy. Fiberoptic bronchoscopy with bronchoalveolar lavage may assist in the diagnosis of pneumonia caused by *P. jiroveci*, *M. tuberculosis*, and certain fungi. However, routine bacterial culture is not specific for the diagnosis of pneumonia caused by bacteria that can colonize the respiratory tract. The specificity of this procedure can be increased by quantitative cultures and cytologic examination of the specimen for intracellular bacteria. The specificity of bronchoscopy cultures may be increased by use of the protected brush technique with quantitative cultures. Bronchoscopy allows for direct inspection of the airways and sampling from the site of infection. Percutaneous fine-needle lung aspiration has been performed in some situations. This procedure is the most sensitive and specific of all diagnostic maneuvers; however, complications include bleeding and pneumothorax, which may increase patient morbidity.

Table 15–2. Sputum-guided potential pathogens for severe community-acquired pneumonia.

Staining Characteristic	Potential Pathogen
Gram-positive diplococci	<i>Streptococcus pneumoniae</i>
Gram-positive cocci in clusters	<i>Staphylococcus aureus</i>
Gram-negative coccobacilli	<i>Haemophilus influenzae</i> <i>Moraxella catarrhalis</i>
Gram-negative bacilli	Enteric gram-negative rods (<i>Escherichia coli</i> , <i>Klebsiella pneumoniae</i> , <i>Pseudomonas aeruginosa</i>)
Mixed bacteria	Oral contamination Mixed aerobes and anaerobes
No organisms present	Viruses <i>Mycoplasma pneumoniae</i> <i>Chlamydia pneumoniae</i> <i>Coxiella burnetii</i> <i>Legionella</i> species
Acid-fast stain-positive	<i>Mycobacterium pneumoniae</i> <i>Nocardia</i> species
KOH/calcofluor white stain-positive	<i>Coccidioides immitis</i> <i>Histoplasma capsulatum</i> <i>Blastomyces dermatitidis</i> <i>Cryptococcus neoformans</i>
Silver stain-positive	<i>Pneumocystis jiroveci</i>

Differential Diagnosis

The differential diagnosis of severe community-acquired pneumonia is extensive. In addition to the many infectious causes of pneumonia, diseases that can mimic community-acquired pneumonia include cardiogenic pulmonary disease, ARDS, pulmonary emboli with infarction, pulmonary hemorrhage, and lung cancer. Other less common diseases are pneumonitis owing to collagen-vascular diseases, radiation or chemical pneumonitis, hypersensitivity pneumonitis, sarcoidosis, pulmonary alveolar proteinosis, and occupational lung disease.

Treatment

A. Empirical Antibiotic Therapy—Because it is impossible to cover all pathogens empirically, the physician must use the available data to make an informed decision regarding therapy. Table 15–3 provides a guide for treatment of pneumonia according to pathogen. In most situations involving hospitalized patients, when no clues to etiologic agent can be obtained from history, physical examination, or laboratory data, empirical antibiotic therapy should consist of a third-generation cephalosporin in combination with a macrolide or a quinolone.

Table 15-3. Empirical antibiotic therapy for community-acquired pneumonia in patients requiring ICU admission.

Patient Category	Most Likely Causative Organisms	Empirical Antibiotic Choices ¹
ICU patient	<i>S. pneumoniae</i> <i>Legionella</i> sp. <i>M. pneumoniae</i>	Third-generation cephalosporin ² plus either IV azithromycin or respiratory fluoroquinolone ³
ICU patient with increased risk for <i>P. aeruginosa</i> (recent antibiotic use, hospitalization, or structural lung disease)	<i>S. pneumoniae</i> <i>Legionella</i> sp. <i>H. influenzae</i> <i>C. pneumoniae</i> Enteric gram-negative rods <i>P. aeruginosa</i>	Antipseudomonal, antipneumococcal β -lactam ⁴ plus ciprofloxacin or levofloxacin (750 mg/day). Or Antipseudomonal, antipneumococcal β -lactam ⁴ plus aminoglycoside and azithromycin Or Antipseudomonal, antipneumococcal β -lactam ⁴ plus aminoglycoside and respiratory fluoroquinolone ³
ICU patient with increased risk for <i>S. aureus</i> (gram-positive cocci in clusters in a tracheal aspirate or in an adequate sputum sample, end-stage renal disease, injection drug use, prior influenza, prior antibiotic therapy, necrotizing pneumonia in absence of risks for aspiration.)	Community-acquired methicillin-resistant <i>S. aureus</i> (CA-MRSA)	Add vancomycin or linezolid

¹Initial empirical therapy. Changes should be based on results of microbiologic studies and clinical response.

²Third-generation cephalosporin (eg, ceftriaxone or cefotaxime).

³Fluoroquinolone with increased activity against *S. pneumoniae* (eg, levofloxacin).

⁴Cefipime, piperacillin-tazobactam, imipenem, or meropenem.

B. Resistance Issues and Therapeutic Implications—

S. pneumoniae is the most common cause of community-acquired pneumonia, and the emergence of penicillin-resistant strains of this pathogen should be considered when choosing empirical therapy for critically ill patients. There is marked geographic variation in the rates of penicillin resistance. Up to 35% of isolates in the United States are not fully susceptible to penicillin, and up to 22% are highly resistant to penicillin. However, resistance to third-generation cephalosporins is less likely. In general, the levels of β -lactam antibiotics that can be achieved in the lung and bloodstream with intravenous therapy far exceed the minimum inhibitory concentration (MIC) for pneumococci with intermediate and high levels of resistance (as long as the MIC is $<4 \mu\text{g/dL}$). Thus, in most cases, in the absence of meningitis, a third-generation cephalosporin is adequate. Few data are available regarding pneumococcal infections when the MIC for the organism is greater than $4 \mu\text{g/dL}$. Infection with an organism with this level of resistance is associated with increased mortality. Some authorities suggest using vancomycin, a carbapenem, one of the newer respiratory quinolones, or possibly linezolid if infection with such a strain is suspected. Risk factors for drug-resistant *S. pneumoniae* include extremes of age, recent antimicrobial therapy, coexisting illnesses, immunodeficiency or HIV-infection, attendance at a

day-care center or family member of a child attending a day-care center, and institutionalization.

► Urosepsis

ESSENTIALS OF DIAGNOSIS

- The patient may be asymptomatic.
- Flank or abdominal pain.
- Pyuria and white blood cell casts.
- Positive urine culture.

General Considerations

In the United States, acute pyelonephritis accounts for over 100,000 hospitalizations each year. The physician must be alert for complications such as underlying immunosuppression, urinary tract obstruction, and intrarenal or perinephric abscess formation. When hypotension or other signs of sepsis are present, patients should be admitted to the ICU for appropriate hemodynamic monitoring and management.

Pathophysiology

There are two primary routes by which bacteria invade the urinary system. In what is by far the most common route of infection, bacteria gain access to the bladder via the urethra. Urinary tract infections are common in women because the relatively short female urethra allows retrograde passage of bacteria into the bladder. In contrast, urinary tract infection in men is a rare event in the absence of a urethral catheter or unless there is obstruction of the urethra (eg, prostatic hyperplasia), preventing adequate bladder drainage. Once bacteria have entered the bladder, they may under some circumstances ascend the ureters to the renal pelvis and parenchyma. This process is facilitated by the presence of vesicoureteral reflux. For example, in the renal transplant patient, the transplanted kidney is placed in the pelvis with the ureter surgically implanted in the bladder; as a result, simple cystitis frequently leads to acute transplant pyelonephritis.

Infection of the urinary tract by hematogenous spread is a much less common occurrence. Staphylococcal bacteremia or endocarditis can lead to seeding of renal parenchyma with subsequent abscess formation. However, experimentally produced gram-negative bacteremia rarely leads to acute pyelonephritis.

Microbiologic Etiology

The majority (70–95%) of cases of community-acquired acute urinary tract infections are caused by *E. coli*, with *Staphylococcus saprophyticus*, enterococci, *Proteus mirabilis*, *Klebsiella* species, and *Enterobacter* species identified in most of the remaining cases. The list of etiologic agents is modified by factors such as use of indwelling urinary catheters, residence in an institutionalized setting, urinary tract instrumentation, immunosuppression, or recent broad-spectrum antibiotic administration. In any of these settings, multidrug-resistant gram-negative bacilli, coagulase-negative staphylococci, or *Candida* species may be responsible for infection.

Clinical Features

A. Symptoms and Signs—Patients with urinary tract infections as the source of sepsis may present with localizing symptoms such as flank pain or dysuria. However, many patients present with nonspecific complaints, such as nausea, vomiting, abdominal pain, fever, and chills. Physical

examination may detect the presence of flank tenderness. An indwelling bladder catheter should trigger a prompt evaluation of the urinary tract for the source of sepsis.

B. Laboratory Findings—Routine laboratory tests such as a complete blood count and chemistry panel should be obtained. Microscopic evaluation of a urine specimen is the most important diagnostic test, typically revealing hematuria, proteinuria, and pyuria (≥ 10 leukocytes/ μL of urine), often with white blood cell casts. Gram stain of the urine should be performed; the presence of one organism per oil-immersion field correlates with 10^5 bacteria per milliliter of urine or more, with a sensitivity and specificity approaching 90%. The presence of 5 or more organisms per oil-immersion field increases the specificity to 99%. Additionally, determining the morphology of the infecting bacteria (ie, gram-negative bacillus or gram-positive cocci) may be used to direct empirical therapy. Identification of the pathogen and the results of antimicrobial susceptibility testing are usually available within 48 hours, allowing tailoring of antimicrobial therapy. Any patient sick enough to warrant hospitalization should have blood cultures sent. A renal ultrasound examination or an abdominal CT scan should be obtained in any patient with suspected upper urinary tract obstruction admitted to the ICU.

C. Complications—Possible complications of acute pyelonephritis include urosepsis, perinephric abscess, intrarenal abscess, urinary tract obstruction, and emphysematous pyelonephritis. In general, any patient who appears toxic or has persistent fever or positive blood cultures beyond the third day of appropriate therapy should undergo investigation for obstruction, abscess, or other complications.

Perinephric abscesses usually are confined to the perinephric space by Gerota's fascia but may extend into the retroperitoneum. Thirty percent of patients with perinephric abscess have a normal urinalysis, and up to 40% have a sterile urine culture. Intrarenal abscess is usually a complication of systemic bacteremia; thus the etiologic agent is often a *Staphylococcus*. A plain film of the abdomen may reveal an abdominal mass, an enlarged indistinct kidney shadow, or loss of the psoas margin. Rapid diagnosis of perinephric or intrarenal abscess can be made by renal ultrasound, CT scan, or MRI. Renal ultrasound can detect an abscess once it reaches 2–3 cm in size, whereas CT scan and MRI are more sensitive, detecting abscesses as small as 1 cm in diameter. Definitive treatment requires drainage of larger abscesses, either by percutaneous access or open surgical drainage, with concomitant antimicrobial therapy.

Emphysematous pyelonephritis is a rare complication of urinary tract infections seen in patients with diabetes, papillary necrosis, renal obstruction, or renal insufficiency. The infecting organism is typically *E. coli*, *Klebsiella* species, or *Proteus* species. Mortality is high, approaching 50% despite appropriate antimicrobial therapy. Diagnosis is easily made with a plain film or with the more sensitive CT scan of the abdomen; both will reveal gas in the renal parenchyma.

Treatment

In all patients, initial antimicrobial therapy should target the organism seen on the Gram-stained smear of the urinary sediment. In the absence of an identified organism on Gram stain, empirical therapy should consist of a third-generation cephalosporin, an extended-spectrum penicillin (eg, piperacillin), a fluoroquinolone, and/or an aminoglycoside depending on the severity of the infection, the patient's renal function and risk for renal insufficiency, and other factors. If *Enterococcus* is suspected, ampicillin or piperacillin with or without an aminoglycoside is appropriate. For emphysematous pyelonephritis, immediate nephrectomy usually is required.

▶ Infective Endocarditis

ESSENTIALS OF DIAGNOSIS

- ▶ Clinical presentation varies depending on infecting organism.
- ▶ Patients with *S. aureus* infective endocarditis typically present with a short prodrome and a sepsis syndrome. Clues to the diagnosis of subacute infective endocarditis include a new regurgitant murmur, Roth spots, Osler nodes, Janeway lesions, splinter hemorrhages, hematuria, and splenomegaly.
- ▶ Blood cultures are needed for diagnosis.

General Considerations

The incidence of infective endocarditis in the general population is estimated to be 1.7–6.2 cases per 100,000 person-years. Risk factors include underlying valvular abnormalities. Congenital or rheumatic heart disease, mitral valve prolapse (particularly when regurgitation or thickened, redundant valve leaflets are present), calcific valvular heart disease, and prosthetic valves are implicated in a large percentage of cases. Another increasingly important risk factor is injection drug use. Among injection drug users, the presentation of infective endocarditis is usually acute, reflecting the virulent nature of *S. aureus*, the pathogen most commonly associated with infective endocarditis in this population.

Pathophysiology

The first step in infective endocarditis is the establishment of bacteremia, which may occur during a dental or other medical

procedure, as a complication of injection drug use, or from minor trauma. However, in most cases, no initiating event is identified. The organism attaches to the abnormal endothelial surface of the cardiac valve, and the vegetation propagates with further bacterial proliferation. The complications that then arise are the result of either (1) direct local invasion (eg, periannular abscess formation), (2) systemic embolization (eg, splenic, renal, or cerebral embolic), or (3) immunologic phenomena (eg, glomerulonephritis or vasculitis).

Microbiologic Etiology

The microbiologic etiology of infective endocarditis has undergone a shift in the past 3–4 decades. In the 1960s and 1970s, *viridans* streptococci and enterococci accounted for up to 80% of cases and staphylococci for approximately 15%. In more recent series, the *viridans* streptococci and enterococci still account for 50% of cases, but staphylococci are now implicated in approximately 50% of cases of acute infective endocarditis.

The most common bacterial cause of native-valve infective endocarditis remains the *viridans* streptococci group. As noted earlier, *S. aureus* infective endocarditis usually occurs in injection drug users and diabetics, who tend to have skin and nasal colonization with the organism. Other less common pathogens include *S. pneumoniae*; groups A, B, C, and G streptococci; and *Listeria monocytogenes*, *P. aeruginosa*, *Serratia marcescens*, and rarely, *Neisseria gonorrhoeae*. In cases of culture-negative endocarditis, the HACEK group of microorganisms (*Haemophilus parainfluenzae*, *H. aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*); nutritionally variant streptococci (now *Abiotrophia* species); *Brucella*, *Legionella*, and *Bartonella* species; *C. burnetii*; and fungi all should be considered. The most common reason for culture-negative infective endocarditis is prior antibiotic therapy.

Clinical Features

A. Symptoms and Signs—The clinical presentation of infective endocarditis varies dramatically depending on the infecting organism. Patients with *S. aureus* infective endocarditis typically present with a short prodrome and a sepsis syndrome. Only rarely are the immunologic phenomena associated with subacute infective endocarditis present. Among injection drug users, infection usually involves the tricuspid valve. Thus pulmonary manifestations predominate, which may manifest as multiple parenchymal infiltrates, cavities, pleural effusion, or empyema. A murmur may not be readily appreciated. The less virulent organisms, such as the *viridans* streptococci, typically present with the classic subacute infective endocarditis syndrome. Nonspecific symptoms such as fatigue, malaise, or back pain usually have been present for weeks. Clues to the diagnosis of subacute infective endocarditis include a new regurgitant murmur, Roth spots, Osler nodes, Janeway lesions, splinter hemorrhages, hematuria, and splenomegaly.

Complications of infective endocarditis, such as congestive heart failure or CNS emboli, may necessitate admission to an ICU.

B. Laboratory and Radiographic Findings—The first clue to the diagnosis of infective endocarditis is often a blood culture yielding growth of an appropriate organism. In the patient with suspected infective endocarditis who presents with subacute symptoms, three separate sets of blood cultures should be obtained prior to initiating empirical antimicrobial therapy. A complete blood count may reveal only leukocytosis in a patient with acute *S. aureus* infective endocarditis; however, evidence of anemia of chronic disease may be present in a patient with subacute infective endocarditis. Urinalysis may reveal hematuria, proteinuria, or pyuria. A chemistry panel may demonstrate renal insufficiency (the result of renal infarction), septic emboli, or immune-complex glomerulonephritis. Patients may have other non-specific indicators of acute inflammation, such as an elevated erythrocyte sedimentation rate or C-reactive protein, hypergammaglobulinemia, or a positive test for rheumatoid factor. Chest x-ray may reveal multiple pulmonary infiltrates, cavitary lesions, pleural effusion in right-sided disease, or pulmonary edema in left-sided disease. A 12-lead ECG should be obtained on all patients to look for intracardiac conduction delay, manifested as a new first-, second-, or third-degree heart block, suggesting the presence of an aortic ring abscess. Any patient with neurologic symptoms should undergo brain CT scan to look for embolic events or intracranial hemorrhage from rupture of an infected (“mycotic”) aneurysm.

Diagnosis of infective endocarditis is aided by use of the modified Duke criteria (Table 15–4). Echocardiography should be obtained on all patients in whom the diagnosis is entertained because it provides both diagnostic and prognostic information. The sensitivity of the transthoracic echocardiogram for demonstrating valvular vegetations is only about 60–70%, and for this reason, the procedure cannot exclude infective endocarditis entirely. On the other hand, transesophageal echocardiography has a reported sensitivity approaching 95% and is particularly useful in detecting periannular aortic abscess formation.

C. Complications—Because the most seriously ill patients with infective endocarditis are admitted to the ICU, this population is likely to have a high rate of complications. Thus it is important for the physician to remain vigilant for these potential life-threatening events.

Congestive heart failure is the most common complication of acute infective endocarditis. It may occur acutely as a result of perforation of a valve leaflet or rupture of a chorda tendinea, from valvular outlet obstruction owing to large vegetations, from creation of fistulous tracts leading to high-output failure, or from prosthetic valve dehiscence. Congestive heart failure also may present insidiously as a result of progressive valvular insufficiency or ventricular dysfunction. Congestive heart failure that is refractory to medical management necessitates valve replacement.

Systemic embolization occurs in up to a third of patients with infective endocarditis. Risk factors for embolic events include vegetation size greater than 1 cm on the transesophageal echocardiogram, vegetation location on the anterior leaflet of the mitral valve, increasing vegetation size during appropriate antimicrobial therapy, and infection with *S. aureus*, *Candida* species, one of the HACEK group, or the *Abiotrophia* species. There is general agreement that the occurrence of two or more serious embolic events while on appropriate antimicrobial therapy is an indication for valve replacement.

Periannular extension of infection occurs in 10–40% of cases of native valve infective endocarditis and 55–100% of cases involving a prosthetic valve. Periannular abscess formation is more common when the aortic valve is involved. The infection spreads from the aortic ring and can rupture through the membranous septum to involve the atrioventricular node; thus the finding of a new intracardiac conduction delay is often a first clue to this life-threatening complication. Creation of an intracardiac shunt also can occur. Periannular extension of infection is best diagnosed by transesophageal echocardiography, which has a sensitivity of 87% and a specificity of 95%. In most cases, periannular abscess formation requires valve replacement.

In a patient with infective endocarditis who has persistent bacteremia, fever, or sepsis in the setting of appropriate antimicrobial therapy, the possibility of a splenic or renal abscess should be considered. Splenic infarction occurs in about 40% of cases of left-sided endocarditis; of these, 5% progress to abscess formation. Abdominal CT scan or MRI may be useful for diagnosis. Renal abscesses may require drainage in conjunction with appropriate antimicrobial therapy, depending on their size. Splenectomy is the definitive treatment for splenic abscess.

One of the most feared complications of infective endocarditis is the development of an infected (“mycotic”) aneurysm. The most common site of involvement is the intracranial arteries, followed by the visceral bed and the upper and lower extremities. The incidence of intracranial mycotic aneurysms in patients with infective endocarditis is about 1.2–5%. The overall mortality of this complication is 6–30% without rupture and 80% with rupture. The diagnostic method of choice is four-vessel cerebral angiography. Decisions regarding therapy, including potential surgery, should be individualized.

Treatment

The spectrum of initial antimicrobial therapy in a critically ill patient with suspected infective endocarditis should be broad, directed at the pathogens implicated most commonly in this disease. Initial therapy should include vancomycin to cover MRSA, a penicillin with activity against streptococci and enterococci, and an aminoglycoside for synergy against these organisms. If infection with *S. aureus* is highly likely,

Table 15-4. Modified Duke clinical criteria for infective endocarditis.

Definite infective endocarditis	<ol style="list-style-type: none"> Two major criteria, or One major criterion and three minor criteria, or Five minor criteria
Possible infective endocarditis	<ol style="list-style-type: none"> One major criterion and one minor criterion, or Three minor criteria
Endocarditis rejected	<ol style="list-style-type: none"> Firm alternate diagnosis explaining evidence of infective endocarditis, or Resolution of infective endocarditis syndrome with antibiotic therapy for less than 4 days, or No pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for less than 4 days, or Does not meet criteria for possible infective endocarditis, as above
Definitions for modified Duke clinical criteria	
Major criteria	
1. Blood culture positive for IE	<ol style="list-style-type: none"> Typical microorganisms consistent with IE from two separate blood cultures: <ol style="list-style-type: none"> <i>Viridans</i> streptococci, <i>Streptococcus bovis</i>, HACEK group, <i>S. aureus</i>, or Community-acquired enterococci, in the absence of a primary focus, or Microorganisms consistent with IE from persistently positive blood cultures, defined as follows: <ol style="list-style-type: none"> At least two positive cultures of blood samples drawn 12 hours apart, or All of three or a majority of more than four separate cultures of blood (with first and last samples drawn at least 1 hour apart) Single positive blood culture for <i>C. burnetii</i> or IgG antibody to phase I antigen $\geq 1:800$ by IFA
2. Evidence of endocardial involvement	<ol style="list-style-type: none"> Echocardiogram¹ positive for IE, defined as follows: <ol style="list-style-type: none"> Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation, or Abscess, or New partial dehiscence of prosthetic valve New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)
Minor criteria	<ol style="list-style-type: none"> Predisposition, predisposing heart condition or injection drug use Fever, temperature $>38^{\circ}\text{C}$ Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, or Janeway's lesions Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor Microbiological evidence: positive blood culture but does not meet a major criterion as noted above² or serologic evidence of active infection with organism consistent with IE

¹Transesophageal echocardiogram recommended in patients with prosthetic valves, rated at least "possible IE" by clinical criteria, or complicated IE (paravalvular abscess); otherwise, use transthoracic echocardiogram.

²Excludes single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis.

some infectious disease specialists use a semisynthetic penicillin such as nafcillin or oxacillin in conjunction with vancomycin to optimize coverage of both methicillin-sensitive and methicillin-resistant strains. When faced with a patient who has a history of a serious allergic reaction to penicillin, the physician should use vancomycin in lieu of β -lactams. Subsequent antibiotic therapy must be tailored once the infecting organism and its drug susceptibility pattern are known.

▶ Necrotizing Soft Tissue Infections

ESSENTIALS OF DIAGNOSIS

- ▶ Patients complain of pain out of proportion to physical findings.
- ▶ Essential to differentiate a necrotizing soft tissue infection from a simple cellulitis.
- ▶ Metabolic acidosis, renal insufficiency, and other signs of organ dysfunction may be present.

General Considerations

Necrotizing fasciitis is an uncommon soft tissue infection caused by a variety of toxin-producing bacteria. There is fascial necrosis, often with less marked involvement of overlying skin and underlying muscle, and signs of systemic toxicity. The true incidence of necrotizing soft tissue infections is difficult to quantify because they are not reportable. Necrotizing fasciitis can result from a large number of associated conditions, including trauma, surgical procedures, and relatively benign local infections of the skin or soft tissues. The mortality rate ranges between 15% and 52% in most series. Risk factors for necrotizing soft tissue infections include diabetes mellitus (the most common preexisting condition), peripheral vascular disease, alcoholism, injection drug use, obesity, malnutrition, and immunosuppression, including HIV infection.

The multitude of terms used to describe soft tissue infections may be confusing to the reader: *hemolytic streptococcal gangrene*, *progressive synergistic bacterial gangrene*, *necrotizing erysipelas*, *suppurative fasciitis*, *acute dermal gangrene*, *Fournier's gangrene*, and *progressive postoperative bacterial synergistic gangrene* all have appeared in the literature. Distinguishing between the various categories of necrotizing soft tissue infections is not always necessary because prognosis and treatment of these conditions are quite similar.

Pathophysiology

In the pathogenesis of necrotizing soft tissue infections, bacteria typically are introduced into the skin or soft tissues by trauma, either inadvertently or iatrogenically. Inciting events that have been reported to lead to soft tissue infections include surgery, blunt or penetrating trauma, insect bites, varicella infection, injection drug use, perforated viscus, perineal abscess, diverticulitis, percutaneous drainage of intraabdominal abscess, renal calculi, dental infection or procedure, pharyngitis, and exposure to sea water. Hematogenous introduction of the bacteria into soft tissue has been documented with *S. pyogenes* and *S. aureus* (including methicillin-resistant *S. aureus*).

Once bacteria gain entry into the host tissues, bacterial toxins and endogenous cytokines act synergistically to produce tissue damage. Both exotoxin A and exotoxin B have been identified in invasive group A streptococcal infections. Histopathologic examination of involved tissue typically reveals widespread necrosis of the fascia and subcutaneous fat and thrombosis and endarteritis of small vessels. Occasionally, myonecrosis of underlying skeletal muscle will be observed.

Microbiologic Etiology

There are three predominant types of necrotizing fasciitis, with distinctions based on microbiologic etiology. Type 1 is polymicrobial infection, with a combination of non-group A streptococci, anaerobes, and facultative anaerobes, usually Enterobacteriaceae. Among persons developing type 1 necrotizing fasciitis, certain host factors are associated with infection by specific bacteria. For example, diabetics tend to become infected with *Bacteroides* species, *S. aureus*, and the Enterobacteriaceae. Immunosuppressed patients may become infected with *P. aeruginosa* and other Enterobacteriaceae. Of note, recent reports describe necrotizing fasciitis owing to MRSA in patients with underlying HIV infection. *Clostridium* species are seen more commonly following trauma. On average, four different species of bacteria are identified by culture in patients with type 1 necrotizing fasciitis.

Type 2 necrotizing fasciitis is defined by infection with group A β -hemolytic streptococci, occurring either alone or in combination with staphylococci. Type 3 necrotizing fasciitis is characterized by infection with marine vibrios following exposure to sea water. This group of gram-negative rods consists of *Vibrio vulnificus*, *V. parahaemolyticus*, *V. damsela*, and *V. alginolyticus*; *V. vulnificus* is considered to be the most virulent.

Clinical Features

A. Symptoms and Signs—The typical patient presents with a history of 5–7 days or fewer of localized pain, redness, and swelling. On physical examination, the patient may be tachycardiac or tachypneic (in compensation for metabolic acidosis). Fever is not uniformly present, with up to 50% of

patients being afebrile. An area of what initially appears to be simple cellulitis may be noted, with localized warmth, erythema, and tenderness of the skin and soft tissues. An important clue to the diagnosis of necrotizing fasciitis is the presence of pain disproportionate to physical findings. Rapid progression of soft tissue involvement is typical, with the evolution of a smooth, tense, and edematous lesion to blister and bulla formation with an underlying dusky blue hue to skin surfaces. With progression of soft tissue involvement, the subcutaneous nerves are destroyed, resulting in anesthesia of overlying skin. However, physical findings may be non-specific: About 75% of patients present only with pain, swelling, and cutaneous erythema. Specific findings suggestive of invasive soft tissue involvement, such as crepitus and blistering, are present in less than 40% of patients.

B. Laboratory Findings—Complete blood count, a chemistry panel, and liver enzymes should be obtained on all patients. Leukocytosis with left shift is typically present; blood chemistries may reveal metabolic acidosis, renal insufficiency, and other evidence of organ dysfunction. Creatine kinase may be elevated, reflecting myonecrosis. One retrospective study identified a white blood cell count of greater than 14,000/ μ L, a serum sodium of less than 135 mmol/L, and a serum urea nitrogen of greater than 15 mg/dL as useful in distinguishing patients with necrotizing fasciitis from patients with cellulitis. Plain films occasionally reveal gas in the soft tissue, a finding that is specific for necrotizing fasciitis. MRI may be a more sensitive tool in differentiating a necrotizing soft tissue infection from simple cellulitis; however, this diagnostic modality is not readily available at all centers. Diagnosis requires surgical exploration of the involved soft tissue—the hallmark of necrotizing fasciitis is nonadherence of fascia to underlying muscles on blunt dissection. In some cases, a full-thickness biopsy with immediate frozen section will reveal fascial necrosis. Surgically debrided tissue should be submitted for aerobic and anaerobic bacterial cultures to allow appropriate tailoring of antibiotic therapy. Gram stain of an aspirate from the necrotic center of the lesion has been shown to correlate well with culture results.

Differential Diagnosis

The differential diagnosis of necrotizing fasciitis includes cellulitis, erysipelas, thrombophlebitis, myositis, and compartment syndrome. In many cases, the differentiation of these entities from necrotizing fasciitis can be made on clinical grounds.

Treatment

A. Empirical Antibiotic Therapy—Empirical antimicrobial treatment of necrotizing fasciitis should include coverage of aerobic gram-positive cocci, aerobic gram-negative rods, and anaerobes. Initial antimicrobial choices could include a penicillin or a first-generation cephalosporin along with an

aminoglycoside and either clindamycin or metronidazole. Given the dramatic increase in rates of community-acquired MRSA infections, empirical therapy should include clindamycin, trimethoprim-sulfamethoxazole, or in some cases, vancomycin. If *S. pyogenes* is suspected, the treatment of choice is high-dose penicillin. In this setting, animal data support the addition of clindamycin; in the presence of a high inoculum of organisms in a stationary phase of growth, penicillin-binding proteins are not fully expressed, reducing the efficacy of penicillin. Furthermore, clindamycin acts as a protein synthesis inhibitor at the ribosome, which may suppress streptococcal toxin production. If *Vibrio* infection is suspected, tetracycline should be added to the regimen. When clostridial myonecrosis is a consideration, high-dose penicillin with or without clindamycin should be initiated.

B. Surgery—Because of tissue hypoxia, necrosis, and blood vessel thrombosis, antibiotics alone never should be considered definitive therapy for necrotizing fasciitis. Early debridement of all necrotic tissue is imperative for control of infection. The goal of surgery is twofold: to render a prompt diagnosis and to perform definitive debridement. Patients require frequent reevaluation of the surgical site—at least every 12 hours. Repeat debridement is often necessary.

C. Adjunctive Therapies—Supportive care is critical, with appropriate fluid resuscitation and nutritional support to promote wound healing. The issue of adjunctive hyperbaric oxygen therapy is controversial; however, the data to support its use consist of retrospective studies, case reports, and animal studies. If hyperbaric oxygen is readily available, its use can be considered. However, it never should be considered an alternative to adequate surgical debridement.

Prognosis

The mortality rate associated with necrotizing fasciitis is high. Risk factors for mortality have been identified as age over 60 years, female sex, extent of infection on presentation, delay in surgical debridement, elevated creatinine, elevated blood lactate, white blood cell count greater than 30,000/ μ L, presence of bacteremia, and degree of organ dysfunction on admission. The physician should maintain a high level of suspicion when evaluating patients with soft tissue infections because early diagnosis with prompt surgical debridement remains the most important modifiable determinant of prognosis.

▶ Intraabdominal Infections

ESSENTIALS OF DIAGNOSIS

- ▶ Symptoms may be nonspecific, with patients reporting vague abdominal pain, anorexia, and fever.
- ▶ Abdominal examination may reveal absent or diminished bowel sounds, with peritoneal signs.
- ▶ Laboratory findings are nonspecific in patients with intraabdominal sepsis.

General Considerations

Intraabdominal infections are a significant cause of mortality and morbidity in the ICU. The actual incidence of intraabdominal infections is difficult to quantify because this category includes a wide range of diagnoses.

Pathophysiology

See Table 15–5.

Microbiologic Etiology

See Table 15–5. The majority of intraabdominal infections are polymicrobial in nature, caused by Enterobacteriaceae, anaerobes, or streptococci. The organisms isolated from a given intraabdominal infection reflect the flora native to the involved region of the GI tract. The normal flora of the stomach, duodenum, and proximal small bowel consist of small numbers of viridans streptococci and other microaerophilic streptococci. The distal small bowel is populated with larger numbers of Enterobacteriaceae, enterococci, and anaerobes. The colon is estimated to contain up to 10^{12} organisms per

Table 15–5. Intraabdominal infections: Pathophysiology, microbiology, and treatment.

Intraabdominal Infection	Pathophysiology	Microbiologic Etiology	Diagnostic Tests	Empirical Antimicrobial Therapy
Peritonitis (spontaneous)	Translocation of bacteria across gut lumen in cirrhosis	<i>E. coli</i> (most frequent), <i>K. pneumoniae</i> , <i>S. pneumoniae</i> , streptococci, enterococci	Paracentesis (neutrophils $>250/\mu\text{L}$, positive Gram stain or culture)	Third-generation cephalosporin (preferably cefotaxime or ceftriaxone)
Peritonitis (secondary)	Perforation of viscus	Enterobacteriaceae, anaerobes, streptococci, enterococci, <i>Candida</i> species	Paracentesis (polymicrobial Gram stain or culture), plain films or CT showing free peritoneal air	β -lactam/ β -lactamase inhibitor <i>or</i>
Intraperitoneal abscess	Complication of spontaneous or secondary peritonitis	Enterobacteriaceae, anaerobes, streptococci, <i>Candida</i> species	CT scan, ultrasound, perhaps radionuclide scan	Third-generation cephalosporin (or cefepime) + metronidazole <i>or</i>
Pancreatic abscess	Complication of pancreatitis (biliary, ethanol, postoperative, or post-traumatic)	Enterobacteriaceae, anaerobes, streptococci, enterococci, <i>Candida</i> species	CT scan or ultrasound	Quinolone + metronidazole <i>or</i>
Hepatic abscess	Local spread from contiguous infection or hematogenous seeding of liver	Mixed facultative and anaerobic species (most common), unless biliary tract source (enteric gram-negative bacilli and enterococci); consider <i>E. histolytica</i>	CT scan or ultrasound	Carbapenem <i>or</i> Monobactam + metronidazole

gram of feces. The predominant flora consists of anaerobes, Enterobacteriaceae, and enterococci. *Candida* species colonize the GI tract in approximately 50% of individuals, which may be an important pathogen in patients with bowel perforation. The normal microbiologic flora of the GI tract are altered dramatically by antibiotic therapy, selecting for increased colonization with *Candida* species, enterococci, and other relatively resistant gram-negative bacilli such as *Pseudomonas* and *Enterobacter* species.

Intraabdominal infections may be caused by pathogens not typically associated with GI flora. In patients with specific risks (ie, suspected exposure or immunocompromised), the following organisms should be considered: *M. tuberculosis*, *N. gonorrhoeae*, *C. trachomatis*, *C. immitis*, *Yersinia enterocolitica*, and *Actinomyces*.

Clinical Features

A. Symptoms and Signs—The symptoms and signs of intraabdominal sepsis not only vary among patients but also depend on the underlying etiology of the infection. Symptoms may be nonspecific, with patients reporting vague abdominal pain, anorexia, or subjective fever. Patients may be febrile or hypothermic; tachycardia is common, and tachypnea may be present in compensation for an underlying metabolic acidosis. Abdominal examination may reveal absent or diminished bowel sounds, with peritoneal signs. Patients who are morbidly obese, elderly, neutropenic, or receiving steroids or other immunosuppressive agents are more likely to have nonspecific complaints, along with relatively benign abdominal findings on physical examination, even in the presence of severe intraabdominal pathology. Thus the physician must maintain a high level of suspicion when evaluating these patient populations.

B. Laboratory Findings—Laboratory findings are nonspecific in patients with intraabdominal sepsis. Peripheral leukocytosis is common, although leukopenia may be seen in some patients, perhaps owing to intraabdominal sequestration of white blood cells. Metabolic acidosis may be present and should prompt consideration of bowel ischemia. Elevation of liver aminotransferases, although relatively common, is a nonspecific finding in intraabdominal infection and only rarely heralds a focal intrahepatic infection. Elevation of serum alkaline phosphatase and total bilirubin mandates prompt investigation of the biliary tree to rule out cholecystitis, cholangitis, or an obstructing mass. An elevated serum amylase or lipase may point to pancreatitis, although an abnormal serum amylase also may be seen with bowel infarction or perforation. If ascites is present, a diagnostic paracentesis should be performed, with assessment of cell count, protein, albumin, Gram stain, and culture of ascitic fluid.

C. Imaging Studies—Supine and upright films of the abdomen may reveal free air if viscus perforation is present. Other diagnostic clues may be present on plain radiographs, such as an elevated hemidiaphragm that may herald an

intraabdominal abscess. Abdominal ultrasound is another radiographic diagnostic tool that is often readily available and relatively inexpensive to perform. Abdominal ultrasonography is particularly useful in detecting pathology of the right upper quadrant, retroperitoneum, and pelvis, where its sensitivity is about 90%. However, ultrasound is less sensitive in the interloop areas, and the presence of large amounts of bowel gas may limit the utility of ultrasonography. CT scan of the abdomen is more sensitive than ultrasound in the diagnosis of intraabdominal pathology; however, it is more expensive and requires administration of intravenous and oral contrast agents. MRI may be a useful diagnostic tool because it avoids the need for intravenous contrast agent administration; however, it is costly, not readily available in all centers, and is not usable in unstable or mechanically ventilated patients.

Treatment

Most intraabdominal infections are caused by polymicrobial enteric flora; thus empirical therapy should be targeted toward facultative gram-negative bacilli and anaerobes. In the past, aminoglycosides were used as first-line therapy against gram-negative bacilli but are no longer used widely because newer agents have demonstrated improved penetration and reduced toxicity. β -lactam/ β -lactamase-inhibitor combinations, a carbapenem, a third- or fourth-generation cephalosporin, a quinolone, and a monobactam in conjunction with metronidazole are all recommended regimens. None of these regimens has demonstrated consistent superiority over the others. While metronidazole resistance among *B. fragilis* is rare, increasing prevalence of clindamycin-resistant *B. fragilis* has rendered this agent less useful for anaerobic coverage. The combination of metronidazole and aztreonam is not used widely because of the lack of gram-positive coverage. The decision to add an antifungal agent should be individualized. Immediate empirical antifungal therapy is rarely indicated unless a primary fungal process is suspected. If, during the course of therapy, *Candida* is isolated from blood or peritoneal cultures, or if histopathologic evidence of fungal tissue invasion is obtained, initiation of antifungal therapy with fluconazole or other agent is appropriate. In addition to empirical antimicrobial therapy, surgical consultation should be obtained for all patients with suspected intraabdominal sepsis.

► Infections in Special Hosts

Many patients have underlying diseases that render them susceptible to specific pathogens. Included among these are

patients with neutropenia, organ transplant recipients, diabetics, asplenic individuals, patients on chronic corticosteroid therapy, and HIV-infected patients. Knowledge of an underlying condition may lead a physician to modify or broaden empirical antibiotic therapy when such a patient is admitted to the ICU with infection or suspected infection. The physician also should keep in mind that relative immunosuppression may alter or minimize presenting symptoms and physical findings. Patients with HIV infection represent a population with specific management issues (see Chapter 27). In general, immunocompromised patients who require intensive care for an infectious process should have an infectious disease consultant involved in their care.

The Neutropenic Patient

Advances in the fields of oncology and hematology have led to increasing numbers of patients undergoing intensive chemotherapy for hematologic or solid-organ malignancies, with significant resulting immunosuppression. One of the major complications of such therapy—and an important cause of morbidity and mortality—is supervening infection. At least 50% of febrile neutropenic patients have either established or occult infection; only 30–50% of these episodes can be documented microbiologically. Because these patients have a diminished immune response to infection owing to their neutropenia, it often happens that no obvious signs of infection such as purulent drainage, erythema, or edema are present. Fever is frequently the only sign. Empirical antimicrobial therapy of the febrile neutropenic patient is the standard of care.

Using the Infectious Disease Society of America (IDSA) guidelines, neutropenia is defined as fewer than 500 neutrophils/ μL or fewer than 1000 neutrophils/ μL with an anticipated decline to fewer than 500 neutrophils/ μL . Fever is defined as a single oral measurement of 38.3°C or greater or 38°C or greater over a period of 1 hour. A thorough history and physical examination should be performed in patients with neutropenia and fever, with scrutiny of the skin, oropharynx, and perirectal areas to localize a source of infection. Blood cultures for bacteria and fungi, a chest x-ray, liver enzymes, a complete blood count, and a chemistry panel should be obtained. Once such tests have been performed, empirical antimicrobial therapy should be initiated without delay. In previous decades, the most common pathogens identified in febrile neutropenic patients were aerobic gram-negative bacilli of enteric origin, including *E. coli*, *Klebsiella* species, and *P. aeruginosa*. However, an increasing incidence of bacteremia owing to gram-positive organisms such as *S. epidermidis*, *S. aureus*, β -hemolytic streptococci, and enterococci has been documented in recent years, thought to be the result of increased use of indwelling intravenous catheters, administration of chemotherapeutic regimens that induce mucositis, induction of profound and prolonged neutropenia, unrecognized herpetic mucositis, routine use of H_2 antagonists, and use of prophylactic antimicrobial agents with broad gram-negative coverage (such as trimethoprim-sulfamethoxazole or ciprofloxacin).

Initial empirical therapy should be targeted against gram-negative bacilli using an antipseudomonal antibiotic (eg, piperacillin, ceftazidime, cefepime, meropenem, or imipenem-cilastin) in conjunction with an aminoglycoside. Monotherapy with ceftazidime, cefepime, meropenem, or imipenem-cilastin can be considered. The decision to add vancomycin to initial empirical therapy should be individualized; if an indwelling catheter is considered a likely source of infection, if resistant gram-positive infection is considered likely because of prophylactic administration of antibiotics, or if significant mucositis, hypotension, or other hemodynamic instability is present, then vancomycin may be added to the initial regimen. However, it has been demonstrated that patients do not suffer increased morbidity or mortality if vancomycin is withheld until clinical or microbiologic evidence for such an infection exists.

Once results of blood and other body fluid cultures become available, antimicrobial therapy may be directed at specific organisms identified. If, however, the patient remains febrile after 5–7 days of broad-spectrum antimicrobial therapy and no source of infection has been found, empirical antifungal therapy should be considered. Amphotericin B traditionally has been the antifungal agent of choice in this setting. Acceptable alternatives include lipid formulations of amphotericin B or echinocandins. Approximately one-third of neutropenic patients who remain febrile for 1 week or more on broad-spectrum antimicrobial therapy will be found to have a systemic fungal infection, usually with *Candida* or *Aspergillus* species. Importantly, isolation of *C. glabrata* and *C. krusei* is more common than *C. albicans* in some centers, and affects the choice of empirical antifungal agent.

Organ Transplant Recipients

Organ transplant recipients, because of the nature of their immunosuppressive therapy, are particularly vulnerable to infectious complications. Susceptibility to specific infectious complications in the transplant host varies over time in the posttransplant setting. A patient's risk of acquiring a particular infection is determined by his or her state of immunosuppression, as well as individual epidemiologic exposures, both in the community and in the hospital (eg, *M. tuberculosis* or *Legionella*). In the first month after transplantation, 90% of infectious complications are typical hospital-acquired infections, such as transplant wound infection, pneumonia, urinary tract infection, or catheter-related infection. Rarely, a systemic infection may be transmitted with the allograft, or more commonly, an underlying latent infection in the transplant recipient may recrudescence with immunosuppression. One to six months following transplantation, organ transplant recipients experience maximal T-cell immune dysfunction and therefore are particularly vulnerable to intracellular pathogens (eg, cytomegalovirus, human herpes virus 7, *P. jiroveci*, *L. monocytogenes*, cryptococci, *Toxoplasma*, and *M. tuberculosis*) and endemic mycoses that may reactivate during this period. In the absence of an

environmental exposure to a specific pathogen, other opportunistic infections are rare during this time period. Six months after transplantation, an individual's risk of infection depends on the clinical course and health care status. In the 80% of patients who have experienced an uneventful posttransplant course, infectious complications are typically the same as those of the community at large (eg, influenza and pneumococcal infection). Another approximately 10% of patients will develop chronic or progressive viral infections such as cytomegalovirus, hepatitis B virus, hepatitis C virus, or Epstein-Barr virus. In the remaining 10% of patients, chronic or recurrent rejection requires repeated courses of high-dose immunosuppressive therapy. This population remains at risk for infection with the intracellular pathogens mentioned earlier, as well as with *Aspergillus* species.

Asplenic Patients

The spleen serves a critical function in antibody synthesis, microbial filtration, and opsonin production. Patients with asplenia therefore are uniquely susceptible to overwhelming infection with encapsulated organisms such as *S. pneumoniae*, *N. meningitidis*, and *H. influenzae*. Other less common pathogens seen in the asplenic host include *K. pneumoniae*, *S. agalactiae*, *E. coli*, *Capnocytophaga canimorsus*, and *S. aureus*. They are also prone to severe infection with intracellular parasites such as *Babesia* and *Plasmodium*. When attempting to identify at-risk patients, a history of surgical splenectomy should be elicited from the patient. When the patient cannot provide an accurate history, physical examination may reveal the presence of a surgical splenectomy scar. However, a functional asplenic state may be overlooked. Conditions that can lead to functional asplenia include congenital hyposplenism, sickle cell disease, graft-versus-host disease, rheumatoid arthritis, systemic lupus erythematosus, amyloidosis, ulcerative colitis, celiac disease, and chronic alcoholism. A clue to asplenia is the presence of Howell-Jolly bodies on peripheral blood smear because these inclusions typically are removed by a functioning spleen. In an asplenic patient with overwhelming sepsis, high-grade bacteremia is often present; thus Gram stain of the buffy coat may reveal the infecting organism. Empirical antimicrobial therapy should include coverage for the encapsulated organisms, with a third-generation cephalosporin being a reasonable choice.

Patient on Chronic Corticosteroid Therapy

In one meta-analysis, the rate of infection in patients taking steroids was 12.7% compared with 8% in patients not on chronic steroids. The rate of infection was not increased in patients taking less than 10 mg/day or a cumulative dose of less than 700 mg prednisone. In addition to increased susceptibility to community-acquired pathogens, patients on chronic steroid therapy are particularly vulnerable to intracellular pathogens. Examples include *Salmonella* species, *Legionella* species, *L. monocytogenes*, *M. tuberculosis*, and

various viruses (eg, herpesviruses). Other organisms that must be considered when evaluating a steroid-treated patient with clinical evidence of severe infection include *Candida* species, *Aspergillus* species, *C. neoformans*, *Nocardia* species, *Toxoplasma gondii*, and *P. jiroveci*.

Patients with Diabetes Mellitus

Patients with diabetes mellitus often have more severe manifestations of infectious disease than other hosts. In addition, there are specific disease entities that occur more commonly in diabetics than in other hosts. For example, rhinocerebral mucormycosis should be considered in any patient with diabetic ketoacidosis and facial pain, ocular complaints, or neurologic symptoms. Physical examination may be unremarkable or may reveal a black eschar on the hard palate or nasal mucosa, facial swelling, and/or proptosis late in the course of the infection. Definitive diagnosis of this life-threatening infection is made by tissue biopsy to demonstrate fungal elements invading tissues. Therapy consists of surgical debridement with adjunctive high doses of liposomal intravenous amphotericin B. Diabetics are also uniquely susceptible to urinary tract infections. Serious complications of urinary tract infections are not uncommon, such as emphysematous pyelonephritis, which requires surgical therapy along with antimicrobial therapy. Emphysematous cholecystitis may develop in the diabetic host, usually the result of an anaerobic infection with clostridia. Emphysematous cholecystitis should be suspected when gas is seen on abdominal plain film or CT scan; emergent cholecystectomy is indicated for this condition. Because of impaired vascular perfusion, patients with diabetes mellitus are prone to more severe necrotizing soft tissue infections, necessitating a high degree of vigilance for these life-threatening infections, with rapid diagnosis and immediate surgical debridement.

▶ Principles of Antibiotic Use in the ICU

The choice of antimicrobial agents to be used in established or strongly suspected bacterial or other infections must be based on an assessment of what organisms are most likely to be involved. Initial empirical therapy should be dictated, when possible, by results of Gram-stained smears of properly collected specimens such as sputum, urine, aspirated purulent material, or body fluids (eg, blood, cerebrospinal fluid, peritoneal fluid, synovial fluid, pleural fluid, or pericardial fluid).

Epidemiologic factors, site of infection, and the clinical status of the patient also must be considered in selecting antibiotics. The results of pretreatment cultures can provide a definitive microbiologic diagnosis, and *in vitro* antibiotic susceptibility testing, if appropriate, can be performed. Interpretation of microbiologic cultures obtained after initiation of antimicrobial therapy is difficult; in this setting, the presence of sterile cultures may be misleading.

Some general guidelines may be helpful in selecting therapy. Certain pathogens have a predilection for causing infection at specific sites, for example, *S. pneumoniae* (ie, pneumonia or meningitis) and *E. coli* (ie, urinary tract infections or bacteremia). Certain antimicrobial agents have predictable activity against specific organisms, for example, penicillins for streptococci and vancomycin for staphylococci and streptococci, including methicillin-resistant strains. However, an increasing number of microorganisms are manifesting resistance to standard antimicrobials (Table 15–6). Therefore, obtaining cultures in conjunction with susceptibility testing is imperative.

Despite the availability of numerous antimicrobial agents, most pathogens are optimally treated with only a few drugs. Antimicrobial therapy should be as specific, nontoxic, and inexpensive as confirmatory cultures and susceptibility tests allow. Used wisely, antimicrobials rarely fail; regimens should not be changed haphazardly. Any changes should be based on a complete database, which includes results of standardized susceptibility testing performed in a reliable laboratory. In the ICU patient, the choice of antibiotics may be dictated by the presence of hepatic or renal dysfunction. In addition, the doses of some agents must be modified in patients with impaired excretion of the drugs because of decreased kidney or liver function.

This section describes some of the newer antimicrobial agents with the goal of establishing general guidelines for their use. It is important to keep in mind that the choice of a specific agent should be based on the nature of the infection as well as patient factors; the newest antimicrobial drug is often not the best choice.

Table 15–6. Emerging resistance to antibiotics.

Organisms With Emerging Resistance	Antibiotics
<i>Streptococcus pneumoniae</i>	Beta-lactams, macrolides, quinolones
<i>Staphylococcus aureus</i>	Beta-lactams, aminoglycosides, vancomycin, linezolid, quinolones
Enterococcus	Aminoglycosides, penicillin, vancomycin, linezolid, quinupristin-dalfopristin
<i>Haemophilus influenzae</i>	Ampicillin (beta-lactamase-negative), chloramphenicol
<i>Pseudomonas aeruginosa</i> (including other group 1 beta-lactamase-producing gram-negative bacilli)	Aminoglycosides, beta-lactams, carbapenems, quinolones
Enterobacteriaceae	Beta-lactams
<i>Acinetobacter baumannii</i>	Beta-lactams, carbapenems, quinolones, aminoglycosides
<i>Bacteroides fragilis</i>	Clindamycin

Since the development and use of the sulfonamides in the 1930s and penicillin in the 1940s, numerous effective antibacterial and antifungal agents—and, more recently, antiviral agents—have become available. However, there exists a paucity of new antimicrobial agents under development targeting the increasingly resistant bacteria responsible for infection, threatening our ability to provide optimal treatment. The similarities of many of existing antibiotics are more striking than their differences. Nonetheless, many antibiotics occupy specific niches in the treatment of the infected patient.

Cephalosporins

Cefepime has been referred to as a fourth-generation cephalosporin. It has excellent activity against the Enterobacteriaceae, *Enterobacter* species, *P. aeruginosa*, and *S. pneumoniae*; moderate activity against *S. aureus*; and limited antianaerobe activity.

Carbapenems

Imipenem, meropenem, and ertapenem are the three carbapenems currently available for use. The presence of the carbapenem ring increases the potency and antibacterial spectrum of these agents. In place of an acylamino side

group off the β -lactam ring—found in the penicillins and cephalosporins—imipenem has a short hydroxyethyl side chain that protects the ring from degradation by bacteria-produced β -lactamases. The carbapenems are active against most aerobic and anaerobic gram-positive and gram-negative organisms. Imipenem and meropenem have activity against *P. aeruginosa* and *Acinetobacter* species, whereas ertapenem does not. Imipenem is available only in combination with cilastatin sodium; the latter is added to prevent renal metabolism of the imipenem, which decreases nephrotoxicity. Imipenem–cilastatin sodium has been associated with adverse CNS reactions, including seizures. Slight structural modifications have rendered meropenem resistant to degradation by the dehydropeptidases of the renal brush border, conferred slightly greater activity against aerobic gram-negative bacilli but slightly less activity against aerobic gram-positive cocci, and decreased the epileptogenic potential of the drug.

Quinolones

The quinolones are a class of antimicrobial agents that has expanded significantly in recent years. Quinolones act by binding to bacterial DNA gyrase and topoisomerase intravenously, thus preventing DNA replication. Resistance occurs via accrual of mutations at the enzyme target or by active efflux of the drug out of bacterial cells. Ciprofloxacin, an early quinolone, has activity primarily against gram-negative organisms and staphylococci, with limited activity against streptococci and anaerobes. It is the only fluoroquinolone with reliable activity against *P. aeruginosa*. Some newer agents (eg, levofloxacin, gemifloxacin, and moxifloxacin) have greater potency against streptococci, particularly *S. pneumoniae*, including penicillin-resistant *S. pneumoniae*. They also have excellent activity against aerobic gram-negative bacilli but less activity against *P. aeruginosa*. All quinolones have activity against atypical pneumonia pathogens, including *Legionella*, *C. pneumoniae*, *M. pneumoniae*, *C. trachomatis*, and some mycobacteria. In general, the quinolones have excellent bioavailability and may be given either orally or intravenously.

Tigecycline

Tigecycline, a new semisynthetic glycolcycline related to tetracycline, possesses in vitro antibacterial activity against many clinically important gram-positive and gram-negative aerobic and anaerobic bacteria, including some with resistance to other classes of agents (eg, vancomycin-resistant enterococci [VRE], MRSA, and multidrug-resistant *Acinetobacter*). Tigecycline may be useful in the treatment of complicated skin and skin-structure infections and complicated intraabdominal infections. Because of its limited activity against *P. aeruginosa* and *Proteus* species, tigecycline is not recommended for the treatment of serious infections caused by these organisms. Tigecycline should be

used carefully to avoid selective pressure leading to the development of resistance. It is available for parenteral use only, has a large volume of distribution, and is cleared by hepatic metabolism and excretion. There is no dose adjustment for renal insufficiency. Nausea and vomiting are the most frequently reported side effects.

Triazoles

The triazoles are fungistatic drugs that inhibit the fungal cytochrome P450 enzyme to block the transformation of lanosterol to ergosterol, the major sterol in the fungal cell membrane. The result is osmotic instability and loss of integrity of the fungal cell wall. Fluconazole is available in both oral and parenteral forms, and essentially equivalent blood levels are achieved by either route. Fluconazole has a wide volume of distribution, achieving high levels in urine, sputum, saliva, peritoneal fluid, vaginal secretions, bile, cerebrospinal fluid, skin, liver, and prostate. Achievable cerebrospinal fluid levels are about 60–80% of serum levels. Fluconazole is 80% excreted unchanged in the urine, and dose adjustment is required for renal insufficiency. Fluconazole is active against *C. albicans*, *C. tropicalis*, *C. parapsilosis*, *C. immitis*, and *C. neoformans*. It has been shown to be effective in the treatment of hematogenous, mucosal, and end-organ candidal infection. Caution should be used when treating infection with certain non-*albicans* species such as *C. krusei* and *C. glabrata* because these organisms are less sensitive to fluconazole.

Itraconazole is another triazole that is available for clinical use. A parenteral form is available. Oral formulations have inconsistent absorptions and so should be avoided in the critically ill patient. Compared with fluconazole, itraconazole has greater activity against *Aspergillus*, *B. dermatitidis*, *H. capsulatum*, and *Sporothrix schenckii*.

Voriconazole is available in both parenteral and oral forms. Voriconazole is active against all *Candida* species, including *C. krusei* and *C. glabrata*, many *Aspergillus* species, *B. dermatitidis*, *C. immitis*, *H. capsulatum*, *Scedosporium/Pseudoallescheria*, and *Fusarium* species. Like fluconazole, voriconazole has a large volume of distribution and excellent oral bioavailability. Voriconazole is indicated for the treatment of invasive aspergillosis, *Candida* esophagitis, and invasive fungal infections caused by *Pseudallescheria boydii* and *Fusarium* species.

Amphotericin B Lipid Formulations

Amphotericin B desoxycholate has long been the standard for treatment of severe mycoses. It is a fungicidal drug that binds to ergosterol in the cell wall and causes osmotic instability and cell death. The major weakness of amphotericin B desoxycholate is its numerous adverse effects, especially nephrotoxicity. The new lipid formulations of amphotericin B are costly but have the advantage of inducing less

nephrotoxicity. There are currently three formulations available: amphotericin B lipid complex, amphotericin B colloidal dispersion, and liposomal amphotericin B. They are approved for use in patients with invasive fungal infections who are intolerant of amphotericin B desoxycholate. Liposomal amphotericin B has an additional indication for empirical therapy in febrile patients with neutropenia. There are some data, mostly from retrospective comparisons and a few prospective trials, suggesting improved response rates with lipid formulations and a lower incidence of nephrotoxicity. Owing to the significant cost differential between the lipid formulations of amphotericin B and amphotericin B desoxycholate, use of the lipid formulations generally is reserved for specific subgroups of patients. For example, in high-risk patients such as bone marrow transplant recipients with suspected invasive aspergillosis, earlier use of the lipid formulations may be warranted in an attempt to improve response rates and to decrease renal toxicity.

Echinocandins

Caspofungin, micafungin, and anidulafungin belong to the class of antifungal drugs called the *echinocandins*, which inhibit β -(1,3) glucan synthesis with resulting damage to fungal cell walls. Caspofungin is available for parenteral use only. It has activity against *Candida* and *Aspergillus* species. Caspofungin has been demonstrated to be equivalent to amphotericin B in the treatment of invasive candidiasis and candidemia. Caspofungin has an indication for empirical therapy in the febrile neutropenic patient. Anidulafungin is approved for parenteral treatment of candidemia and candidal peritonitis and intraabdominal abscesses, as well as esophageal candidiasis. Micafungin is approved for candidemia, acute disseminated candidiasis, candida peritonitis, candidal esophagitis, and antifungal prophylaxis for hematopoietic stem cell transplant recipients.

Macrolides

The three macrolides available for clinical use in the United States are erythromycin, clarithromycin, and azithromycin. In comparison with erythromycin, the latter two have greater activity against *H. influenzae*, *C. trachomatis*, *M. avium* complex, and other nontuberculous mycobacteria. The role of these agents in the critically ill patient is limited to treatment of patients with suspected atypical pneumonias. All three agents possess good activity against *M. pneumoniae*, *C. pneumoniae*, and *Legionella* species. Erythromycin and azithromycin are available in a parenteral formulation, whereas clarithromycin is available only in an oral form.

Quinupristin-Dalfopristin

Quinupristin-dalfopristin is a formulation of two bacteriostatic antimicrobial agents that, when combined, are bactericidal. Its antimicrobial activity is the result of inhibition of protein synthesis at the 50S ribosome. Quinupristin-dalfopristin is available for intravenous use only. Its spectrum of

activity is similar to that of vancomycin and includes *S. pneumoniae*, other streptococci, *S. aureus*, and coagulase-negative staphylococci. It is bacteriostatic for *Enterococcus faecium* and has no activity against *E. faecalis*. The niche for quinupristin-dalfopristin is in the treatment of vancomycin-resistant *E. faecium* and possibly glycopeptide-insensitive *S. aureus*.

Linezolid

Linezolid belongs to the class of drugs known as *oxazolidinones*. These drugs block bacterial protein synthesis at the ribosome at a very early stage. Because of its novel mechanism of action, linezolid does not share cross-resistance with other antimicrobial agents. Linezolid's spectrum of activity is essentially identical to that of vancomycin. Much like quinupristin-dalfopristin, the major indication for use of this agent is the treatment of vancomycin-resistant enterococcus and glycopeptide-insensitive *S. aureus* infections. Linezolid is approved for treatment of pneumonia, bacteremia, and skin and soft tissue infections owing to gram-positive organisms. Linezolid is available in both oral and parenteral formulations, with excellent oral bioavailability.

Daptomycin

Daptomycin belongs to a new class of antimicrobial agents; it is a cyclic lipopeptide antibiotic that is rapidly bactericidal against *S. aureus*, streptococci, and enterococci, including multidrug-resistant strains. It is available for parenteral use only and is approved for use in complicated skin and soft tissue infections caused by staphylococci, streptococci, and *E. faecalis*.

► Evaluation of the ICU Patient with New Fever

The evaluation of new fever in the ICU setting involves consideration of diagnoses much different from those encountered in patients in a community setting. Many noninfectious causes of fever must be considered and excluded in order to avoid missing important diagnoses and perhaps administering antimicrobial agents unnecessarily.

Clinical Features

A. History and Examination—When eliciting a history, the physician should pay special attention to changes in quality and quantity of respiratory secretions, changes in the patient's tolerance to oral intake, the condition of the patient's skin, and the presence or absence of diarrhea. Because many patients in an ICU will be unable to provide a history, information should be elicited from family members and caregivers, and a careful review of medical records and laboratory data and a thorough physical examination should be performed.

It is recommended that temperatures be taken using an electronic probe in the mouth, rectum, or external auditory canal. Axillary temperature measurements may be spuriously low and so should not be used. Sinusitis should be considered in patients with nasotracheal or nasogastric tubes—which block the sinus ostia, thus predisposing to infection. Careful auscultatory examination should be performed to look for new pulmonary findings that may indicate a nosocomial pneumonia or a new or changing murmur that may indicate endocarditis. Abdominal examination should be performed to assess the presence or absence of bowel sounds and any focal tenderness or masses. All intravascular catheter sites should be scrutinized for signs of inflammation at the catheter exit site or along the subcutaneous tunnel. The patient's skin requires careful inspection for any lesions that may indicate hematogenous seeding (either bacterial or fungal), skin eruptions that may indicate a drug reaction, and decubitus ulcers or surgical wounds that may be infected.

B. Laboratory and Imaging Studies—Laboratory evaluation should include a complete blood count, routine chemistries with liver enzymes, and urinalysis. Cultures of blood and urine should be obtained routinely. Other evaluations should be directed by the results of the history and physical examination. A chest radiograph and sputum sample for culture should be obtained when nosocomial pneumonia is suspected. Stool specimens for *C. difficile* toxin should be collected from patients who develop diarrhea while hospitalized. Routine stool cultures and stool for ova and parasites are not useful in evaluation of new fever in a patient in the ICU. Any wounds that appear infected should be debrided, with cultures performed on any purulent material. If the abdominal examination or the liver enzymes suggest an intraabdominal process, a right upper quadrant ultrasound or CT scan of the abdomen and pelvis may be requested. If sinusitis is suspected, CT scan or MRI of the

sinuses may be helpful, although impractical in the unstable or ventilated patient.

Treatment

Empirical therapy will depend on the results of the physical examination and initial laboratory data.

► Nosocomial Pneumonia

ESSENTIALS OF DIAGNOSIS

- Fever, tachypnea, tachycardia, and abnormal breath sounds.
- Risk factors include altered mental status, lung disease, endotracheal tube, or tracheostomy.
- Change in volume or appearance of sputum.
- Infiltrates or other changes on chest x-ray.
- Hypoxemia or worsening arterial blood gases.

General Considerations

It is estimated that at least 5% of hospitalized patients will develop a nosocomial infection. Pneumonia is the second most common nosocomial infection after urinary tract infection and is the leading cause of death owing to hospital-acquired infection. Although often considered separately, ventilator-associated pneumonia (VAP) is a very important subset of nosocomial pneumonia.

Pathophysiology

Pneumonia develops from one of three mechanisms: (1) inhalation of an aerosol containing infectious microorganisms, (2) hematogenous seeding of microorganisms in the lung, or (3) aspiration of oropharyngeal flora.

A. Inhalational Pneumonia—Infectious particles less than 3–5 μm in diameter are capable of reaching the terminal bronchi and alveoli during inhalation. *M. tuberculosis*, *Legionella*, and influenza virus—as well as many fungi—are known to cause nosocomial pneumonia by this route of spread. Contaminated respiratory equipment has been recognized as a source of infected aerosols and a cause of gram-negative bacillary necrotizing pneumonia. Hospital policies

and procedures requiring rigorous, frequent changing and disposal of equipment have markedly decreased the incidence of inhalation pneumonia in the hospital setting.

B. Hematogenous Pneumonia—Pneumonia caused by the hematogenous seeding of infection is uncommon. Patients predisposed to hematogenous pneumonia are those with *S. aureus* or *Candida* infections associated with infected intravenous catheters, septic thrombophlebitis, or endocarditis of the right side of the heart. Pneumonia develops as a consequence of infected thrombi forming within the intravascular space and traveling through the bloodstream to reach the pulmonary circulation (septic pulmonary emboli).

C. Aspiration Pneumonia—Aspiration of oropharyngeal bacterial flora is the most common mechanism responsible for nosocomial pneumonia. Although all individuals aspirate microscopic quantities of oropharyngeal secretions, certain factors increase the risk of pneumonia. Such factors include (1) high frequency and large volume of secretions aspirated, (2) aspiration of particularly virulent bacterial species, (3) the presence of particulate matter in the aspirate, and (4) abnormalities of the lower airway and alveolar defense mechanisms. Aerobic enteric gram-negative bacilli are not usually part of the flora colonizing the oropharynx in normal, healthy, nonhospitalized individuals. However, oropharyngeal colonization by gram-negative bacilli occurs within a days of admission to the ICU. Patients receiving antibiotics develop gram-negative colonization more rapidly. Cross-infection and cross-colonization from patient to patient contribute to the pathogenesis when infection control measures are substandard.

Prophylaxis of stress ulcers with the use of antacids or H_2 -receptor antagonists is considered a risk factor for gram-negative aspiration pneumonia via gastric acid neutralization, allowing subsequent overgrowth of enteric gram-negative bacilli, although this theory remains controversial.

Microbiologic Etiology

The microbiology of pneumonia in hospitalized patients is significantly different from that of pneumonia acquired outside the hospital. Early-onset nosocomial pneumonia (<4–7 days) in patients who have not received prior antibiotic therapy is typically caused by Enterobacteriaceae, *Haemophilus* species, *S. aureus*, and pneumococci. Patients who develop late-onset pneumonia (>4–7 days) and who have received prior antibiotic therapy are at risk for infection with *P. aeruginosa*, *A. baumannii*, *Stenotrophomonas maltophilia*, and MRSA. Approximately 20–40% of nosocomial pneumonias are polymicrobial in etiology. Anaerobic bacteria are not considered an important pathogen in nosocomial pneumonia. *Legionella* species have been implicated as the cause of nosocomial pneumonia in some hospitals.

Clinical Features

The diagnosis of pneumonia depends on physical examination findings, microbiologic analysis of lower respiratory tract secretions, and review of the chest x-ray. Although risk factors

for development of pneumonia should be considered in assessing the likelihood of pneumonia, any critically ill patient—especially one with underlying heart or lung disease—should be considered at risk for nosocomial pneumonia. Studies have identified a number of risk factors in the development of nosocomial pneumonia. Among the most important of these factors are neurologic impairment, witnessed aspiration, mechanical ventilation (with increasing risk associated with prolonged need for mechanical ventilation), underlying chronic lung disease, the presence of ARDS, increasing age, use of a nasogastric tube, enteral feeding, endotracheal cuff pressure, severity of underlying illness, need for tracheostomy, and supine position of the patient.

A. Symptoms and Signs—Patients with suspected nosocomial pneumonia should undergo prompt assessment prior to initiation of therapy. The clinical features of pneumonia in hospitalized patients are subtle and variable, and in some cases, there may be no symptoms or examination findings. Use of clinical and radiographic features alone to diagnose nosocomial pneumonia will lead to the misclassification of many disorders as nosocomial pneumonia. Some diagnostic clues include altered mental status, fever, tachypnea, tachycardia, and abnormal breath sounds. Physical findings commonly include crackles or rales rather than evidence of lung consolidation. Wheezing may be present, and localized wheezing may suggest aspiration of a foreign body. The presence of preexisting abnormal lung findings may make the diagnosis difficult. Patients with a tracheostomy or endotracheal tube may first manifest a lower respiratory tract infection by a change in gross appearance of the respiratory secretions or an increase in oxygen requirement. The physician should query the respiratory therapist or nurse regarding changes in quantity and appearance of these secretions. The development of purulent sputum or an increase in the quantity of secretions suggests heavy bacterial colonization or infection, often prior to the development of a radiographic infiltrate.

B. Laboratory Findings—Most patients in the ICU are too debilitated to produce an adequate sputum sample; samples of respiratory secretions may be obtained in such cases by endotracheal suctioning or fiberoptic bronchoscopy. It is clear that endotracheal aspirates alone are often inaccurate in diagnosing the etiologic agent of a nosocomial pneumonia. Quantitative endotracheal aspirates, a protected specimen brush, or bronchoalveolar lavage often will provide more useful information. However, most diagnostic modalities for nosocomial pneumonia are neither sensitive nor specific. Respiratory cultures obtained by any means must be interpreted with caution because the airways of hospitalized patients are almost always colonized with various potentially pathogenic bacteria. A Gram stain of the sputum may help to identify the etiologic agent and suggest appropriate empirical therapy. A sputum Gram stain that reveals 10 or fewer squamous epithelial cells and more than 25 polymorphonuclear cells per high-power field can be considered an adequate specimen. Typically, the Gram stain is more helpful than culture results in patients already receiving antimicrobial agents that may inhibit bacterial growth in culture.

Invasive methods of diagnosis such as bronchoscopy with or without protected specimen brush should not be used to determine whether or not to initiate therapy for hospital-acquired pneumonia, although results of such studies may be useful in modifying subsequent therapy. Good outcome remains most closely correlated with correct early antimicrobial therapy.

A complete blood count, blood cultures, and a chest x-ray are essential. The chest x-ray may reveal an infiltrate, but nonspecific findings such as atelectasis may be the only finding. Patients with prior pulmonary disease often have preexisting abnormalities on chest x-ray that make it difficult to identify new infiltrates. Blood cultures, when positive, should be considered definitive for the etiologic agent; 10–20% of hospital-acquired pneumonias are associated with a positive blood culture. Pleural fluid, if present, should be sampled by thoracentesis for Gram stain, culture for aerobic and anaerobic organisms, and determination of cell count, pH, total protein, and LDH concentration. Serologic studies are seldom useful in determining the cause of nosocomial pneumonia.

Differential Diagnosis

The differential diagnosis of nosocomial pneumonia includes virtually all processes associated with pulmonary infiltrates. ARDS, pulmonary emboli with infarction, cardiogenic pulmonary edema, lung cancer, and atelectasis often are difficult to differentiate from an infectious lung process. Less common diseases to be considered include collagen-vascular disease, pulmonary hemorrhage, radiation pneumonitis, hypersensitivity pneumonitis, sarcoidosis, occupational lung diseases, and pulmonary alveolar proteinosis.

Treatment

A. Antibiotics—Empirical antimicrobial therapy for nosocomial pneumonia should be based on clinical features, epidemiologic and host factors, and results of an initial sputum Gram stain. Surveillance data relating to local nosocomial flora leading to pneumonia in the ICU should be reviewed. Antibiotic therapy should be administered intravenously and should target a broad spectrum of bacteria. The possibility of resistant microorganisms should be considered in the hospitalized patient with nosocomial pneumonia. In patients with early-onset pneumonia, a third-generation non-antipseudomonal cephalosporin or a β -lactam/ β -lactamase inhibitor (such as piperacillin-tazobactam), or in some cases a fluoroquinolone should be adequate. In patients with late-onset pneumonia, cefipime, imipenem, meropenem, ceftazidime, or a β -lactam/ β -lactamase inhibitor in combination with an aminoglycoside or fluoroquinolone provides the broadest coverage for infections caused by most Enterobacteriaceae, *P. aeruginosa*, and *S. aureus*. If the prevalence of MRSA strains is significant, and staphylococcal pneumonia is a consideration, vancomycin should be included in the initial drug regimen. Quinolones have excellent activity against most Enterobacteriaceae as well as *H. influenzae* but possess less activity against streptococci and

staphylococci (except for levofloxacin and the newer quinolones) and little to no activity against most anaerobes. New data suggest that shorter courses of antibiotics (5–8 days) than traditionally used are effective, safe, and result in less antibiotic resistance.

B. Supportive Care—Patients with pneumonia require suctioning of respiratory secretions, postural drainage, and occasionally, fiberoptic bronchoscopy. Coughing is the most effective way to clear the large airways of respiratory secretions. In patients with endotracheal tubes or tracheostomies, use of appropriate suctioning must substitute for cough. Postural drainage and chest percussion may be useful in selected patients, but only if it can be demonstrated that removal of respiratory secretions is improved. In certain patients, fiberoptic bronchoscopy can be helpful in identifying endobronchial obstruction, and this technique may aid in suctioning secretions from particular airways. Most patients with pneumonia receive bronchodilator therapy, but the effectiveness of these agents in patients without obstructive lung disease is not known.

Prevention

Prevention of nosocomial pneumonia is of utmost importance in decreasing morbidity and mortality rates and controlling the costs of hospital care. Recognition of the aspiration-prone patient is essential. Patients with nasogastric tubes for enteral feeding should have the head of the bed elevated 30–45 degrees during feeding and be monitored for excess gastric residuals that lead to aspiration. All patients should be turned frequently whenever possible. Appropriate disposal, disinfection, or sterilization of respiratory equipment is critical for prevention of contamination and subsequent inhalation pneumonias. Nurses, physicians, and respiratory therapists must use sterile technique for endotracheal suctioning. Meticulous hand washing before and after patient examination and the wearing of gloves when appropriate will help to decrease the overall incidence of nosocomial infections in the ICU. In intubated patients, subglottic suctioning has been shown to be effective in reducing ventilator-associated pneumonia. Other interventions that may help in preventing nosocomial pneumonia include placing patients in the semirecumbent position, avoidance of prolonged nasal intubation (which may lead to nosocomial sinusitis), and use of noninvasive positive-pressure ventilation rather than intubation whenever possible.

► Urinary Catheter–Associated Infections

ESSENTIALS OF DIAGNOSIS

- Although the patient may be asymptomatic, suprapubic tenderness suggests lower tract infection; fever and flank pain suggest upper tract infection.
- Pyuria and white blood cell casts.
- Positive urine culture.

General Considerations

A urinary (bladder) catheter provides a portal of entry into the urinary tract for microorganisms. Urinary catheter–associated infections account for up to 40% of all nosocomial infections. Fewer than 5% of patients who develop bacteriuria will become bacteremic; however, the tremendous frequency of nosocomial bacteriurias accounts for the observation that urinary catheter–associated infections account for 15% of all nosocomial bacteremias. Early recognition and appropriate treatment of urinary catheter-associated infections can reduce morbidity and length of stay in the ICU significantly.

The urinary catheter allows transit of microorganisms colonizing the perineum and the urethral meatus to pass through the urethra and enter the bladder. Most catheter-associated bacteriuria occurs by extraluminal ascent of bacteria via the mucous film coating the outer surface of the catheter; these organisms colonize the patient's perineum. Bacteria also ascend intraluminally through the catheter because of failure of the closed drainage system or contamination of the collection bag. Bacteriuria occurs in catheterized patients at a rate of 3–10% per catheter-day, with 10–25% of these patients developing symptoms of local infection and bacteremia and sepsis occurring in 2–4%.

The most common microorganisms causing infection in short-term catheterized patients in the ICU include Enterobacteriaceae (such as *E. coli*, *Klebsiella* species), *P. aeruginosa*, *Enterobacter* species, enterococci, and *Candida* species. Polymicrobial infections occur in up to 15% of

catheterized patients; anaerobic infections are extremely rare. Candiduria is common in patients receiving corticosteroids or broad-spectrum antibiotics and in those with diabetes mellitus. Urinary tract infections with *Candida* species or *S. aureus* should raise the question of hematogenous spread because a urinary tract infection with one of these organisms can be a marker of disseminated disease.

Risk factors for catheter-associated bacteriuria include prolonged duration of catheterization, older age, severe underlying illness, diabetes mellitus, absence of systemic antibiotic use, female sex, abnormal serum creatinine, errors in catheter care, and periurethral colonization with potential uropathogens. Once bacteriuria has occurred, it is difficult to prevent subsequent infection; thus prevention of the initial bacteriuria is critical. The only two factors shown to decrease the risk of nosocomial catheter-associated bacteriuria are maintenance of a closed catheter system with aseptic insertion of catheter and early removal of the urinary catheter.

Clinical Features

A. Symptoms and Signs—Diagnosis of catheter-related urinary tract infection is straightforward, although many patients with catheter-associated urinary tract infections are asymptomatic. Up to 30% of patients will have fever or other symptoms of urinary tract infection. Fever or other systemic signs of infection, as well as pain localized to the flank, suggest upper tract infection.

B. Laboratory Findings—The white blood cell count may be elevated with serious infection. Definitive diagnosis is based on urinalysis and results of urine culture. Direct examination of the urine continues to be valuable for early diagnosis of bacterial infections of the genitourinary tract. Pyuria indicates the presence of urinary infection rather than simple bacterial colonization of the urine; the presence of white blood cell casts suggests upper tract disease. The presence of one or two leukocytes per high-power field (400×) or bacteria seen under oil immersion (1000×) in unspun urine has a 95% correlation with the presence of more than 100,000 cfu/mL of urine. Thus microscopy is useful for identification of urinary tract involvement with a high urine bacterial count.

The presence of bacteria in a concentration greater than 100,000 cfu/mL with accompanying pyuria is consistent with infection. In catheterized patients, bacterial counts of more than 1000 cfu/mL, if untreated, will increase to more than 100,000 cfu/mL within 24–48 hours. Urine culture for bacteria and fungi must be submitted to the laboratory with prompt processing. Alternatively, specimens may be refrigerated at 4°C, where bacterial counts will remain stable for up to 24 hours. Urine left at room temperature for over 2 hours after collection will have significantly higher urine bacterial colony counts, thereby confounding the diagnosis of urinary tract infection.

Most microbiology laboratories routinely identify and perform antimicrobial susceptibility tests on microorganisms

present in numbers of 10^4 CFU/mL or more. If polymicrobial bacteriuria is anticipated (eg, chronic indwelling catheter or neurogenic bladder), the laboratory should be alerted to this possibility.

C. Imaging Studies—Seriously ill patients presenting with a urinary tract infection, whether catheter-related or not, who have high fever, flank pain, or urosepsis require further evaluation for upper tract disease. Ultrasonography is useful to assess the anatomy of the genitourinary tract and to rule out an obstructed ureter. Further studies, including an intravenous pyelogram, retrograde pyelogram, or CT scan may be necessary to diagnose renal abscess, perinephric abscess, or nephrolithiasis.

D. Complications—Complications of bladder and kidney infections are common and potentially serious. The urinary tract is the most common site of origin of gram-negative bacteremia and sepsis. Acute pyelonephritis, chronic pyelonephritis, emphysematous pyelonephritis, renal abscess, and urosepsis may complicate an untreated urinary tract infection.

Differential Diagnosis

Urinary tract infections should be differentiated from asymptomatic bacteriuria, urethritis, prostatitis, sexually transmitted diseases, pelvic inflammatory disease, diverticulitis, intraabdominal abscess, and peritonitis.

Treatment

A. Asymptomatic Patient with Bacteriuria—Antibiotic therapy in the asymptomatic bacteriuric patient with an indwelling catheter and an unremarkable urinalysis is discouraged because bacteriuria will recur when treatment is discontinued and selection of antibiotic-resistant organisms is likely.

B. Patient with Abnormal Urinalysis and Bacteriuria—In patients with abnormal urinalysis (typically pyuria) and bacteriuria, the urinary catheter should be removed and antibiotics initiated. If the patient requires an indwelling catheter for bladder drainage, a new catheter can be reinserted. In general, empirical therapy should be directed against nosocomial gram-negative pathogens; a third-generation cephalosporin, a quinolone, or an aminoglycoside is usually appropriate initial antibiotic treatment. Therapy may be discontinued in uncomplicated cases at 7 days. However, more seriously ill patients with prolonged fever, suspected upper tract involvement, positive blood cultures, renal insufficiency, or sepsis require a longer course of intravenous antibiotics and further evaluation for upper tract disease.

C. Candiduria—Asymptomatic candiduria in immunocompromised patients or symptomatic candidal urinary tract infections in all patients require antifungal treatment. Oral fluconazole and a short course of intravenous amphotericin B

are both effective for candidal infections confined to the bladder. Upper tract infection requires systemic treatment with oral or intravenous fluconazole or intravenous amphotericin B; complications such as fungal ball, renal or perirenal abscess, or hematogenous dissemination should be considered. In all cases, the catheter should be removed or changed. Asymptomatic candiduria in most patients without immunocompromise usually will clear once the indwelling catheter has been removed and antimicrobial therapy discontinued.

Current Controversies and Unresolved Issues

The appropriate course of action to take with a hospitalized patient who develops asymptomatic nosocomial bacteriuria associated with a urinary catheter remains controversial. The literature suggests that the treatment of bacteriuria in an attempt to avoid complications is not useful. One approach is to remove the catheter as soon as possible after discovery of bacteriuria, with a repeat urinalysis and urine culture 3–5 days later. If the urinalysis is normal and the urine culture is sterile, it is likely that the infection has cleared. If bacteriuria persists, the patient must be monitored for resolution or be treated with a short course of antibiotic therapy. Exceptions to this rule include the presence of bacteriuria with organisms that have a high predilection for causing subsequent bacteremia (eg, *Serratia marcescens*) and bacteriuria in patients at risk for serious complications (eg, neutropenic or pregnant patients).

Questions about the value of screening tests for bacteriuria in patients who have urinary catheters are unresolved. Several tests correlate reasonably well with bacteriuria of 100,000 cfu/mL or more. The leukocyte esterase–nitrate test has a sensitivity of about 85% in detecting bacteria at 10^5 cfu/mL or more. However, the predictive value of a positive test is much lower (25–50%) than that of a negative test.

Attempts to decrease the incidence of bacterial colonization by use of nitrofurazone- or silver alloy-coated urinary catheters have been investigated. It appears that such catheters may decrease the incidence of bacteriuria. Economic evaluations seem to indicate that these catheters are cost-effective when used in patients requiring in-dwelling catheters for short duration.

▶ Intravenous Catheter–Associated Infections

ESSENTIALS OF DIAGNOSIS

- ▶ **Exit-site infection:** erythema, tenderness, induration, and exudate at cutaneous exit site.
- ▶ **Tunnel infection:** induration, erythema, tenderness at least 1 cm deep to the skin exit site and without purulent drainage through the exit site.
- ▶ **Catheter sepsis:** fever, tachypnea, and tachycardia with positive blood cultures and no other site of infection identified.

General Considerations

Obtaining short-term central intravenous and arterial access by means of indwelling catheters is an integral part of the monitoring and management of patients in the ICU. These catheters are required for administration of antimicrobial therapy, blood products, fluid and electrolyte replacement, and monitoring of hemodynamic status. Short-term catheters may be metal needles or Teflon or other synthetic catheters inserted into vessels with only a short distance between the skin and intravascular space. These include radial, dorsalis pedis, and femoral artery catheters, intravenous catheters inserted into superficial veins on the extremities, and large-bore central venous catheters inserted into subclavian or internal jugular veins in the neck. The wide-lumen catheters through which pulmonary artery catheters and temporary transvenous cardiac pacemakers are placed are also considered short-term catheters.

Patients requiring long-term central venous catheters, used primarily for administration of cancer chemotherapy or for total parenteral nutrition, are often admitted to the ICU. These long-term catheters have in common a subcutaneous tunnel through which the catheter passes after entering the skin and before entering the vein. The presence of a Dacron cuff just inside the exit site of the catheter stimulates growth of the surrounding tissue, thus preventing microorganisms from entering the catheter tract. This permits long-term use of the catheter with a greatly decreased incidence of catheter-related infection.

Two relatively recent additions to the armamentarium of long-term venous access catheters are the midline catheters and the peripherally inserted central venous catheters (PICCs). The midline catheter is inserted into the proximal basilic or cephalic vein or into the distal subclavian vein via the antecubital fossa. PICCs are inserted into the superior vena cava via the antecubital fossa as well. These methods of venous access are associated with fewer mechanical complications and lower rates of phlebitis and bloodstream infection and are easier to maintain. It appears that the PICC can be left in place for a long duration, but the specifics are not yet known.

Pathophysiology

Infection of intravascular catheters typically results from one of four events. The most common mechanism of infection is migration of cutaneous colonizing organisms from the insertion site to the catheter tip, frequently seen with short-term catheters. Inadvertent contamination of the catheter hub by the physician or nurse at the time of insertion or by frequent device manipulation also can lead to infection and is an important factor in long-term catheter infection. Contamination of the infusate and hematogenous seeding of the intravascular device from another primary site of infection are less common problems.

Microbiologic Etiology

Gram-positive organisms—most commonly coagulase-negative staphylococci, followed by *S. aureus*—and enterococci are implicated in most bloodstream infections owing to intravenous devices. The incidence of nosocomial infections owing to *Candida* species, especially *C. albicans*, has increased dramatically in recent years. Approximately 15–20% of bloodstream infection are due to gram-negative bacilli (eg, *E. coli*, *Klebsiella* species, *Enterobacter* species, and *P. aeruginosa*). It is important to remember that virtually any organism can cause intravenous catheter infection in an immunocompromised host.

Clinical Features

A. Symptoms and Signs—When evaluating a patient with a possible catheter-related infection, several syndromes need to be considered. If an intravascular catheter is removed, growth of 15 colony-forming units (semiquantitative) or more or 10³ organisms (quantitative culture) or more from a distal or proximal segment of the intravascular catheter in the absence of accompanying clinical symptoms defines bacterial colonization of the catheter. An exit-site infection is characterized by the presence of erythema, tenderness, induration, and purulence within 2 cm of the exit site of the catheter. A tunnel infection is manifested by erythema, tenderness, and induration in the tissues over the catheter and more than 2 cm from the exit site. Finally, a catheter-related bloodstream infection is defined as isolation of the same organism from both the catheter tip and peripherally drawn blood cultures in the appropriate clinical setting with no other source of infection identified.

It is important to distinguish patients with severe neutropenia and catheter-related infections from their immunocompetent cohorts. These patients may not manifest typical inflammatory changes at the site of infection—especially notable is the lack of purulent drainage. However, erythema is still present with infection, and patients may complain of local tenderness; either finding should alert the physician to the probability of infection.

Complications that may occur as a result of catheter-related infections include septic thrombophlebitis and endocarditis. Associated risk factors for catheter-related

infections include extremes of age, altered host defenses (especially skin diseases), severity of the underlying disease, use of a multilumen catheter, and the presence of infections remote from the catheter site. However, the most important hospital-related risk factor is the duration of use of a particular catheter site. Total parenteral nutrition also has been identified as a risk factor for catheter-related infection, perhaps because of the length of time the catheter remains in place, as well as the fact that total parenteral nutrition solutions may act as a culture medium to promote the growth of various organisms. Location of the central venous catheter influences the risk of infection. Femoral catheters are most prone to infection, followed by internal jugular catheters; the latter is probably the result of contamination with oropharyngeal secretions and difficulty with immobilization. Subclavian catheters are least prone to infection.

B. Laboratory Findings—Local catheter-related infections (eg, exit-site or tunnel infections) may be associated with few or no laboratory abnormalities. Culture of drainage fluid or exudate associated with the exit site may be helpful in determining a causative organism.

Bacteremia (positive blood cultures) may be related to intravascular devices and may occur with or without sepsis. Device-related bacteremia has been defined using quantitative blood culture techniques. A device-related bacteremia is defined as (1) more than a 5–10-fold increase in colony-forming units of bacteria per milliliter of blood obtained through the device compared with blood drawn from a distant peripheral vein, (2) in the absence of positive peripheral blood cultures, more than 1000 cfu/mL in blood obtained through the device, or (3) organisms isolated from a catheter tip on removal in the appropriate clinical setting. When no other clinical source of infection is evident, resolution of fever on removal of the device is also suggestive of catheter-related infection.

Differential Diagnosis

Exit-site, catheter-tunnel, or catheter infection must be differentiated from chemical phlebitis, which can cause erythema, tenderness, and induration of the vessel wall and overlying skin. Fever also may be present in chemical phlebitis, but systemic symptoms and signs consistent with sepsis are absent, and exudate cannot be expressed from the exit site. Thrombophlebitis may complicate catheter-related infection. Pain, tenderness, and erythema at the infected site, as well as edema distal to the site, are common presenting signs. Thrombosis of a central venous catheter can cause edema proximal to the site of thrombosis, but tenderness, erythema, and fever are typically absent. Catheter tip sepsis usually presents with no symptoms or signs of local infection and must be differentiated from infection from any other source.

Treatment

A. Exit-Site Infections—Short-term catheters suspected of being infected should be removed. However, there is increasing

interest in maintaining long-term catheters in the presence of certain infections. Few data are available to assist in developing recommendations regarding removal or maintenance of an infected long-term catheter. From the published data that do exist, it appears that treatment of an infected catheter with antibiotics alone is successful in about 50% of cases. Thus, in some settings, it may be reasonable to attempt to eradicate a long-term catheter exit-site infection with local care plus intravenous antibiotics. Empirical therapy should include vancomycin to cover coagulase-negative staphylococci and *S. aureus*, as well as an aminoglycoside or a cephalosporin with activity against *P. aeruginosa* and other gram-negative bacilli. Definitive therapy can be selected using culture results. If there is no response within a few days, or if the exit-site infection appears to be progressing to involve the catheter tunnel—or if fungi or resistant bacteria are isolated—the catheter should be removed.

B. Tunnel Infections—Patients with tunnel infections require removal of the catheter for definitive therapy. The tunnel itself may require surgical incision and debridement. Empirical antibiotic therapy should consist of vancomycin to treat coagulase-negative staphylococci and *S. aureus* and a third-generation cephalosporin or an aminoglycoside to treat gram-negative bacilli.

C. Catheter-Tip Sepsis—Short-term catheters should be removed and antibiotics administered. For a long-term catheter, catheter-tip sepsis may be treated initially with intravenous antibiotics while leaving the catheter in place. However, if the patient is in septic shock, the long-term catheter should be removed immediately. Vancomycin in conjunction with a third-generation cephalosporin or aminoglycoside is appropriate initial therapy. Definitive therapy should be guided by the results of the blood culture. Patients should be treated for a total of 2–3 weeks. Catheter-tip sepsis in certain patient populations mandates immediate removal of a long-term catheter. These include patients with neutropenia, severe immunocompromise, persistent bacteremia or sepsis despite appropriate antibiotics, septic thrombosis, and those whose catheters are infected with *S. aureus*, *Candida* or other fungi, or antibiotic-resistant bacteria.

Management decisions must be based on the clinical circumstance. The intravascular device should be removed immediately in any patient in whom rapid resolution of the signs of infection does not occur. It should be emphasized that neutropenic patients may not develop the classic local signs of infection; therefore, the diagnosis of catheter-associated infection in these patients may be difficult.

Finally, the risk of catheter-related infection may be significantly reduced by appropriate care of the catheter and by observing strict hand washing, dressing, and glove precautions.

Current Controversies and Unresolved Issues

A. Prevention of Catheter-Related Infection—The challenge of preventing intravenous catheter infections in the ICU while providing reliable access for intravenous

antimicrobial therapy, total parenteral nutrition, hemodynamic monitoring, or temporary hemodialysis is daunting. Many recommendations have been put forward for prevention of catheter-related infections, but only a few are supported by data. The most important are (1) use of full sterile barrier precautions during insertion; (2) skin decontamination with chlorhexidine; and (3) routine inspection and care of the catheter site.

Recently, the use of antibiotic-impregnated catheters has been proposed in an attempt to decrease the incidence of catheter-site colonization and subsequent bloodstream infection. A meta-analysis suggested that central venous catheters impregnated with chlorhexidine–silver sulfadiazine were effective in decreasing catheter-related bacteremia in patients at high risk for infection (ie, patients who require short-term catheters and multilumen catheters). Minocycline-rifampin-impregnated central venous catheters (CVCs) appear to have a lower rate of catheter-related bacteremia. Second-generation antiseptic catheters reduced colonization of bacteria on the catheters at the time of removal. The impact of these catheters on the development of subsequent infection is not as clear.

The cost associated with catheter-tip sepsis has been estimated to be about \$6000 per bacteremic episode. Adopting approaches to decrease catheter infection will reduce morbidity and the overall cost of care.

B. Diagnosis of Catheter-Related Bacteremia—The laboratory diagnosis of catheter-related bacteremia continues to be difficult. Semiquantitative culture of the external surface of the catheter tip is the method used most often to detect catheter colonization and device-related bacteremia. However, this method may fail to detect significant colonization of the internal lumens of catheters. Several quantitative methods have been described, including time to positivity and quantitative blood cultures drawn through the catheter (compared with peripheral blood cultures).

C. Duration of Intravascular Catheter Use—Recent studies have attempted to clarify the utility of routine change of the catheter site and the safety of exchanging a central venous catheter over a guidewire. Pulmonary artery catheters—despite the need for manipulation of the catheter during measurements—can be left in place unless there is unexplained fever, positive blood culture, or evidence of skin-site infection. However, maintenance of a catheter at a given site for a maximum of 7 days would appear to be a reasonable limit. Central venous catheters may be left in place without a predetermined duration of placement; they should be removed in the presence of a positive blood culture, an infected insertion site, suspicion of catheter-related infection, or when there is no further need for the catheter. It does not appear that routine replacement of central venous catheters is indicated.

Microorganisms most commonly cause catheter-related infection by migrating along the outer site of the catheter from the skin surface to the tip. Nevertheless the, exchange of

a central venous or pulmonary artery catheter at the same site using a guidewire has become accepted practice in many ICUs if no evidence of catheter infection is present.

▶ Clostridium Difficile–Associated Diarrhea

ESSENTIALS OF DIAGNOSIS

- ▶ Watery diarrhea and low-grade fever.
- ▶ Previous or current treatment with antibiotics—but may occur as long as 6 weeks after antibiotic has been stopped.
- ▶ Presence of *C. difficile* toxin in stool.
- ▶ Sigmoidoscopy may reveal white or yellow plaques of pseudomembranous colitis.

General Considerations

Diarrhea developing in an ICU patient can be due to infectious or noninfectious causes. The most important infectious cause of nosocomial diarrhea is infection with *C. difficile*. Nosocomial gastroenteritis caused by *Salmonella*, *Shigella*, *E. coli*, and *Campylobacter* is exceedingly rare and should be considered only in outbreak situations.

At least two things must occur for a patient to develop *C. difficile*-associated diarrhea: acquisition of or colonization with *C. difficile* and administration of an inducing agent. More than 20% of patients hospitalized for over a week become colonized with *C. difficile*. The risk of acquisition of *C. difficile* increases with length of hospital stay, reaching 50% in patients hospitalized over 1 month. It appears that the administration of certain antibiotics or chemotherapeutic agents induce the organisms to elaborate toxins: toxin A is an enterotoxin, and toxin B is a cytotoxin. The spectrum of disease encountered

with this disorder ranges from simple diarrhea to pseudomembranous colitis, rarely complicated by toxic megacolon, which can result in colonic perforation and death.

The most common antibiotics implicated in the development of *C. difficile*-associated diarrhea are ampicillin, clindamycin, and the cephalosporins. Antibiotics less commonly associated include trimethoprim-sulfamethoxazole, the quinolones, aztreonam, the carbapenems, and metronidazole. Vancomycin, erythromycin, tetracycline, and the aminoglycosides rarely cause *C. difficile*-associated diarrhea. Although the disorder is often self-limited, resolving when antibiotics are stopped and treatment is initiated, severe complications may occur. Recently, *C. difficile* strains associated with quinolone and cephalosporin use have been responsible for several ICU outbreaks. The presence of this particularly virulent *C. difficile* led to increased attributable mortality in these patients.

Clinical Features

A. Symptoms and Signs—*C. difficile* typically produces watery diarrhea and low-grade fever with or without abdominal pain. Diarrhea may develop after a single dose of an antibiotic or may be delayed as long as 6 weeks following the last dose of the antimicrobial agent. If the patient develops pseudomembranous colitis, sigmoidoscopy may reveal characteristic white or yellow plaques or pseudomembranes. Patients may become seriously ill, with fluid and electrolyte imbalance, toxic megacolon, and colonic perforation.

B. Laboratory Findings—It is recommended that diarrheal stools of patients who have been hospitalized for more than 72 hours with a history of prior antibiotic use be evaluated for *C. difficile*-associated diarrhea. The diagnosis rests on the identification of *C. difficile* toxin in the stool. The most sensitive and specific test for this disorder is a tissue culture assay for toxin B cytotoxicity, with a sensitivity of 94–100% and a specificity of 99%. However, this test is cumbersome to perform and takes 1–3 days to complete. Enzyme-linked immunoassays for identification of toxins A and B have a sensitivity of 63–99% and a specificity of 75–100%. In 20% of patients, toxin assays on multiple stool samples may be required to demonstrate the presence of the toxin.

Identification of fecal leukocytes is neither sensitive nor specific for *C. difficile*-associated diarrhea. Nosocomial acquisition of enteric pathogens such as *Salmonella*, *Shigella*, and *C. jejuni* is extremely rare; thus, performing routine stool cultures is not cost-effective in hospitalized patients with diarrhea.

Differential Diagnosis

Noninfectious causes of nosocomial diarrhea include various medications, enteral feeding, inflammatory bowel disease, ischemic colitis, GI bleeding from a variety of lesions, and systemic illness. Antimicrobial administration can cause diarrhea by altering normal bowel flora (eg, ceftriaxone, tetracycline, and amoxicillin-clavulanic acid) or by bowel irritation (eg, erythromycin). Infectious causes of nosocomial

diarrhea are rare and include enteric pathogens and cytomegalovirus colitis in the immunocompromised host.

Treatment

If antibiotic-associated colitis develops in patients receiving antibiotic therapy, improvement often occurs with discontinuation of antibiotics. Specific antimicrobial therapy should be administered to those with persistent diarrhea or in patients with severe illness. Asymptomatic carriers of *C. difficile* should not be treated because doing so may prolong the carrier state. Oral vancomycin and metronidazole are equally effective for most patients. Metronidazole is less expensive and does not exert selective pressure for vancomycin-resistant enterococci; for these reasons, it is thus the agent of choice. It should be given at a dose of 500 mg orally three times a day for 10–14 days. In patients unable to tolerate oral medications, intravenous metronidazole at a dose of 500 mg every 8 hours can be used as initial therapy. Vancomycin is recommended at a dosage of 125–250 mg orally every 6 hours for 10–14 days in the event of treatment failure, for persistent symptoms, or probably for severe cases. As many as 20% of patients will relapse within the first 2 weeks of completing a course of treatment, although most will respond to a second course of metronidazole. Risk factors for relapse include chronic renal failure, multiple previous episodes of *C. difficile*-associated diarrhea, continuation of other antimicrobial therapy, community-acquired *C. difficile*-associated diarrhea, and high white blood cell counts.

Patients diagnosed with or suspected of having *C. difficile*-associated diarrhea should be managed with enteric precautions. The organism is particularly well suited to survive for prolonged periods on a variety of surfaces and has been cultured from hospital carpeting, beds, and walls. It is easily transmitted by the hands of hospital personnel from patient to patient. Therefore, appropriate isolation precautions are essential when caring for these patients. Note that conventional handwashing is necessary for hospital personnel because alcohol-based hand cleansers do not kill *C. difficile* spores.

It has become clear that *C. difficile* is a significant nosocomial pathogen; thus prevention and control in the hospital setting are crucial. *C. difficile*-associated diarrhea has been strongly associated with the use of certain antimicrobial agents, so alteration of patterns of antimicrobial use may be helpful in reducing its incidence.

Given the high recurrence rate of *C. difficile*-associated diarrhea, various non-antimicrobial approaches have been employed to allow the bowel to reestablish its normal flora, such as oral administration of *Saccharomyces boulardii*, lactobacilli, or normal fecal flora. However, these strategies have not been adequately studied to support formal recommendations.

▶ Hematogenously Disseminated Candidiasis

ESSENTIALS OF DIAGNOSIS

- ▶ Fever despite broad-spectrum antibacterial therapy and negative bacterial blood cultures.
- ▶ Possible skin manifestations.
- ▶ Consider in neutropenic hosts and patients with long-term vascular access.

General Considerations

Candida species are an increasing cause of nosocomial bloodstream infections and are associated with high rates of mortality and morbidity. Patients at increased risk for hematogenously disseminated candidiasis include those with extensive burns, indwelling venous catheters, broad-spectrum antibiotic exposure, immunosuppression (especially neutropenia), severe mucositis, previous surgical procedures (particularly GI surgery), total parenteral nutrition, concomitant bacteria or other infections, and mucosal colonization by *Candida* species. Mortality from candidemia is highest among those patients with high APACHE II scores, severe underlying disease, and persistent candidemia despite appropriate antifungal therapy.

Microbiologic Etiology

C. albicans is the species most commonly isolated from blood cultures; however, recent emergence of non-*albicans* species has been noted, most notably an increase in the incidence of *C. glabrata*. Why non-*albicans* species are increasingly isolated is not entirely clear. However, the widespread use of empirical fluconazole may exert selective pressure leading to the emergence of *Candida* species that are less sensitive to the triazoles.

Fungemia caused by *C. tropicalis* usually occurs as a result of endogenous infection, although cases of nosocomial transmission also have been documented. Most isolates of *C. tropicalis* are sensitive to amphotericin B, flucytosine, and the triazoles. *C. glabrata*, a pathogen with decreased susceptibility to fluconazole, is the second most common *Candida* species isolated in nosocomial bloodstream infections.

C. parapsilosis infection occurs almost exclusively in the presence of indwelling venous catheters, prosthetic devices, or invasive devices and is not usually a member of the patient's endogenous flora. This organism is usually susceptible to both amphotericin B and fluconazole. *C. krusei* is considered to be resistant to fluconazole and is seen most commonly in neutropenic patients, especially those receiving fluconazole for antifungal prophylaxis or empirical therapy.

Clinical Features

A. Symptoms and Signs—Most patients with hematogenously disseminated candidiasis have no systemic symptoms or signs of infection other than persistent fever in the setting of broad-spectrum antibiotics. Careful physical examination should be performed to assess the presence of skin lesions characteristic of candidemia. Three types of lesions have been described with hematogenously disseminated candidiasis: The classic lesion is macronodular, erythematous, and 0.5–1 cm in diameter. Lesions resembling ecthyma gangrenosum and purpura fulminans also have been described. In all three types of lesions, the organisms are seen readily on histopathologic examination of punch biopsy specimens. Any new neurologic symptom should prompt a CT scan or MRI of the brain because candidal micro- and macroabscesses of the CNS have been described in patients with candidemia. Patients should undergo daily physical examination looking for new cardiac murmurs, bone or joint findings, and hepatosplenomegaly. Endocarditis, osteomyelitis, arthritis, and hepatosplenic candidiasis are all documented complications of candidemia. All patients should have a thorough ophthalmoscopic examination to rule out candidal endophthalmitis, typically appearing as white “cotton ball” lesions that may extend into the vitreous.

B. Laboratory Findings—Laboratory findings in hematogenously disseminated candidiasis are nonspecific. The rate of pre-mortem diagnosis of disseminated candidemia is typically low. With the development of new blood culturing techniques such as the BACTEC system, the yield of positive blood cultures for *Candida* has increased, although it is still less than 50%. Thus the diagnosis is made mainly on clinical grounds. Appropriate imaging studies should be obtained when there is suspicion of end-organ dissemination; biopsy of suspicious lesions should be pursued to look for histopathologic evidence of invasive candidal infection.

Treatment

A. Empirical Antifungal Therapy—The diagnosis of hematogenously disseminated candidemia typically is made on clinical grounds, and patients are often treated empirically based on the presence of multiple risk factors or evidence for mucosal colonization with *Candida* species. A critical intervention in the treatment of candidemia is the removal of all potentially infected venous catheters, especially in neutropenic patients.

The antifungal agent of choice depends on the clinical status of the patient and the physician's knowledge of the possible infecting *Candida* species. In the pretriazole era, amphotericin B was used exclusively in all patients with suspected or documented fungal infection. However, data now suggest that in a nonneutropenic patient who is hemodynamically stable, fluconazole will provide response rates of 60–100%. Factors that may prompt the physician to use amphotericin B as empirical therapy include hemodynamic instability or known colonization of the patient with non-*albicans* species, such as *C. glabrata* or *C. krusei*. Caspofungin or micafungin are other alternatives. There is general agreement that a neutropenic patient with suspected invasive fungal infection should receive amphotericin B, micafungin or caspofungin. Flucytosine may be used in combination with either amphotericin B, micafungin or fluconazole in severe infections. Itraconazole is available in an intravenous formulation, but formal studies to support recommendations for its use have not been completed.

▶ Antimicrobial Resistance in the ICU

Critically ill patients often receive broad-spectrum antimicrobial therapy during their hospitalization; thus the ICU is fertile ground for the emergence of antimicrobial resistance. In this section, specific resistance problems encountered in the ICU will be reviewed, including vancomycin-resistant enterococci, methicillin-resistant *S. aureus*, glycopeptide-insensitive *S. aureus*, gram-negative bacilli with extended-spectrum β -lactamases, gram-negative bacilli that produce group 1 β -lactamases, and *Acinetobacter baumannii*.

Vancomycin-Resistant Enterococci

A. Incidence—Enterococci are normal inhabitants of the GI tract and generally are considered to be organisms of low virulence. Patients with serious nosocomial infections caused by enterococci have high morbidity and mortality rates owing to their underlying disease. In the past, most enterococcal infections were caused by *E. faecalis*, and only about 5–10% of infections owing to enterococci were due to *E. faecium*. However, the emergence of glycopeptide-resistant *E. faecium* has led to a shift in the relative frequency of infection with this species. The most common site of origin of enterococcal infection is the urinary tract, followed by intraabdominal or pelvic infection as part of a polymicrobial process. Bacteremia usually occurs as a complication of one of the

preceding or may result from infection of an indwelling venous catheter or prosthetic device.

National nosocomial surveys have demonstrated an increase in the prevalence of vancomycin-resistant enterococci among enterococcal isolates to levels of 25% or greater. Case-control studies have identified several risk factors for acquisition of vancomycin-resistant enterococci. Host factors include advanced age, severity of underlying disease, hematologic malignancy, neutropenia, cirrhosis, hemodialysis, recent intraabdominal surgery, prior nosocomial infection, the presence of pressure sores, prolonged hospitalization, invasive procedures, contact with another person colonized or infected with vancomycin-resistant enterococci, and previous antimicrobial therapy (especially with a third-generation cephalosporin and vancomycin). Patients in certain health care settings, including long-term care facilities, outpatient dialysis units, ICUs, and oncology or transplant wards, have the highest prevalence of vancomycin-resistant enterococci carriage.

B. Mechanism of Resistance—Enterococci develop resistance to vancomycin through acquisition of genes conferring resistance; these genes are specified as *vanA* or *vanB*. The most common phenotype, *vanA*, is transmitted by a transposon and confers high-level resistance to vancomycin and teicoplanin. The *vanB* phenotype is chromosomally based and confers variable resistance to vancomycin while maintaining susceptibility to teicoplanin. Both phenotypes are easily transferable among different enterococci via conjugation. The mechanism of resistance involves a change in the cell wall building block, D-alanine-D-alanine, the target site for vancomycin, to D-alanine-D-lactate.

C. Therapy—Treatment of serious vancomycin-resistant enterococcal infections is difficult. Many strains are resistant to ampicillin and aminoglycosides, so the remaining options are few in number, and antienterococcal activity is limited. Carbapenems, fluoroquinolones, tetracyclines, chloramphenicol, rifampin, novobiocin, and nitrofurantoin all have been used in various combinations in an attempt to treat infection with vancomycin-resistant enterococci. Quinupristin-dalfopristin, linezolid, and daptomycin are drugs recently licensed in the United States that include vancomycin-resistant enterococci in their spectrum of activity. Urinary tract infections may be treated successfully with nitrofurantoin and removal of the urinary catheter. Mixed infections, such as intraabdominal abscesses or skin and soft tissue infections, should undergo aggressive debridement. Indwelling venous catheters and prosthetic devices should be removed whenever possible. Treatment of serious vancomycin-resistant enterococcal infection should include at least two antimicrobial agents to which the organism is susceptible, and one of these should be an aminoglycoside unless the class is contraindicated or resistance is present.

D. Prevention—In the United States, most carriage of vancomycin-resistant enterococci and outbreaks of infection are

due to patient-to-patient spread. Thus strict infection control measures are necessary to prevent spread and persistence of the organisms. Strict contact isolation should be observed for any patient infected or colonized with the organism. In addition, the use of empirical vancomycin for the treatment of hospitalized patients should be limited to those with clear indications.

Methicillin-Resistant *S. aureus* (MRSA)

A. Incidence—The National Nosocomial Infection Surveillance surveys have demonstrated an increase in the percentage of MRSA from about 2–3% of all *S. aureus* isolates in 1975 to over 50% in the current era. The incidence of community-acquired MRSA is also increasing. The major route of spread of MRSA is direct patient-to-patient contact or via the hands of medical personnel. Common sites of MRSA colonization include the anterior nares, wounds, burns or other areas of decreased skin integrity, the perineal area, the upper respiratory tract, and the skin adjacent to invasive devices, gastrostomy tubes, and tracheostomies. Risk factors for both colonization and infection with MRSA include previous hospitalization, prolonged hospital stay, hospitalization in a burn unit or ICU, chronic prior antimicrobial therapy, exposure to a colonized health care worker or patient, the presence of surgical wounds or burns, and the use of invasive devices.

B. Mechanism of Resistance—Resistance of *S. aureus* to methicillin is transmitted chromosomally via the *mecA* gene. Acquisition of this gene results in altered penicillin-binding protein 2A. Presence of the *mecA* gene is also associated with resistance to other antibiotics, including all β -lactams, aminoglycosides, macrolides, tetracycline, rifampin, and fluoroquinolones.

C. Therapy—Most strains of MRSA are sensitive to the glycopeptide vancomycin. In the United States, vancomycin is the drug of choice for serious infections with MRSA. There may be a role for quinupristin-dalfopristin, linezolid, and daptomycin in the treatment of infections with this organism. Eradication of MRSA carriage may be attempted with either topical or systemic antimicrobials or by bathing with antiseptic soaps. The efficacy of any of these approaches in eradication is inconsistent and often incomplete. Many community-acquired strains of MRSA are susceptible to trimethoprim-sulfamethoxazole, clindamycin, rifampin, and in some cases macrolides.

Vancomycin-Insensitive *S. aureus* (VISA) and Vancomycin-Resistant *S. aureus* (VRSA)

A. Incidence—The emergence of VISA is probably the most disturbing development to occur in the antibiotic era. Vancomycin insensitivity among *S. aureus* is defined as an MIC to vancomycin of 8–16 $\mu\text{g}/\text{mL}$. The first reported case of infection with this organism occurred in Japan in May of 1996. Most patients with VISA were on hemodialysis, and

most had had recurrent MRSA bacteremias that were treated with prolonged courses of vancomycin. The first case of vancomycin-resistant *S. aureus* (MIC to vancomycin of 32 $\mu\text{g}/\text{dL}$ or more) was reported in 2002, with only a few additional cases reported subsequently.

B. Mechanism of Resistance—The mechanism of vancomycin insensitivity is not clear. Scanning and transmission electron microscopy of the insensitive organisms show a thickened bacterial cell wall. A fully vancomycin-resistant *S. aureus* strain has been created in vitro, demonstrating a similarly thickened bacterial cell wall. It is hypothesized that decreased vancomycin access to the target sites may occur as a result of sequestration of the drug in the cell wall. Full vancomycin resistance is mediated via the *vanA* gene, which confers vancomycin resistance to enterococci.

C. Therapy—Therapy of VISA and VRSA infection is not standardized; thus antimicrobial therapy should be based on the organism's susceptibility profile. Preliminary in vitro data suggest that as the bacteria become more resistant to vancomycin, they become more susceptible to oxacillin. Thus there may be a role for combination therapy with vancomycin and oxacillin in infections with VISA. A role for quinupristin-dalfopristin, linezolid, and daptomycin in the treatment of these infections is a possibility as well.

Gram-Negative Bacilli Producing Extended-Spectrum β -Lactamases (ESBLs)

A. Incidence—Bacterial strains with ESBLs were first identified in the mid-1980s. Most are strains of *K. pneumoniae* or *E. coli*. ESBL production has been noted in other species of Enterobacteriaceae as well but with much lower frequency. The actual incidence of ESBL-producing strains is difficult to quantify because surveillance and reporting are incomplete. Most strains are isolated from hospitalized patients. Risk factors for acquisition include prolonged hospital stay; severity of illness; admission to an ICU, oncology unit, or nursing home; emergency surgical or invasive procedures; central venous, arterial, or urinary catheterization; and prior extended-spectrum cephalosporin use. Notably, outbreaks with ESBL-producing strains have been linked to heavy ceftazidime use within a hospital.

B. Mechanism of Resistance—The ESBLs are descendants of the β -lactamases responsible for ampicillin resistance in *E. coli* and penicillin resistance in *K. pneumoniae*. This plasmid-mediated gene confers resistance not only to the extended-spectrum cephalosporins but also to aztreonam. The gene also may encode resistance to aminoglycosides, tetracyclines, trimethoprim-sulfamethoxazole, and chloramphenicol. The plasmids bearing these genes are stable and are easily transmissible from bacteria to bacteria.

C. Therapy—On routine susceptibility testing, ESBL-producing strains may appear to be sensitive to the extended-spectrum cephalosporins and aztreonam. Clues to

the presence of an ESBL-producing strain are (1) clinical failure in the setting of “appropriate” antimicrobial therapy, (2) presence of resistance to certain antibiotics, such as aminoglycosides, tetracyclines, trimethoprim-sulfamethoxazole, and chloramphenicol, which are often transmitted on the same plasmid as the ESBL, and (3) diminished susceptibility to ceftriaxone, ceftazidime, or aztreonam (if this pattern is seen, resistance to all extended-spectrum cephalosporins and aztreonam should be presumed). ESBL-producing organisms usually display susceptibility to cephamycins (eg, cefotetan and cefoxitin) and the carbapenems, with variable susceptibility to the β -lactam/ β -lactamase inhibitor combinations. Carbapenems are the mainstay of therapy in the seriously ill patient infected with an ESBL-producing organism because cases of cephamycin resistance have been reported to emerge during the course of cephamycin therapy.

Gram-Negative Bacilli Producing Group 1 β -Lactamases

A. Incidence—Group 1 β -lactamases are chromosomally based β -lactamases. The most commonly encountered organisms with group 1 β -lactamase production are *Enterobacter* species, *P. aeruginosa*, *Citrobacter* species, *S. marcescens*, and some *Proteus* species. According to the National Nosocomial Infection Surveillance System, infections owing to these organisms have been increasing in incidence. This recent trend is of concern given the resistance of these pathogens to extended-spectrum cephalosporins, with documented cephalosporin resistance developing even while on appropriate therapy. Risk factors for acquisition of these pathogens include prior therapy with ceftizoxime, cefotaxime, or ceftazidime and perhaps with extended-spectrum penicillins—as well as length of previous antimicrobial therapy.

B. Mechanism of Resistance—The mechanism of resistance of group 1 β -lactamase-producing organisms is induction of a chromosomally based gene that encodes for production of a group 1 β -lactamase (a cephalosporinase) that inactivates all cephalosporins.

C. Therapy—Therapy should be based on antimicrobial susceptibility data for a given strain. These organisms usually retain their sensitivity to the carbapenems and the fluoroquinolones. Emergence of resistance in the setting of ongoing antimicrobial therapy occurs in approximately 5% of patients and is more likely to occur with use of a third-generation cephalosporin rather than an aminoglycoside or an extended-spectrum penicillin. Whether combination therapy will decrease the risk of emerging resistance is not yet known. At this time, it appears that monotherapy with an extended-spectrum cephalosporin should be avoided when treating infection caused by group 1 β -lactamase-producing organisms.

Acinetobacter baumannii

A. Incidence—*A. baumannii* is a gram-negative coccobacillus that may occur as a normal skin colonizer. It is considered to

be relatively nonvirulent; however, the worldwide emergence of this organism has been noted increasingly in the nosocomial setting, sometimes in persistent outbreaks in ICUs. The treatment challenge with this organism results from its inherent resistance to a wide array of antimicrobial agents. Risk factors for infection include underlying illness, prior broad-spectrum antimicrobial therapy use, length of ICU stay with use of invasive devices, and prior colonization with the organism.

B. Mechanism of Resistance—The mechanism of resistance to the β -lactam drugs is the production of a plasmid-mediated penicillinase. Resistance to cephalosporins occurs as a result of overproduction of a chromosomal cephalosporinase.

C. Therapy—As with most multidrug-resistant pathogens, therapy should be based on available susceptibility data. However, pending such information, one of the carbapenems can be considered for empirical therapy because these agents tend to retain their activity against *A. baumannii*. There is, however, increasing resistance owing to bacterial production of carbapenemases. Other considerations include tigecycline and colistin.

Infection Control Concepts

The specter of antimicrobial resistance increasingly threatens physicians' ability to treat bacterial infections. To complicate matters, there is limited development of new antimicrobial agents targeting resistant bacteria. Numerous studies have demonstrated a stepwise increase in incidence of drug resistance from the community to the general inpatient ward to the ICU. Control of antimicrobial resistance is the responsibility of every critical care physician. This can be broken down into two critical components: (1) prevention of emergence of new resistance mechanisms or resistant species and (2) prevention of spread of organisms from patient to patient.

A. Prevention of Emergence of Resistance—The central component of prevention is reducing selection pressure for resistance by judicious use of antimicrobials. Several studies have demonstrated that while overuse of antibiotics can foster antimicrobial resistance, changes in antibiotic use can result in recovery of susceptibility. Judicious antimicrobial use includes careful consideration of which patients are appropriate candidates for antimicrobial therapy, when antimicrobial therapy should be initiated, which antimicrobial agents should be administered, and for what duration. The goal of antimicrobial therapy in the ICU is to expeditiously treat a seriously ill patient with suspected or confirmed infection with the appropriate agent(s). The physician should make every attempt to differentiate between true bacterial infection and simple colonization. Moreover, it should be kept in mind that not all fever is the result of infection; when no source of infection can be identified, noninfectious causes of fever should be considered (Table 15–7). Prophylactic use of antimicrobial agents should be avoided in the absence of a clear indication.

Table 15-7. Some noninfectious causes of fever in the ICU.

Common causes

Drug fever
Malignancy
Deep venous thrombosis
Posttransfusion
Postoperative (atelectasis)
Thrombophlebitis
Chemical aspiration pneumonitis

Less common causes

Hyperthyroidism
Adrenal insufficiency
Transplant rejection
Alcohol withdrawal, drug withdrawal
Pancreatitis
Pulmonary embolism
Hematoma

Much controversy surrounds the empirical use of combination therapy (eg, a β -lactam plus an aminoglycoside) in a patient suspected of being infected with an aerobic gram-negative bacillus. Some in vitro data suggest that combination therapy may decrease the emergence of chromosomally mediated resistance, although it actually may worsen plasmid-mediated resistance. While it is acceptable to use broad-spectrum empirical antimicrobial therapy initially, antibiotics should be tailored once culture data become available. In addition, focal collections of purulent material should be drained whenever possible to decrease inoculum size, thereby improving the outcome of antimicrobial therapy. Prolonged courses or inappropriately broad-spectrum antibiotics should be avoided.

B. Prevention of Spread of Infection—Prevention of nosocomial spread of infection involves prompt identification of patients colonized or infected with multidrug-resistant organisms plus rapid institution of appropriate isolation procedures. Even in wards or ICUs not known to have patients colonized or infected with multidrug-resistant organisms, routine hand washing with antiseptic soaps or use of alcohol-based cleansers by all health care personnel is critical.

BOTULISM & TETANUS

Patients with botulism and tetanus have primarily neurologic complications that almost always require management in an ICU. Both disorders are caused by toxins produced by clostridia. In tetanus, patients have traumatic or surgical wounds contaminated by *C. tetani*. Most cases of botulism are due to ingestion of preformed food-borne toxin; however, botulism may result from toxin produced by cutaneous infection with *C. botulinum*.

▶ Botulism

ESSENTIALS OF DIAGNOSIS

- ▶ Nausea, vomiting, dysphagia, diplopia, dilated and fixed pupils.
- ▶ Sudden weakness in a previously healthy person.
- ▶ Cranial nerves affected first (except I and II), followed by descending symmetric paralysis or weakness.
- ▶ Autonomic nervous system involvement: paralytic ileus, gastric dilation, urinary retention, and orthostatic hypotension.
- ▶ Absence of sensory or mental status changes.
- ▶ Botulism toxin isolated from serum, stool, or other body fluids.

General Considerations

Botulism is an acute neurologic disorder caused by the production of a neurotoxin produced by *C. botulinum*. Improperly canned or home-prepared foods are common sources of the toxin. There are three clinical forms of botulism: food-borne botulism, wound botulism, and infant botulism. Infant botulism results from the ingestion of botulism spores, which germinate in the intestine and produce toxin. Most infants recover with supportive care only. Food-borne and wound botulism are generally more serious illnesses.

A. *C. botulinum* and Botulism Toxins—*C. botulinum* is an anaerobic gram-positive rod that survives in soil and marine

sediment by spore formation. Under anaerobic conditions that permit germination, toxin production occurs. Although boiling for 10 minutes will kill bacteria and destroy toxins, spores are heat-resistant and can survive boiling for 3–5 hours. Food contaminated by botulism toxin may have no detectable change in appearance or taste.

Botulism toxin is the most potent toxin known on a per-weight basis. Eight immunologically distinct toxins have been described: A, B, C α and C β , D, E, F, and G. Each strain of *C. botulinum* can produce only a single toxin type. Toxins A, B, and E have been the most common causes of human disease. Toxins A and B are the most potent; even small tastes of food contaminated with these toxins have resulted in full-blown disease.

Specific *C. botulinum* toxins appear to be geographically distributed throughout the world. In the United States, toxin A is found predominantly west of the Mississippi, whereas toxin B is found in the eastern states. Toxin E is found in the Great Lakes region and in Alaska, where one of the highest rates of botulism worldwide is seen.

Toxins produced by *C. botulinum* block acetylcholine release at peripheral neuromuscular and autonomic nerve junctions, resulting in weakness, flaccid paralysis, and sometimes respiratory failure. Toxin binding is irreversible.

B. Food-Borne Botulism—Botulism toxins are large proteins. In food-borne botulism, ingested preformed toxin is absorbed in the stomach and upper small intestine. Toxins are reduced in size by proteolytic enzymes, but their activity remains unchanged. Pancreatic trypsin actually may enhance the toxicity of some toxin strains. In addition to improperly home-canned foods, outbreaks of botulism have been traced to noncanned foods such as eviscerated dried fish, yogurt flavored with hazelnut conserve, a garlic-in-oil product, homemade salsa, cheese sauce, baked potatoes sealed in aluminum foil, and sautéed onions stored under a layer of butter.

Botulism toxin has potential as a weapon of bioterrorism, both from ingestion and by inhalation. Clinical findings would be identical, but possible features would include a large outbreak with common environmental exposure, an unusual toxin type, or multiple simultaneous outbreaks.

C. Wound Botulism—Wound botulism results when *C. botulinum* grows and produces toxin in traumatized, devitalized tissue. The wound may appear insignificant. Toxin production is followed by onset of symptoms after an incubation period of 4–14 days. Many cases of wound botulism have occurred in teenagers, children, and injection drug users. Sinus infection with *C. botulinum* has been reported after intranasal cocaine use; evidence suggests that botulism toxin can be inhaled or inoculated through the eye. In recent years, there has been a dramatic increase in the number of cases of wound botulism linked to the subcutaneous injection of impure “black tar” heroin imported from Mexico, perhaps the result of contamination of the drug during the “cutting” process with adulterants such as dirt.

D. Adult Infectious Botulism—While most cases of adult botulism are the result of ingested preformed toxin, there have been cases of botulism in patients with documented *C. botulinum* colonization of the intestinal tract. Risk factors include abdominal surgery, GI tract abnormalities, and recent antibiotic administration, all of which presumably alter the normal GI flora.

Clinical Features

The diagnosis of food-borne botulism should be considered when an acute illness with GI or neurologic manifestations affects two or more persons who have shared a meal during the preceding 72 hours. Wound botulism presents with similar neurologic symptoms but without GI complaints.

A. Symptoms and Signs—An initial pentad of signs and symptoms has been described in botulism, consisting of nausea and vomiting, dysphagia, diplopia, dilated and fixed pupils, and an extremely dry mouth unrelieved by drinking fluids. Over 90% of patients have at least three of these signs or symptoms. Symptoms can occur as early as 2 hours or as late as 8 days after toxin ingestion but usually occur within 18–36 hours. Onset of symptoms can be abrupt or may evolve over several days. Abnormalities of cranial nerve motor functions are followed by descending symmetric paralysis or weakness. Respiratory muscle weakness may be subtle or may progress rapidly to respiratory failure. Somatic musculature is affected last. Patients may develop autonomic nervous system manifestations, including constipation from paralytic ileus, gastric dilation, urinary retention, and orthostatic hypotension.

Notably absent in patients with botulism are sensory disturbances, changes in sensorium, and fever. Cranial nerves I and II are spared. Deep tendon reflexes may be intact, diminished, or absent, but pathologic reflexes cannot be demonstrated. In addition, the heart rate may be normal or slow unless secondary infection is present.

B. Laboratory Findings—The diagnosis of botulism is confirmed by isolating botulism toxin through a mouse neutralization bioassay. Toxin may be identified in samples of serum, stool, vomitus, gastric aspirate, and suspected foods. *C. botulinum* may be grown on selective media from samples of stool or foods. Specimens for toxin analysis should be refrigerated, but culture samples for *C. botulinum* should not. Because the toxin may enter the bloodstream through the eye or a small break in the skin, only experienced personnel, preferably immunized with botulinum toxoid, should handle specimens.

Electromyography may be useful in establishing a diagnosis of botulism but can be nonspecific and nondiagnostic even in severe cases. Low-amplitude and short-duration motor unit action potentials, small M-wave amplitudes, and posttetanic fasciculation may be seen. A modest increment in M-wave amplitude with rapid repetitive nerve stimulation may help to localize the disorder to the neuromuscular

junction. Single-fiber electromyography may be a more useful and sensitive method for the rapid diagnosis of botulism intoxication, particularly when signs of general muscular weakness are absent. Cerebrospinal fluid is normal.

Differential Diagnosis

Differentiating botulism from other diseases is critical to early implementation of appropriate therapy. [Table 15–8](#) lists diseases that must be differentiated from botulism.

Treatment

A. Supportive Care—Meticulous supportive care is essential for patients with all forms of botulism. If respiratory failure has not already occurred at the time of diagnosis, the patient should be hospitalized in a monitored setting with serial measurements of vital capacity. Respiratory failure can occur with unexpected rapidity. Pulmonary infections are a common complication of botulism, often the result of aspiration of oropharyngeal secretions or a complication of atelectasis. The development of fever should prompt an evaluation of possible pneumonia. Improvement in ventilatory and upper airway muscle strength in patients who develop respiratory failure is most significant over the first 12 weeks, but recovery may not be complete for up to a year.

Wound botulism requires thorough debridement of the infected wound and administration of penicillin in addition to antitoxin therapy.

B. Botulism Antitoxin—Botulism antitoxin should be administered to all patients with food-borne or wound botulism. Because only equine antitoxin is available, all patients first must undergo testing for hypersensitivity to equine serum. Twenty percent of patients will experience some degree of hypersensitivity, and anaphylaxis also can occur. Trivalent antitoxin for toxins A, B, and E is distributed through the Centers for Disease Control and Prevention. Polyvalent antitoxin for toxins A, B, C, D, E, and F is also available for specific outbreaks.

Antitoxin should be given as soon as available, but it may be beneficial even when given several weeks after toxin ingestion because circulating toxin can be detected in serum up to

30 days after intoxication. Antitoxin will not neutralize toxin already bound to neuromuscular junctions, and although it can slow disease progression, it has no effect on established neurologic impairment. Two vials of the appropriate antitoxin should be given, one intramuscularly and one intravenously. This regimen may be repeated after 2–4 hours.

Because of the risk of adverse reactions, prophylactic antitoxin is not recommended for those who have been exposed to botulism toxin but have no symptoms. If ingestion is recognized early, patients may undergo gastric lavage or induced vomiting in an attempt to eliminate the toxin prior to absorption.

Current Controversies and Unresolved Issues

Administration of antibiotics to patients with food-borne botulism is controversial, although some physicians give penicillin to eradicate potential bowel carriage of the organism. The benefit of this approach is uncertain.

Guanidine hydrochloride is thought to increase acetylcholine release from terminal nerve endings and is advocated by some in the treatment of botulism. Reports of its efficacy are conflicting.

▶ Tetanus

ESSENTIALS OF DIAGNOSIS

- ▶ Generalized weakness or stiffness, with trismus (“lock-jaw”) and severe generalized spasms.
- ▶ Opisthotonos and abdominal rigidity.
- ▶ Respiratory failure, tachycardia, hypertension, fever, and diaphoresis may be present.

General Considerations

Although entirely preventable by appropriate vaccination, tetanus still occurs in developing countries and infrequently in developed countries. It remains endemic in developing countries. In the United States, 50–70 cases are reported annually, typically in patients who have never received a primary immunization series with tetanus toxoid. Many elderly patients and patients born or raised in developing countries have not been vaccinated and are at risk. Elderly women may be at higher risk than elderly men because many men were vaccinated during military service. Male gender and black race are risk factors for tetanus in the United States, perhaps because of the higher incidence of trauma in these groups.

Table 15–8. Differential diagnosis of botulism.

Myasthenia gravis
Tick paralysis
Poliomyelitis
Guillain-Barré syndrome (Miller-Fisher variant)
Psychiatric disorder
Stroke (brain stem)
Rabies
Diphtheria
Eaton-Lambert syndrome

Injection drug users, particularly “skin poppers,” are predisposed to tetanus. Tetanus is more frequent in warmer climates and months in part because of the greater frequency of contaminated wounds. Tetanus is not transmitted from person to person.

A. *C. tetani* and Tetanospasmin—The clinical syndrome of tetanus is caused by a potent neurotoxin, tetanospasmin, released from *C. tetani*. A slender, motile, gram-positive nonencapsulated anaerobic rod, *C. tetani* is a spore-forming organism that is found commonly in nature. Spores may be found in soil and dust but are particularly common in areas contaminated with human or animal excreta. Spores may remain viable for years and then germinate when they are introduced into an appropriate anaerobic environment such as devitalized tissue. The presence of other bacterial organisms appears to enhance the reversion of spores to vegetative forms and the release of tetanospasmin.

B. Pathophysiology—Tetanospasmin migrates into the CNS either transsynaptically along peripheral motor nerves or by hematogenous or lymphatic routes. It binds to the presynaptic inhibitory neurons and prevents the release of acetylcholine from nerve terminals in muscle. The functional loss of inhibitory neurons allows lower motor neurons to increase muscle tone, producing rigidity and spasm of both agonist and antagonist muscles. Once tetanospasmin is fixed to nervous tissue, it cannot be neutralized by antitoxin. Tetanospasmin also binds to cerebral gangliosides, which may be the cause of seizures seen in tetanus. Disturbances of the autonomic nervous system are common, manifested by sweating, fluctuating blood pressure, tachycardia and cardiac arrhythmias, and increased production of catecholamines.

Clinical Features

Tetanus may occur in the neonate in the first month of life or as one of three patterns in adult patients. Generalized tetanus is the most common adult presentation. Local tetanus and, even more rarely, cephalic tetanus are manifested by local muscle spasms in areas contiguous with an infected wound. Both local and cephalic tetanus may progress to generalized tetanus. Tetanus is a diagnosis of exclusion. If the diagnosis is not considered, the opportunity for early treatment will be lost.

A. Introduction of *C. tetani*—The wound into which *C. tetani* has been introduced may appear insignificant. However, particularly high-risk wounds include those contaminated with dirt, feces, soil, or saliva, as well as any puncture wound, crush wound, burn, decubitus ulcer, or frostbite injury. Tetanus also has been reported following elective and emergency surgical procedures, particularly those involving the GI tract. The postpartum uterus is also susceptible to *C. tetani* infection. Thus tetanus should be considered in the postoperative patient who develops crampy abdominal pain and abdominal wall rigidity with no history of tetanus vaccination. *C. tetani* may be harbored in the middle ear (chronic

otitis media) and in wounds of the head, predisposing a patient to cephalic tetanus.

B. Symptoms and Signs—Tetanus can present 1–54 days following a puncture or other wound, but an incubation period shorter than 14 days is most common. Longer incubation periods generally are related to injury sites farther away from the CNS. Generalized weakness or stiffness is a frequent initial symptom, with trismus (“lockjaw”) being the most common complaint. As symptoms progress over 1–7 days, severe generalized reflex spasms develop. Opisthotonos, abdominal rigidity, and a grotesque facial expression called *risus sardonicus* are classic signs. Spasms may be precipitated by minor disturbances such as a draft or noise or by jarring the bed. In the absence of seizures, the patient’s sensorium is usually clear. Involvement of the respiratory muscles may lead to hypoventilation. Autonomic dysfunction may occur, causing tachycardia, hypotension, fever, and diaphoresis, and can be difficult to manage.
