Foreword

Cardiovascular disease has become the foremost cause of death and permanent disability in western countries, and is set to become the foremost cause of death and permanent disability worldwide by the year 2020. We are confronting a pandemic that will be a heavy burden on the population and that will cause much human suffering. The burden on health systems is also considerable in terms of healthcare expenditure, which looks set to continue growing. Cardiovascular disease is becoming increasingly common, in particular all types of atherothrombosis. This is driven by the rapid increase in the prevalence of risk factors among the world's population, such as the increasing frequency of obesity, type 2 diabetes, smoking, physical inactivity and psychological stress combined with a gradual increase in consumption of energy-dense foods and lower consumption of fruit and vegetables. In this context, the burden of cardiovascular disease will continue to increase with a gradual increase in life expectancy in the population.

Despite major progress in this field over the last 50 years, there is still much to learn about the progression of cardiovascular disease, particularly in understanding the mechanism of disease, the pathophysiology and evolution of diagnostic methods. The explosion of imaging techniques combined with ever more refined biological assays, particularly those based on genomics and proteomics, have all helped to make the diagnosis of cardiovascular diseases considerably more accurate and rapid. This exponential progress is the result of very active research and heavy investment in this field. This exciting progress has been translated from basic research into clinical management, thanks to active clinical research in cardiovascular disease. A large number of clinical trials, surveys and registries have helped us to understand both the impact of cardiovascular disease on the population and the impact of new strategies for diagnosis and management. European cardiologists have played an active part in advancing research in cardiovascular disease in basic, clinical and population sciences. The overall result is an improvement in diagnostic and therapeutic potential, as well as better prevention measures. Patients now benefit from a greater diversity of therapeutic options than ever before. The dissemination of this increased knowledge base is of paramount importance because physicians need to be aware of the best evidence concerning the most suitable treatment strategies for a particular disease. They need to implement this information in their daily routine practice, and keep abreast of changes and improvements in the management of cardiovascular disease. The ESC mission statement is to improve the quality of life of the European population by reducing the burden of cardiovascular disease. To fulfil its mission, the ESC has taken on the responsibility of training cardiologists and disseminating knowledge through congress activity, writing and publication of guidelines and, now, publication of The *ESC Textbook of Cardiovascular Medicine*. This is the first textbook to be proposed by an international society of

cardiology. More specifically, the goals of the textbook are to address the knowledge requirements specified in the ESC Core Syllabus, to be consistent with ESC Guidelines and best practice and to produce a clinically focused resource for cardiologists and trainees. In all, The ESC Textbook of Cardiovascular Medicine is set to become the new benchmark for cardiologists in Europe and beyond. The textbook is available in traditional printed format, as well as an online edition complete with CME-accredited self-assessment programmes. The online edition will be regularly updated, and it is hoped that translations will be available in the future. A large number of prominent European cardiologists have contributed to this comprehensive textbook that covers all aspects of cardiovascular disease from diagnosis to management and prevention. As a teaching text, this textbook covers knowledge that every general cardiologist needs to know and keep current, but does not address all the information needs of subspecialists. The concise and practical style was deliberately chosen to make this textbook easy to use. We would like to take this opportunity to thank all those who have contributed so generously their experience, and time, in order to produce this work, most particularly the authors and the co-editors. The wealth of their experience will be invaluable in bringing the most pertinent information to our colleagues throughout Europe and around the world. We are confident that this textbook will enjoy wide recognition, and hope that it will become a reference work for cardiologists around the globe.

Jean-Pierre Bassand President European Society of Cardiology 2002–2004

Michael Tendera President European Society of Cardiology 2004-2006

Preface

The goal of every good medical textbook is to teach excellence in medicine. This is the main purpose of this new *ESC Textbook of Cardiovascular Medicine*. This book specifically attempts to draw together all up-to-date strands of relevant information and use all appropriate modern educational methods to ensure good and comprehensive learning. It is not merely a treatise on theory but a practical compendium on cardiac and vascular disease. Yogi Berra, the great Yankee baseball player, once said 'theory and practice are in theory the same, but in practice they are not!' It is the editors' intention to harmonize theory and practice in this new teaching text. The *ESC Textbook of Cardiovascular Medicine* is the first ever cardiovascular textbook to be published in partnership with an international medical society, and is set to become the standard text in Europe and beyond. Initiated by the ESC Board and strongly supported by the President, it represents a major undertaking and long-term commitment from the ESC.

Everything a trainee or practising cardiologist needs to know

As a teaching or training text structured around the ESC Core Syllabus, The *ESC Textbook of Cardiovascular Medicine* contains the knowledge that every general cardiologist should strive to attain and keep current. It does not try to contain everything a subspecialist should know about the field. The textbook is consistent with the ESC Guidelines and with best practice. The book has 120 contributors from 12 European countries who were chosen as much for their ability as writers as for their knowledge. The result is a balanced, expert and comprehensive review of each topic. It covers the entire field of cardiovascular medicine and, unlike other texts, the first six chapters are dedicated to diagnostic imaging. Imaging modalities are also discussed within the subsequent chapters on different disorders and diseases and referenced back to the first chapters.

Easy to navigate and lavishly illustrated

All chapters follow the same format so that there are no inconsistencies in style or content. Each chapter opens with a brief 'Summary' box detailing the scope of the chapter and ends with a 'Personal perspectives' box in which the author outlines state-of-the-art and future directions for the area. The ESC Textbook of Cardiovascular Medicine is succinct, focused and practical to use. Only key references are included so that readability is not inhibited by overly dense text. It is also visually appealing, with an image on every two-page spread. There are over 700 full colour images and over 230 informative tables. All of the illustrations (and many of the ECG traces too) have been

redrawn to ensure consistency of style and quality. This truly outstanding art programme means that techniques and concepts are easy to grasp.

Accompanying online version and CME accreditation

An online version of The ESC Textbook of Cardiovascular Medicine is provided with each printed copy. A card with the website address and a unique access number is bound into every book. The unique access number is used when registering, at which point a user name and password can be chosen. Using the website is straightforward and technical help is available if needed. The online version contains all the text and images from The *ESC Textbook of Cardiovascular Medicine* as well as: l an excellent full text search facility; l downloadable PDF chapter files; l links from reference lists to PubMed; l a database of video clips supplied by the authors; l chapter-based CME multiple choice questions. The provision of high-quality CME for cardiologists and trainees in Europe is a key priority of the ESC. In line with this aim, accreditation of chapters in The ESC Textbook of Cardiovascular Medicine is awarded by EBAC (The European Board for Accreditation in Cardiology). Having read a chapter, you are required to submit your answers to a set of multiple choice questions relating to the chapter's content. Your score is then displayed and feedback is given on the correctly answered questions. Feedback is not given on incorrect answers so that the test may be attempted again. Having successfully completed a chapter (achieving a pass mark of 60% or above), you can download an EBAC certificate from the website. The editors wish to acknowledge the great help provided to them by the editorial staff at Blackwell Publishing. Gina Almond and Julie Elliott, in particular, have been engaged and involved in the production of this book from start to finish.

1 The Morphology of the Electrocardiogram

Antoni Bayés de Luna, Velislav N. Batchvarov and Marek Malik

Summary

The 12-lead electrocardiogram (ECG) is the single most commonly performed investigation. Almost every hospitalized patient will undergo electrocardiography, and patients with known cardiovascular disease will do so many times. In addition, innumerable ECGs recorded are made for life insurance, occupational fitness and routine purposes. Most ECG machines are now able to read the tracing; many of the reports are accurate but some are not. However, an accurate interpretation of the ECG requires not only the trace but also clinical details relating to the patient. Thus, every cardiologist and physician/cardiologist should be able to understand and interpret the 12-lead ECG. Nowadays, many other groups, for example accident and emergency physicians, anaesthetists, junior medical staff, coronary care, cardiac service and chest pain nurses, also need a good grounding in this skill. In the last several decades a variety of new electrocardiographic techniques, such as short- and long-term ambulatory ECG monitoring using wearable or implantable devices, event ECG monitoring, single averaged ECGs in the time, frequency and spatial domains and a variety of stress recoding methods, have been devised. The cardiologist, at least, must understand the application and value of these important clinical investigations. This chapter deals comprehensively with 12-lead electrocardiography and the major pathophysiological conditions that can be revealed using this technique. Cardiac arrhythmias and other information from ambulatory and averaging techniques are explained only briefly but are more fully covered in other chapters, for example those devoted to specific cardiac arrhythmias.

Introduction

Broadly speaking, electrocardiography, i.e. the science and practice of making and interpreting recordings of cardiac electrical activity, can be divided into morphology and arrhythmology. While electrocardiographic morphology deals with interpretation of the shape (amplitude, width and contour) of the electrocardiographic signals, arrhythmology is devoted to the study of the rhythm (sequence and frequency) of the heart. Although these two parts of electrocardiography are closely interlinked, their methodological distinction is appropriate. Intentionally, this chapter covers only electrocardiographic morphology since rhythm abnormalities are dealt with elsewhere in this book.

Morphology of the ECG

The electrocardiogram (ECG), introduced into clinical practice more than 100 years ago by Einthoven, comprises a linear recording of cardiac electrical activity as it occurs over time. An atrial depolarization wave (P wave), a ventricular depolarization wave (QRS complex) and a ventricular repolarization wave (T wave) are successively

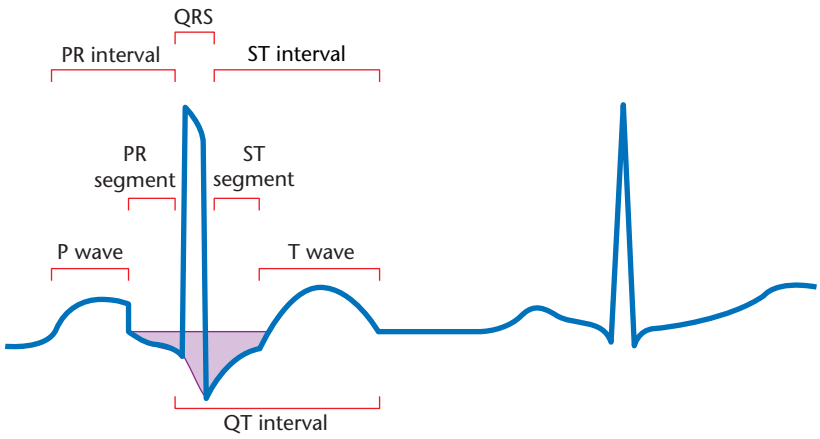

Figure 1.1 ECG morphology recorded in a lead facing the left ventricular free wall showing the different waves and intervals. Shading, atrial repolarization wave.

recorded for each cardiac cycle (Fig. 1.1). During normal sinus rhythm the sequence is always P–QRS–T. Depending on heart rate and rhythm, the interval between waves of one cycle and another is variable.

Electrophysiological principles [1–6]

The origin of ECG morphology may be explained by the dipole-vector theory, which states that the ECG is an expression of the electro-ionic changes generated during myocardial depolarization and repolarization. A pair of electrical charges, termed a dipole, is formed during both depolarization and repolarization processes (Fig. 1.2). These dipoles have a vectorial expression, with the head of the vector located at the positive pole of a dipole. An electrode that faces the head of the vector records a positive deflection.

To ascertain the direction of a wavefront, the ECG is recorded from different sites, termed 'leads'. When recording the 12-lead ECG six frontal leads (I, II, III, aVR, aVL, aVF) and six horizontal leads (V1–V6) are used. There are three bipolar leads in the frontal plane that connect the left to right arm (I), the left leg to right arm (II) and the left leg to left arm (III). According to Einthoven's law, the voltage in each lead should fit the equation II = I + III. These three leads form Einthoven's triangle (Fig. 1.3A). Bailey obtained a reference figure (Bailey's triaxial system) by shifting the three leads towards the centre.

There are also three augmented bipolar leads (aVR, aVL and aVF) in the frontal plane (Fig. 1.3B). These are de-

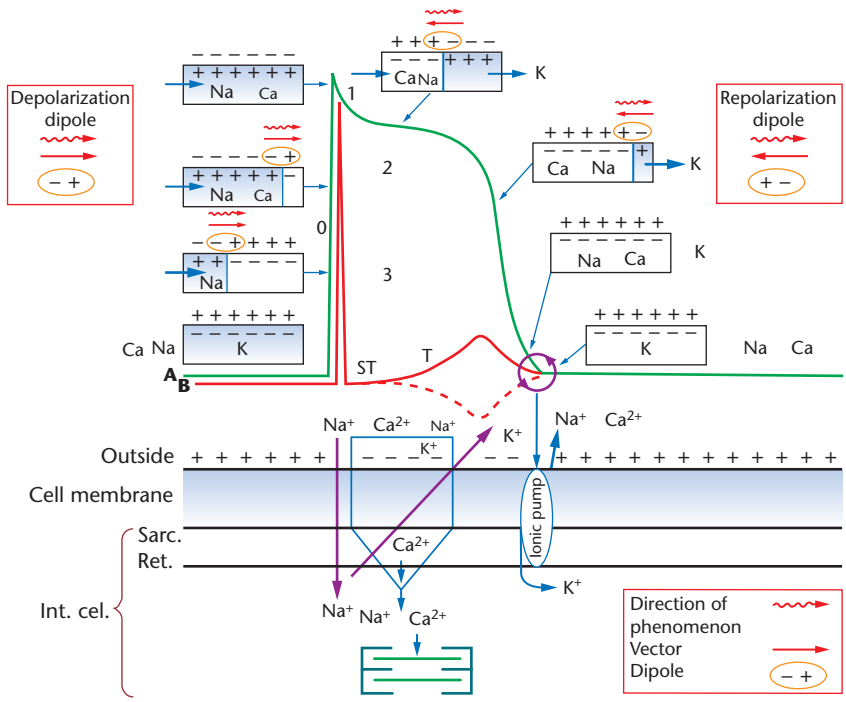

Figure 1.2 Scheme of electro-ionic changes that occur in the cellular depolarization and repolarization in the contractile myocardium. (A) Curve of action potential. (B) Curve of the electrogram of a single cell (repolarization with a dotted line) or left ventricle (normal curve of ECG with a positive continuous line). In phase 0 of action potential coinciding with the Na^+ entrance, the depolarization dipole (–+) and, in phase 2 with the K^+ exit, the repolarization dipole (+–), are originated. At the end of phase 3 of the action potential an electrical but not ionic balance is obtained. For ionic balance an active mechanism (ionic pump) is necessary.

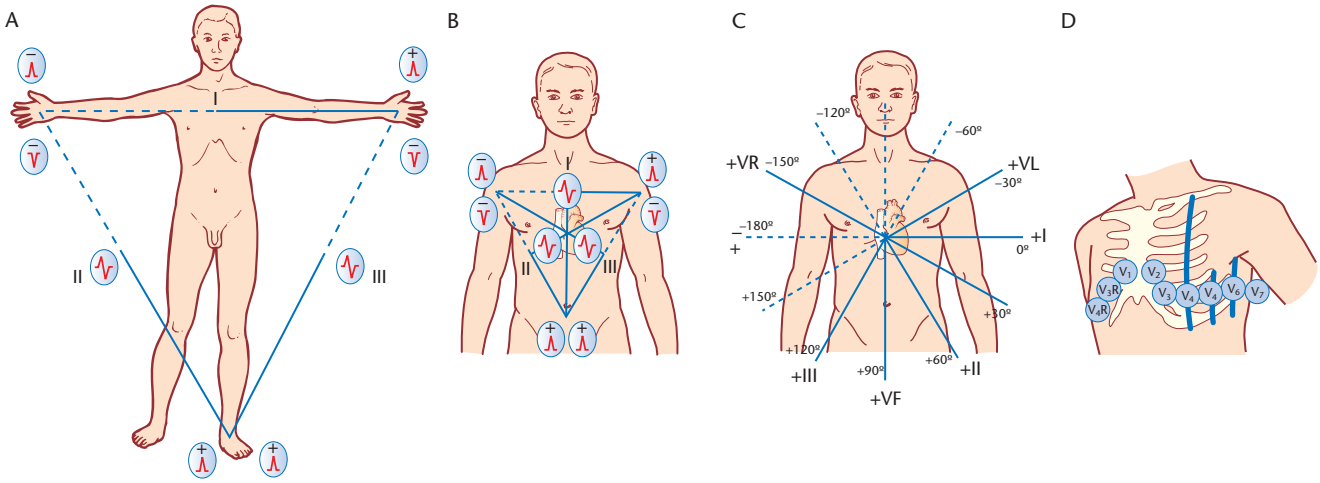

Figure 1.3 (A) Einthoven's triangle. (B) Einthoven's triangle superimposed on a human thorax. Note the positive (continuous line) and negative (dotted line) part of each lead. (C) Bailey's hexaxial system. (D) Sites where positive poles of the six precordial leads are located.

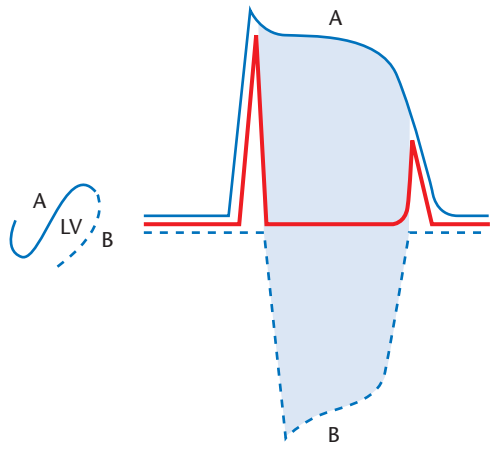

Figure 1.4 Correlation between global action potential, i.e. the sum of all relevant action potentials, of the subendocardial (A) and subepicardial (B) parts of the left ventricle and the ECG waveform. Depolarization starts first in the furthest zone (subendocardium) and repolarization ends last in the furthest zone (subendocardium). When the global action potential of the nearest zone is 'subtracted' from that of the furthest zone, the ECG pattern results. (LV = left ventricle.)

scribed as 'augmented' because, according to Einthoven's law, their voltage is higher than that of the simple bipolar leads. By adding these three leads to Bailey's triaxial system, Bailey's hexaxial system is obtained (Fig. 1.3C). In the horizontal plane, there are six unipolar leads (V1–V6) (Fig. 1.3D).

One approach to understanding ECG morphology is based on the concept that the action potential of a cell or the left ventricle (considered as a huge cell that contributes to the human ECG) is equal to the sum of subendocardial and subepicardial action potentials. How this occurs is shown in Fig. 1.4. This concept is useful for understanding how the ECG patterns of ischaemia and injury are generated (see Fig. 1.17).

Normal characteristics

Heart rate

Normal sinus rhythm at rest is usually said to range from 60 to 100 b.p.m. but the nocturnal sleeping heart rate may fall to about 50 b.p.m. and the normal daytime resting heart rate rarely exceeds 90 b.p.m. Several methods exist to assess heart rate from the ECG. With the standard recording speed of 25 mm/s, the most common method is to divide 300 by the number of 5-mm spaces (the graph paper is divided into 1- and 5-mm squares) between two consecutive R waves (two spaces represents 150 b.p.m., three spaces 100 b.p.m., four spaces 75 b.p.m., five spaces 60 b.p.m., etc.).

Rhythm

The cardiac rhythm can be normal sinus rhythm (emanating from the sinus node) or an ectopic rhythm (from a site other than the sinus node). Sinus rhythm is considered to be present when the P wave is positive in I, II, aVF and V2–V6, positive or biphasic (+/–) in III and V1, positive or –/+ in aVL, and negative in aVR.

PR interval and segment

The PR interval is the distance from the beginning of the P wave to the beginning of the QRS complex (Fig. 1.1). The normal PR interval in adult individuals ranges from

0.12 to 0.2 s (up to 0.22 s in the elderly and as short as 0.1 s in the newborn). Longer PR intervals are seen in cases of atrioventricular (AV) block and shorter PR intervals in pre-excitation syndromes and various arrhythmias. The PR segment is the distance from the end of the P wave to QRS onset and is usually isoelectric. Sympathetic overdrive may explain the down-sloping PR segment that forms part of an arc with the ascending nature of the ST segment. In pericarditis and other diseases affecting the atrial myocardium, as in atrial infarction, a displaced and sloping PR segment may be seen.

QT interval

The QT interval represents the sum of depolarization (QRS complex) and repolarization (ST segment and T wave) (Fig. 1.1). Very often, particularly in cases of a flat T wave or in the presence of a U wave, it is difficult to measure the QT interval accurately. It is usual to perform this measurement using a consistent method in order to ensure accuracy if the QT interval is studied sequentially. The recommended method is to consider the end of repolarization as the point where a tangent drawn along the descending slope of the T wave crosses the isoelectric line. The best result may be obtained by measuring the median duration of QT simultaneously in 12 leads. Automatic measurement may not be accurate but is often used clinically [7].

It is necessary to correct the QT interval for heart rate (QTc). Different heart rate correction formulae exist. The most frequently used are those of Bazett and Fridericia:

$$\text{Bazett (square root) correction: QT corrected} = \text{QT measured}/\text{RR interval (s)}^{0.5}$$

$$\text{Fridericia (cube root) correction: QT corrected} = \text{QT measured}/\text{RR interval (s)}^{0.33}$$

Although these correction methods are not accurate and are highly problematic in cases when a very precise QTc value is needed, their results are satisfactory in standard clinical practice. Because of its better accuracy the Fridericia formula is preferred to that of Bazett.

A long QT interval may occur in the congenital long QT syndromes or can be associated with sudden death [8], heart failure, ischaemic heart disease, bradycardia, some electrolyte disorders (e.g. hypokalaemia and hypocalcaemia) and following the intake of different drugs. Generally, it is believed that if a drug increases the QTc by more than 60 ms, torsade de pointes and sudden cardiac death might result. However, torsade de pointes rarely occurs unless the QTc exceeds 500 ms [9]. A short QT interval can be found in cases of early repolarization, in association with digitalis and, rarely, in a genetic disorder associated with sudden death [10].

P wave

This is the atrial depolarization wave (Fig. 1.1). In general, its height should not exceed 2.5 mm and its width should not be greater than 0.1 s. It is rounded and positive but may be biphasic in V1 and III and –/+ in aVL. The atrial repolarization wave is of low amplitude and usually masked by coincident ventricular depolarization (QRS complex) (see shading in Fig. 1.1).

QRS complex

This results from ventricular depolarization (Figs 1.1 and 1.5). According to Durrer *et al*. [11], ventricular depolarization begins in three different sites in the left ventricle and occurs in three consecutive phases that give rise to the generation of three vectors [6].

The ventricular depolarization signal is often described generically as a QRS complex. Usually the deflection is triphasic and, provided that the initial wave is negative (down-going), the three waves are sequentially known as Q, R and S. If the first part of the complex is up-going the deflection is codified as an R wave, etc. If the R or S wave is large in amplitude, upper case letters (R, S) are used, but if small in amplitude, lower case letters (r, s) are used. A normal or physiological initial negative wave of the ventricular depolarization waveform is called a q wave. It must be narrow (< 0.04 s) and should not usually exceed 25% of the amplitude of the following R wave, though some exceptions exist mainly in leads III, aVL and aVF. If the initial deflection is wider or deeper, it is known as a Q wave. Different morphologies are presented in Fig. 1.5.

The QRS width should not exceed 0.095 s and the R wave height should not exceed 25 mm in leads V5 and V6 or 20 mm in leads I and aVL, although a height greater than 15 mm in aVL is usually abnormal.

ST segment and T wave

The T wave, together with the preceding ST segment, is formed during ventricular repolarization (Fig. 1.1). The T wave is generally positive in all leads except aVR, but may be negative, flattened or only slightly positive in V1, and flattened or slightly negative in V2, III and aVF. The T wave presents an ascending slope with slower inscription than the descending slope. In children, a negative T wave is normal when seen in the right precordial leads (paediatric repolarization pattern) (Fig. 1.6F). Under normal conditions, the ST segment is isoelectric or shows only a slight down-slope (< 0.5 mm). Examples of normal ST–T wave variants are displayed in Fig. 1.6 (the figure caption provides comment on these patterns). Occasion-

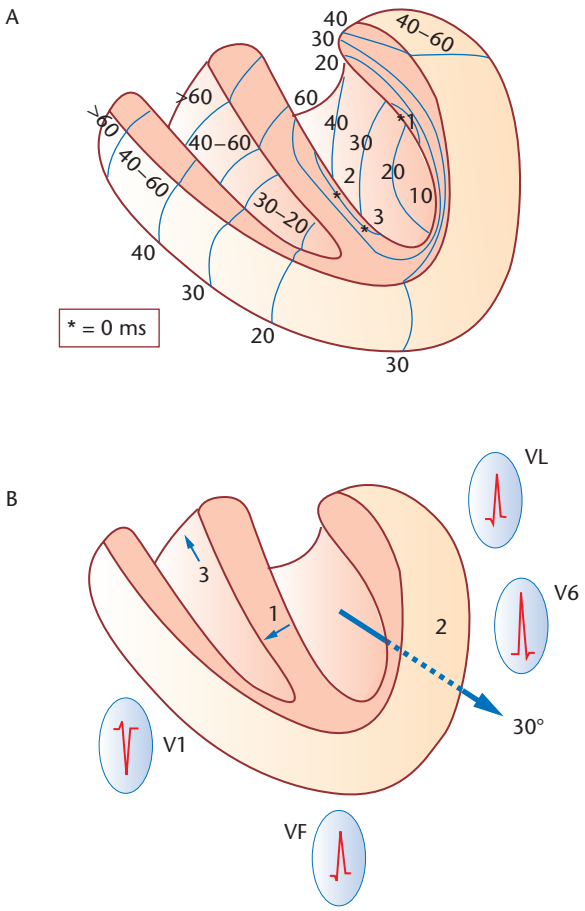

Figure 1.5 (A) The three initial points (1, 2, 3) of ventricular depolarization are marked by asterisks. The isochrone lines of the depolarization sequence can also be seen (time shown in ms). (B) The first vector corresponds to the sum of depolarization of the three points indicated in (A) and because it is more potent than the forces of the right vector, the global direction of vector 1 will be from left to right. The second vector corresponds to depolarization of the majority of the left ventricle and usually is directed to the left, downward and backward. The third vector represents the depolarization of basal parts of the septum and right ventricle.

ally, after a T wave, a small U wave can be observed, usually showing the same polarity as the T wave (Fig. 1.1).

Electrocardiographic morphological abnormalities

Electrocardiography can be considered the test of choice or the gold standard for the diagnosis of AV blocks, abnormal intra-atrial and intraventricular conduction, ventricular pre-excitation, most cardiac arrhythmias and, to some extent, acute myocardial infarction. However, in other cases, such as atrial and ventricular enlargement, abnormalities secondary to chronic coronary artery disease (ECG pattern of ischaemia, injury or necrosis), other repolarization abnormalities and certain arrhythmias, electrocardiography provides useful information and may suggest the diagnosis based on predetermined electrocardiographic criteria. However, these criteria have lesser diagnostic potential compared with other electrocardiology or imaging techniques (e.g. echocardiography in atrial or ventricular enlargement). In some circumstances, electrocardiography is the technique of choice and the electrocardiographic criteria in use are diagnostic for those conditions (e.g. bundle branch block), while for other conditions (e.g. cavity enlargement) the criteria are only indicative. In order to know the real value of the ECG criteria in these cases, it is important to understand the concepts of sensitivity, specificity and predictive accuracy [1].

Atrial abnormalities

Electrocardiographic patterns observed in patients with atrial hypertrophy and atrial dilation (atrial enlargement) and with atrial conduction block are encompassed by this term (Fig. 1.7).

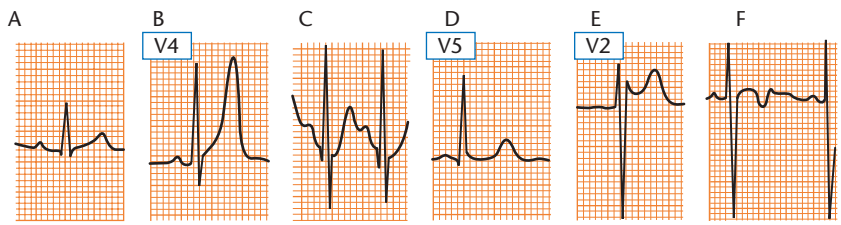

Figure 1.6 Different morphologies of normal variants of the ST segment and T wave in the absence of heart disease. (A) Normal ST/T wave. (B) Vagotonia and early repolarization. (C) Sympathetic overdrive. ECG of a 22-year-old male obtained with continuous Holter monitoring during a parachute jump. (D) Straightening of ST with symmetric T wave in a healthy 75-year-old man without heart disease. (E) Normal variant of ST ascent (saddle morphology) in a 20-year-old man with pectus excavatum. (F) Normal repolarization in a 3-year-old child.

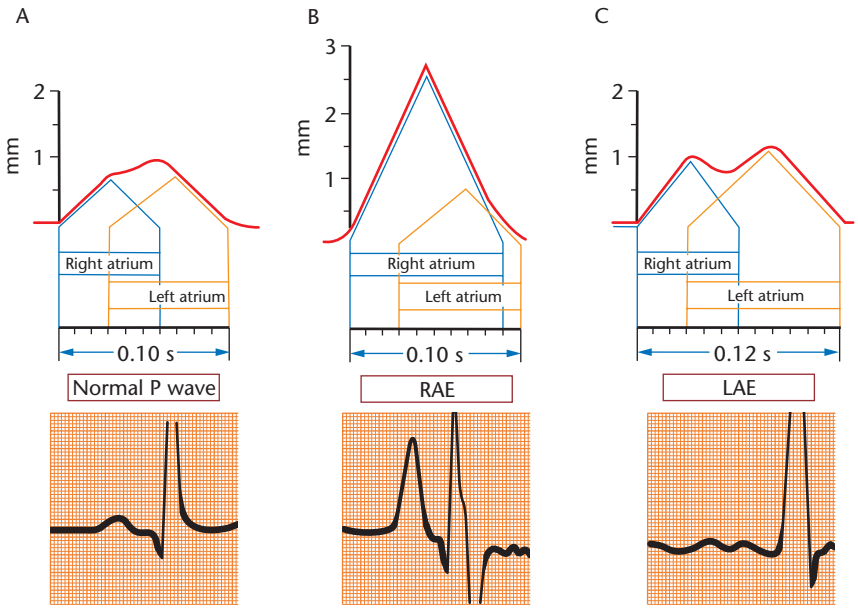

Figure 1.7 Schematic diagrams of atrial depolarization in (A) normal P wave, (B) right atrial enlargement (RAE) and (C) left atrial enlargement (LAE) with interatrial conduction block. An example of each of these P waves is shown beneath each diagram.

Right atrial enlargement (Fig. 1.7B)

Right atrial enlargement is usually present in patients with congenital and valvular heart diseases affecting the right side of the heart and in cor pulmonale.

Diagnostic criteria

The diagnostic criteria of right atrial abnormality are based on P-wave amplitude abnormalities (≥ 2.5 mm in II and/or 1.5 mm in V1) and ECG features of associated right ventricular abnormalities.

Left atrial enlargement (Fig. 1.7C)

Left atrial enlargement is seen in patients with mitral and aortic valve disease, ischaemic heart disease, hypertension and some cardiomyopathies.

Diagnostic criteria

1. P wave with duration ≥ 0.12 s especially seen in leads I or II, generally bimodal, but with a normal amplitude.
2. Biphasic P wave in V1 with a terminal negative component of at least 0.04 s. Criteria 1 and 2 have good specificity (close to 90%) but less sensitivity (< 60%).
3. P wave with biphasic (±) morphology in II, III and aVF with duration ≥ 0.12 s, which is very specific (100% in valvular heart disease and cardiomyopathies) but has low sensitivity for left atrial abnormality [12,13].

Interatrial block

PARTIAL BLOCK

P-wave morphology is very similar to that seen with left atrial abnormality. Usually the negative part in V1 may be less prominent than in atrial hypertrophy or dilation, although it is not surprising that the morphology of left atrial abnormality and atrial block are similar because the features of left atrial abnormality are more dependent on delayed interatrial conduction than on atrial dilation.

ADVANCED INTERATRIAL BLOCK WITH LEFT ATRIAL RETROGRADE ACTIVATION

This is characterized by a P wave with duration ≥ 0.12 s and with biphasic (±) morphology in II, III and aVF. A biphasic P-wave morphology in V1 to V3/V4 is also frequent (see below). This morphology is a marker for paroxysmal supra-ventricular tachyarrhythmias [12,13] and is very specific (100%) for left atrial enlargement.

Ventricular enlargement

The electrocardiographic concept of enlargement of the right and left ventricle encompasses both hypertrophy and dilation and, of course, the combination. The diagnostic criteria for ventricular enlargement when QRS duration is less than 120 ms are set out below. The criteria for the diagnosis of right and/or left ventricular enlargement combined with intraventricular block (QRS duration ≥ 120 ms) are defined elsewhere [1,5,14,15].

Right ventricular enlargement

Right ventricular enlargement (RVE) is found particularly in cases of congenital heart disease, valvular heart disease and cor pulmonale. Figure 1.8 shows that

Table 1.1 Electrocardiographic criteria of right ventricular enlargement

	Criterion	Sensitivity (%)	Specificity (%)
V1	R/S V1 ≥ 1	6	98
	R V1 ≥ 7 mm	2	99
	qR in V1	5	99
	S in V1 < 2 mm	6	98
	IDT in V1 ≥ 0.35 s	8	98
V5-V6	R/S V5–V6 ≤ 1	16	93
	R V5–V6 < 5 mm	13	87
	S V5–V6 ≥ 7 mm	26	90
V1 + V6	RV1 + SV5-V6 > 10.5 mm	18	94
ÂQRS	ÂQRS ≥ 110°	15	96
	SI, SII, SIII	24	87

IDT, intrinsicoid deflection (time from QRS onset to R wave peak).

Table 1.2 Morphologies with dominant R or R′ (r′) in V1

Clinical setting	QRS width	P-wave morphology in V1
No heart disease		
Incorrect electrode placement	< 0.12 s	Various changes
Normal variant (post-term infants, scant Purkinje fibres in anteroseptal zone)	< 0.12 s	Normal
Chest anomalies	< 0.12 s	Normal
Typical right bundle branch block	From < 0.12 to ≥ 0.12 s	Normal
Atypical right bundle branch block		
Ebstein's disease	Often ≥ 0.12 s	Often tall, peaked and + or ±
Arrhythmogenic right ventricular dysplasia	Often ≥ 0.12 s	Often abnormal
Brugada's syndrome	Sometimes ≥ 0.12 s	Normal
Right ventricular or biventricular enlargement (hypertrophy)	< 0.12 s	Often tall and peaked
Wolff–Parkinson–White syndrome	From < 0.12 to ≥ 0.12 s	Normal P, short PR
Lateral myocardial infarction	< 0.12 s	Normal P

the ECG pattern in V1 (prominent R wave) is related more to the degree of RVE than to its aetiology.

Diagnostic criteria

The electrocardiographic criteria most frequently used for the diagnosis of RVE are shown in Table 1.1, along with their sensitivities (low) and specificities (high). The differential diagnosis of an exclusive or dominant R wave in V1 (R, Rs or rSR′ pattern) is given in Table 1.2.

1 Morphology in V1: morphologies with a dominant or exclusive R wave in V1 are very specific, but not so sensitive (< 10%) for the diagnosis of RVE. Nevertheless, other causes that may cause a dominant R pattern in V1 must be excluded (see Table 1.2). An rS or even QS morphology in V1, together with RS in V6, may often be observed in chronic cor pulmonale, even in advanced stages or in the early stages of RVE of other aetiologies (Fig. 1.8).

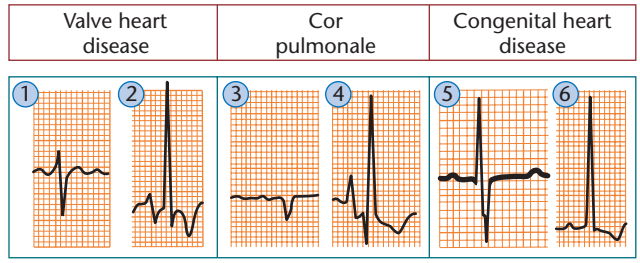

Figure 1.8 ECG pattern of right ventricular enlargement: note that QRS in V1 depends more on the severity of right ventricular enlargement than on aetiology of the disease. 1, 3 and 5 represent examples of mild mitral stenosis, cor pulmonale and congenital pulmonary stenosis respectively, while 2, 4 and 6 are cases of severe and long-standing mitral stenosis, cor pulmonale with severe pulmonary hypertension, and congenital pulmonary stenosis respectively.

2 Morphology in V6: the presence of forces directed to the right expressed as an S wave in V5–V6 is one of the most important ECG criteria.
3 Frontal plane QRS electrical axis (ÂQRS): ÂQRS ≥ 110° is a criterion with low sensitivity but high specificity (95%) provided that left posterior hemiblock, an extremely vertical heart position and lateral left ventricular wall infarction have been excluded.
4 SI, SII, SIII: an S wave in the three bipolar limb leads is frequently seen in chronic cor pulmonale with a QS or rS pattern in V1 and an RS pattern in V6. The possibility of this pattern being secondary to a positional change or simply to peripheral right ventricular block must be excluded [16].

The combination of more than one of these criteria increases the diagnostic likelihood. Horan and Flowers [15] have published a scoring system based on the most frequently used ECG criteria for right ventricular enlargement.

Left ventricular enlargement

Left ventricular enlargement, or ischaemic heart disease, is found particularly in hypertension, valvular heart disease, cardiomyopathies and in some congenital heart diseases.

In general, in patients with left ventricular enlargement, the QRS voltage is increased and is directed more posteriorly than normal. This explains why negative QRS complexes predominate in the right precordial leads. Occasionally, probably related to significant cardiac laevorotation or with more significant hypertrophy of the left ventricular septal area than of the left ventricular free wall, as occurs in some cases of apical hypertrophic cardiomyopathy, the maximum QRS is not directed posteriorly. In this situation a tall R wave may be seen even in V2.

The normal q wave in V6 may not persist if hypertrophy is associated with fibrosis and/or partial left bundle branch block. In Fig. 1.9, the ECG from a case of aortic valvular disease without septal fibrosis shows a q wave in V6 and a positive T wave, whereas the ECG from another case with fibrosis does not have a q wave in V6 [17,18]. The ECG pattern is more related to disease evolution than to the haemodynamic overload (Fig. 1.10), although a q wave in V5–V6 remains more frequently in long-standing aortic regurgitation than in aortic stenosis. The pattern of left ventricular enlargement is usually fixed but may be partially resolved with medical treatment of hypertension or surgery for aortic valvular disease.

Diagnostic criteria

Various diagnostic criteria exist (Table 1.3). Those with good specificity (≥ 95%) and acceptable sensitivity (40–50%) include the Cornell voltage criteria and the Romhilt and Estes scoring system.

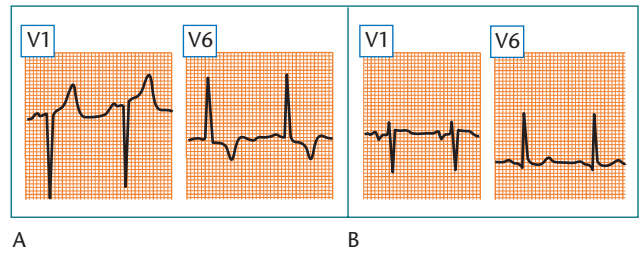

Figure 1.9 The most characteristic ECG feature of left ventricular enlargement is tall R waves in V5–6 and deep S waves in V1–2. The presence of a normal septal q wave depends on whether septal fibrosis is present. This figure shows two examples of aortic valvular disease both with left ventricular enlargement: (A) no fibrosis and a normal septal q wave; (B) abnormal ECG (ST/T with strain pattern) and no septal q wave due to extensive fibrosis.

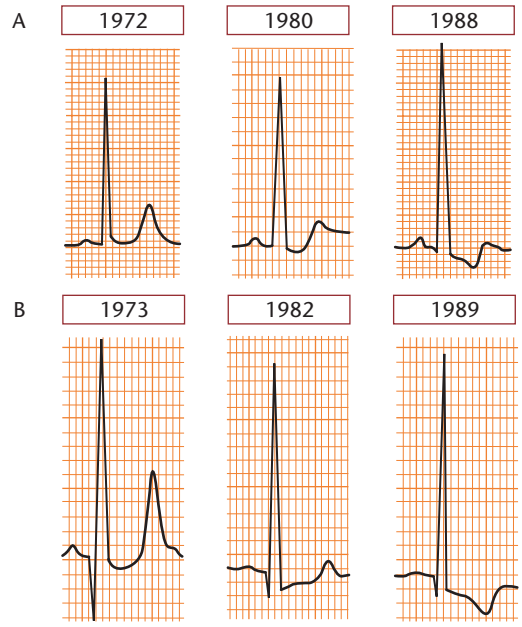

Figure 1.10 Examples of different ECG morphologies seen during the evolution of aortic stenosis (A) and aortic regurgitation (B).

Intraventricular conduction blocks

Ventricular conduction disturbances or blocks can occur on the right side or on the left. They can affect an entire ventricle or only part of it (divisional block). The block of conduction may be first degree (partial block or conduction delay) when the stimulus conducts but with

Table 1.3 Electrocardiographic criteria of left ventricular enlargement

Voltage criteria	Sensitivity (%)	Specificity (%)
RI + SIII > 25 mm	10.6	100
R aVL > 11 mm	11	100
R aVL > 7.5 mm	22	96
SV1 + RV5–6 ≥ 35 mm (Sokolow–Lyon)	22	100
RV5–6 > 26 mm	25	98
Cornell voltage criterion: R aVL + SV3 > 28 mm (men) or 20 mm (women)	42	96
Cornell voltage duration: QRS duration × Cornell voltage > 2436 mm/seg	51	95
In V1–V6, deepest S + tallest R > 45 mm	45	93
Rohmilt–Estes score > 4 points	55	85
Rohmilt–Estes score > 5 points	35	95

delay, third degree (advanced block) when passage of the wavefront is completely blocked, and second degree when the stimulus sometimes passes and sometimes does not.

Advanced or third-degree right bundle branch block (Fig. 1.11)

Advanced right bundle branch block (RBBB) represents complete block of stimulus in the right bundle or within the right ventricular Purkinje network. In this situation, activation of the right ventricle is initiated by condution through the septum from the left-sided Purkinje system.

Diagnostic criteria

1. QRS ≥ 0.12 s with slurring in the mid-final portion of the QRS.
2. V1: rsR′ pattern with a slurred R wave and a negative T wave.
3. V6: qRs pattern with S-wave slurring and a positive T wave.
4. aVR: QR with evident R-wave slurring and a negative T wave.
5. T wave with polarity opposite to that of the slurred component of the QRS.

Partial or first-degree RBBB

In this case, activation delay of the ventricle is less delayed. The QRS complex is 0.1–0.12 s in duration, but V1 morphology is rsR′ or rsr′.

Advanced (third degree) left bundle branch block (Fig. 1.12)

Advanced left bundle branch block (LBBB) represents complete block of stimulus in the left bundle or within the left ventricular Purkinje network. In this situation, activation of the left ventricle is initiated by conduction through the septum from the right-sided Purkinje system.

Diagnostic criteria

1. QRS ≥ 0.12 s, sometimes over 0.16 s, especially with slurring in the mid-portion of the QRS.
2. V1: QS or rS pattern with a small r wave and a positive T wave.
3. I and V6: a single R wave with its peak after the initial 0.06 s (delayed intrinsicoid deflection).
4. aVR: a QS pattern with a positive T wave.
5. T waves with their polarity usually opposite to the slurred component of the QRS complex.

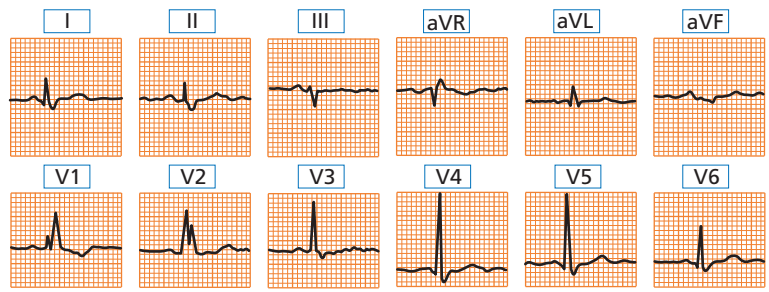

Figure 1.11 ECG in a case of advanced right bundle branch block.

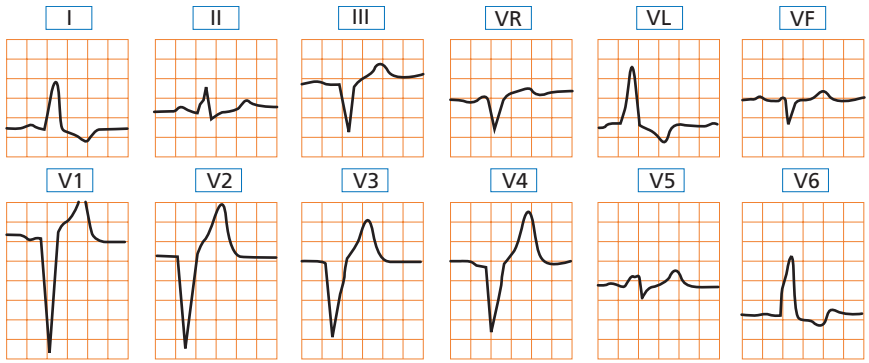

Figure 1.12 ECG in a case of complete left bundle branch block.

Partial or first-degree LBBB

In this case, left ventricular activation is less delayed. The QRS complex is 0.1–0.12 s in duration and presents as a QS complex or a small r wave in V1 and a single R wave in I and V6. This is explained by the fact that due to the delay in activation the first vector that is responsible for formation of the r wave in V1 and the q wave in V6 is not formed. This pattern is partly explained by the presence of septal fibrosis [17].

Divisional left ventricular block (hemiblocks)

The stimulus is blocked or delayed in either the supero-anterior (left anterior hemiblock) or inferoposterior division (left posterior hemiblock) of the left bundle branch [19].

LEFT ANTERIOR HEMIBLOCK

A typical example of left anterior hemiblock (LAH) is illustrated in Fig. 1.13. The differences between LAH and the SI, SII, SIII pattern can also be seen. Inferior wall myocardial infarction and Wolff–Parkinson–White (WPW) syndrome should also be ruled out.

Diagnostic criteria

1 QRS complex duration < 0.12 s.
2 ÂQRS deviated to the left (mainly between –45° and –75°).
3 I and aVL: qR, in advanced cases with slurring especially of the descending part of R wave.
4 II, III and aVF: rS with SIII > SII and RII > RIII.
5 S wave seen up to V6.

LEFT POSTERIOR HEMIBLOCK

In order to make the diagnosis of left posterior hemiblock (LPH), electrocardiographic and clinical characteristics (mainly RVE and an asthenic habitus) must be absent. It is also helpful if evidence of other left ventricular abnormalities is present. A typical electrocardiographic morphology in the frontal and horizontal planes of LPH is shown in Fig. 1.14b.

Diagnostic criteria

1 QRS complex duration < 0.12 s.
2 ÂQRS shifted to the right (between +90° and +140°).
3 I and aVL: RS or rS pattern.
4 II, III and aVF: qR morphology.
5 Precordial leads: S waves up to V6.

The evidence that the ECG pattern suddenly appears confirms the diagnosis of LPH (see Fig. 1.14).

Bifascicular blocks

The two most characteristic bifascicular blocks are advanced RBBB plus LAH and advanced RBBB plus LPH. On some occasions there is RBBB with alternans

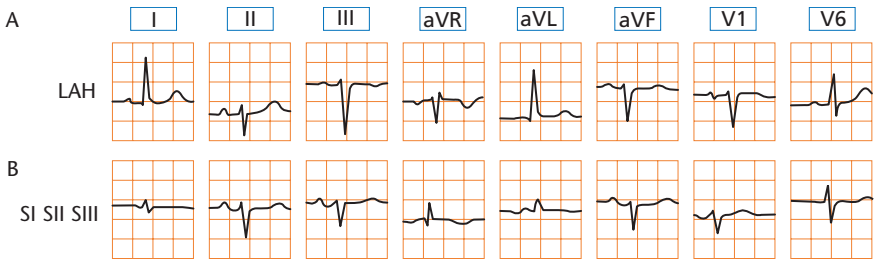

Figure 1.13 (A) An example of left anterior hemiblock. (B) SI SII SIII pattern. See in this case SII > SIII and there is S in lead I.

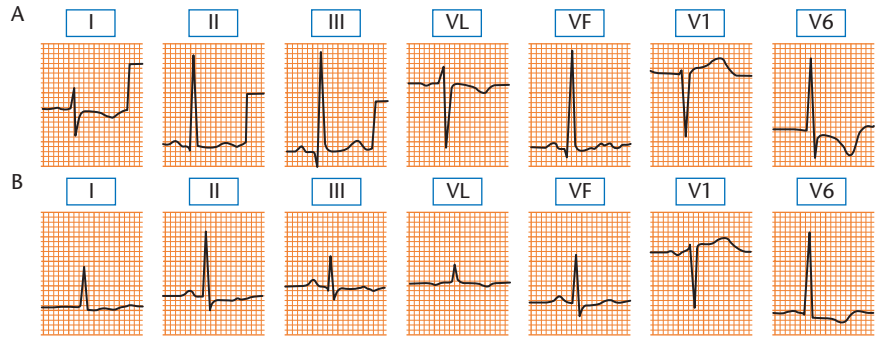

Figure 1.14 (A) An example of left posterior hemiblock. (B) The ECG of same patient some days before. The sudden appeareance of ÂQRS shifted to the right confirms the diagnosis of LPH.

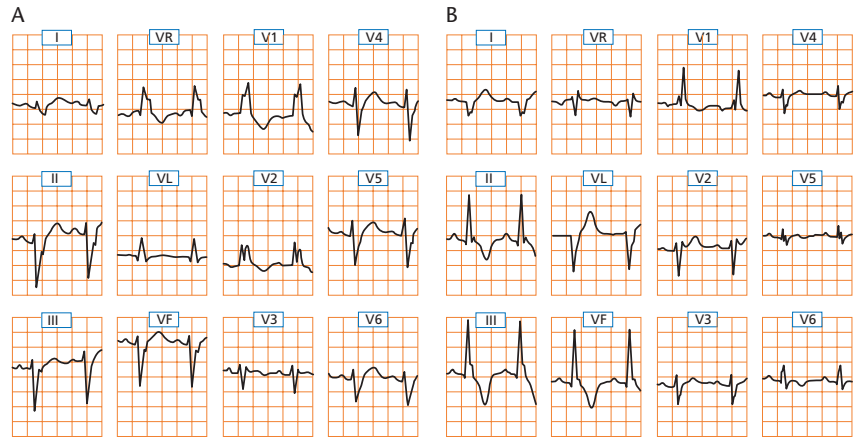

Figure 1.15 (A) Right bundle branch block plus left anterior hemiblock and, the following day, (B) right bundle branch block plus left posterior hemiblock.

of LAH and LPH (one form of trifascicular block) (Fig. 1.15).

ADVANCED RBBB PLUS LAS (Fig. 1.15A)
The diagnostic criteria are as follows.
1 QRS complex duration > 0.12 s.
2 QRS complex morphology: the first portion is directed upwards and to the left as in LAH, while the second portion is directed anteriorly and to the right as in advanced RBBB.

ADVANCED RBBB PLUS LPH (Fig. 1.15B)
The diagnostic criteria are as follows.
1 QRS complex duration > 0.12 s.
2 QRS complex morphology: the first portion of the QRS complex is directed downwards as in isolated LPH, while the second portion is directed anteriorly and to the right similar to advanced RBBB.

Ventricular pre-excitation

Ventricular pre-excitation (early excitation) occurs when the depolarization wavefront reaches the ventricles earlier (via an anomalous pathway) than it would normally (via the AV node/His–Purkinje conduction system). Early excitation is explained by fast conduction through the anomalous pathway that connects the atria with the ventricles, the so-called Kent bundles (WPW-type pre-excitation) [20]. Sometimes, pre-excitation of the His–Purkinje network occurs because of an anomalous atrio-His tract (or simply because of the presence of accelerated AV conduction). This produces short PR-type pre-excitation, called Lown–Ganong–Levine syndrome when associated with junctional tachycardias [21]. Rarely, an anomalous pathway including a section of the normal or accessory AV nodal tissue (Mahaim fibre) produces pre-excitation [22]. The importance of pre-excitation lies in its association with supraventricular tachycardias and sometimes sudden death [23] and the risk of its being mistaken (in the case of WPW pre-excitation) for other pathologies, such as myocardial infarction or hypertrophy. The presence of pre-excitation may also mask other ECG diagnoses.

WPW-type pre-excitation [20,23–25]

The electrocardiographic diagnosis is made by the presence of a short PR interval plus QRS abnormalities characterized by a slurred onset (delta wave) (Fig. 1.16) and T-wave abnormalities.

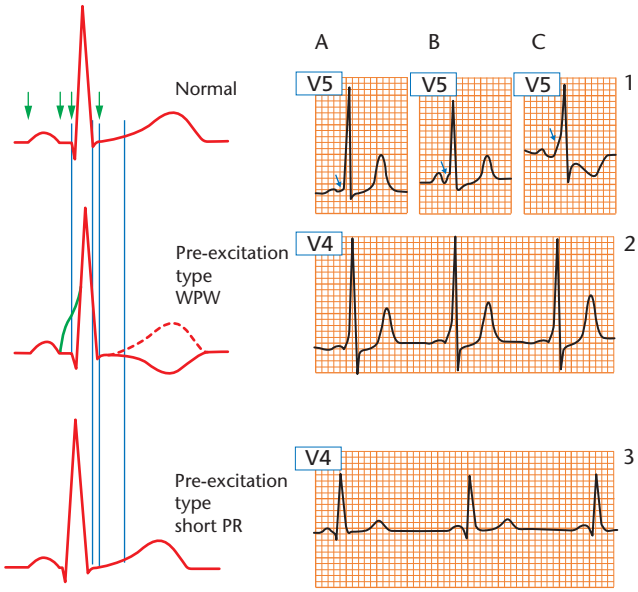

Figure 1.16 *Left*: Comparison of ECGs with normal ventricular activation, Wolff–Parkinson–White (WPW)-type pre-excitation and short PR-type pre-excitation. *Right*: (1) delta waves of different magnitude: (A) minor pre-excitation; (B, C) significant pre-excitation; (2) three consecutive QRS complexes with evident WPW-type pre-excitation; (3) short PR-type pre-excitation.

SHORT PR INTERVAL

In WPW pre-excitation, the PR interval is usually between 0.08 and 0.11 s. However, this form of pre-excitation can also occur with a normal PR interval in the presence of conduction delay within the anomalous pathway or because the anomalous pathway is remotely situated (usually left-sided). Only comparison with a baseline ECG tracing without pre-excitation will confirm whether the PR interval is shorter than usual.

QRS ABNORMALITIES

The QRS complexes are abnormal, i.e. wider than normal (often > 0.11 s) with a characteristic initial slurring (delta wave), caused by early direct activation of the ventricular myocardium as opposed to activation via the His–Purkinje network (Fig. 1.16). Different degrees of pre-excitation (more or less delta wave, QRS widening and T-wave abnormalities; see below) may be observed [1].

QRS complex morphology in the different surface ECG leads depends on the ventricular location of the anomalous pathway. Accordingly, WPW-type pre-excitation may be divided with respect to the location of the pathway [1]. Different algorithms exist to predict the location of the anomalous pathway [25]. However, electrophysiological studies are required to determine the exact location. Precise localization of the anomalous pathway is critical for successful ablation, a procedure performed to destroy the pathway, eliminate pre-excitation and avoid recurrence of paroxysmal supraventricular tachycardias.

REPOLARIZATION ABNORMALITIES

Repolarization is altered (T-wave polarity opposite to that of the pre-excited R wave) except in cases with minor pre-excitation. The changes are secondary to the alteration of depolarization and are more prominent when pre-excitation is greater.

DIFFERENTIAL DIAGNOSIS OF WPW-TYPE PRE-EXCITATION

Right-sided pre-excitation can be mistaken for LBBB; left-sided pre-excitation can be mistaken for RBBB, RVE and various myocardial infarction patterns. In all these cases, a short PR interval and the presence of a delta wave indicate the correct diagnosis of WPW-type pre-excitation.

SPONTANEOUS OR PROVOKED CHANGES IN MORPHOLOGY DUE TO ANOMALOUS CONDUCTION

Changes in the degree of pre-excitation are frequent. Pre-excitation can increase if conduction through the AV node is depressed (vagal manoeuvres, drugs, etc.) and can decrease if AV node conduction is enhanced (adrenaline, physical exercise, etc.).

Short PR-type pre-excitation (Lown–Ganong–Levine syndrome)

This type of pre-excitation is characterized by a short PR interval without changes in QRS morphology [21] (Fig. 1.16). It is impossible to be sure with a surface ECG whether the short PR interval is due to pre-excitation via an atrio-His pathway that bypasses slow conduction in the AV node or whether it is simply due to a rapidly conducting AV node. Associated arrhythmias (atrial, AV nodal and anomalous pathway dependent re-entry) are frequent in Lown–Ganong–Levine syndrome. Sudden death is very uncommon.

Mahaim-type pre-excitation

Mahaim-type pre-excitation usually presents with a normal PR interval, an LBBB-like QRS morphology and often an rS pattern in lead III [22]. A marked delta wave is usually not present. It is due to an accessory AV node connected directly to the right ventricle or is the result of an anomalous pathway linking the normal AV node to the right ventricle.

Electrocardiographic pattern of ischaemia, injury and necrosis [26–53]

The ionic changes, pathological alterations and electrophysiological characteristics that accompany different

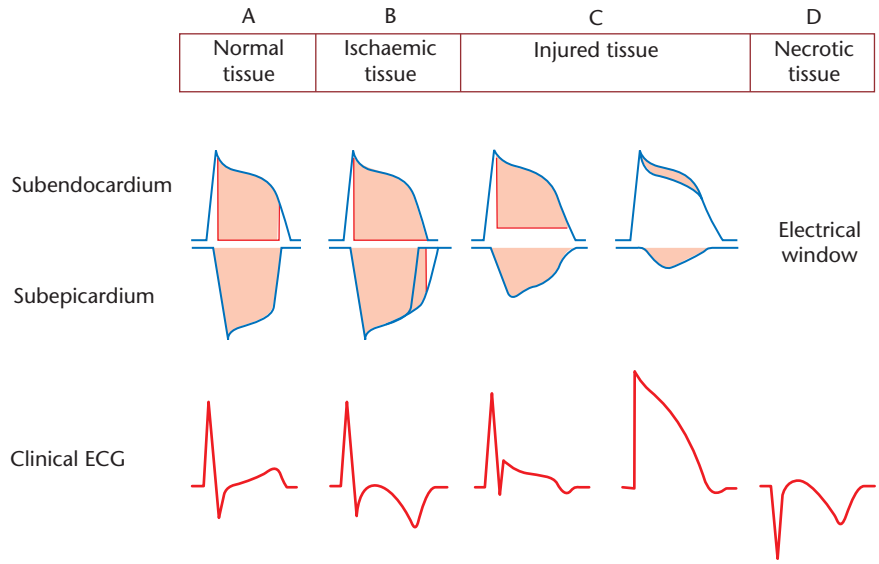

Figure 1.17 Corresponding electrical changes in subepicardial and subendocardial 'global action potentials' and the resulting ECG patterns in normal, ischaemic, injured or necrotic tissue. Correlations for normal tissue (A), subepicardial ischaemia (B), subepicardial injury (C) and necrotic tissue (D) are shown (see also Fig. 1.4).

stages of clinical ischaemia/infarction are illustrated in Fig. 1.17. The classic ECG sequence that appears in cases of complete coronary occlusion is as follows. The ECG pattern of subendocardial ischaemia (increase of T-wave amplitude) appears first. When the degree of clinical ischaemia is more important, the pattern of injury (ST-segment elevation) is present. Finally, necrosis of the myocardium is indicated by the development of a Q-wave pattern.

Electrocardiographic pattern of ischaemia

From an experimental perspective, ischaemia may be subepicardial, subendocardial or transmural. From the clinical point of view, only subendocardial and transmural ischaemia exist and the latter presents the morphology of 'subepicardial' ischaemia owing to the proximity of the subepicardium to the exploring electrode.

Experimentally and clinically, the ECG pattern of ischaemia (changes in the T wave) may be recorded from an area of the left ventricular subendocardium or subepicardium in which ischaemia induces a delay in repolarization. If the ischaemia is subendocardial, a more positive than normal T wave is recorded; in the case of subepicardial ischaemia (in clinical practice transmural), flattened or negative T waves are observed.

Alterations of the T wave due to ischaemic heart disease

The negative T wave of subepicardial ischaemia (clinically transmural) is symmetric, usually with an isoelectric ST segment. It is a common finding, especially in the long term after a Q-wave myocardial infarction (Figs 1.17D and 1.18D). It may also be a manifestation of acute coronary syndrome (ACS).

The electrocardiographic pattern of ischaemia is observed in different leads according to the affected zone. In the case of inferolateral wall involvement, T-wave changes are observed in II, III, aVF (inferior leads) and/or V6, I, aVL (lateral leads). In V1–V2 (inferobasal segment),

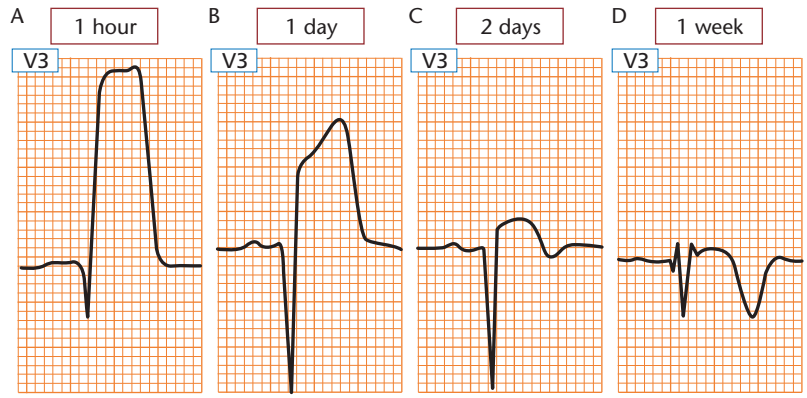

Figure 1.18 Evolutionary pattern of an extensive anterior wall myocardial infarction: (A) 1 h after the onset of pain; (B) 1 day later; (C) 2 days later; (D) 1 week later.

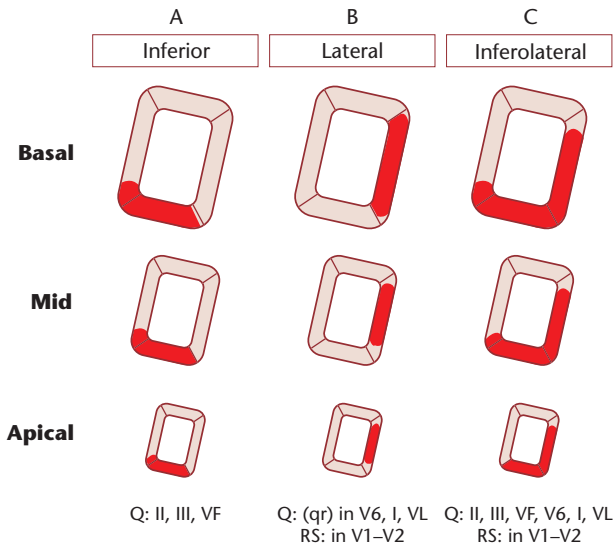

Figure 1.19 Anatomical–ECG correlations in myocardial infarction affecting (A) inferior wall, (B) lateral wall and (C) the entire inferolateral zone.

the T wave is positive instead of negative due to a mirror image (in subepicardial inferobasal injury ST depression instead of elevation, and in the case of necrosis a tall R wave instead of a Q wave) (Fig. 1.19). In anteroseptal involvement, T-wave changes are found from V1–V2 to V4–V5. If recorded in right precordial leads, it may correspond to a proximal occlusion of the left anterior descending (LAD) artery.

In contrast, an increase in T-wave amplitude, a common feature of subendocardial ischaemia, is recognized less frequently and the difficulty of diagnosis is increased because of its transient nature. It is observed in the initial phase of an attack of Prinzmetal angina (Fig. 1.20A) and occasionally in the hyperacute phase of ACS (Fig. 1.20B). Sometimes, it is not easy to be sure when a positive T wave may be considered abnormal. Therefore, sequential changes should be evaluated.

Table 1.4 Causes of a more-positive-than-normal T wave (other than ischaemic heart disease)

Normal variants: vagotonia, athletes, elderly
Alcoholism

Stroke
Hyperkalaemia
Advanced AV block (tall and peaked T wave in the narrow QRS complex escape rhythm)

ALTERATIONS OF THE T WAVE IN VARIOUS CONDITIONS OTHER THAN ISCHAEMIC HEART DISEASE

The most frequent causes, apart from ischaemic heart disease, of a negative, flattened or more-positive-than-normal T wave are summarized in Tables 1.4 and 1.5. Examples of some of these T-wave abnormalities not due to ischaemic heart disease are shown in Fig. 1.21. Pericarditis is a very important differential diagnosis of the pattern of subepicardial ischaemia. The ECG in pericarditis shows a pattern of extensive subepicardial ischaemia with less frequent mirror images in the frontal plane, and with less negative T waves.

Electrocardiographic pattern of injury [26–36]

Experimentally and clinically, the ECG pattern of injury (changes in the ST segment) is recorded in the area of myocardial subendocardium or subepicardium where

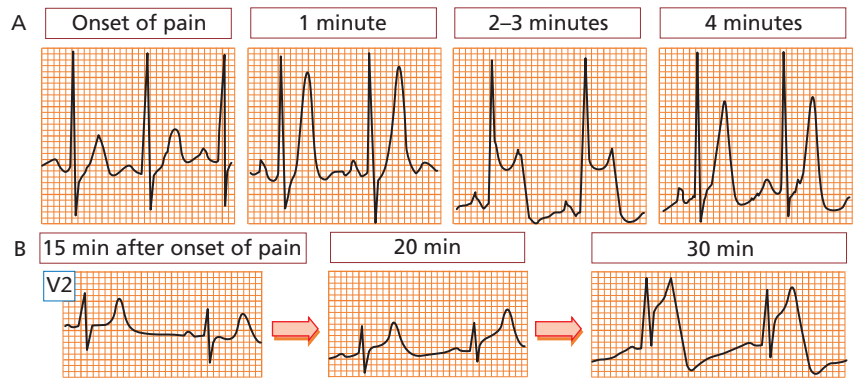

Figure 1.20 (A) Patient with Prinzmetal angina crisis: sequence of Holter ECGs recorded during a 4-min crisis. Note how the T wave becomes peaked (subendocardial ischaemia), with a subepicardial injury morphology appearing later; at the end of the crisis, a subendocardial ischaemia morphology reappears before the basal ECG returns. (B) A 45-year-old patient presenting with acute chest pain with a tall peaked T wave in right precordial leads following a normal ST segment as the only suggestive sign of acute coronary syndrome. A few minutes later, ST-segment elevation appears, followed by an increase in R wave and decrease in S wave.

Table 1.5 Causes of negative or flattened T waves (other than ischaemic heart disease)

Normal variants: children, black race, hyperventilation, females
Pericarditis
Cor pulmonale and pulmonary embolism
Myocarditis and cardiomyopathies
Alcoholism
Stroke
Myxoedema
Athletes
Medication: amiodarone, thioridazine
Hypokalaemia

Post-intermittent depolarization abnormalities ('electrical memory')
Left bundle branch block
Pacemakers
Wolff–Parkinson–White syndrome

diastolic depolarization occurs as a consequence of a significant decrease in blood supply.

In the leads facing the injured zone, ST depression is recorded if the current of injury is dominant in the subendocardium (ECG pattern of subendocardial injury), while ST elevation is observed if the current of injury is subepicardial (clinically transmural) (ECG pattern of subepicardial injury). Mirror image patterns also exist, for example if subepicardial injury occurs in the posterior part of the lateral wall of the left ventricle, ST-segment elevation will be observed in the leads on the back while ST depression will be seen in V1–V2 as a mirror image. Also, the mirror images, or reciprocal changes, are very useful for locating the culprit artery and the site of the occlusion (Fig. 1.22).

The different morphologies of subepicardial injury in the evolution of acute Q-wave anterior myocardial infarction are shown in Fig. 1.18 and the various subendocardial injury ECG patterns observed in the course of an acute non-Q-wave myocardial infarction are shown in Fig. 1.23.

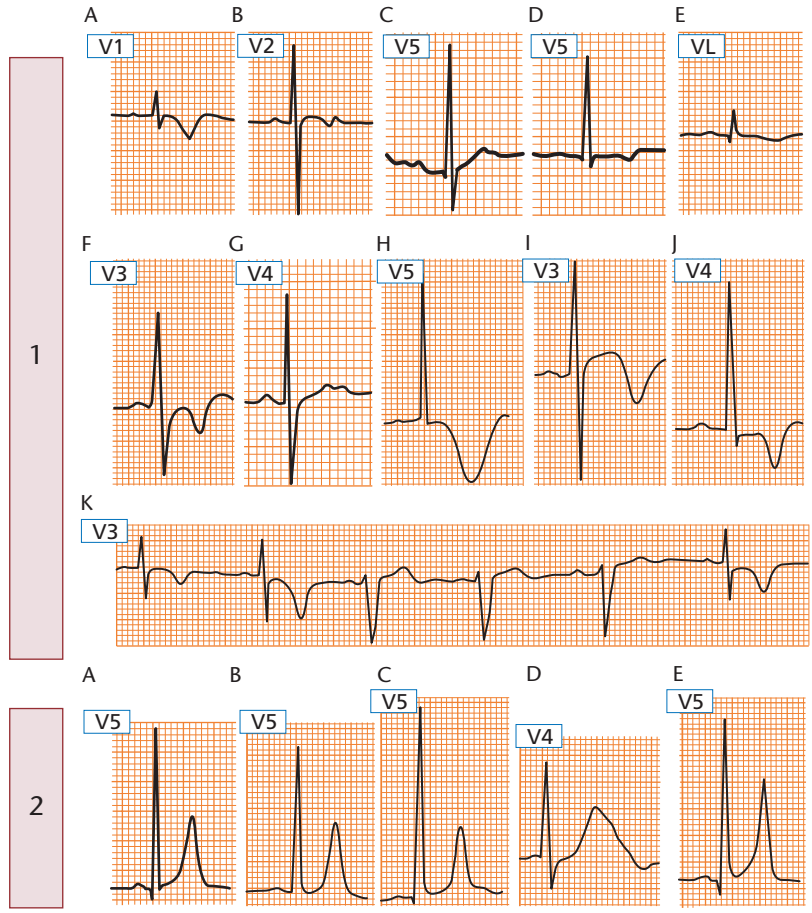

Figure 1.21 T-wave morphologies in conditions other than coronary artery disease. (1) Some morphologies of flattened or negative T waves: (A, B) V1 and V2 of a healthy 1-year-old girl; (C, D) alcoholic cardiomyopathy; (E) myxoedema; (F) negative T wave after paroxysmal tachycardia in a patient with initial phase of cardiomyopathy; (G) bimodal T wave with long QT frequently seen after long-term amiodarone administration; (H) negative T wave with very wide base, sometimes observed in stroke; (I) negative T wave preceded by ST elevation in an apparently healthy tennis player; (J) very negative T wave in a case of apical cardiomyopathy; (K) negative T wave in a case of intermittent left bundle branch block in a patient with no apparent heart disease. (2) Tall peaked T wave in (A) variant of normal (vagotonia with early repolarization), (B) alcoholism, (C) left ventricular enlargement, (D) stroke and (E) hyperkalaemia.

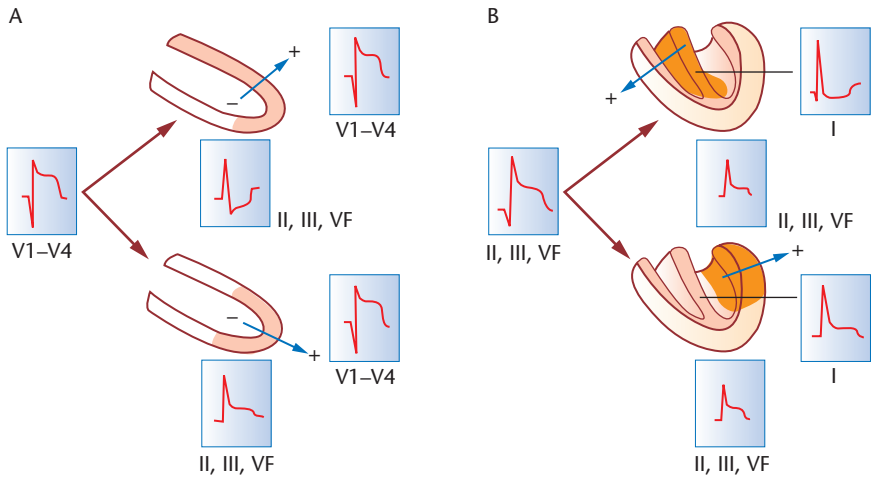

Figure 1.22 (A) ST elevation in precordial leads: as a consequence of occlusion of the left anterior descending artery (LAD), the ST changes in reciprocal leads (II, III, VF) allow identification of the site of occlusion, i.e. proximal LAD (above) shows ST depression or distal LAD (below) shows ST elevation. (B) ST elevation in inferior leads (II, III, aVF): the ST changes in other leads, in this case lead I, provide information on whether the inferior infarction is likely to be due to occlusion of the right coronary artery (above) (ST depression) or left circumflex artery (below) (ST elevation).

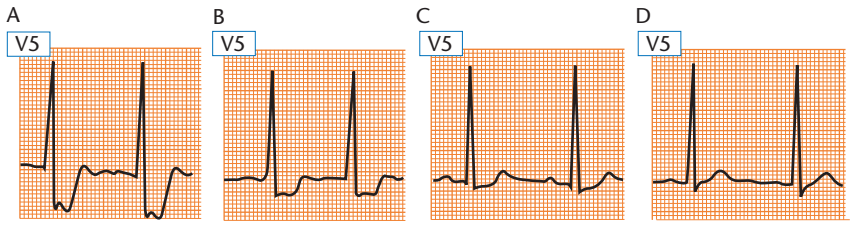

Figure 1.23 A 65-year-old patient with non-Q wave infarction. Note the evolutionary morphologies (A–D) during the first week until normalization of the ST segment.

ECG PATTERNS FOR CLASSIFICATION, OCCLUDED ARTERY IDENTIFICATION AND RISK STRATIFICATION OF ACUTE CORONARY SYNDROMES (ACS)

ACS may be classified into two types according to ECG expression: with or without ST-segment elevation. This classification has clear clinical significance as the former is treated with fibrinolysis and the latter is not. Figure 1.24 shows the different ECG presentations in ACS and their evolution.

ACS WITH ST ELEVATION [26–33]

New occurrence of ST elevation ≥ 2 mm in leads V1–V3 and ≥ 1 mm in other leads is considered abnormal and evidence of acute coronary ischaemia in the clinical setting of ACS. Sometimes minor ST elevation may be seen as a normal variant in V1–V2. Because of modern treatment, some acute coronary syndromes with ST elevation do not lead to Q-wave myocardial infarction and may not provoke a rise in enzymes. Nevertheless, the majority will develop a myocardial infarction, usually of Q-wave type (Fig. 1.24).

LAD artery occlusion leads to ST-segment elevation predominantly in precordial leads, while right coronary artery (RCA) or left circumflex (LCX) artery occlusion gives rise to ST-segment elevation in the inferior leads (Fig. 1.22). The extent of myocardium at risk can be estimated based on the number of leads with ST changes ('ups and downs') [26]. This approach has some limitations, especially related to the pseudo-normalization of ST changes in the right precordial leads that often occurs when the RCA occludes prior to the origin of the right ventricular artery.

Proximal LAD occlusion (before the first diagonal and septal arteries) as well as RCA occlusion proximal to the right ventricular artery have a poor prognosis. It is therefore useful to predict the site of occlusion in the early phase of ACS to enable decisions regarding the need for urgent reperfusion strategies. Careful analysis of ST changes in the 12-lead ECG recorded at admission may predict the culprit artery and the location of the occlusion. ST elevation is found in leads that face the head of an injury vector, while in the opposite leads ST depression can be recorded as a mirror image. Algorithms for the prediction of the sites of arterial occlusion are shown in Figs 1.25 and 1.26.

The right ventricular involvement that usually accompanies proximal RCA occlusion may be shown by ST changes in the right precordial leads (V3R, V4R) [27] (Fig. 1.26). ST-segment changes in these leads, though specific, disappear early during the evolution of myocardial infarction. Furthermore, these leads are often not recorded in emergency rooms. Thus, the real value of these changes is limited and in order to identify the culprit artery (RCA or LCX) in the case of an acute inferior myocardial infarction, we use the algorithm shown in Fig. 1.26 [31].

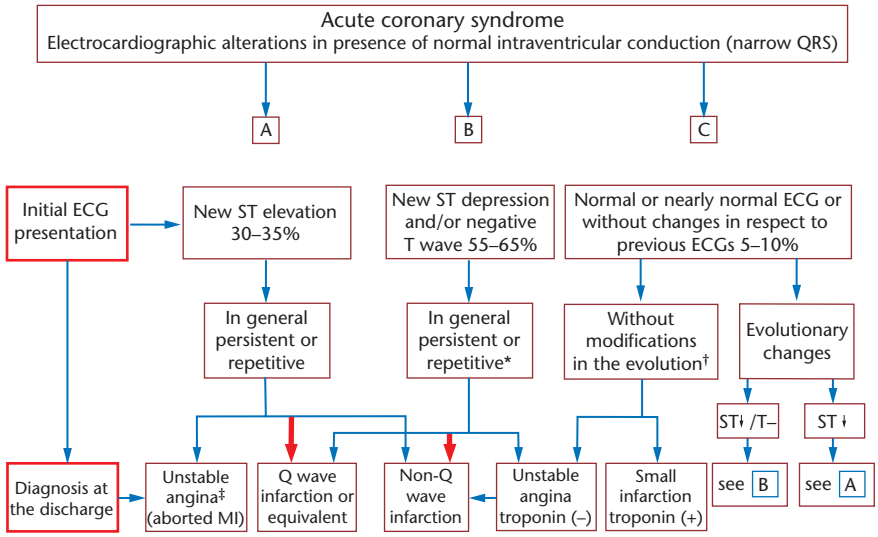

Figure 1.24 ECG alterations observed in patients with acute coronary syndrome (ACS) presenting with narrow QRS complex. Note the initial ECG presentations: (A) new ST elevation; (B) new ST depression/negative T wave; (C) normal or nearly normal ECG T wave or without changes in respect to previous ECGs. The approximate incidence of each presentation and the likely final discharge diagnosis based on both clinical and ECG settings are indicated. *In ACS with ECG pattern of ST depression or negative T waves, troponin levels allow differentiation between unstable angina (troponin negative) and non-Q-wave infarction (troponin positive). Usually, cases with short-duration ECG changes, particularly with negative T waves, present with negative troponin levels and correspond to unstable angina. †According to ESC/ACC guidelines in patients presenting with chest pain or its equivalent suggestive of ACS with accompanying normal ECG, troponin level is a key factor in differentiating between small myocardial infarction (MI) and unstable angina. ‡Sometimes, thanks to quick treatment, patients present with normal troponin levels despite important ST elevation in the initial ECG (aborted MI).

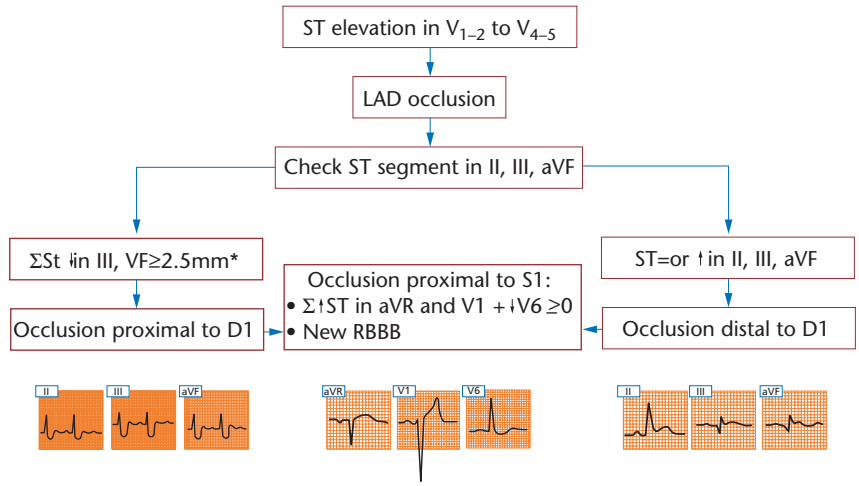

Figure 1.25 Algorithm for locating occlusion of left anterior descending artery (LAD) in evolving myocardial infarction with ST elevation (STEMI) in precordial leads, with ECG examples of the different situations. *Cases with ST depression < 2.5 mm are the most difficult to classify.

Furthermore, the criterion of isoelectric or elevated ST in V1 has the highest accuracy in predicting proximal RCA occlusion [32]. In these cases the ST elevation in V1 may also occur in V2 or V4 but with a V1/V3–4 ratio over 1. This differentiates these cases from cases of antero-inferior infarction [33], in which there is also ST elevation in inferior and precordial leads but the ST elevation V1/V3–4 ratio is less than 1.

ACS WITHOUT ST ELEVATION

ACS with ST depression in eight or more leads has a worse prognosis as it frequently corresponds to a left main artery subocclusion or its equivalent (three-vessel disease). Generally, in these cases ST elevation in aVR can be observed as a mirror image [34] (Fig. 1.27). If, in cases of ACS without ST elevation, ST depression in V4–V5 is followed by a final positive T wave, the prognosis is better

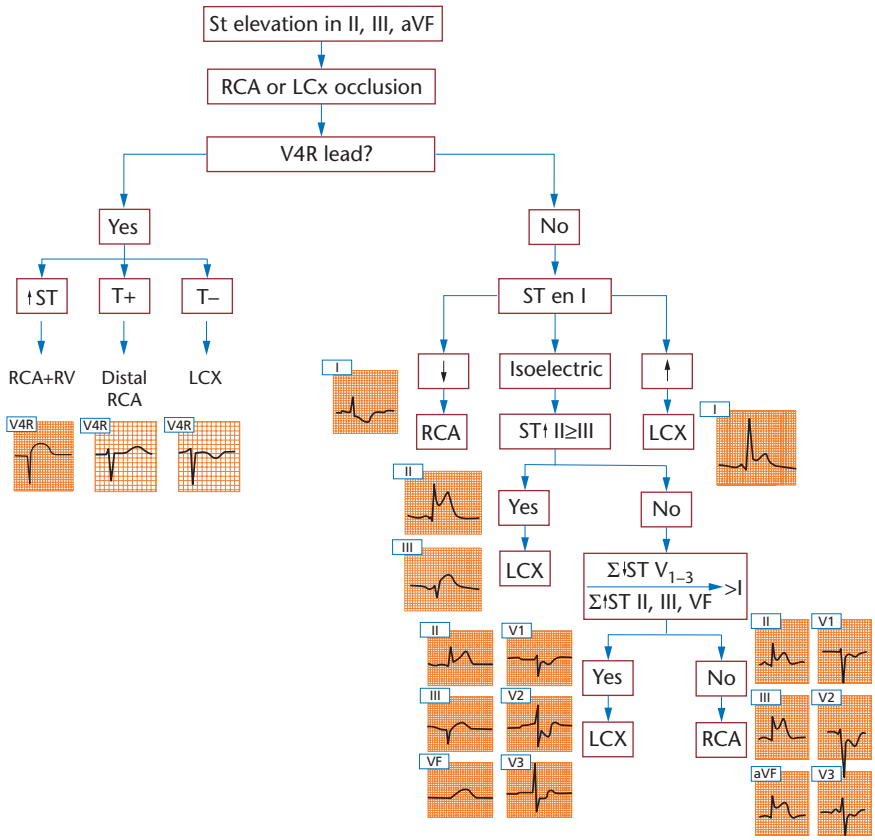

Figure 1.26 Algorithm for locating occlusion of right coronary artery (RCA) or left circumflex artery (LCx) in evolving myocardial infarction with ST elevation (STEMI) in inferior leads, with ECG examples of different situations.

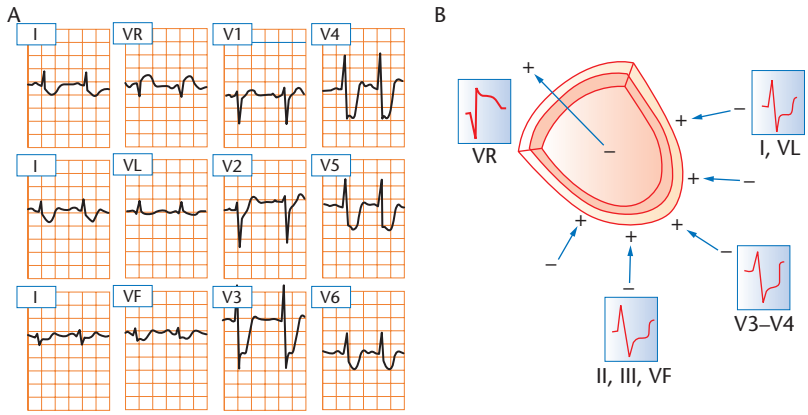

Figure 1.27 (A) ST-segment depression in more than eight leads and ST-segment elevation in VR in a case of non-STEMI due to involvement of the left main coronary artery. Note that the maximum depression occurs in V3–V4 and ST-segment elevation occurs in aVR as a mirror image. (B) Schematic representation that explains how ST-segment depression is seen in all leads, except for aVR and V1, in a case of non-Q-wave infarction secondary to the involvement of the left main coronary artery. The vector of circumferential subendocardial injury is directed from the subepicardium to the subendocardium and is seen as a negative vector in all leads except VR.

and single-vessel (often the proximal LAD) disease may be present [35]. The presence of deep negative T waves from V1 to V4–V5 suggests subocclusion of the proximal LAD. On the other hand, in the group of ACS with ST depression and/or negative T waves, the presence in leads with dominant R waves of mild ST depression usually signifies a worse prognosis than negative T waves.

ST-segment alterations remote from the acute phase of ischaemic heart disease

ST-segment elevation is usually found in association with coronary spasm (Prinzmetal angina) often preceded by peaked and tall T waves [36] (see Fig. 1.20A). Occasionally, upward convex ST elevation may persist after the acute phase of a myocardial infarction. It has been

Table 1.6 Most frequent causes of ST-segment elevation (other than ischaemic heart disease)

Normal variants: chest abnormalities, early repolarization, vagal overdrive. In vagal overdrive, ST-segment elevation is mild and generally accompanies the early repolarization image. T wave is tall and asymmetric
Athletes: sometimes an ST-segment elevation exists that may even mimic an acute coronary syndrome with or without negative T waves, at times prominent. No coronary involvement has been found, although this abnormality has been observed in sportsmen who die suddenly; thus its presence implies the need to exclude hypertrophic cardiomyopathy
Acute pericarditis in its early stage and myopericarditis
Pulmonary embolism
Hyperkalaemia: the presence of a tall peaked T wave is more evident than the accompanying ST-segment elevation, but sometimes it may be evident
Hypothermia
Brugada's syndrome
Arrhythmogenic right ventricular cardiomyopathy
Dissecting aortic aneurysm
Left pneumothorax
Toxicity secondary to cocaine abuse, etc.

classically considered to be related to left ventricular aneurysm. The specificity of this sign is high but its sensitivity is low. On the other hand, slight persistent ST-segment depression is frequently observed in coronary disease due to persistence of ischaemia. An exercise test may increase this pattern.

ST-SEGMENT ALTERATIONS IN CONDITIONS OTHER THAN ISCHAEMIC HEART DISEASE

Different causes of ST-segment elevation, aside from ischaemic heart disease, are shown in Table 1.6. Representative examples are illustrated in Fig. 1.28. The most frequent causes of ST-segment depression in situations other than ischaemic heart disease are shown in Table 1.7.

Electrocardiographic pattern of necrosis [37–53]

Classically, the electrocardiographic pattern of established necrosis is associated with a pathological Q wave, generally accompanied by a negative T wave (necrosis Q wave) [1] (Table 1.8). The specificity of this criterion is high but its sensitivity is low (around 60%) and is even lower with current treatment regimens and the new definition of myocardial infarction (ESC/ACC consensus) [37,38].

Table 1.7 Most frequent causes of ST-segment depression (other than ischaemic heart disease)

Normal variants: sympathetic overdrive, neurocirculatory asthenia, hyperventilation
Medications: diuretics, digitalis
Hypokalaemia
Mitral valve prolapse
Post-tachycardia
Secondary: bundle branch block, ventricular hypertrophy

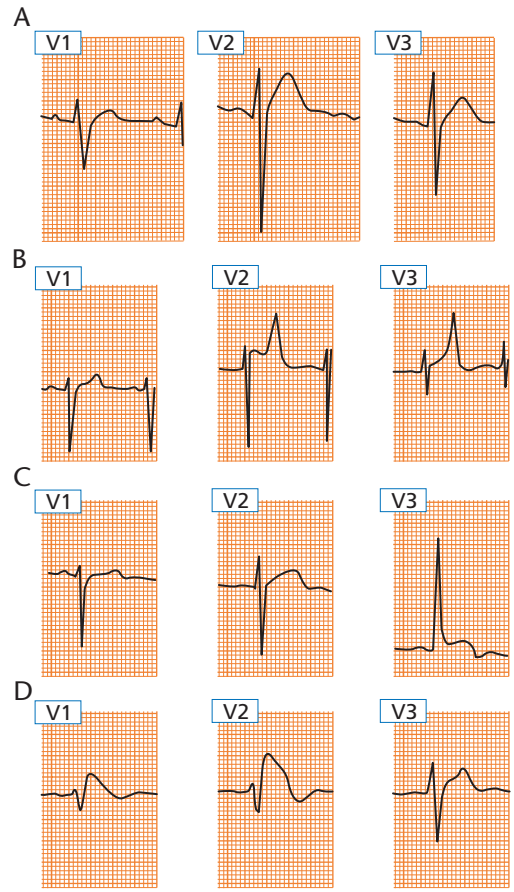

Figure 1.28 The most frequent causes of ST elevation other than ischaemic heart disease: (A) pericarditis; (B) hyperkalaemia; (C) in athletes; (D) Brugada pattern.

Figure 1.18 shows the ECG morphology seen with transmural involvement after total occlusion of a coronary artery. After an initial stage of ST-segment elevation, a Q wave with a negative T wave appears. It was thought that cases of non-Q-wave infarction had a predominantly subendocardial location (electrically 'mute'). Thus, it was considered that Q-wave infarction signified transmural involvement, while non-Q-wave infarction implied subendocardial compromise.

It is now well known that, from a clinical point of view, isolated subendocardial infarctions do not exist [39]. Nevertheless, there are infarctions that compromise a great portion of the wall, but with subendocardial predominance, which may or may not develop a Q wave. Furthermore, there are completely transmural infarctions (such as infarctions of basal parts of the cardiac

Table 1.8 Characteristics of the pathological Q wave, named 'necrosis Q wave' when secondary to myocardial infarction

Characteristics of pathological Q wave

Duration: ≥ 30 ms in I, II, III, aVL and aVF, and in V3–V6. The presence of a Q wave is normal in aVR. In V1–V2, all Q waves are pathological. Usually also in V3, except in cases of extreme laevo-rotation (qRs in V3)

Depth: above the limit considered normal for each lead, i.e. generally 25% of the R wave (frequent exceptions, especially in aVL, III and aVF)

Present even a small Q wave in leads where it does not normally occur (e.g. qrS in V1–V2)

Q wave with decreasing voltage from V3–V4 to V5–V6, especially if accompanied by a decrease of voltage in R wave compared with previous ECG

Criteria for diagnosing location of myocardial infarction

Anteroseptal zone

Q wave, regardless of duration and depth, in V1–V3

Presence of Q wave > 30 ms in duration and over 1 mm in depth in leads I, aVL, V4–V6

Inferolateral zone

Presence of Q wave in II and aVF; lead III is not used due to false-positive cases

Q wave may appear in lateral leads (V6 or V6 and/or I and aVL)

ECG may present equivalent of Q wave (increase in R wave in V1–V2) or be practically normal in cases of involvement of posterior part of lateral wall

walls, especially the posterior part of the lateral wall) that may not develop a Q wave. This assumption has been recently confirmed by magnetic resonance imaging (MRI) [40]. Consequently, the distinction between transmural (Q-wave infarction) and subendocardial (non-Q-wave infarction) can no longer be supported.

Q-wave infarction

Genesis of Q Wave The appearance of the Q wave of necrosis may be explained by the electrical window theory of Wilson (Fig. 1.29). The vector of necrosis is equal in magnitude but opposite in direction to the normal vector that would be generated in the same zone without necrosis. The onset of ventricular depolarization changes when the necrotic area corresponds to a zone that is depolarized within the first 40 ms of ventricular activation, which applies to the majority of the left ventricle except the posterobasal parts.

Location of infarction In everyday practice the nomenclature of the affected myocardial infarction zone is still determined by the presence of Q waves in different leads as proposed more than 50 years ago by Myers *et al.* [41]

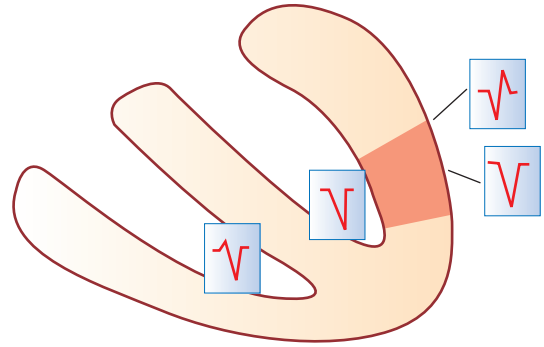

Figure 1.29 According to Wilson the necrotic zone is an electrical window that allows the intraventricular normal QS morphology to be recorded from the opposing necrotic wall of the left ventricle. The lead facing the necrotic myocardium 'looks' into the cavity of the left ventricle.

based on their classical pathological study. According to this classification, the presence of Q waves in V1–V2 represents septal infarction, in V3–V4 anterior infarction, in V1–V4 anteroseptal infarction, in V5–V6 low lateral infarction, in V3–V6 anterolateral infarction, in V1–V6 anteroseptolateral infarction, and in I and aVL high lateral infarction.

However, this classification has some limitations. Correlation with coronary angiography and imaging techniques including MRI [42–46] has revealed the following.

1 The presence of a Q wave in V1–V2 does not imply involvement of the entire septal wall; as a matter of fact the initial vector of ventricular depolarization originates in the mid-low part of the anterior septum. Therefore, the upper part of the septum need not be involved for the appearance of a Q wave in V1–V2.
2 Correlation with cardiovascular magnetic resonance (CE-CMR) [45,46] has demonstrated that: (a) the posterior wall often does not exist, therefore the basal part of the inferior wall should be called the inferobasal segment (segment 4); (b) the necrosis vector (NV) of the inferobasal segment faces V3–V4 and not V2–V1, therefore the RS morphology does not originate in V1; in those cases where the inferobasal segment does not bench upwards (the entire inferior wall is flat), the NV is directed only upwards and contributes to the Q wave in II, III and VF; (c) in cases of isolated lateral infarction, the NV may face V1, explaining the RS morphology seen in this lead.
3 In rare cases, if the LAD is very long, the occlusion of this artery proximal to S1 and D1 may not cause Q waves in I and aVL because the vector of necrosis of the lateral wall may be masked by the vector of necrosis of the inferior wall.
4 Because of new treatments for revascularization given

Type of MI		Infarction area (CMR)	ECG pattern	Name given to MI	Most probable place of occlusion
ANTEROSEPTAL ZONE	A1 n=7		Q in V1–2 SE: 86% ES: 98%	Septal	LAD 
	A2 n=7		Q in V1–2 to V4–V6 SE: 86% ES: 98%	Apical/ anteroseptal	LAD 	A3 n=6		Q in V1–2 to V4–V6 I and VL SE: 83% ES: 98%	Extensive anterior	LAD 
	A4 n=4		Q (qs or r) in VL (I) and sometimes V2–3 SE: 70% ES: 100%	Limited anterior	LAD 
INFEROLATERAL ZONE	B1 n=6		Q (qr or r) in I, VL, V5–6 and/or RS in V1 SE: 50% ES: 98%	Lateral	LCX 
	B2 n=8		Q in II, III, VF SE: 87.5% ES: 98%	Inferior	RCA LCX 	B3 n=10		Q in II, III, VF (B2) + Q in I, VL, V5, 6 and / or RS in V1 (B1) SE: 70% ES: 100%	Inferolateral	

Figure 1.30 Relationship between infarcted area, ECG pattern, name given to infarction and the most probable culprit artery and place of occlusion. LAD, left anterior descending artery; RCA, right coronary artery; LCX, left circumflex artery.

in the acute phase, the necrotic zone is often very limited compared with the zone at risk in the acute phase.

5 The location of precordial, especially mid-precordial (V3–V5), leads may change from one day to another and therefore it is difficult to make a diagnosis based on the presence or absence of Q waves in these leads.

As a result of these limitations, a study on correlations between ECG patterns and different myocardial areas of necrosis detected by CMR has been undertaken in the chronic phase of myocardial infarction [45,46]. The left ventricle was divided into two zones, anteroseptal and inferolateral. Figure 1.30 shows seven ECG patterns that accurately correlate with seven areas of necrosis detected on CMR (four anteroseptal and three inferolateral) (see also Figs 1.31 and 1.32). Nevertheless, some areas, especially at the base, frequently present with normal ECGs in the chronic phase [46].

Quantification A quantitative QRS score has been developed by Selvester *et al.* [47] to estimate the extent of myocardial necrosis especially in the case of anterior myocardial infarction. Recently, the same group demonstrated that MRI may improve its accuracy [48]. The most significant error was the misinterpretation of Q waves in V1–V2 as indicating basal septal and anterior wall

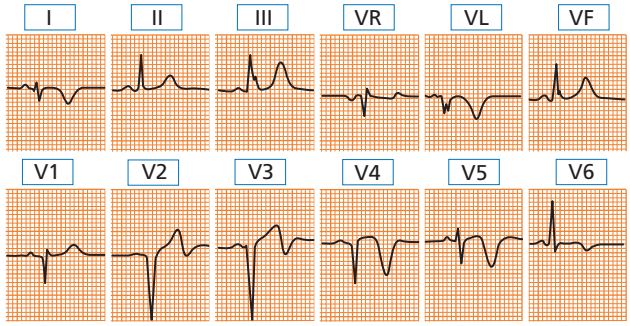

Figure 1.31 ECG of extensive anterior myocardial infarction (A3 type in Fig. 1.30).

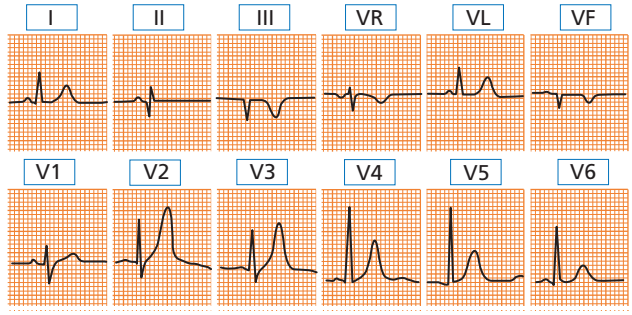

Figure 1.32 ECG of inferolateral myocardial infarction (B3 type in Fig. 1.30).

involvement. As already stated this is incorrect because the first vector (r wave in V1–V2) is generated in the mid-low anterior part of the septum. Also recently, it has been found that pre-discharge scoring in patients with anterior Q waves did not correlate with the amount of myocardial damage as estimated by radionuclide techniques in patients treated with and without thrombolytics [49]. Furthermore, spontaneous changes in the QRS score from discharge to 6 months seem to be of limited value in identifying patients with late improvement of perfusion or left ventricular function.

Differential diagnosis of pathological Q wave

Although the specificity of a pathological Q wave for diagnosing myocardial infarction is high, similar Q waves can be seen in other conditions. The diagnosis of myocardial infarction is based not only on electrocardiographic alterations but also on the clinical evaluation and enzyme changes. The pattern of ischaemia or injury accompanying a pathological Q wave is supportive of the Q wave being secondary to ischaemic heart disease. The main causes of pathological Q waves other than myocardial necrosis are listed in Table 1.9. On the other hand, in 5–25% of Q-wave infarctions (with the highest incidence in inferior wall infarction) the Q wave disappears with time, which explains the relatively poor sensitivity of the Q wave for detecting old myocardial infarction.

Table 1.9 Pathological Q wave not secondary to myocardial infarctioon

During the evolution of an acute disease involving the heart
Acute coronary syndrome with an aborted infarction
Coronary spasm (Prinzmetal angina type)
Acute myocarditis
Presence of transient apical dyskinesia that also shows ST-segment elevation and a transient pathological q wave (Tako-tsubo syndrome) [53]
Pulmonary embolism
Miscellaneous: toxic agents, etc.
Chronic pattern
Recording artefacts
Normal variants: aVL in the vertical heart and III in the dextrorotated and horizontal heart
QS in V1 (hardly ever in V2) in septal fibrosis, emphysema, the elderly, chest abnormalities, etc.
Some types of right ventricular hypertrophy (chronic cor pulmonale) or left ventricular hypertrophy (QS in V1–V2, or slow increase in R wave in precordial leads, or abnormal q wave in hypertrophic cardiomyopathy)
Left bundle branch conduction abnormalities
Infiltrative processes (e.g. amyloidosis, sarcoidosis, tumours, chronic myocarditis, dilated cardiomyopathy)
Wolff–Parkinson–White syndrome
Dextrocardia
Phaeochromocytoma

Diagnosis of necrosis in the presence of ventricular blocks, pre-excitation or ventricular pacemaker

Complete RBBB Since cardiac activation begins normally in RBBB, the presence of a myocardial infarction causes an alteration in the first part of the QRS complex that can generate a Q wave, just as with normal ventricular conduction. Furthermore, in the acute phase the ST–T changes can be seen exactly as with normal activation. Patients with ACS with ST elevation that during its course develops new-onset complete RBBB usually have the LAD occluded before the first septal and first diagonal arteries (Fig. 1.25). This is explained by the fact that the right bundle branch receives its blood supply from the first septal artery.

Complete LBBB In the acute phase, the diagnosis of myocardial infarction in the presence of complete LBBB may be suggested by ST-segment changes [50]. In the chronic phase, detection of underlying myocardial infarction is difficult. Ventricular depolarization starts close to the base of the anterior papillary muscle of the right ventricle. This causes a depolarization vector that is directed forward, downwards and to the left. Trans-septal depolarization of the left ventricle initiates subsequent

vectors. As a result, even if important zones of the left ventricle are necrotic, the overall direction of the initial depolarization vector does not change and it continues to point from right to left, preventing the inscription of a Q wave. Nevertheless, small 'q' waves or tall R waves may occasionally be observed [6]. The correlation of clinical and ECG changes with enzyme changes and radionuclide studies have confirmed that the presence of Q waves in I, aVL, V5 and V6 and R waves in leads V1–V2 are the most specific criteria for diagnosing myocardial infarction in the presence of LBBB in the chronic phase [51].

Diagnosis of Q-wave myocardial infarction in the presence of a hemiblock In general, necrosis associated with LAH may be diagnosed without difficulty. In the case of an ECG with left-axis deviation of the QRS and Q waves in II, III and aVF, the presence of QS without a terminal 'r' wave confirms the association with LAH. In some cases, mainly in small inferior myocardial infarctions, LAH may mask myocardial necrosis. The initial vector is directed more downwards than normal as a result of LAH and masks any necrosis vector due to a small inferior myocardial infarction.

LPH may mask or decrease an inferior necrosis pattern by converting a QS or Qr morphology in II, III and aVF into QR or qR pattern. It may also cause a small positive wave in I and aVL in the case of a lateral myocardial infarction because the initial vector in LPH may be directed more upwards than usual as a result of LPH and mask the necrosis vector of a small lateral infarction.

Pre-excitation and pacemakers It is difficult to diagnose myocardial infarction in the presence of pre-excitation. Sometimes it may be suggested by changes of repolarization especially in the acute phase of ACS. Also, in patients with pacemakers the changes in repolarization, especially ST elevation, may suggest ACS [52]. In the chronic phase of myocardial infarction the presence of a spike qR pattern, especially in V5–V6, is a highly specific but poorly sensitive sign of necrosis.

Value of the ECG in special conditions [1,4,14]

The most characteristic ECG patterns in different clinical conditions, such as electrolyte imbalance, hypothermia and in athletes, are shown in Fig. 1.33.

ECG patterns associated with sudden cardiac death

Figure 1.34 shows the most characteristic ECG patterns in genetically induced conditions that may trigger sudden death, such as long QT syndrome, Brugada's syndrome and arrhythmogenic right ventricular dysplasia. Hypertrophic cardiomyopathy is often associated with an ECG showing left ventricular hypertrophy without clear differentiation from other causes of left ventricular hypertrophy. However, a typical ECG pattern is sometimes present (Fig. 1.34).

ECG of macroscopic electrical alternans [1]

Alternans of ECG morphologies is diagnosed when there are repetitive changes in the morphology of alternate QRS complexes, ST segments or rarely P waves. The presence of definite QRS alternans during sinus rhythm

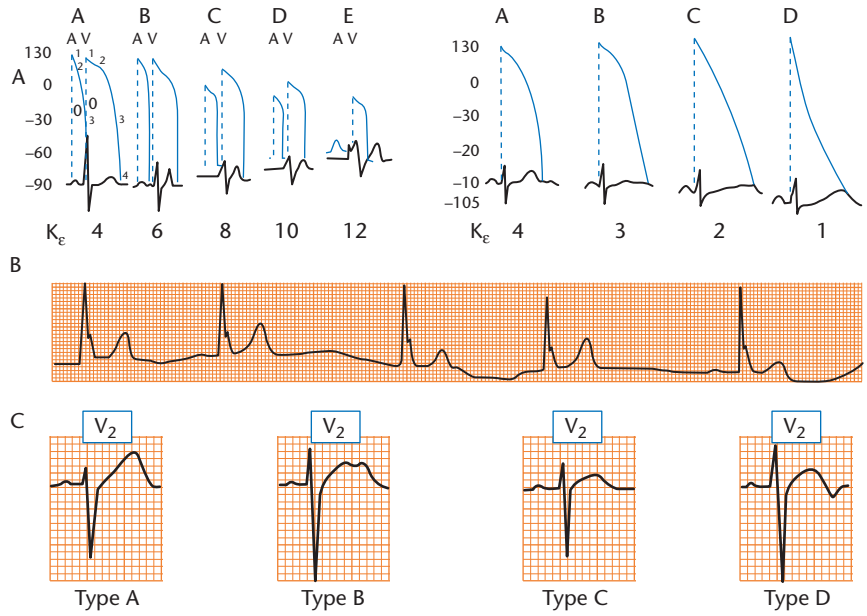

Figure 1.33 ECG patterns in (A) hyperkalaemia and hypokalaemia (see different patterns at different levels of K^+); (B) hypothermia (note the Osborne or 'J' wave at the end of the QRS and bradycardia with different repolarization abnormalities); (C) athletes without evidence of heart disease.

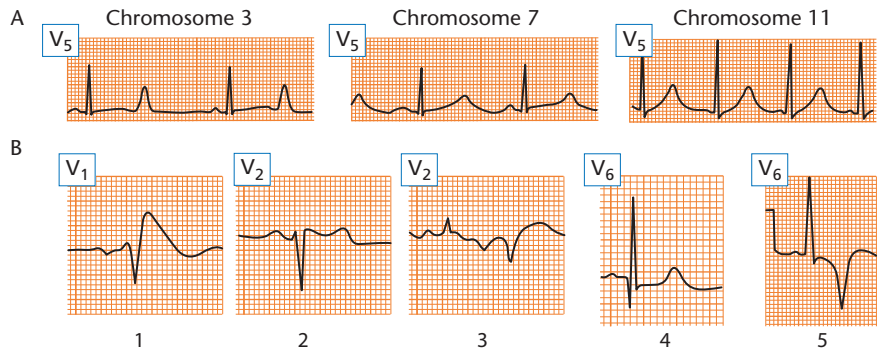

Figure 1.34 Other ECG patterns associated with sudden cardiac death. (A) Long QT syndrome related to genetic abnormalities on chromosomes 3, 7 and 11. (B1,2) The Brugada pattern: (1) typical, with coved ST elevation; (2) atypical, with wide r′ and 'saddleback' ST elevation (also a possible normal variant). (B3) Arrhythmogenic right ventricular cardiomyopathy. Note the atypical complete right bundle block, negative T waves in V1–V4 and premature ventricular impulses from the right ventricle. QRS duration is much longer in V1 than in V6. (B4) Typical pattern of a pathological Q wave in a patient with hypertrophic cardiomyopathy. (B5) Typical ECG pattern from a patient with hypertrophic apical cardiomyopathy.

may occasionally be observed in mid-precordial leads, particularly in very thin subjects during respiration. True alternans of QRS complexes (change in morphology without change of width) is suggestive of a large pericardial effusion and sometimes cardiac tamponade (Fig. 1.35A). Alternans of QRS morphology may also be observed during supraventricular arrhythmias, especially in patients with WPW syndrome. True alternans of

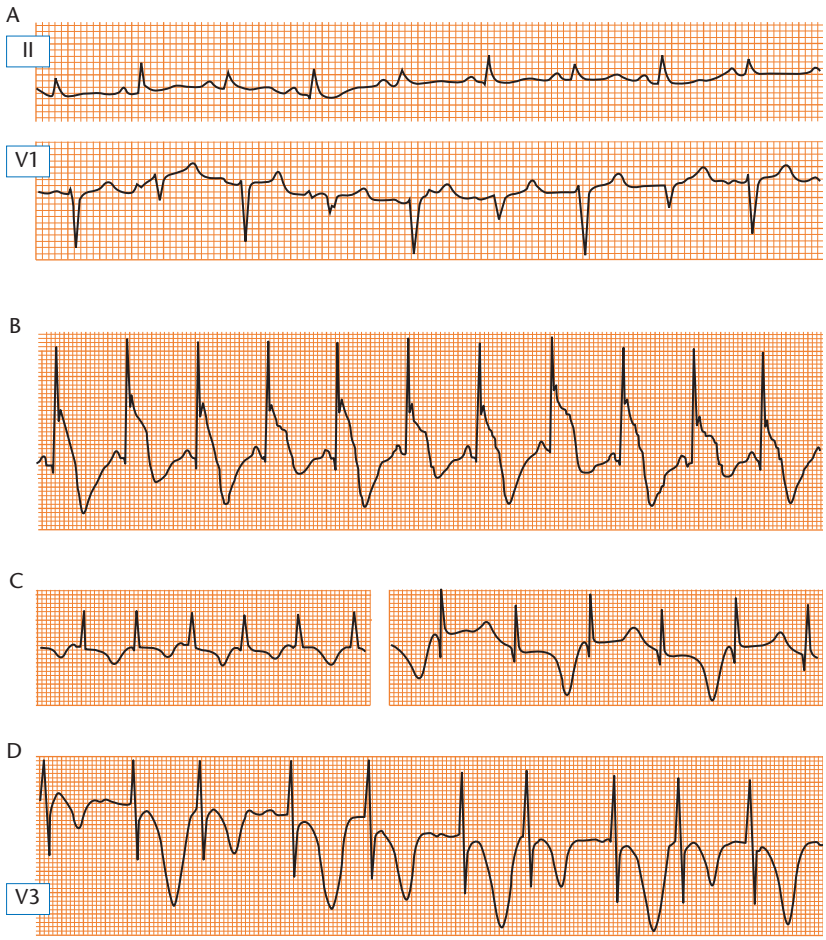

Figure 1.35 Typical examples of electrical alternans: (A) alternans of QRS in a patient with pericardial tamponade; (B) ST–QT alternans in Prinzmetal angina; (C) repolarization alternans in congenital long QT syndrome; (D) repolarization alternans in significant electrolyte imbalance.

QRS complexes can be confused with QRS changes, such as alternating bundle branch block or WPW pattern, with normal conduction. In these situations, two clearly distinct QRS–T morphologies exist with different QRS widths and sometimes with changes in the PR interval.

Alternans of the ST–T components of the ECG may be observed in the hyperacute phase of severe myocardial ischaemia (Fig. 1.35B), in congenital long QT syndrome (Fig. 1.35C) and with significant electrolyte imbalance (Fig. 1.35D). Techniques now exist to detect microvolt T-wave alternans, which are potentially important for risk stratification [54–57].

Incorrect electrode placement and cable connection

Reversal of the left arm, right arm or left leg electrode

The most common technical errors are incorrect cable connections to the peripheral electrodes. Table 1.10 presents the changes in the peripheral leads resulting from incorrect connection of the right arm, left arm and left leg electrode cables.

Most frequently, the left arm and right arm electrode cables are reversed. The mistake is easily recognizable during sinus rhythm by the presence of a negative P wave in lead I in the absence of other ECG signs of dextrocardia, such as mostly negative QRS complexes in leads V3–V6 (Fig. 1.36) [58]. The T wave may or may not be inverted depending on the underlying pathology. In the presence of atrial fibrillation, if the QRS complex in lead I is inverted compared with the QRS in lead V6, the arm electrodes have likely been reversed [59].

Reversal of the right arm and left leg electrode cables produces an ECG pattern that might resemble inferior myocardial infarction as aVF has the appearances of aVR. This technical error can also be suspected from an inverted P wave in aVF.

Reversal of the left arm and left leg electrodes is difficult to recognize, unless a previously recorded ECG is available for comparison [58–60]. In the presence of some ECG abnormalities, this technical error might be more easily suspected than in a normal ECG, e.g. during atrial flutter by the appearance of saw-tooth flutter waves in leads I, III and aVL but not lead II [58].

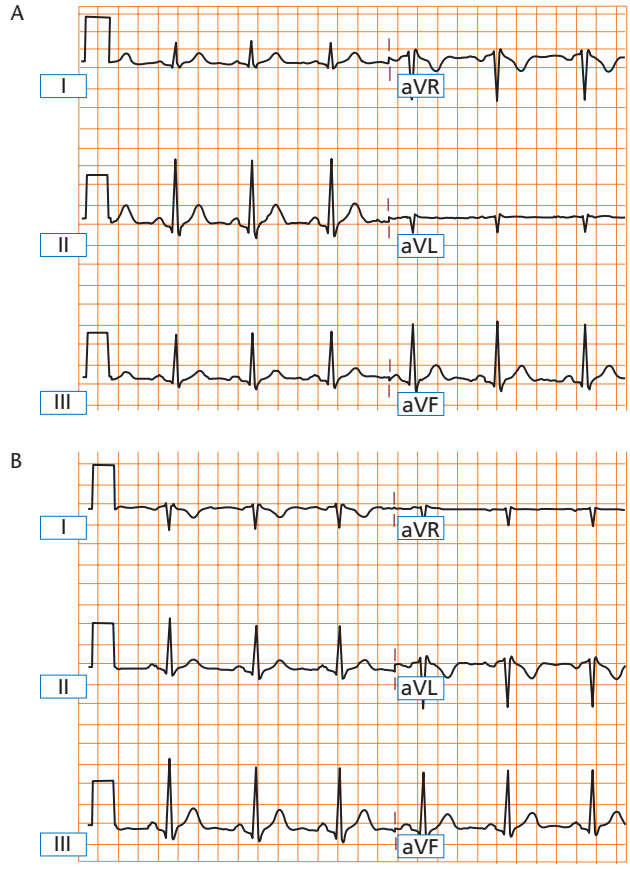

Figure 1.36 Limb leads of a 12-lead ECG recorded with correct cable connections (A) and after intentional reversal of the left arm and right arm electrode cables (B).

Table 1.10 Changes in the six peripheral leads resulting from errors in connecting the right arm, left arm and left leg cables

	Lead*					
Reversal	**'I'**	**'II'**	**'III'**	**'aVR'**	**'aVL'**	**'aVF'**
Left arm–right arm	Inverted I	III	II	aVL	aVR	Unchanged
Left arm–left leg	II	I	Inverted III	Unchanged	aVF	aVL
Right arm–left leg	Inverted III	Inverted II	Inverted I	aVF	Unchanged	aVR

*The leads as they appear in the ECG recorded with wrong connections.

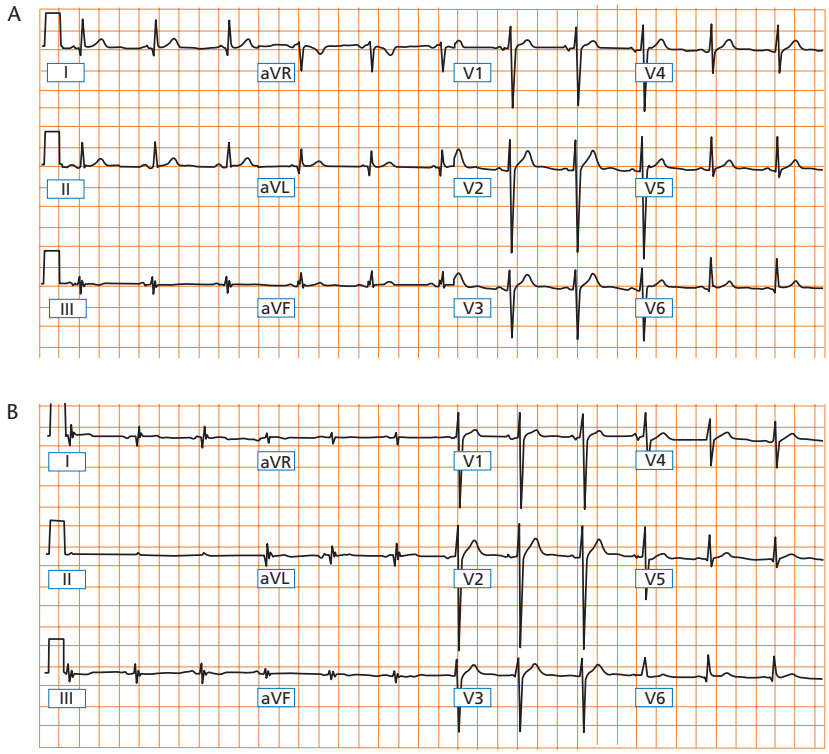

Figure 1.37 Standard 12-lead ECG recorded with correct cable connections (A) and after intentional reversal of the right arm and right leg electrode cables (B).

Incorrect connections of the right leg (ground) electrode

The ground electrode, which is placed on the right leg by convention, can be positioned anywhere on the body without affecting the ECG waveforms. However, when the ground electrode cable is interchanged with the right arm or left arm electrode cables, significant changes occur in both the morphology and amplitude of most peripheral leads [58–61]. Three possible lead reversals are of practical importance: right arm–right leg reversal (the most frequent), left arm–right leg reversal, and interchange of both leg cables with the corresponding arm cables. Reversal of the right and left leg electrodes does not change the ECG noticeably, because the potential at both legs is practically the same.

The hallmark of these misplacements is that one standard lead (I, II or III) shows almost a straight line (potential difference between both legs). When the right arm and right leg cables are reversed, this is seen in lead II (Fig. 1.37), whereas with left arm and right leg cable reversal, it is seen in lead III. Likewise, when both leg electrode cables are switched with the corresponding arm cables, lead I shows a very low potential [61]. Importantly, the central terminal is affected by these three connection errors. This may lead to visible changes in the precordial leads [58].

Errors in connection of precordial electrodes

Interchange of precordial cables is a common technical error that is usually easy to spot. It may be suspected if the transition of the P wave, QRS complex and T wave is unexplainable [58], for example lower amplitude of R wave and deeper S wave in V3 compared with V2 when V2 and V3 cables are reversed, or lack of the normal increase in amplitude of the T wave from V2 to V3 to V4, etc. [59].

Incorrect electrode placement

Incorrect (and hence most likely variable and inconsistent) placement of the precordial electrodes is a well-recognized and important source of inaccuracy [62]. It has been repeatedly shown that a change in the precordial electrode positions by as little as 2 cm can produce diagnostically important differences [63–65]. For example, Herman *et al.* [65] have demonstrated that even a 2-cm vertical displacement of the precordial electrodes produced a greater than 25% change in R-wave amplitude in half of their patients, leading to altered R-wave progression in 20% of patients and a shift in the precordial transition zone in 75%.

Precordial electrode displacement of such magnitude often occurs even when experienced clinicians or ECG

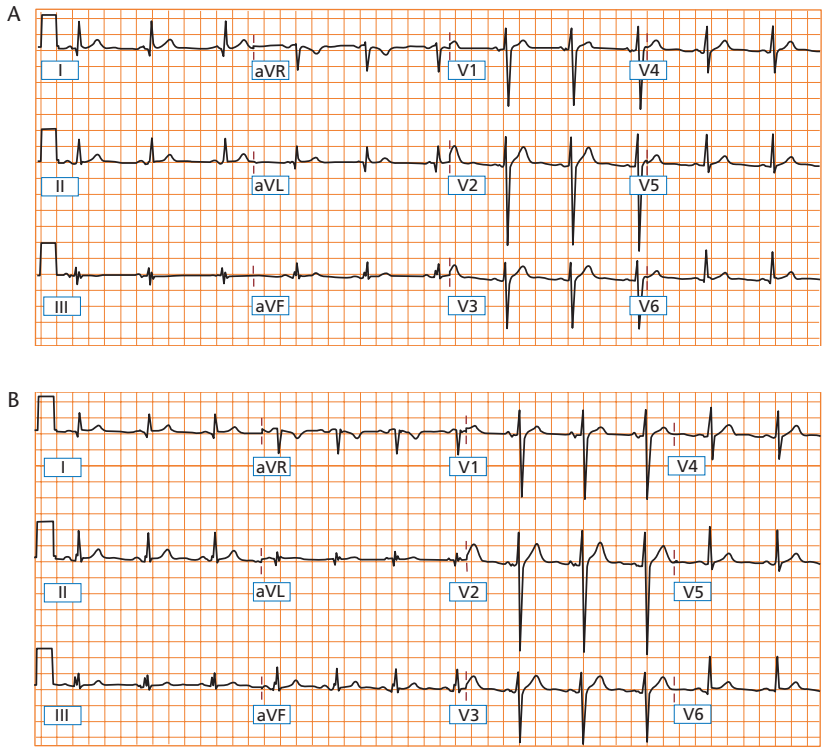

Figure 1.38 Standard 12-lead ECG recorded with the peripheral electrodes in the standard position (A) and positioned according to the Mason–Likar system (B).

technicians are recording the ECG [66,67]. Frequent mistakes include positioning V1 and V2 too high, in the third and even in the second instead of the fourth intercostal space, with resultant vertical misplacement of all precordial leads, excessively wide separation of V1 and V2, and placement of V4 and V5 too low and too lateral [66]. When V1 and V2 are placed one or more intercostal spaces higher, they tend to show an rSr′ configuration with inverted P and T waves, resembling incomplete RBBB.

There is still no universal agreement [68–70] about whether the precordial electrodes in female patients should be placed underneath or on top of the left breast. However, when the electrodes are placed over the left breast instead of beneath it, they are likely vertically displaced. In general submammary placement is recommended.

It is common practice in many centres to attach the arm electrodes above the wrists (forearms, upper arms) or above the ankles, in the belief either that it makes no difference where exactly on the limb they are placed or that it decreases the noise. However, it has been shown that there is a small potential difference between the upper arm and the wrists [59–71], and a similar potential difference is likely to exist between the ankles and the upper leg. However, these differences are hardly noticeable to the naked eye and will not affect the clinical (visual) interpretation of the ECG, hence the recommendation of the American Heart Association that 'the electrodes may be placed on any part of the arms or of the left leg as long as they are below the shoulders in the former and below the inguinal fold anteriorly and the gluteal fold posteriorly in the latter' [72].

In exercise electrocardiography and recently in 12-lead ambulatory (Holter) electrocardiography the Mason–Likar electrode system [73] is used, in which the limb leads are moved onto the torso. There are very significant differences between the conventional 12-lead ECG and one recorded using the Mason–Likar electrode system, including rightward shift of the mean QRS axis, reduction of R-wave amplitude in leads I and aVL and significant increase in R wave in leads II, III and aVF (Fig. 1.38). The precordial leads are also affected because of the altered potential of the central terminal [74].

Ventricular signal-averaged electrocardiography

Signal-averaged electrocardiography (SAECG) is the most widely used method of high-resolution electrocardiography and aims to record cardiac signals from

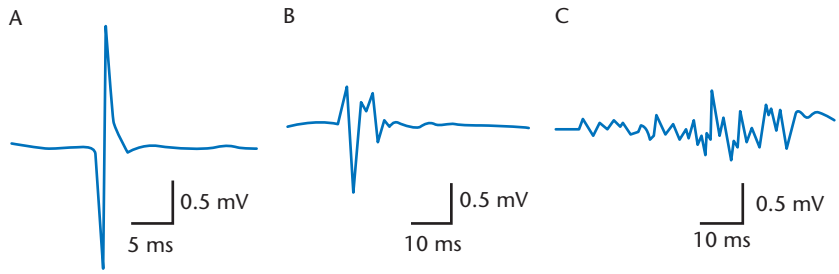

Figure 1.39 Development of low-amplitude fractionated electrograms in experimental models of myocardial infarction in canine hearts. Bipolar subepicardial electrograms are shown recorded from (A) a non-infarcted preparation, (B) 5-day-old infarction and (C) 2-month-old infarction. The low-amplitude fractionated electrograms shown in (C) reflect zones of abnormal conduction, which represent a substrate for the development of re-entrant arrhythmias. These can be recorded as late potentials on the signal-averaged ECG. Reproduced with permission from Gardner *et al*. [80].

the body surface that are not visible or apparent from the standard ECG [75]. In its most popular form, ventricular SAECG uses temporal averaging in order to improve the signal-to-noise ratio and enable the detection of low-amplitude potentials usually outlasting the QRS complex (so-called 'late potentials') [75–77]. Late potentials on SAECG reflect low-amplitude fractionated electrograms generated by surviving myocardial fibres within or surrounding regions of myocardial infarction (less frequently by other forms of ischaemic heart disease or other cardiac diseases) that are activated after a delay and thus create a substrate for re-entrant ventricular arrhythmias (Fig. 1.39) [78–80].

The SAECG is recorded using orthogonal bipolar XYZ ECG leads, which are averaged, filtered and combined into a vector magnitude called the filtered QRS complex. The most frequently used time-domain analysis (Fig. 1.39) of the filtered QRS complex includes:

1 filtered QRS duration;
2 root-mean-square voltage of the terminal 40 ms of the filtered QRS (RMS40);
3 duration that the filtered QRS complex remains < 40 μV (LAS).

The abnormal SAECG recorded with a 40-Hz high-pass filter (i.e. the presence of late potentials) is characterized by a filtered QRS complex > 114 ms, RMS40 < 20 μV and LAS > 38 ms [76,81], of which the most important is the prolonged filtered QRS duration (Figs 1.40 and 1.41) [82].

The ventricular SAECG is most frequently used in patients recovering from myocardial infarction. Studies during the 1980s showed that late potentials are recorded much more frequently (in up to 93%) in patients recovering from myocardial infarction who develop sustained ventricular arrhythmias or sudden cardiac death. Although the presence of late potentials is not a highly specific or sensitive marker of sudden cardiac death, SAECG was considered a useful test, alone or in combination with other risk factors, for prediction of arrhythmic events in patients recovering from myocardial infarction because of its high (up to 97%) negative predictive value despite its very low (about 20%) positive predictive value [75,83].

The widespread use of thrombolysis/revascularization, beta-blockers and other advances in the treatment of myocardial infarction during the 1990s considerably decreased the rate of sudden cardiac death and sustained ventricular arrhythmias [84] and reduced the prevalence of late potentials following myocardial infarction [85]. Recent large studies on patients receiving modern treat-

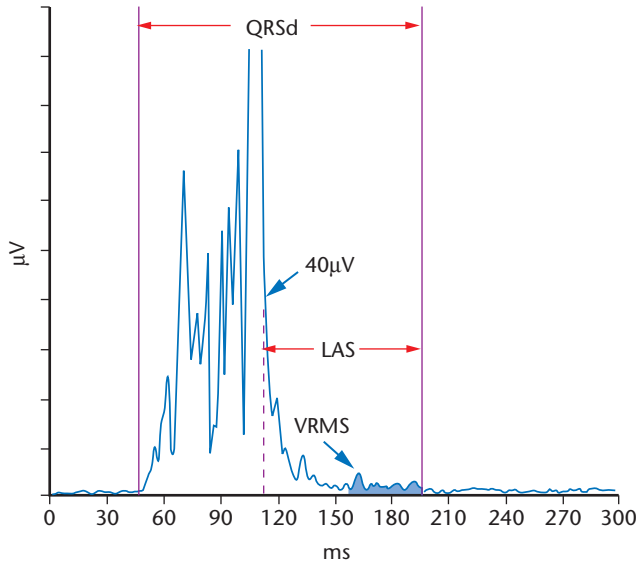

Figure 1.40 Schematic presentation of the three parameters that characterize the filtered QRS complex of the ventricular signal-averaged ECG. Note the low noise level of all three recordings.

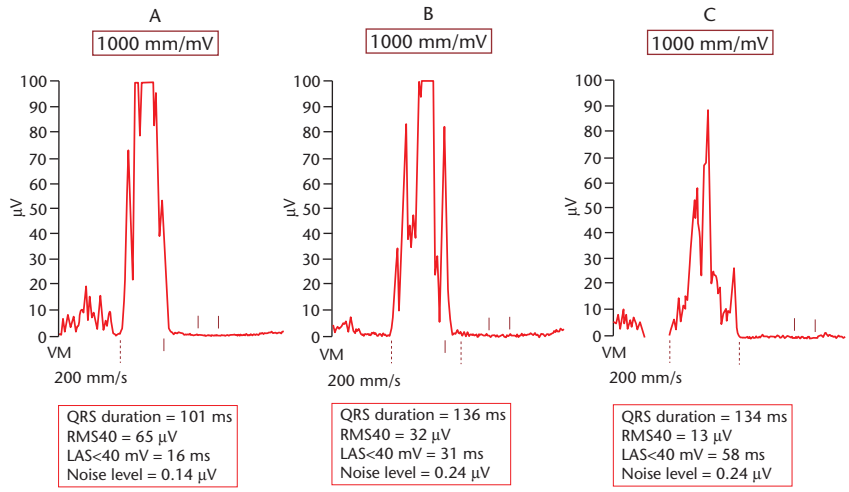

Figure 1.41 Examples of normal and abnormal ventricular signal-averaged ECG (SAECG). (A) Normal SAECG. (B) SAECG recorded in a 67-year-old man with mild heart failure and no history of arrhythmias. Only the filtered QRS duration is prolonged. (C) A clearly abnormal SAECG recorded in a man with severe heart failure. Note that all three parameters of the filtered QRS are abnormal.

ment after myocardial infarction demonstrated greatly reduced predictive power of SAECG for sudden cardiac death following myocardial infarction [86]. Nonetheless, a recently published substudy of the Multicenter Unsustained Tachycardia Trial (MUSTT) [87] demonstrated that in patients with ischaemic heart disease, left ventricular ejection fraction < 40% and non-sustained ventricular tachycardia, a filtered QRS duration > 114 ms was an independent predictor of cardiac and arrhythmic mortality. Because of its high negative predictive value (> 90%), SAECG is considered useful in the management of patients with syncope of unknown cause and ischaemic heart disease [75].

The value of SAECG in non-ischaemic cardiac diseases is less well investigated and established. Late potentials have been shown to independently predict adverse outcome in patients with non-ischaemic dilated cardiomyopathy in some studies [88] but not in others [89]. Although late potentials are more frequently recorded in patients with hypertrophic cardiomyopathy compared with healthy subjects, SAECG does not seem to have practical value for prediction of arrhythmic events in these patients [90]. Due to the localized character of the conduction abnormalities, SAECG can be useful as an additional diagnostic test in arrhythmogenic right ventricular cardiomyopathy [91].

In addition to time-domain analysis, other methods of analysis of the SAECG, such as spectrotemporal analysis [92,93], spectral turbulence analysis [94] and methods of high-resolution electrocardiography not based on temporal averaging (e.g. spatial averaging, which enables beat-to-beat analysis of late potentials [95]), have also been proposed but their clinical applicability is still unknown.

Atrial signal-averaged electrocardiography

Signal-averaged electrocardiography of the P wave (P-SAECG) was developed during the 1990s [96,97] as a result of growing awareness of the enormous clinical and socioeconomic significance of atrial fibrillation (AF) and hence of the need for simple and easily applicable methods for prediction of its occurrence or recurrence. Similarly to ventricular SAECG, the goal of P-SAECG is to detect and quantify intra-atrial conduction defects, one of the main factors for development of AF, which cannot simply be discerned from the shape and duration of the P wave on the standard ECG [98,99].

At present, most clinical studies have been performed using time-domain analysis of the P-SAECG. Similarly to ventricular SAECG, the filtered X, Y and Z leads are combined into a vector magnitude, and the latter is characterized by a set of parameters, such as the filtered P-wave duration, the integral of the P wave and the amplitude (RMS voltage) in different segments (e.g. the last 10, 20 or 30 ms) [96].

Several studies have demonstrated that the preoperatively assessed P-SAECG (mainly increased signal-averaged P-wave duration) independently predicts occurrence of AF following coronary artery bypass surgery [100–104]. P-SAECG has been shown to be useful for identifying patients at risk of transition from paroxysmal to sustained forms of AF [105], for prediction of AF recurrence after cardioversion [106,107], for prediction of paroxysmal AF in patients with congestive heart failure [108] and for assessment of antiarrhythmic drug efficacy for prophylaxis of paroxysmal AF [109].

A limited number of studies suggest that spectral analysis of the P-SAECG can provide additional information to the standard time-domain methods, but its clinical value is still unknown.

Microvolt T-wave alternans

Visible variations of the shape, amplitude or polarity of the T wave on an alternate-beat basis, described as T-wave alternans, have been recognized as a harbinger of ventricular arrhythmias in many clinical conditions, such as congenital long QT syndrome, myocardial ischaemia, electrolyte disturbance and toxic myocarditis [110–112]. In the 1980s, progress in computerized electrocardiography and signal processing led to the discovery, and routine clinical assessment, of microvolt (a few milliseconds) T-wave alternans (MTWA) induced by an increase in heart rate and invisible to the naked eye [113]. Subsequently, experimental studies demonstrated that MTWA is caused by non-uniform alterations (sequential shortening and lengthening) of action potential duration in different parts of the myocardium, which produce repolarization gradients that alternate in magnitude and direction on every other beat and thus create conditions for re-entry [114,115].

The methodology of measurement, the technical aspects and the interpretation of MTWA tests have recently been reviewed in detail (Fig. 1.42) [116]. Whilst early clinical studies used invasive atrial pacing in order to achieve the necessary increase in heart rate [117], currently MTWA is assessed using bicycle or treadmill exercise. Hohnloser *et al*. [118] demonstrated that the two methods were equivalent, both in terms of average heart rate at which MTWA becomes detectable and in terms of diagnostic yield.

During the last decade, a number of clinical studies have demonstrated a strong link between abnormal MTWA and arrhythmic events including sudden cardiac death in different cardiac patient populations [119,120]. Abnormal MTWA has been shown to strongly predict inducibility of ventricular tachycardia or ventricular fibrillation during electrophysiological study [121,122] and all-cause mortality [123] or arrhythmic events in patients recovering after myocardial infarction [124,125] and in those with dilated cardiomyopathy [126,127], Brugada's syndrome [128], non-ischaemic cardiomyopathy [129] or heart failure [130].

Three recent studies have demonstrated that MTWA testing can identify patients at high risk of arrhythmic death who might benefit from an implantable cardioverter-defibrillator (ICD) within the population of patients with left ventricular dysfunction after myocardial infarction (MADIT II type patients). In a meta-analysis of patients drawn from two previously published prospective studies on MTWA, Hohnloser *et al*. [131] reported a 15.6% rate of cardiac arrest or sudden cardiac death during a follow-up of 24 months in patients who tested positive or indeterminate (non-negative) for MTWA compared with no events in MTWA-negative patients ($P = 0.02$). Chow *et al*. [132] followed up similar patients for 18 months and reported an 11.8% rate of arrhythmic events (arrhythmic death, resuscitated cardiac arrest, or appropriate ICD discharge) among MTWA-positive patients compared with 2.0% among those who were MTWA negative (relative risk 6.0, $P = 0.035$). Bloomfield *et al*. [133] reported that the actuarial 2-year all-cause mortality rate of patients with abnormal (positive or indeterminate) MTWA was 17.8% compared with 3.2% of patients with negative MTWA (hazard ratio 4.8, $P = 0.02$). The mortality rate of patients with negative MTWA was only 3.8% (3.5% false-negative tests), which suggests that the test could be used for identifying MADIT II type patients who are at low arrhythmic risk and unlikely to benefit from an ICD.

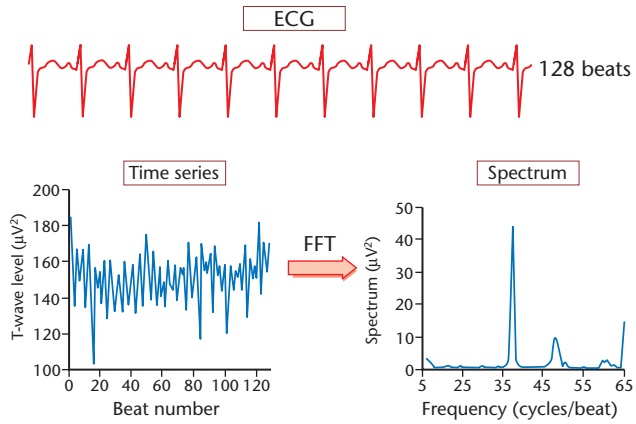

Figure 1.42 Principles of spectral analysis of microvolt T-wave alternans. The amplitudes of the T waves of 128 consecutive beats are measured and a time series consisting of these 128 amplitudes is constructed. The power spectrum of this time series is computed using fast Fourier transform (FFT) analysis. In the power spectrum obtained from recordings during bicycle exercise, peaks corresponding to frequencies of respiration, pedalling and alternans are shown. Microvolt T-wave alternans appears as a peak at half the beat frequency (0.5 cycles/beat). The amplitude of this peak is compared with the mean and standard deviation of the spectrum in a reference 'noise band'. Reprinted with permission from Cohen RJ. TWA and Laplacian imaging. In: Zipes DP, Jalife J (eds) *Cardiac Electrophysiology: From Cell to Bedside*, 2000. Philadelphia: WB Saunders, pp. 781–789.

Personal perspective

It is said by some that the 12-lead ECG could be reduced to a report and the trace itself omitted. For example, in many hospitals it is customary to receive nuclear scintigram reports and even radiography reports without copies of the images themselves. These experiences naturally frustrate most cardiologists, who would like to see the 'raw data' on which others have commented in order that they can make decisions relevant to the life and livelihood of their patients. Analysing the ECG or other images, especially as medical informatics and information technology improves, should not be a technical problem and the cardiologist should insist upon this. Examining the quality of the image, assessing the accuracy and confidence of the report, and assembling multiple images, technical information and patients' details are crucial to modern medicine.

Although electrocardiography is a well-established technique, the refinement of computer interpretation algorithms, improvements in recording technology and the development of completely new techniques (such as T-wave alternans, implantable ECG rhythm and ST-segment surveillance and logging, and very long-term wearable monitoring systems) will continue to evolve. High-resolution electrocardiography, for detecting early disease, discerning the effects of medications on the ECG and the prediction of electrical instability of the heart, will continue to develop. Web-based, ECG-related, patient-accessed systems will become more popular world-wide.

2 Cardiac Ultrasound

Jos Roelandt and Raimund Erbel

Summary

Cardiac ultrasound is a sophisticated imaging modality that has made unique contributions to our understanding of cardiac disease. It allows the cardiologist to observe the heart and to obtain an integrated non-invasive assessment of its structure, function and haemodynamics by simply manipulating a transducer without exposing the patient to any risk. Portability and unprecedented versatility of application are other reasons for its success. Consequently, the method has had an enormous impact on the practice of cardiology. However, the technique is operator-dependent and the performance of an echocardiographic/Doppler examination is therefore related to appropriate training and the cognitive and practical skills of the examiner. Obviously, this relatively short chapter cannot be more than a starting point and is only a frame of reference for learning echocardiography. We provide a cursory description of the physical principles, the instrumentation and the examination using the many diagnostic modalities. The application of echocardiographic/Doppler techniques in specific cardiac conditions and more particularly for myocardial and valve function assessment is also presented. Because of the rapid developments and new applications, for example real-time three-dimensional echocardiography and strain rate imaging, it is mandatory to continuously update knowledge and practical skills.

Principles of echocardiography

Echocardiographic and Doppler examinations require a thorough knowledge of the underlying physical principles, instrumentation and recording techniques. A comprehensive overview of the basic principles pertinent to echocardiographic/Doppler assessment is presented in this chapter. Echocardiography encompasses a group of tests that use ultrasound to examine the heart and obtain diagnostic data in the form of echoes. Ultrasound is a mechanical radiation that requires a medium in order to travel from one point to another by alternate compression and rarefaction. It refers to sound waves of a frequency above the range audible to humans (> 20 000 Hz); in cardiology, frequencies of 2–7 MHz are employed.

Transducers

In order to generate ultrasound waves, piezoelectric crystalline material is used in a transducer that converts electrical energy to mechanical energy (ultrasound) and vice versa [1]. The diagnostic potential of ultrasound waves is the result of their partial reflections when they strike boundaries between media of different acoustic impedances. The difference in density and sound speed is referred to as acoustic impedance mismatch and arises from the difference in structural composition at the boundary. The larger this difference, the stronger the echo reflected from the boundary. Because more than 99% of the ultrasound energy is reflected at the air–tissue boundary, a coupling gel is used between the transducer and skin that causes more than 99% of the energy to be transmitted into the body. Other factors that contribute to the strength of echoes are the angle of incidence, the irregularity of the boundary surface (scattering), the size of the interface relative to the wavelength of the

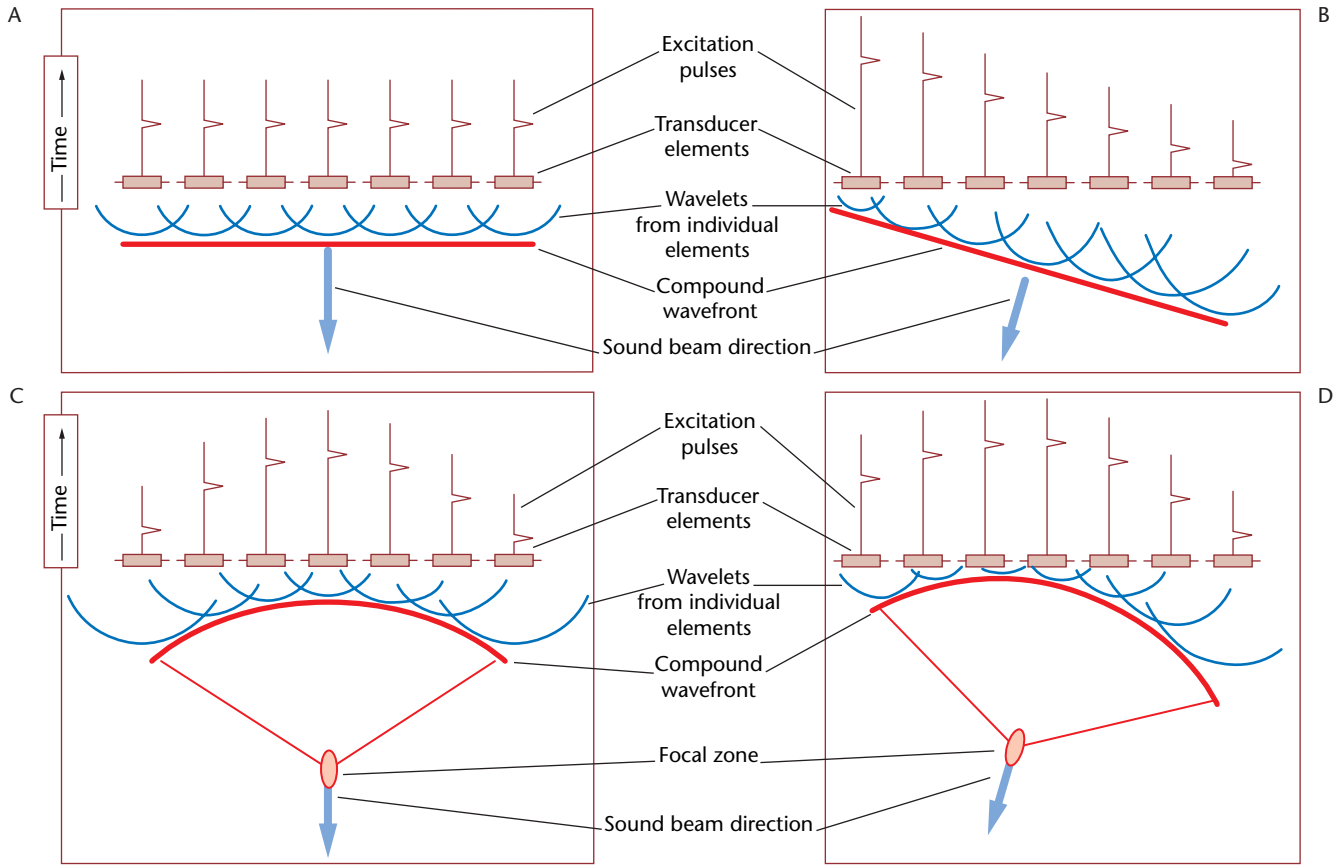

Figure 2.1 The concept of electronic beam steering. (A) Seven elements of a phased-array transducer firing simultaneously. A short distance from the transducer the individual wavelets from each of the elements merge to produce a compound wavefront, which creates a sound beam in the direction perpendicular to the transducer face. (B) The elements are now fired in sequence but are all used to create a single sound beam. When the individual wavelets merge to form a compound wavefront, it is not perpendicular and the sound beam travels away at an angle. Varying the excitation sequence allows rapid steering of a sound beam in any direction through a sector. (C) Electronic beam focusing is realized by exciting the peripheral elements first and the centre element last (cylindrical time-gated excitation). In addition to focusing the transmitted sound beam, it is also possible to focus the returning signals so that at any one instant the transducer array is selectively receiving only those echoes coming from a specified beam direction and depth (dynamic receive focusing). This requires very complicated electronics. (D) The principle of cylindrical time-gated excitation can be used to steer and focus sound beams in any direction during both transmission and reception.

ultrasound and the distance causing attenuation. Therefore, echo signals from deeper structures must be amplified much more than those from nearer structures (time-gain amplification).

Ultrasound waves of relatively low frequency (2 MHz) penetrate to deep structures and are used in adults. In contrast, higher frequencies (5–7 MHz) have less penetration but better axial resolution and are used in paediatric applications. The currently used broadband transducers incorporate multiple frequencies (2–7 MHz), allowing better resolution of structures distant from the transducer. The width of the ultrasound beam is a function of transducer size and operating frequency and determines the lateral resolution or the ability to distinguish two adjacent structures in the direction perpendicular to the sound beam axis. The power density used in diagnostic ultrasound applications is well within accepted limits of safety [2,3].

In ultrasound systems, the level of ultrasound pressure and possible mechanical effects is expressed as the mechanical index (MI) [4].

Phased-array transducers

All modern ultrasound systems make use of phased-array transducers, which create and steer the ultrasound beams [5,6]. These transducers consist of a set of 128 small piezoelectric elements, which have separate electrical connections and are all used at any given time to transmit ultrasound pulses and to receive echoes. The individual elements are electronically excited at a slight different time delay so that the electronic wavefront produced by each

of these elements interferes to synthesize a beam that is directed in a given direction (Fig. 2.1A,B). Hence, the beam is steerable. This approach generates the triangle sector typically seen on the display of ultrasound machines.

Adjusting the time delays allows the ultrasound beam to be dynamically focused during transmission and reception so that at any one instant in time the transducer is selectively receiving only those echoes coming from a specified direction and depth. This is achieved by sequentially firing the outer crystals first and the centre crystals last (Fig. 2.1C and D).

Recently, matrix phased-array transducers have become available with up to 3000 individual elements, which are capable of providing real-time pyramidal volumetric imaging [7].

Parallel processing

Traditionally, sequential single scan lines have created two-dimensional images, which has limited the frame rate. With phased-array transducers it is possible to transmit multiple sound beams simultaneously in different directions by activating the individual crystals in a very complex manner. The echoes from each of these sound beams are independently analysed by a separate signal processing circuitry (parallel processing). Parallel processing allows a significant increase in frame rate for both two- and three-dimensional echocardiography and tissue Doppler imaging.

Harmonic imaging

In harmonic imaging, the ultrasound image is created from echoes that have twice (second harmonic) the frequency of the transmitted ultrasound. Harmonic imaging allows suppression of the near-field artefacts and reduces clutter in the image by suppression of side lobe effects. Its use has now become the standard imaging modality and improves endocardial definition both with and without the addition of echo contrast [8].

Integrated backscatter

Myocardial integrated backscatter is the broadband scattering of a region of interest [9]. Its cyclic variation has been used for tissue characterization and more particularly the identification of ischaemic stunned or hibernating but viable myocardium in infarcted areas, transplant rejection and cardiomyopathies. However, the results are not reproducible with currently available processing software. Integrated backscatter is used for automated endocardial border detection and for tracking its motion and velocity in real time (see Acoustic quantification, below).

Principles of ultrasound imaging

Assuming a constant propagation speed of 1540 m/s for ultrasound in soft tissue, measurement of the time taken from transducer to a boundary allows determination of the distance. In fact, part of the sound energy is reflected from each subsequent tissue boundary along the sound beam pathway and consequently distance measurements to all echo-producing boundaries are available from individual pulses. Most instruments transmit ultrasound pulses for 1 μs and receive echoes over the next 999 μs, yielding a sampling rate of 1000/s. If the pulses are emitted in a constant direction repeatedly, an M-mode display results, showing structure motion along a single 'ice pick' through the heart (Fig. 2.2). In contrast, if the ultrasound beam is moved rapidly at a constant speed across a sector of the heart, a two-dimensional image of the heart is created.

M-mode echocardiography

Echoes returning to the transducer are electronically processed to produce three types of oscilloscope display (Fig. 2.2). In 'A-mode', the height or amplitude represents the intensity of the echoes. The distance of the boundary to the transducer is in practice represented on the oscilloscope display on the vertical axis, and 'B-mode' is an intermediate step where A-mode echoes are converted to dots whose brightness indicates the relative intensity of the echoes. B-mode is well suited to production of a record of echo (structure) motion or 'M-mode' [1,5]. This is obtained by emitting the ultrasound pulse in a constant direction repeatedly and sweeping the dots across the display screen or by moving a recording surface at a constant speed past the B-mode display. M-mode display permits recording of both the depth and motion pattern of intracardiac boundaries or structures. The original M-mode studies were performed using a focused single crystal transducer that was aimed in the desired direction. All systems now use phased-array transducers that allow simultaneous sampling of any of the scan lines and which display both the M-mode and two-dimensional cross-section in real time (Figs 2.3–2.5). Measurements are aided by centimetre depth markers, which are displayed on the oscilloscope at calibrated time intervals of 0.5 s. An electrocardiographic tracing is recorded simultaneously for timing purposes.

M-mode echocardiograms have an excellent time resolution and allow detailed analysis of motion patterns, temporal relationships with physiological parameters and time intervals. They will always remain an integral part of a comprehensive study of a cardiac condition (Fig. 2.6).

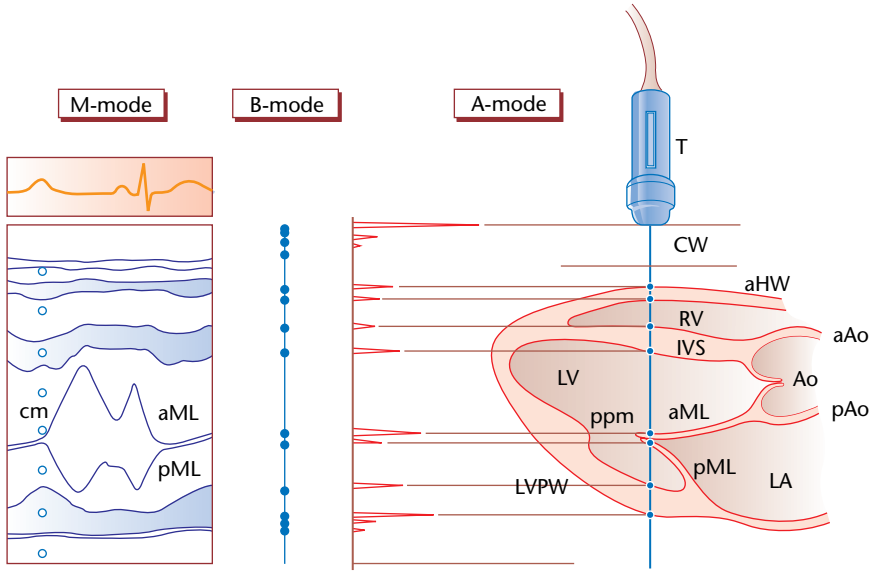

Figure 2.2 Schematic diagram showing the creation of the M-mode echocardiogram. A long-axis cross-section of the heart from base to apex with cardiac structures is shown. The single sound beam produced by the transducer (T) on the chest wall (CW) is aimed so that it traverses from anterior to posterior: anterior heart wall (aHW), right ventricle (RV), interventricular septum (IVS), left ventricular cavity (LV), anterior and posterior mitral valve leaflets (aML and pML) and the posterior wall (LVPW). The echoes originating from the structure boundaries can be represented in three types of oscilloscope display: A-mode, B-mode and M-mode. Ao, aorta; LA, left atrium; aAo and pAo, anterior and posterior aortic wall; ppm, posteromedial papillary muscle.

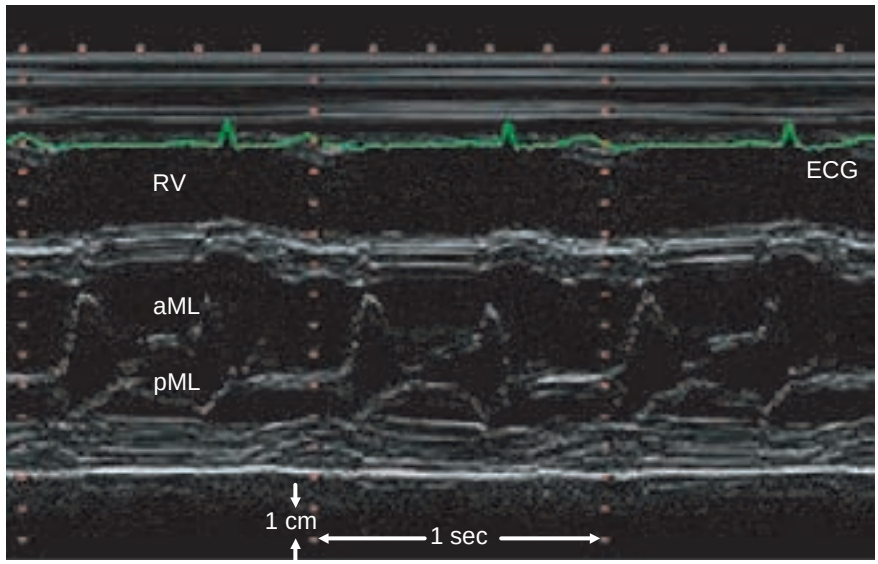

Figure 2.3 M-mode registration of a normal subject showing the structures discussed in Fig. 2.2. The anterior mitral valve leaflet moves anteriorly and the posterior leaflet posteriorly with less excursion but a similar pattern. The recording speed is 50 mm/s. The calibration scale of depth is in centimetres from top to bottom and time in seconds from left to right.

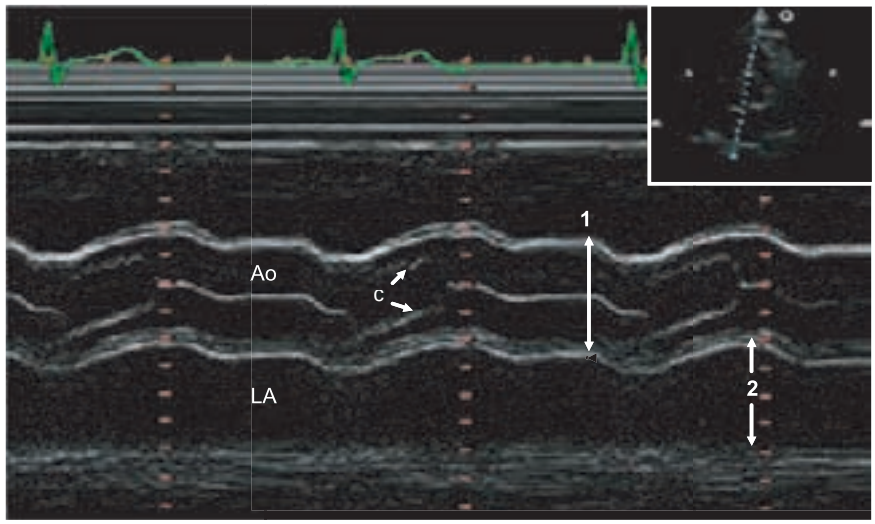

Figure 2.4 Two-dimensional reference image shows the cursor indicating the direction of the sampling sound beam in the short-axis view through the base of the aorta and aortic valve. The aorta (Ao) is seen as two parallel structures moving in an anterior direction in systole. The aortic valve cusps (c) are open in systole and are seen as a single echo when closed in diastole, with the same motion as the aortic walls. The left atrium (LA) is posterior to the aorta. Arrows 1 and 2 indicate the landmarks for diameter measurements (see Table 2.2 and Fig. 2.22).

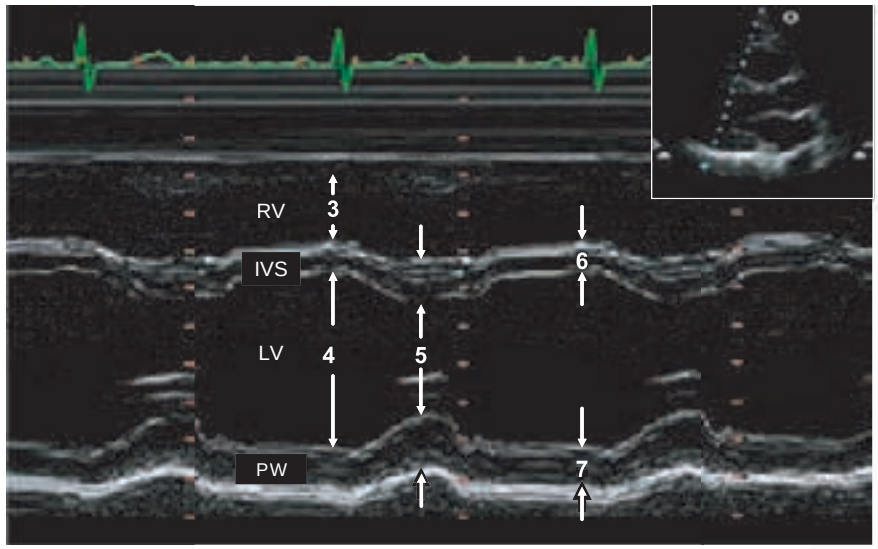

Figure 2.5 M-mode registration of the left ventricle (LV) at the tips of the mitral valve leaflets showing inward motion of the interventricular septum (IVS) and posterior wall (PW) in systole. The cursor in the two-dimensional image shows the direction of the sampling sound beam. The arrows indicate landmarks for diameter measurements of the right ventricle (RV)(3), left ventricular end-diastolic diameter (4), left ventricular end-systolic diameter (5), interventricular septal thickness (6) and posterior wall thickness (7) (see Table 2.2 and Fig. 2.22).

Using the M-scan technique and by sweeping the sound beam from one area of the heart to another while recording, it is possible to derive information concerning the spatial relationship of cardiac structures. However, the need for more accurate spatial information about cardiac structures and function led to the development of real-time two-dimensional imaging systems. Recent digital systems allow M-mode recordings in any direction

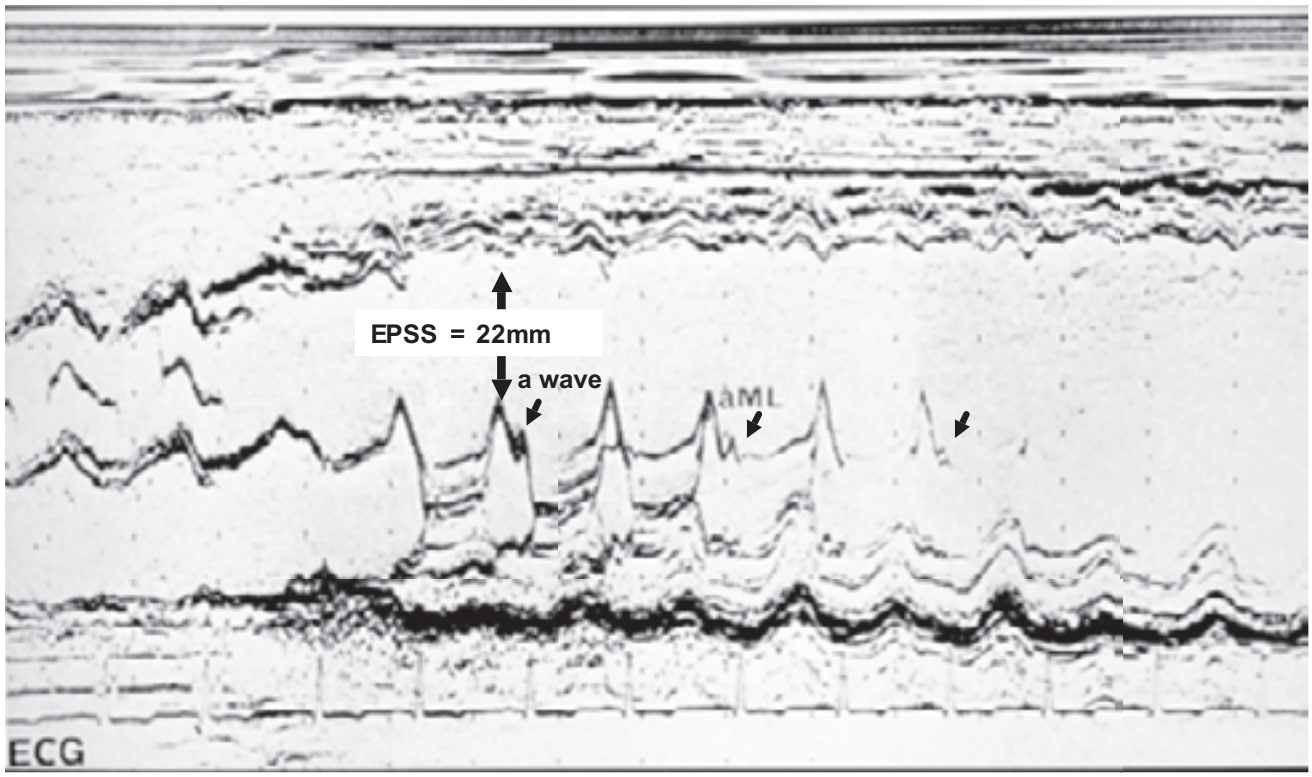

Figure 2.6 M-mode sector scan from aorta towards the left ventricle. The left ventricle is dilated (70 mm). There is an abnormal motion pattern of the interventricular septum and posterior wall showing mechanical alternans. The anterior mitral valve (aML) motion pattern shows alternating presence/absence of the a-wave (arrow) indicating mechanical alternans of the left atrium that is causing the ventricular wall motion abnormality. This detailed analysis requires high temporal resolution and would not be available from two- or three-dimensional echocardiography. Note the mitral E point–septal separation (EPSS) of 22 mm (normal ≤ 7 mm). An increased separation indicates a dilated left ventricle.

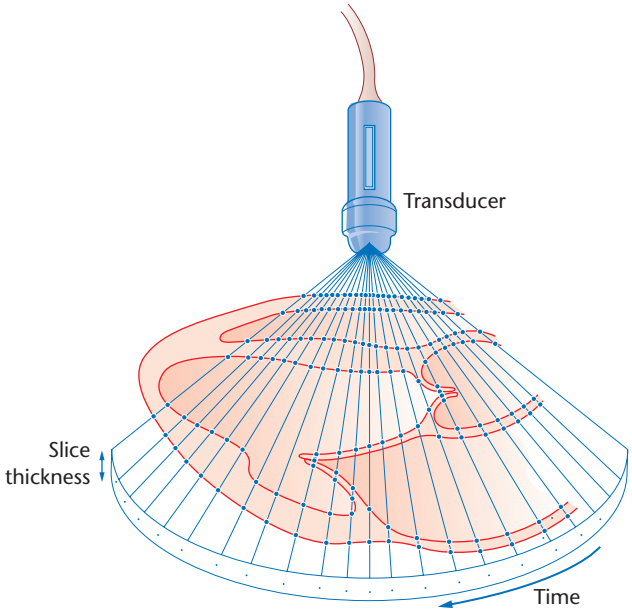

Figure 2.7 How a two-dimensional image of the heart is created. The ultrasound beam is electronically steered through a sector arc of 80° at a uniform speed at an imaging rate of 25/s. The radial scan line data from the transducer are converted into a digital memory matrix (scan converter), which can be frozen and displayed in the horizontal TV/video format. A cursor can be moved over the image to select a scan line to produce an M-mode recording (see Figs 2.2–2.5). The scanning can be stopped either to sample one ultrasound beam direction at a high sampling rate or to intermittently sample for simultaneous M-mode recording at a lower repetition rate and two-dimensional imaging.

independent of transducer orientation to be obtained from the two-dimensional images.

Two-dimensional echocardiography

In modern ultrasound systems the phased-array transducer produces a fan of ultrasound beams, which is used to create a sector-shaped image (Figs 2.7 and 2.8). There is a trade-off between the times taken to create a sector frame, the number of scan lines in the sector frame and the scanning depth because of the limited ultrasound speed of 1540 m/s in tissue. Typically, 25 frames/s are obtained. Parallel processing allows frame rates in excess of 100 frames/s.

Acoustic quantification (colour kinesis)

Acoustic quantification is a real-time automated border detection modality used to identify the blood–endocardial boundary based on their disparate echo signals [10]. It allows continuous real-time display of the endocardial contour of the left ventricle (LV) on a beat-to-beat basis. Colour kinesis allows tracking of endocardial motion velocity in real time (Fig. 2.9). Motion and velocity are captured in a geometric image that shows quantitative information on wall function. Endocardial excursion is mapped in colour schemes on sequential two-dimensional LV images. At a frame rate of 25/s each colour represents a successive 40-ms interval of the contraction period and the thickness of the colour band the endocardial excursion during that interval. This method has advantages for continuous monitoring of regional wall function (e.g. stress echocardiography) but requires excellent image quality and endocardial definition.

Three-dimensional echocardiography

Three-dimensional echocardiography is rapidly becoming an integral part of the echocardiographic examination procedure. The images are more realistic in appearance

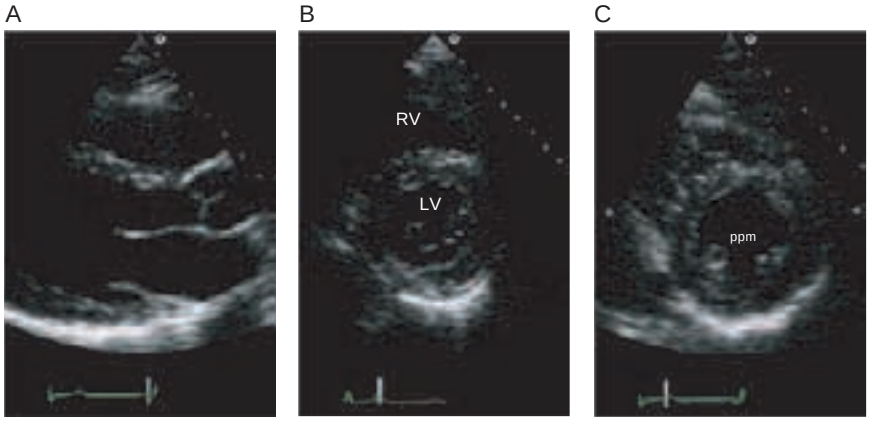

Figure 2.8 (A) Two-dimensional end-diastolic long-axis image of the left ventricle in end-diastole of a normal subject (see Fig. 2.2 for reference). The aortic valve is closed and the mitral leaflets are in an open position. Calibration dots are 1 cm apart. The bar in the ECG indicates the location of the stop frame within the cardiac cycle. Two-dimensional short-axis images of the left ventricle (LV) at mitral valve level (B) and at the level of the papillary muscles (ppm) (C). The left ventricle is circular in shape with discrete structures of the mitral valve in the cavity. The right ventricle (RV) is anterior to the left ventricle.

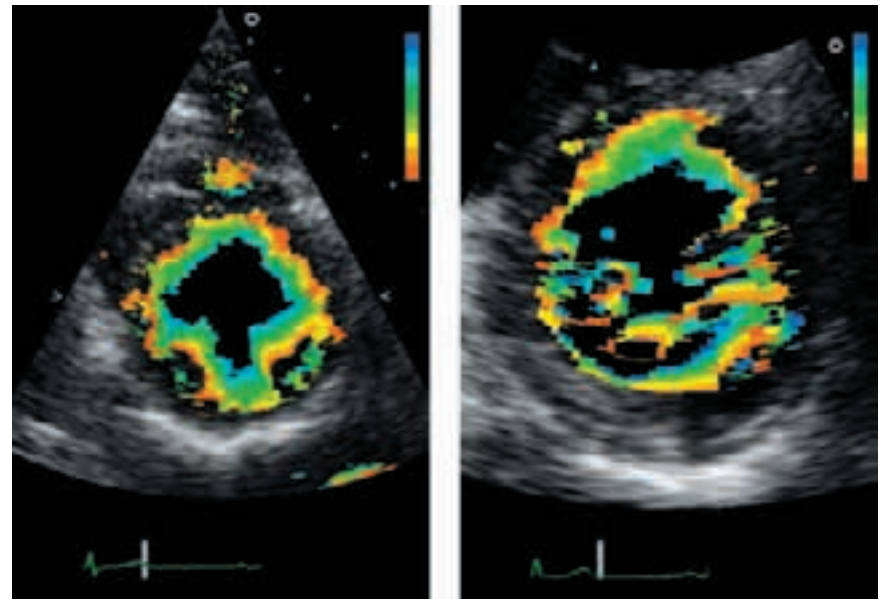

Figure 2.9 (A) Colour kinesis end-systolic image of the left ventricle showing a homogeneous pattern of endocardial inward motion (contraction). There is uniform thickening of the colour bands each indicating a successive interval of 40 ms on a frame-by-frame basis. The thickness of the colour bands represents the degree of endocardial inward motion during that interval. Therefore, this end-systolic frame represents a snapshot of both the amplitude and timing of systolic wall motion. (B) Colour kinesis end-systolic image of a patient with an inferoseptal myocardial infarction. There is thinning of the colour bands in that region indicating decreased wall motion (akinesis) while the increased thickening of the colour bands in the anterior wall indicate compensatory hyperkinesis.

Table 2.1 Three-dimensional echocardiography: the approaches

Off-line reconstruction (spatial and temporal gated image acquisition)

Linear
Fan-like
Rotational (sequential or continuous)
Real-time volumetric acquisition

and provide spatial information and unique *en face* views, referred to as surgical views. Basically, two approaches have been followed: off-line (gated) reconstruction and real-time volumetric imaging (Table 2.1).

In off-line reconstruction, a volumetric dataset is created by the acquisition of a continuum of two-dimensional images in which both spatial orientation and position in the cardiac cycle are simultaneously registered using either an external (random image acquisition) or internal (sequential image acquisition) coordinate system; a workstation is used to input the images for Cartesian coordinate conversion. It is clear that this process takes time [11].

Over the last 10–15 years, complex matrix-array transducers have been developed that allow real-time acquisition of an entire volumetric dataset. In an earlier system, parallel processing was used where 16 simultaneous receive directions for any given transmit pulse are sampled to allow cardiac motion to be captured in a volumetric dataset [7]. In a recent system, each of the 3000 individual elements of a broadband 2–4 MHz matrix-array transducer is used for both transmission and reception in order to register cardiac motion [12]. This system also provides three-dimensional Doppler flow imaging (Figs 2.10 and 2.11).

Volumetric datasets can be rapidly sliced and rotated to show cardiac anatomy from different viewpoints (Fig. 2.12). These capabilities provide an improved understanding of unpredictable pathomorphology and decrease variability in the interpretation of these abnormalities among investigators. Quantitative methods allow exploitation of the spatial information inherently present in the volumetric dataset for more accurate measurements of surfaces, orifices, volumes of cardiac chambers, masses and shapes than with two-dimensional echocardiography (see Reference values for M-mode and two-dimensional echocardiography, below).

Real-time three-dimensional echocardiography is particularly useful in structural abnormalities such as valvular pathologies and congenital defects and in rapidly changing (patho)physiological states such as transient ischaemic wall motion abnormalities in the setting of stress testing and conditions where short-time examination and rapid results are desirable (e.g. critically ill patients, interventional procedures and small children).

The current limitations of real-time three-dimensional echocardiography systems are their limited spatial and temporal resolution. These limitations will be solved when newer sensitive transducers and the next generation of high-speed processors become available. Three-

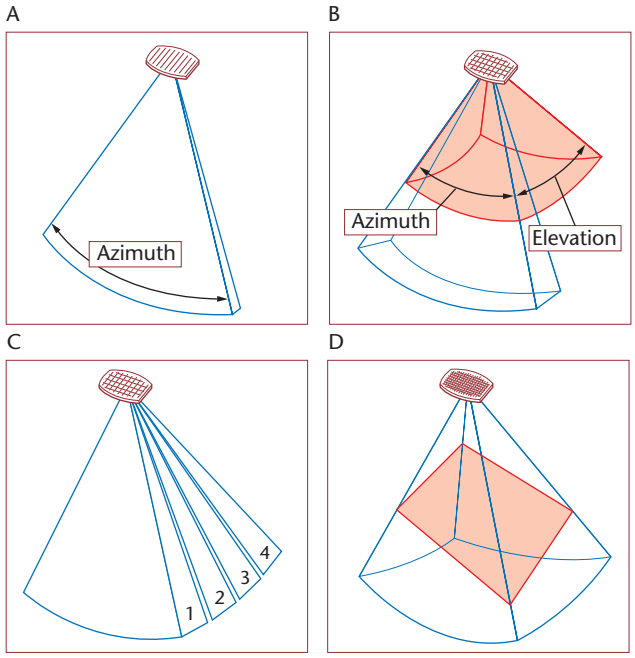

Figure 2.10 Diagrams showing the differences between (A) a single two-dimensional plane obtained with a linear phased-array transducer and (B) a volumetric scan obtained with a matrix phased-array transducer. Because of inherent time limitations of ultrasound speed in tissue, the pyramidal volume is not large enough to acquire the entire volume of the heart or left ventricle in adults. By narrowing the elevation scan angle of the pyramidal volume, a greater depth is achieved (C). Four such subvolumes (1–4) can be acquired using four ECG-triggered heartbeats with respiratory gating or a few seconds of breath-holding. (D) These volumes are then time aligned to render a composite volume encompassing the entire heart or an enlarged left ventricle. This modality is used for left ventricular volume measurement. The volume can be sliced in any direction (C-plane) in addition to perpendicular planes.

dimensional echocardiography, in combination with sophisticated imaging software, data manipulation and new display techniques, will allow unique displays of non-visible dynamic cardiac properties such as elasticity, electrical depolarization, strain and strain rate. These displays are referred to as parametric imaging [13]. Since all imaging information is available in a standardized digital format (DICOM 3.0), it will become possible to exchange clinical data between centres and share expensive facilities for online research between laboratories via ultra-high speed networks.

Another important medical frontier opened by three-dimensional echocardiography is virtual reality, the immersive environment created by a computer. Virtual reality allows the physician to interact with these data and heralds a revolution for medical diagnosis and Internet-based distance learning and treatment, for example by remote robot interventions.

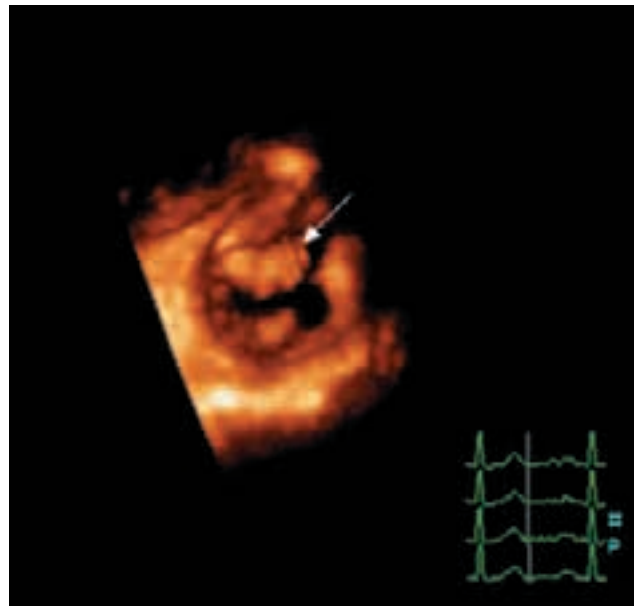

Figure 2.11 Stop-frame image of a patient with mitral valve prolapse seen from a left atrial perspective obtained with a real-time three-dimensional imaging system (surgical view). The arrow indicates the prolapsing anterior mitral valve leaflet.

Hand-held ultrasound systems (ultrasound stethoscopy)

Miniaturization and digital techniques have resulted in the development of high-resolution battery-powered personal imaging devices ranging in size from laptop to almost personal organizer, with excellent grey-scale and colour blood flow imaging capabilities (Fig. 2.13). These devices are appropriately called 'ultrasound stethoscopes' [14]. They extend our physical perception during a clinical examination by 'seeing the invisible pathology', and thus allow assessment of specific clinical problems anywhere and augment the yield of clinical examination at the point of care. In some systems Doppler functions have been integrated to allow basic haemodynamic assessment. Murmurs and abnormal precordial movements can be directly related to cardiac structural, functional and flow abnormalities. A cardiac abnormality (pericardial effusion, dilated heart, valvular disease, mass lesion) is rapidly confirmed during the clinical examination. Often, a specific diagnosis can be made and unsuspected abnormalities found. A major strength is that a limited echocardiographic/Doppler examination may allow exclusion of the cardiac abnormality with great certainty. Overall, they strengthen clinical diagnostic accuracy and

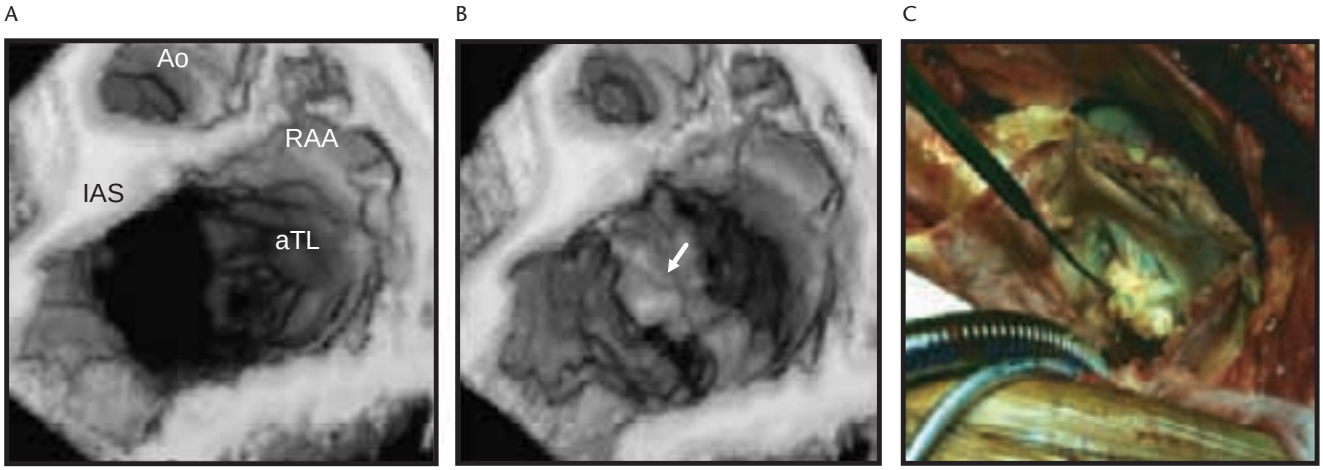

Figure 2.12 Reconstructed three-dimensional images of the tricuspid valve seen from a right atrial perspective. The anterior leaflet (aTL) is flail due to papillary muscle rupture after a car accident. (A) is a diastolic image and (B) shows the anterior leaflet and the flailing papillary muscle (arrow) in the right atrial cavity in systole. (C) is an intraoperative picture showing the flail muscle and leaflet that confirms the three-dimensional findings. Ao, aorta; IAS, interatrial septum; RAA, right atrial appendage.

Figure 2.13 Currently available hand-held ultrasonic imaging systems: (A) Sonoheart (Sonosite, Inc.); (B) iLook (Sonosite, Inc.); (C) a recent laptop-based full-featured Vividi (General Electric) system which is available with transthoracic and transoesophageal imaging probes.

add quantitative information. The ultrasound stethoscope is also suitable for a limited 'goal-oriented' examination (e.g. pericardial effusion after pericardiocentesis, ejection fraction, hypertrophy) and can effectively assist in the initial evaluation and rapid diagnosis of potentially life-threatening conditions or situations where quick decision-making is essential (emergent tamponade, low output state, acute valvular pathology, right ventricular involvement, hypovolaemia and mechanical complications of acute myocardial infarction). The ultrasound stethoscope allows rapid screening for occult aortic abdominal aneurysm, LV hypertrophy in patients with hypertension, hypertrophic cardiomyopathy, etc. Ultrasound stethoscopy is a fast-developing field. Micro-miniaturized ultrasound systems have been incorporated in a transducer assembly that connects to a notebook PC and pocket-size

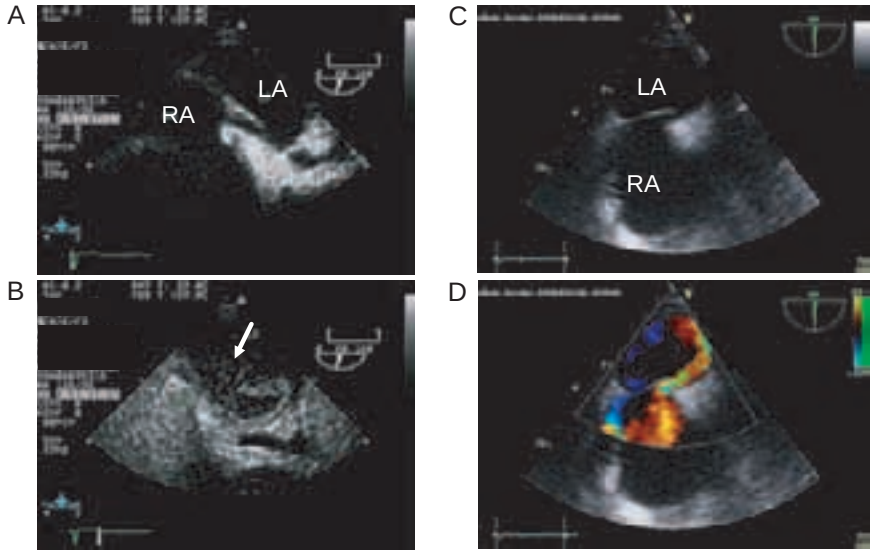

Figure 2.14 Patient with patent foramen ovale (A) before and (B) after intravenous contrast-agitated saline injection. The right atrium (RA) is opacified with contrast, which also appears in the left atrium (LA), proving right-to-left shunting of blood. (C) Patient with a patent foramen ovale and large right-to-left shunting of blood visualized with colour Doppler flow imaging (D).

ultrasound systems based on iPAQ technology are already in use and will soon emerge onto the market.

The small hand-held devices should not be confused with the portable desktop systems, which are full-featured systems with high imaging performance (Fig. 2.13). They integrate most diagnostic functions and are equipped to perform transoesophageal and intracardiac echocardiography. They have considerable digital storage capabilities and connect to the hospital intranet for online consultation and storage. These portable systems will considerably expand the diagnostic applications of cardiac ultrasound in many different clinical scenarios.

Specific applications

Contrast echocardiography

Ultrasound contrast agents (microbubbles containing gas) increase the echogenicity of blood and are used for enhanced endocardial delineation, Doppler signal enhancement and intracardiac shunt detection (Fig. 2.14). In patients with larger-volume shunting and turbulence, colour Doppler flow imaging allows direct visualization of the right-to-left shunt (Fig. 2.14C,D) (see Colour flow imaging, below). Agitation of 5–8 ml of saline with 1 ml of air and a few drops of aspirated blood (stabilizes the microbubbles of air) between two syringes connected by a three-way stopcock provides an excellent contrast medium for right-sided cavity opacification, demonstration of right-to-left shunts and enhancing Doppler signals [15]. Also, other agents such as X-ray contrast, cardiogreen and gelatine produce echo contrast [16].

In the 1990s, important advances were made in microbubble engineering. New ultrasound contrast agents are capable of passing through the pulmonary capillary bed without destruction and behave as red blood cell tracers. At low ultrasound power (low MI), microbubbles scatter ultrasound and generate strong echo signals. At higher MI, they resonate and produce non-linear resonant frequencies, which are detected by harmonic imaging. They produce significant improvement of LV endocardial border identification in patients with poor or suboptimal non-contrast-enhanced echocardiographic images and allow consistent imaging of the coronary microcirculation following peripheral intravenous injection. These agents reside exclusively in the microcirculation, do not pass into the extravascular space and do not penetrate myocardial cells, a major advantage over contrast agents used in other imaging modalities. The method is therefore extremely promising for assessment of myocardial perfusion in various acute and chronic cardiac conditions (Fig. 2.15) [17]. Harmonic imaging is a prerequisite for optimal imaging of the capillary circulation.

Microbubbles can also be targeted specifically to bind unique cell markers and can be used to non-invasively detect incipient disease (e.g. endothelial dysfunction, transplant rejection), thrombi, etc. They can also be engineered for local drug and gene delivery.

Stress echocardiography

Stress echocardiography is a powerful and safe method for diagnosis, localization of the ischaemic wall segment, functional assessment and risk stratification in several

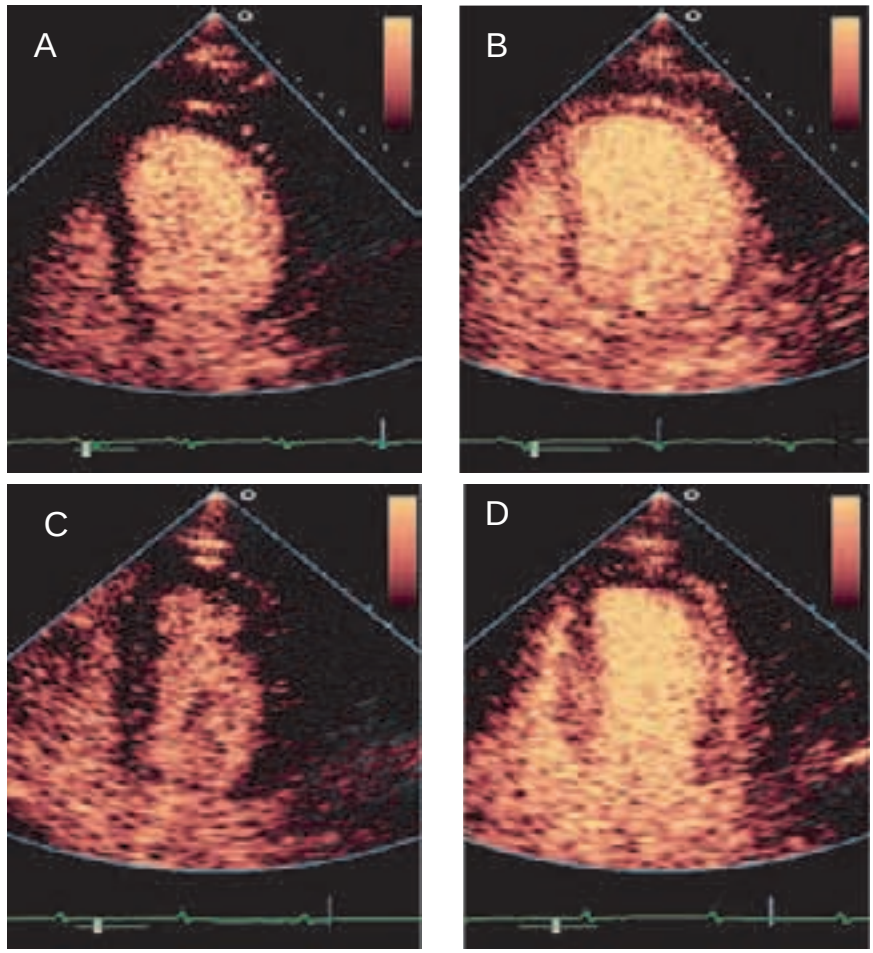

Figure 2.15 Myocardial perfusion imaging (Sonovue Bracco). (A) Four-chamber view in a patient with a dilated left ventricle shows echocontrast in the cavities, which are nicely delineated, but not much in the myocardium; (B) after a few cardiac cycles, the whole myocardium is well opacified indicating normal perfusion. (C) Four-chamber view of a patient with coronary artery disease and opacification of the left ventricular cavity; (D) after a few cardiac cycles, there is a perfusion defect in the apical septal and apical lateral segments.

types of cardiac disease [18]. In patients with coronary artery disease, the increased cardiac workload causes an imbalance in oxygen supply/demand and results in regional ischaemia, with a decrease in myocardial thickening and endocardial inward motion. The indications are similar to those for nuclear perfusion scintigraphy. A variety of stress methods can be used for inducing ischaemia and wall motion abnormality during echocardiographic monitoring. Physical exercise allows a high level of stress but adequate images are difficult to obtain at peak stress [19]. Pharmacological agents are most commonly used. These either increase the heart rate and the inotropic state (dobutamine) or induce maximal coronary vasodilatation (dipyridamole, adenosine), which may induce a 'coronary steal' and induce a wall motion abnormality (Figs 2.16 and 2.17).

The test provides similar sensitivity and specificity as perfusion scintigraphy but requires experienced echocardiographers. Its major advantage over ECG exercise testing is that it has a higher sensitivity (20–25%) and that it is applicable to patients unable to exercise (ageing population). It is less time-consuming, has a greater availability and is less expensive than nuclear studies. Dobutamine stress echocardiography is used to study viability by enhancing wall function in akinetic or hypokinetic segments (low dose) and ischaemia in the same segments (high dose) during the same test in order to plan revascularization procedures in patients after myocardial infarction who received thrombolytic therapy. In fact, dobutamine stress echocardiography has the best sensitivity and specificity of all the available viability tests. Stress echocardiography using specific protocols is also utilized to obtain specific information in valvular heart disease (aortic valve area), cardiomyopathies (outflow obstruction), right ventricular failure and pulmonary hypertension [20] (see Chapters 16, 21 and 25). Digital image technology has made stress echocardiography progressively easier to perform and analyse. However, the analysis is still largely subjective and should become quantitative, which is a major challenge for the immediate future.

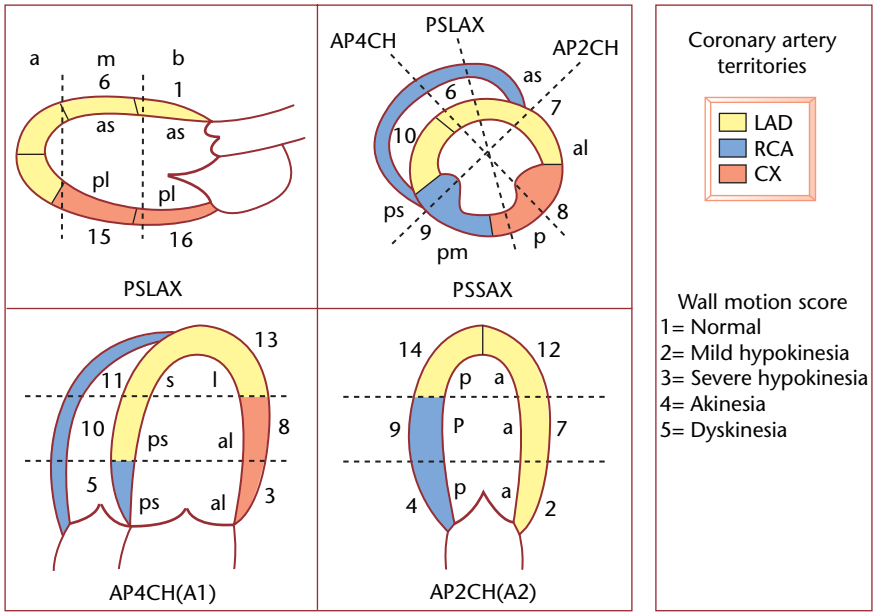

Figure 2.16 Method for standardized qualitative wall function analysis using the 16-segment model. The colour indicates the coronary artery territories supplying the wall segments. Diagrams show the parasternal long-axis (PSLAX), apical four-chamber (AP4CH, corresponding to A_1 in Fig. 2.24), apical two-chamber (AP2CH, corresponding to A_2 in Fig. 2.24) and parasternal short-axis (PSSAX) views. The left ventricular long axis is divided at three levels: apical (a), mid-papillary (m) and basal (b). Some segments are visualized in more than one view (see numbers). In the analysis the motion pattern of the 16 segments is given a wall motion score: normal, hypokinetic (< 25% inward motion), akinetic (25% motion) and dyskinetic (outward motion). a, anterior; as, anteroseptal; al, anterolateral; l, lateral; p, posterior; ps, posteroseptal; pl, posterolateral; pm, posteromedial; s, septal.

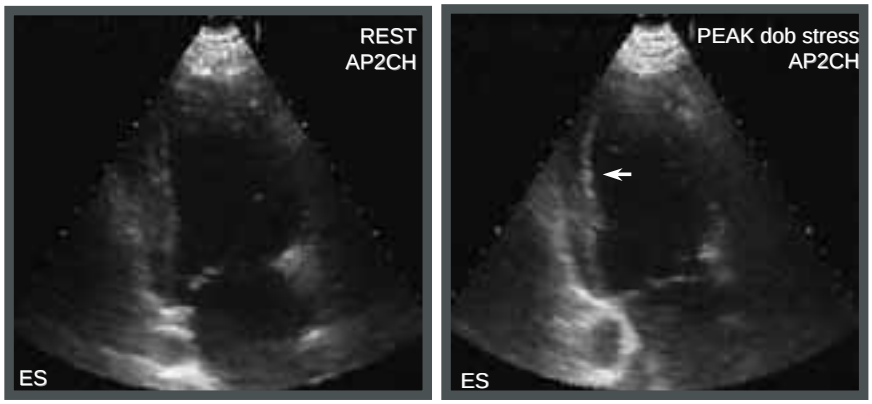

Figure 2.17 Paradoxical outward motion (dyskinesia) of the posterior wall (arrow) visualized in the apical two-chamber view (AP2CH) and induced at peak dobutamine stress. Still frames at rest and peak stress are recorded in end-systole (ES). This is a positive test. The posterior segments are supplied by the right coronary artery (see also Fig. 2.16).

Transoesophageal echocardiography

In transoesophageal echocardiography (TOE), a miniaturized phased-array transducer is incorporated in the tip of a flexible endoscope and can be passed into the oesophagus and stomach. The transducer can be electronically rotated along the long axis of the image sector in a 180° arc and produces an infinite number of transverse and longitudinal images (omniplane or multiplane TOE) combined with all Doppler modalities (Fig. 2.18). The angle of rotation is shown on the display system. The images are of excellent clarity and resolution and provide more detailed information when necessary. The examination involves some discomfort and carries a minimal risk [21], and is used to answer specific clinical questions when precordial images are inadequate either because of the patient's body habitus (obesity, emphysema) or because of shielding of structures of interest by prosthetic components.

The use of TOE has grown explosively in such diverse settings as the out-patient clinic, emergency room and the intensive care unit. It provides a definitive diagnostic modality for a broad range of cardiovascular disease, especially in acute conditions and the critically ill with haemodynamic compromise [22]. This has led to a decline in the use of Swan–Ganz catheters for invasive haemodynamic monitoring. TOE has provided new insights into the pathophysiology of acute aortic syndromes and is now the initial diagnostic method in patients with aortic disease and those suspected of having an acute aortic syndrome (aortic dissection, aortic ulcer, intramural

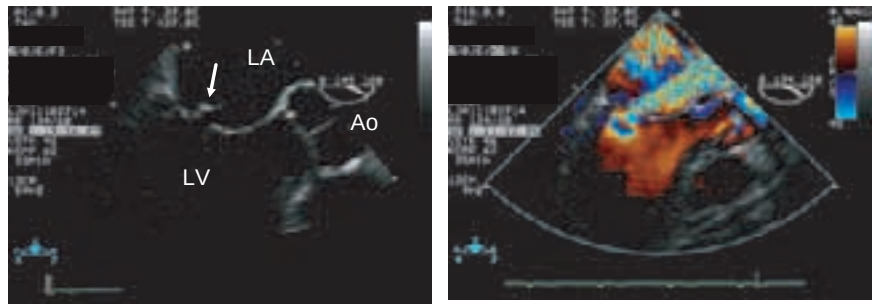

Figure 2.18 Patient with mitral valve prolapse of the posterior leaflet (arrow) seen from a middle-lower oesophageal transducer position with the imaging plane at 140–145°. The colour flow image shows the regurgitant jet directed away from the prolapsing leaflet and striking the posterior aortic wall. This results in an underestimation of the jet size (Coanda effect). The proximal isovelocity surface area is also well seen proximal to the regurgitant orifice. Ao, aorta; LA, left atrium; LV, left ventricle.

haematoma and trauma see p. 87 and Chapter 34). It provides crucial information in these patients and also in those with prosthesis dysfunction, endocarditis and pulmonary embolism [23]. It is also an important tool for cardiac monitoring during anaesthesia and for guiding intracardiac interventions. In patients undergoing surgical interventions, it is the most common and convenient way to obtain echocardiographic data and provides important continuous information on structure and function before and after endovascular aortic repair and cardiopulmonary bypass, does not interfere with the surgical field and influences surgical and haemodynamic management. Transnasal probes for continuous cardiac monitoring are also used [24]. Over the years, TOE has stimulated the collaboration between a wide range of disciplines within hospitals.

Intraoperative echocardiography

Intraoperative echocardiography may be used via the transoesophageal, direct epicardial and epi-aortic routes and has become an integral part of cardiac surgery. It can be adapted to the entire spectrum of cardiac surgical procedures in order to assist both the surgeon and anaesthesiologist [25]. Particularly during minimally invasive port-access surgery and robotic-assisted procedures, it helps to minimize the risk and improves outcome by providing a 'third eye' for guiding surgical manipulations. Epi-aortic imaging is the superior approach for detecting aortic atherosclerosis when manipulations of the aorta are planned.

Substernal (epicardial) echocardiography

A specially constructed mediastinal chest drain tube that allows access to a small TOE probe is used in postoperative intensive care (precordial bandages, ventilation) to evaluate myocardial function and coronary graft flow and allows rapid exclusion of tamponade after chest closure.

Intracardiac echocardiography

Some of the drawbacks of transthoracic and transoesophageal echocardiographic imaging can be overcome with the use of an ultrasound transducer-tipped catheter capable of intracardiac imaging [26]. This has either a mechanically rotating single-element transducer (9 MHz) mounted on a 9F catheter tip or a phased-array transducer (5.5–10 MHz) on a 10F catheter tip. The latter allows spectral Doppler haemodynamic and colour flow information to be obtained as well. The procedure is invasive and allows continuous detailed visualization of endocardial anatomy and is increasingly used for monitoring interventional procedures (device defect closure, valvuloplasty) and electrophysiological procedures, enhancing both success and safety while minimizing radiation exposure [27] (see Chapter 6).

Intravascular/intracoronary echocardiography

Intravascular, and more particularly intracoronary, ultrasound require both a small transducer system mounted on 2–3F catheter tips and a catheter delivery system with optimal steerability and flexibility. Mechanically rotated single-element systems and electronic multielement transducer systems are available with operating frequencies of 30–40 MHz. The method provides detailed information about morphology and pathology of the lumen and vessel wall and has contributed considerably to the understanding of the pathology of atherosclerosis and the mechanisms of intracoronary and pharmacological interventions (see Chapter 6).

Examination techniques

Transthoracic (precordial) echocardiography

To answer a clinical question or solve a diagnostic problem, a standardized examination procedure must be followed. In many situations it may be important to review the patient's file and measure blood pressure; the ECG should always be recorded as a reference trace.

The M-mode registrations are simultaneously sampled from the two-dimensional phased-array transducer. Precise knowledge of the position of the heart in the thorax and intracardiac structure relationships is mandatory and can be found in textbooks [28]. The examination begins with transthoracic two-dimensional scanning from four standard precordial transducer positions: the parasternal and apical views with the patient in the lateral decubitus position and the subcostal and suprasternal views in the supine position (Fig. 2.19). From each position standardized, multiple, cross-sectional images of the heart relative to the perpendicular long and short axes are obtained by angulating and rotating the transducer. An optimal grey-level and gain setting has to be used. The examination procedure is extensively described in textbooks [29–31].

Two-dimensional imaging is also the basis for colour Doppler imaging and guided pulsed- and continuous-wave Doppler interrogation. It is important that the interrogation beam is parallel with the direction of blood flow to avoid underestimation of the maximal frequency shift. Colour flow imaging is used to optimize the alignment of the ultrasound beam with the direction of flow and placing the sample volume.

Transoesophageal echocardiography

Cardiac imaging

The patient is examined in the left lateral decubitus position and the endoscope is introduced after fasting for 4 h, mild sedation and local anaesthesia of the posterior hypopharynx with 10% lidocaine spray. An intravenous line is introduced and heart rate, blood pressure and oxygen saturation are continuously monitored. The procedure is usually well tolerated. Longitudinal, transverse and intermediate images are obtained at three levels (upper transoesophageal, lower-middle transoesophageal

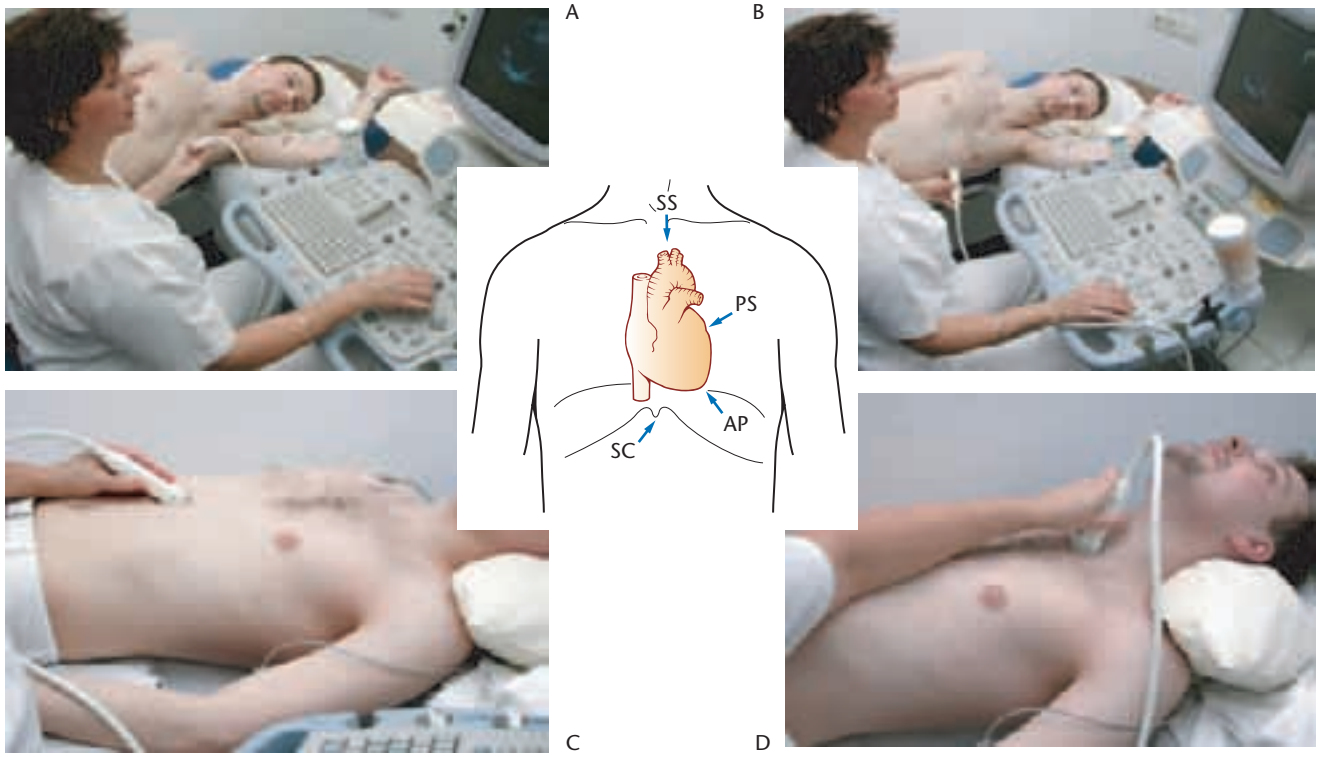

Figure 2.19 The four standard transducer positions for transthoracic two-dimensional echocardiography: (A) left parasternal (PS); (B) apical (AP); (C) subcostal (SC); (D) suprasternal (SS).

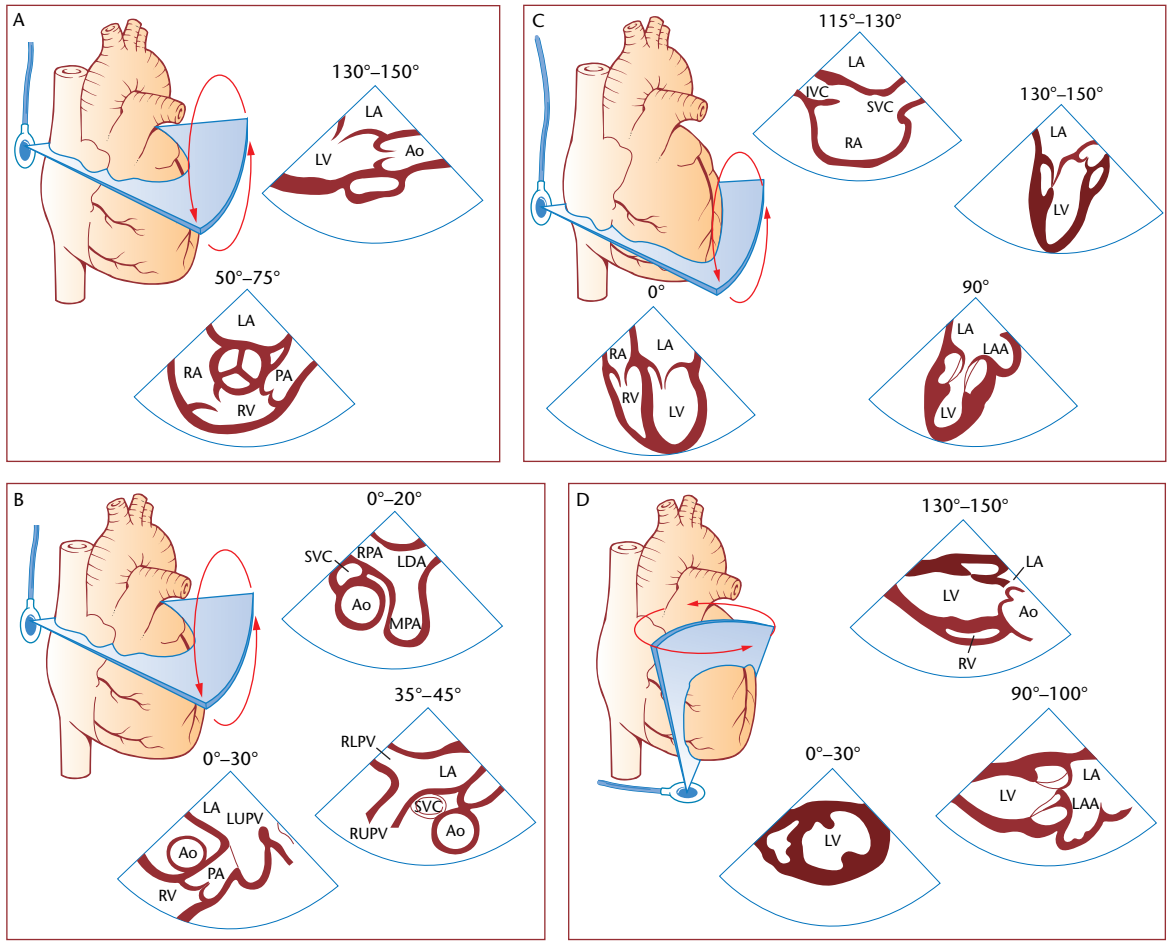

Figure 2.20 Position of the scanning plane is indicated on the display screen: 0° indicates the transverse view, which is orthogonal to the probe, 90° shows a longitudinal view and 180° is the mirror image of 0°. (A) Upper transoesophageal views of the aortic valve in long-axis (130–150°) and short-axis (50–75°) views. (B) Upper transoesophageal views of the great vessels and atrial appendage (counter-clockwise): transverse view of the left atrial appendage and the left upper pulmonary vein (0–30°); intermediate view of ascending aorta, left atrium and right pulmonary veins (35–45°); and, with anterioflexion of the probe, transverse view of the ascending aorta, superior vena cava and main pulmonary artery with its bifurcation are obtained (0–20°). (C) Lower-middle transoesophageal views with exemplary cross-sections corresponding to (counter-clockwise) the four-chamber view of the left ventricle. From this transducer location, right heart structures can be visualized. A right atrial longitudinal view is visualized at 115–130°. (D) Transgastric views with exemplary cross-sections corresponding to (counter-clockwise) transgastric short-axis view at mid-papillary level, transgastric two-chamber view and transgastric long-axis view of the left ventricle after passing the left liver lobe.

and transgastric) by rotating and flexing the transducer tip medially and laterally (Fig. 2.20).

Aortic imaging

The entire thoracic aorta can usually be visualized in horizontal short axis and longitudinal scan planes [32–35] (Fig. 2.21). Standardized imaging sequences have to be used for high-quality examination and optimal diagnostic yield (see also Chapter 34).

Pulmonary artery imaging

Examination of the main, right and left pulmonary artery is important in acute pulmonary hypertension and suspected embolism.

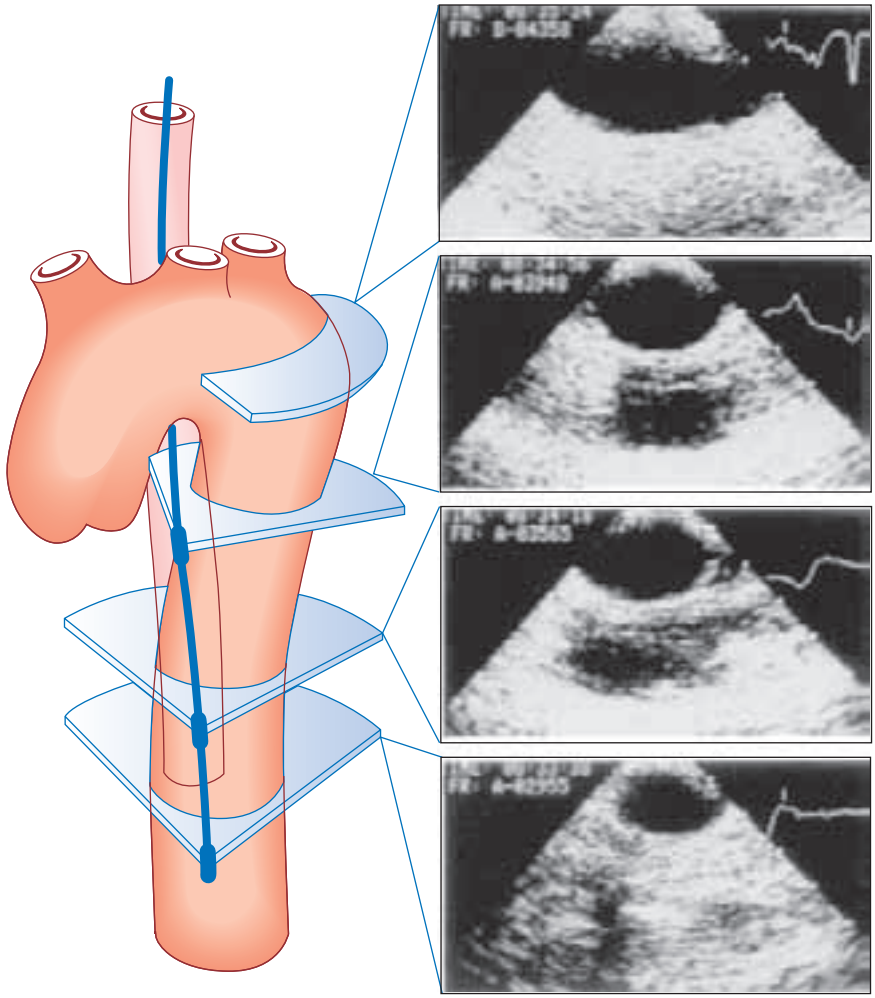

Figure 2.21 Examination of the thoracic aorta in the transverse plane in relation to the oesophagus. The diagram shows the intertwining relationship of the aorta and oesophagus.

Reference values for M-mode and two-dimensional echocardiography

M-mode echocardiography

Echocardiography is a quantitative method and both linear and temporal calibrations are available on each individual recording [36]. M-mode echocardiography provides good structural definition. For rapid assessment, dimensional measurements are made from parasternal M-mode recordings. Landmarks for measurement are given in Figs 2.4 and 2.5 and reference values in Table 2.2. Measurements of structure and cavity dimensions (Fig. 2.22) are more accurate and reproducible when guided by two-dimensional echocardiography. The principles of measurement and reference values corrected for body surface area are given in Fig. 2.22 [37]. Principles are also found in textbooks [30,38].

Despite the availability of three-dimensional echocardiography, which is inherently more accurate, M-mode measurements are still used in most studies to estimate LV myocardial mass and are useful for follow-up of individual patients. An ellipsoid with a long axis (L) twice the length of the short axis is assumed as the geometric model of the LV (Fig. 2.23). The LV end-diastolic short-axis dimension (D) is taken from either the parasternal long-axis or short-axis view.

The volume of a prolate ellipsoid is:

$$V = {}^{1}/_{6}\pi LD^2$$

Since L is assumed to be $2D$, the LV cavity volume is $(1.047)D^3$. The total (epicardial) LV volume includes cavity and myocardium and is calculated by adding interventricular septal thickness (T_{IVS}) and posterior wall thickness (T_{PW}). Consequently:

$$\text{Total LV volume} = 1.047(D + T_{PW} + T_{IVS})^3$$

The myocardial volume is the difference between the epicardial and endocardial volume. Hence:

Table 2.2 Reference values for M-mode diameter measurements

	Men (mm)	Women (mm)
Aortic root	26–36	23–34
Left atrium (end-systole)	30–40	26–38
Right ventricle (end-diastole)	< 30	< 30
Left ventricle		
End-diastole	47–58	43–55
End-systole	28–37	28–40
Fractional (systolic) shortening	> 25%	> 25%
Interventricular septal thickness (T_{IVS})	8–12	7–12
Systolic thickening	> 30%	> 30%
Posterior wall thickness (T_{PW})	7–12	6–11
Systolic thickening	> 30%	> 30%

Ranges represent 90% confidence intervals.

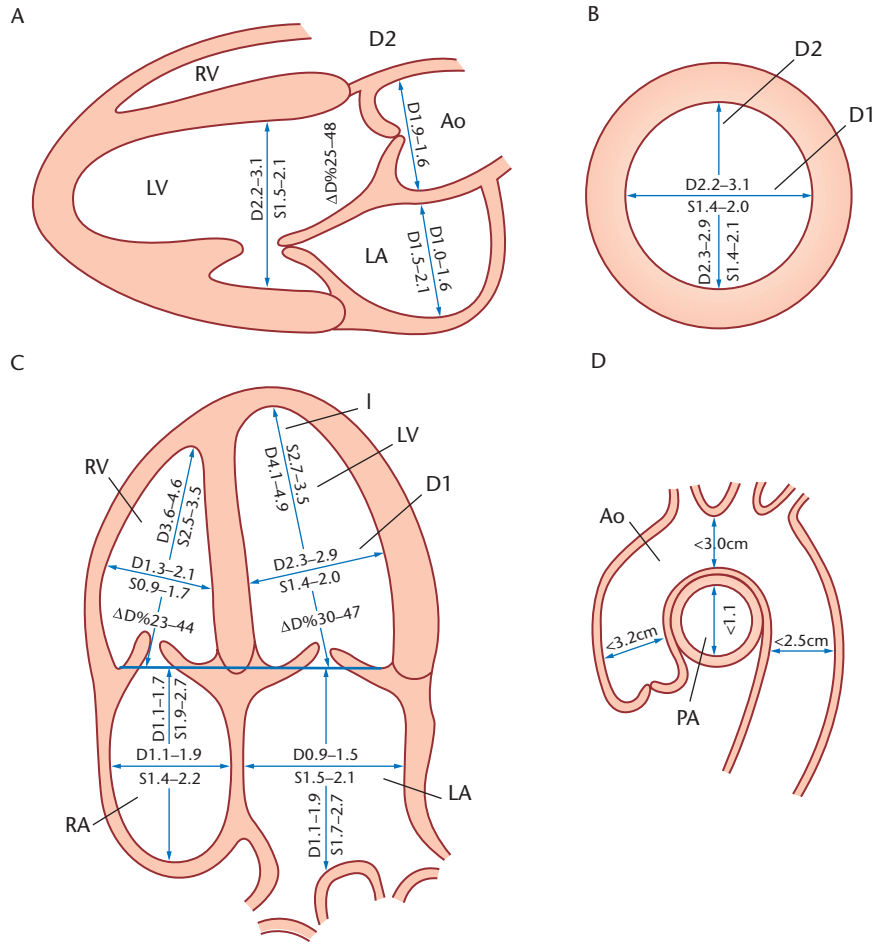

Figure 2.22 Measurements of cardiac structure, cavity dimensions and area can be obtained from three two-dimensional views: (A) parasternal long-axis view; (B) parasternal short-axis view at the chordal level; (C) apical four-chamber views. (D) Long-axis and short-axis view of the aorta and pulmonary artery. Dimensions are given in centimetres corrected for body surface area (m^2) in diastole (D) and systole (S). L, left ventricular long-axis dimension in the apical four-chamber view; D_1, mediolateral left ventricular dimension in the apical four-chamber view; D_2, anteroposterior left ventricular dimension in the parasternal long-axis and short-axis views. Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

$$\text{Myocardial volume} = 1.047[(D + T_{PW} + T_{IVS})^3 - D^3]$$

Hence LV mass (grams)
= myocardial volume – 13.6 (Penn convention) or
= myocardial volume × 1.04 × 0.8 + 0.6

where 1.04 g/ml is the specific gravity of muscle and 0.8 is a correction factor. Normal values are 93 ± 22 g/m^2 for men and 76 ± 18 g/m^2 for women. Upper limits of LV mass (mean ± 2SD) are 132 g/m^2 for men and 110 g/m^2 for women.

Two-dimensional echocardiography

Two-dimensional echocardiography has become the routine examination for cardiac chamber volume and function assessment. This requires adequate endocardial

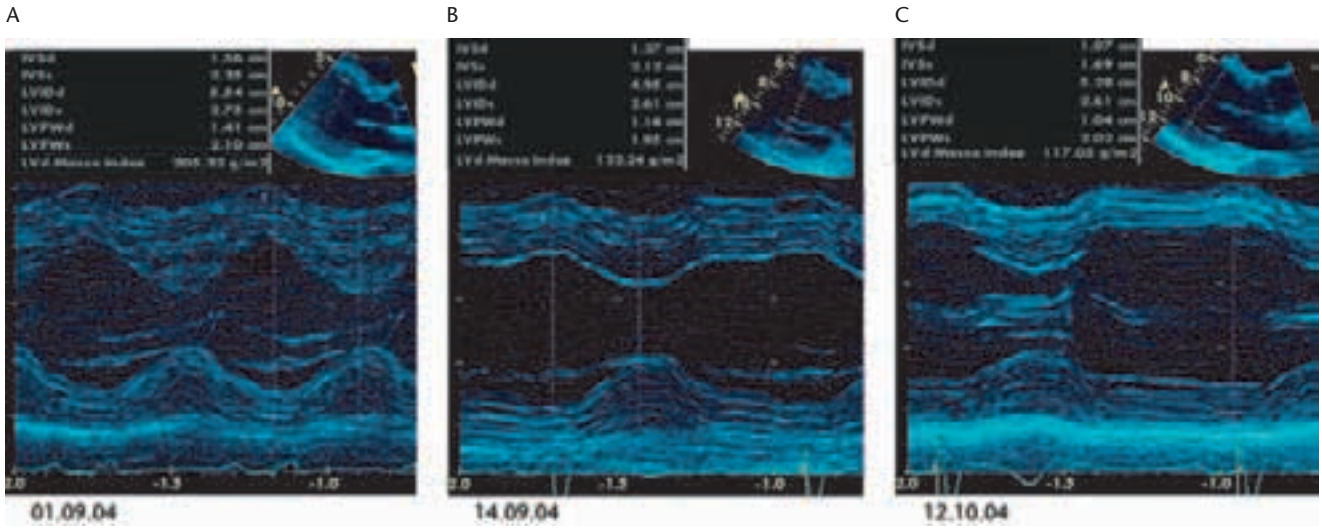

Figure 2.23 (A) M-mode recordings of the left ventricle in a patient with parvovirus B19-induced myocarditis. The admission echo showed thickened interventricular septal and posterior walls of 1.56 and 1.41 cm respectively. The left ventricular mass index was 205 g/m^2. (B) Two weeks later the left ventricular mass index has decreased to 133 g/m^2 and (C) 6 weeks later it was within normal limits (117 g/m^2).

border visualization (contrast LV opacification can be used for better cavity delineation), proper alignment of the imaging planes and careful planimetry. Nevertheless, the ellipsoidal models and the geometric assumptions introduce inaccuracies, especially of the right ventricle (RV) and ventricles with shape abnormalities. Three-dimensional echocardiography is able to overcome these limitations mainly by avoiding both these assumptions and models and has rapidly become the new reference method.

Left ventricular volume

The volume of the LV is calculated from the dimension and area obtained from the orthogonal four-chamber and two-chamber apical views (Fig. 2.24) and a wide range of formulae is used [39]. The biplane disc summation method (also called the modified Simpson's rule) is the most commonly used and also the most accurate [38] (Fig. 2.25). This method should be used whenever possible. Modern equipment has built-in computer software programs for rapid contouring of the LV endocardium (and epicardium, which allows measurement of wall thickening and more accurate mass calculation) and for calculating the cavity area. Volumes are calculated by summating an average of 20 discs (Figs 2.25 and 2.26).

In some patients only an adequate single view can be obtained. In this situation the single plane method of discs can be applied (Figs 2.25 and 2.27). Less accurate

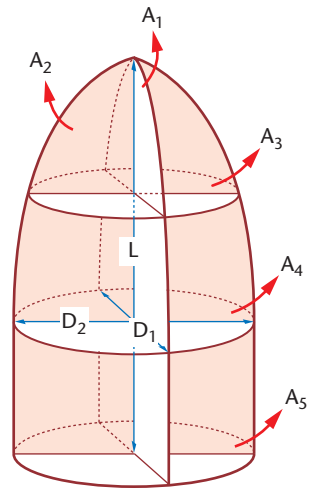

Figure 2.24 Model of the left ventricle and the dimensions and imaging planes used in formulae to calculate cavity volumes from two-dimensional echocardiographic views, assuming a rotation ellipsoid body for which the length and the major and minor axes have to be determined. A_1, cavity area in the four-chamber view; A_2, cavity area in the apical two-chamber view; A_3, cavity area in the parasternal short-axis view at papillary muscle level; A_4, cavity area in the short-axis view at mitral valve level; A_5, basal cavity area in the short-axis view (this surface area is not measured in practice and is taken as A_4). L, left ventricular long axis in either the apical long-axis or four-chamber view; D_1, mediolateral left ventricular dimension in the four-chamber view; D_2, anteroposterior left ventricular dimension in the parasternal short-axis or apical two-chamber view.

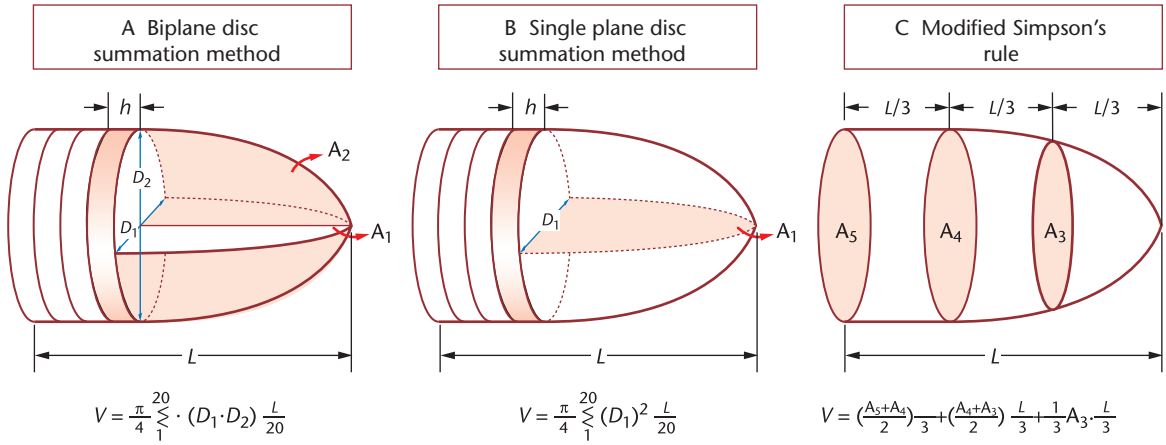

Figure 2.25 Methods for calculating left ventricular volume by the method of discs. (A) Biplane method uses the two orthogonal apical views. The calculation is based on summation of the volumes of discs (calculated from perpendicular diameters D_1 and D_2 and disc thickness) of 20 equal discs, which are summed for calculation of a rotation ellipsoid. (B) In the single plane method, only one diameter is measured in order to calculate the area of volume of each individual disc. (C) In this method the parasternal short-axis views A_4 and A_3 are used ($A_5 = A_4$) for planimetry and the long-axis length (L) is measured from the apical two-chamber view.

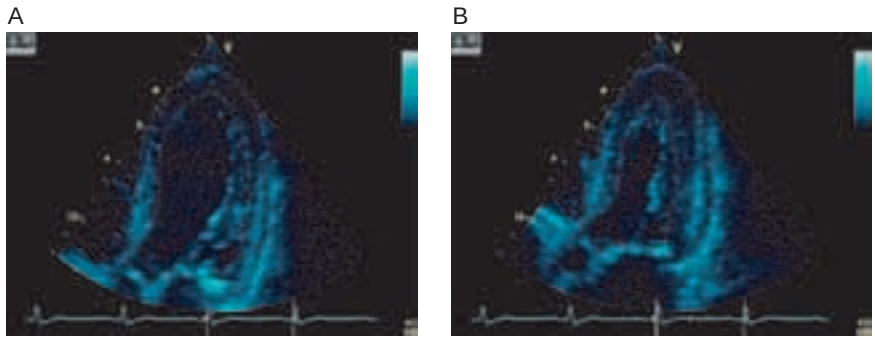

Figure 2.26 (A) End-diastolic and (B) end-systolic apical long-axis views of a normal left ventricle. The endocardial and epicardial contours are traced and the built-in computer software of the ultrasound system allows calculation of volumes, wall thickening and myocardial mass.

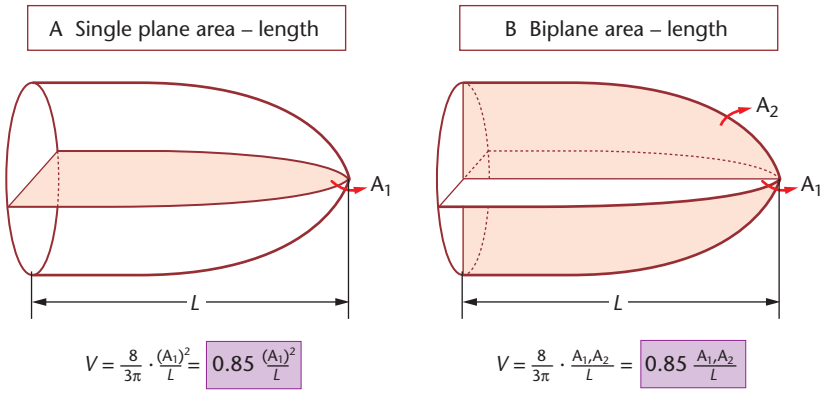

Figure 2.27 The two methods for calculating left ventricular volume assuming a rotation ellipsoid model. (A) Single plane area–length is used when only one apical view is visualized (in this diagram the apical four-chamber view). The area (A_1) is planimetered and the long-axis length (L) is measured. (B) In the biplane area–length method, the areas of the orthogonal four-chamber (A_1) and apical two-chamber (A_2) views are planimetered and the long-axis length (L) measured from either of these views.

is the prolate ellipsoid model, which assumes that the ventricle both in systole and diastole approximates the shape of a prolate ellipse. The area–length method can then be employed in a single plane or in two orthogonal planes. Combined geometric shapes have been proposed to better approximate LV shape for volume calculation (cylinder hemi-ellipse or bullet, cylinder–cone and cylinder truncated cone–cone models). Models based

EDV, end-diastolic volume; ESV, end-systolic volume; EF, ejection fraction.

on short-axis views are not practical because adequate views are difficult to obtain. Reference values for cavity volumes using methods of areas and disc summation are presented in Table 2.3.

It must be taken into account that, because of the position of the transducer on the chest wall relative to the apex of the heart, tangential scanning planes are recorded that underestimate the true LV volume [44]. This assumption has been proved by three-dimensional echocardiography.

Right ventricular volume

Volumetric measurements of the RV are problematic because of its complex geometry (the RV chamber poorly approximates to any convenient model), its variable trabeculation causing difficulties in endocardial border detection, and inadequate imaging planes (by its inaccessibility behind the sternum) [45]. However, biplane disc summation is used in most methods. For RV volume calculation the subtraction method has been developed, which takes into account that the RV has a scale shape [46]. Using the method of discs, the volume of the LV and RV including the interventricular septum (IVS) is calculated and the volumes of the LV and IVS are subtracted:

$$\text{RV} = (\text{LV} + \text{IVS} + \text{RV}) - (\text{LV} + \text{IVS})$$

Three-dimensional echocardiography complemented with contrast cavity delineation offers advantages for volume calculation but data are lacking.

Non-volumetric methods provide both qualitative and semi-quantitative information on function that can be used for patient management (anteroposterior M-mode dimension in combination with septal motion, fractional area change, tricuspid annular plane systolic excursion and velocity, MP index, pulmonary artery pressure). The transtricuspid flow pattern provides information on diastolic RV function in combination with annular tissue Doppler imaging.

Left atrial volume

The anteroposterior diameter of the left atrium (LA) measured in the parasternal long-axis view is commonly used to assess LA size. This measurement is insensitive to LA dilation but specific. Therefore the LA volume should be measured [47]. The area–length and disc summation method can be applied using apical two- and four-chamber views (Fig. 2.28). The normal maximal LA volume is ≤ 36 ml/m^2.

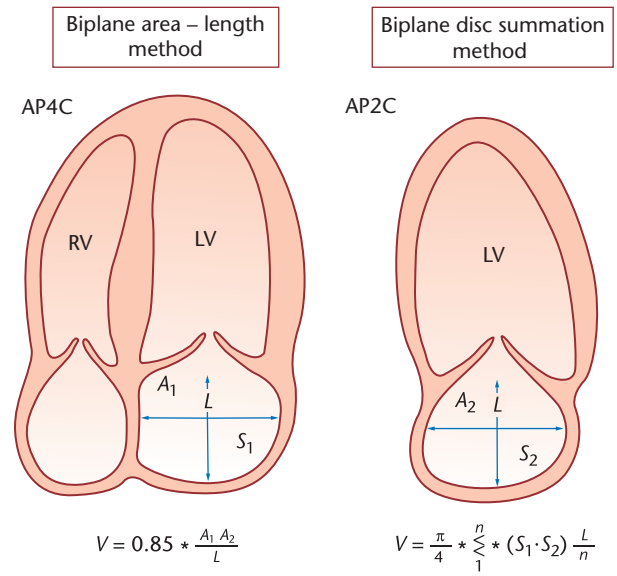

Figure 2.28 Principle of measuring the left atrial volume using the biplane area–length model and biplane disc summation methods at ventricular end-systole. The shortest long-axis (L) dimension from either the AP4C or AP2C view between the posterior wall and the line across the mitral valve hinge points should be taken. S_1, short axis in the AP4C view; S_2, short axis in the AP2C view; A_1 and A_2, surface areas in these views.

Recently, an elliptical model has been proposed that does not require endocardial contour tracing [48]:

$$V = \pi/6 \cdot DLS_1$$

where D is the anteroposterior dimension from M-mode and L and S are measured in the apical long-axis view. Three-dimensional echocardiography provides more accurate and reproducible quantitative data [49].

Principles of Doppler echocardiography

Doppler echocardiography is based on the principle that the echoes reflected from moving red blood cells (or any object) undergo a small shift in frequency. This frequency shift (difference in transmitted versus received frequency) is proportional to the proportion of velocity directed along the ultrasound beam or scan line. Blood cells flowing toward the transmitted ultrasound beam compress the signal frequency (the transducer receives a lower frequency). For blood flow where the direction of the sound beam is not aligned, the shift will be a factor cosine θ less than it would be for on-axis interrogation.

Therefore, the position of the transducer is usually adjusted so that the direction of blood flow is parallel to the sound beam. The frequency shift (Δf) is calculated by knowing the transmitted frequency (f_t), the velocity of the moving object (v), ultrasound speed (c) and the angle of interrogation (θ).

$$\Delta f = \frac{2f_t \cdot v \cdot \cos\theta}{c} \quad \text{and hence} \quad v = \frac{c\Delta f}{2f_t \cos\theta}$$

The 'Nyquist velocity' is the maximum velocity that can be measured without ambiguity (aliasing): it is inversely proportional to the distance and the transmitted frequency. Therefore, to maximize the maximum velocity that can be recorded, it is best to use a low-frequency transducer and bring the transducer as close as possible to the area of interest.

There are five Doppler modalities for cardiac examination: continuous wave, pulsed wave, colour flow mapping, colour M-mode and tissue Doppler velocity imaging.

Pulsed-wave Doppler

Pulsed-wave Doppler can measure velocity at a specific point by intermittently emitting ultrasound pulses and by gating the returning signals to a desired depth (i.e. sample volume at a specific site within the image) (Fig. 2.29A) [50]. However, the maximum measurable velocity is limited by the Nyquist limit. This problem has been overcome to some degree by high-frequency sampling (high pulse repetition frequency). Signals from the receive-transducer contain strong echoes from the relatively slow-moving structures (myocardium, vessel wall) and much weaker signals from the fast-moving red blood cells. By implementation of appropriate thresholding

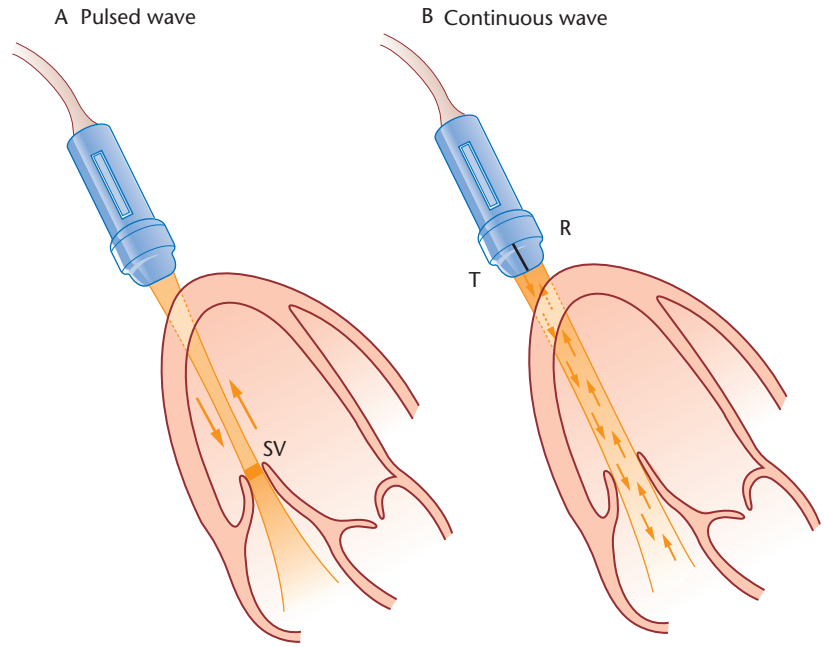

Figure 2.29 (A) In pulsed-wave Doppler there is one transducer that alternately transmits and receives ultrasound information from a single small region or sample volume (SV) within the sound beam. The location of this sample volume is operator-controlled. (B) Continuous-wave Doppler uses two independent transducers, one for constant transmission (T) and one for continuous reception (R) of ultrasound information. This allows recording of the highest velocities within the sound beam but there is no depth information.

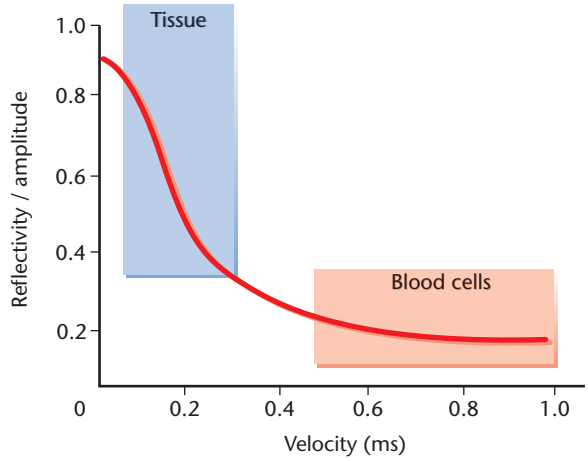

Figure 2.30 Principle of tissue Doppler imaging. Highly reflective slow-moving tissue (myocardium) can be distinguished from poorly reflecting high-velocity blood cells by applying appropriate thresholding and clutter filters.

and clutter filters, the signals can be separated so that high-amplitude/low-velocity information is processed for tissue Doppler velocity imaging and low-amplitude/high-velocity signals for blood flow velocity recording (Fig. 2.30).

Continuous-wave Doppler

Continuous-wave Doppler instruments use two separate transducers, one for transmitting and one for receiving ultrasound signals continuously [50] (Fig. 2.29B). Continuous-wave Doppler is not limited by the Nyquist limit. However, it cannot measure velocity at a specific point but only the maximum velocity along a specific beam direction. It is therefore useful if one knows with a high degree of certainty where the maximum velocity is occurring. Fortunately, high-velocity jets occur only in a few locations in the heart (stenotic and regurgitant lesions and shunts).

Doppler allows study of not only the velocity of the blood flow structures but also the flow period and the direction of flow. Direction is represented as either a positive deflection above the zero baseline (motion towards the transducer) or a negative deflection below the zero baseline (motion away from the transducer). When all velocities (cm/s) during a flow period are added together and divided by the flow duration (s), the result is called the velocity time integral.

Velocity of blood is related to pressure difference through the Bernoulli equation, which is a restatement of the law of conservation of energy in fluids and allows measurement of instantaneous pressure gradients across obstructions and shunts in the cardiovascular system.

Colour flow imaging

A comprehensive cardiovascular ultrasound examination requires blood flow information to be obtained from large segments of blood vessels and cardiac chambers similar to an angiocardiogram. This information must therefore be integrated within the two-dimensional images. This is impossible when using the fast Fourier transform analysis of data from over 100 scan lines to calculate the Doppler shift from a single site because of time constraints. To overcome this problem only mean velocities and their variance are calculated from a few scan lines by autocorrelation techniques. These calculations are relatively simple and rapidly performed on echoes received from each individual sample volume. Each calculation yields information on flow direction, velocity and variance (laminar or turbulent). Flow in the sample volume towards the transducer is encoded in red and brighter colours indicate higher mean velocities. A mosaic of colours indicates increased variance (turbulence). The colour-coded flow parameters are displayed on the screen superimposed on the two-dimensional images in real-time at a frame rate of 25/s (Fig. 2.31). These 'ultrasonic angiograms' allow immediate differentiation between normal and abnormal blood flow and these

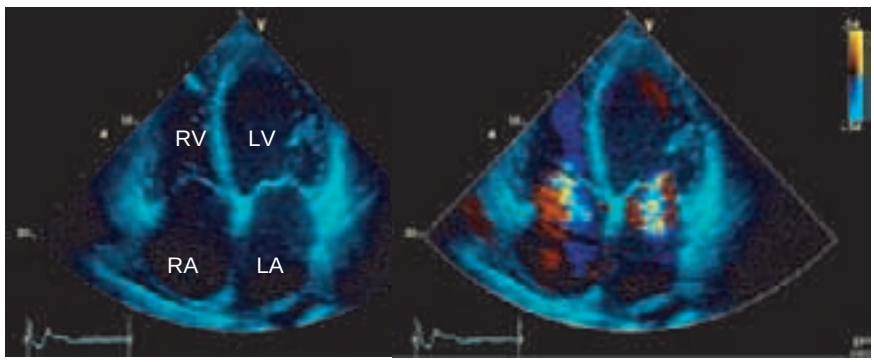

Figure 2.31 Colour flow image of a patient with dilated cardiomyopathy and mitral and tricuspid regurgitation. The apical four-chamber view is shown. The tricuspid regurgitant jet is seen in the right atrium (RA) and a central mitral regurgitant jet in the left atrium (LA) in systole. LV, left ventricle; RV, right ventricle.

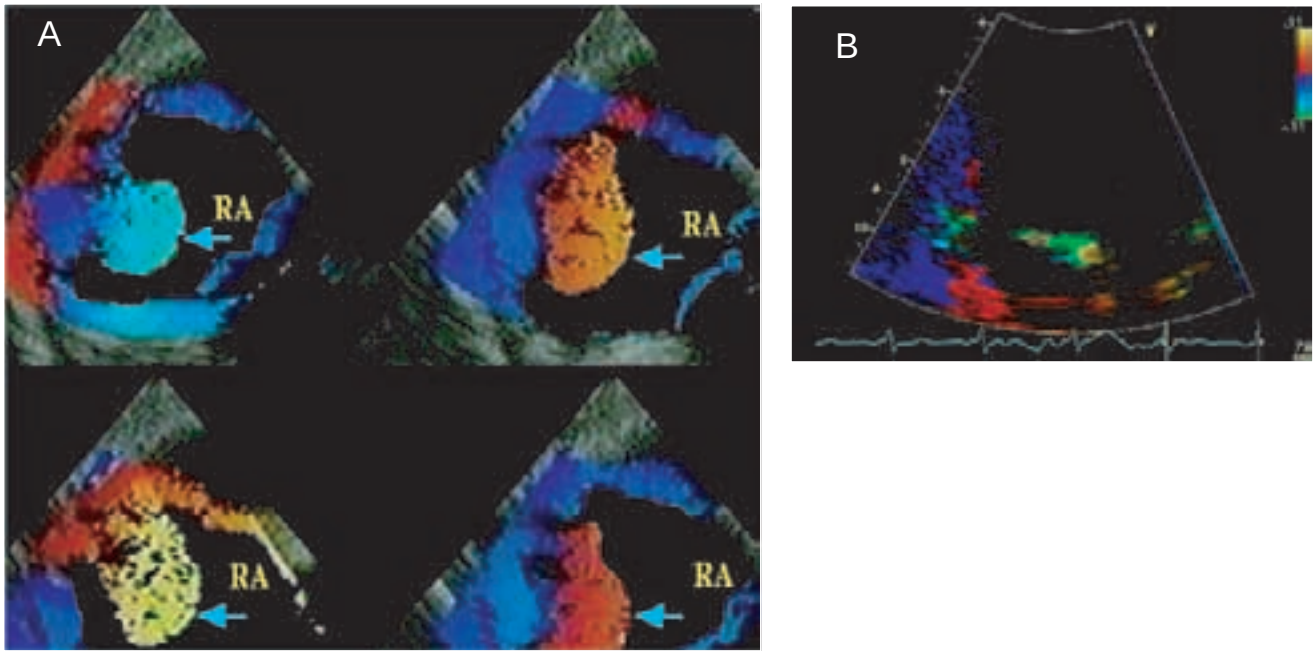

Figure 2.32 Tissue Doppler imaging for structure identification. (A) Lymphoma attached to the right atrial (RA) wall shows coherent motion, seen as a velocity phase shift between the atrial wall and tumour due to Newton's law of inertia of mass. (B) A vegetation on a mitral valve prosthesis shows incoherent motion. This means that the mass lesion is out of phase with cardiac contraction and relaxation, which results in chaotic motion.

areas can then be interrogated with pulsed-wave or continuous-wave Doppler for quantification. Indeed, it must be realized that colour flow imaging is a qualitative method. Colour Doppler flow imaging allows calculation of the flow rate at proximal isovelocity surface areas (PISA method; see Doppler haemodynamics, below) in regurgitant lesions in order to determine the regurgitant volume and valve orifice areas. Pulsed-wave, continuous-wave and colour flow imaging are interdependent but complementary functions for a comprehensive haemodynamic evaluation. Recently, three-dimensional imaging of colour flow Doppler has been introduced, integrating the information of both three-dimensional (patho)anatomy and colour-coded flow and providing spatial and temporal information on the extension, direction, origin and size of intracardiac flow abnormalities.

Colour M-mode Doppler

With colour M-mode both the temporal and spatial propagation of flow is visualized along a single scan line (rather than a single sample volume) selected from a colour flow image over time. This function is used to assess the timing of transient flow events, the length of regurgitant jets and the diastolic propagation of transmitral flow in the LV for diastolic function assessment. Colour M-mode tissue imaging provides myocardial velocities (high amplitude–low velocities, with a low gain filter at different depths of the myocardial wall) and velocity differences across the myocardium (velocity gradients). This requires a perpendicular interrogating beam and basically limits the myocardial segments that can be studied to the anterior septal and posterior walls.

Tissue Doppler imaging

Tissue Doppler imaging (TDI) is an extension of conventional Doppler echocardiography (flow velocities). In this modality the velocity of motion within tissue (tissue velocity imaging) is displayed by eliminating the high-pass wall filter and using a low-gain filter, which eliminates the higher blood flow velocities (see Fig. 2.30). The method allows assessment of regional myocardial function and timing of contraction within the myocardium, assuming that in the normal heart a synchrony is present. Initially, the method provided radial and longitudinal myocardial velocity profiles using pulsed-wave or a spatial colour map of velocities within the myocardium throughout the sector of interest using autocorrelation methods. It should be realized that the method is limited by the angle dependence of the Doppler ultrasound beam.

TDI can also be used for structure identification on the basis of different motion patterns and colour coding [51]:

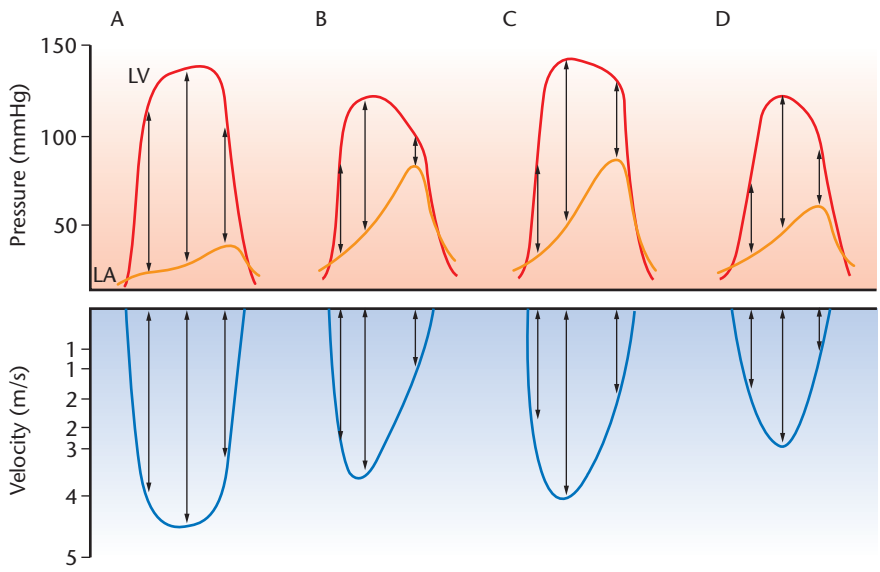

Figure 2.33 Schematic representation of Doppler flow patterns in different forms of mitral regurgitation illustrating the instantaneous interplay of left ventricular (LV) and left atrial (LA) pressures on the resulting waveforms. (A) Mild mitral regurgitation. (B) Severe mitral regurgitation and high compliant left atrium. Because of the high LA compliance in chronic severe mitral regurgitation, the pressure difference falls rapidly resulting in a rapidly decreasing velocity. (C) In acute severe mitral regurgitation, LA compliance is low and the pressure difference remains higher with a higher velocity. (D) In poor LV function, LV pressure rise is decreased (low d*P*/d*t*) and rapidly decreases, resulting in slow rise and rapid decrease of velocities.

- incoherent motion is present in vegetations, free oscillating thrombi and Chiari network (Fig. 2.32);
- coherent motion is observed as a phase difference between tissues, seen in atrial and ventricular thrombi and tumours;
- concordant motion is observed in aortic sclerosis, post-rheumatic valvular lesions and intramural haematoma.

Second-generation tissue Doppler techniques allow transformation of Doppler velocity to an angle-corrected quantitative display or colour-coded wall displacement towards the centre of LV contraction. Subsequently, the method was further developed to measure regional strain and strain rate, which represent local deformation and the rate at which this deformation takes place (time derivative of strain) as a function of stress. Currently, two-dimensional strain and strain-rate calculations are possible based on radiofrequency data analysis from high frame rate imaging using cross-correlation methods [52].

Normal Doppler velocity patterns

Transvalvular velocity patterns

The transmitral blood flow velocity waveforms result from the complex interplay of instantaneous pressure differences (and several other factors) (Figs 2.33 and 2.34). Transmitral pulsed-wave Doppler flow velocities are recorded within the apical four-chamber or apical long-axis views and several measurements can be used to define LV filling haemodynamics. As the mitral valve is funnel-shaped, the velocities increase progressively across the mitral valve apparatus towards the outlet of the mitral funnel. For reasons of reproducibility, all transmitral pulsed-wave Doppler flow measurements must be made with the sample volume in the same position at the outlet of the mitral valve funnel. Figure 2.35 shows the normal transmitral velocity pattern and the parameters that can be measured.

Normal transmitral blood flow is laminar and of relatively low velocity (usually < 1 m/s). There is an early diastolic velocity caused by the continued myocardial relaxation resulting in a LV pressure below LA pressure, which causes the mitral valve to open and rapid LV filling to occur (E wave). E-wave acceleration is directly determined by LA pressure and inversely related to myocardial relaxation. Viscoelastic properties and compliance of the myocardium then come into play, raising LV pressure and resulting in a decreased transmitral flow velocity. The rate of fall in velocity is represented by the deceleration time (DT) and is a measure of how rapidly early diastolic filling stops. DT becomes shorter when LV compliance decreases. There is an inverse relationship between mean LA pressure and DT. Inertia effects may cause continued forward low-velocity flow during mid-diastole. The higher LA pressure during its contraction causes an increase in velocity (A wave) and is an important parameter of diastolic function. Commonly, the E/A ratio is used to assess LV diastolic function and is > 1.

The normal aortic flow velocity pattern is shown in Fig. 2.35. Flow in the left ventricular outflow tract (LVOT) is interrogated with the pulsed-wave sample 1 cm below the aortic valve and the velocities are used in the continuity equation to calculate aortic valve surface area. The reference values in healthy subjects are presented in

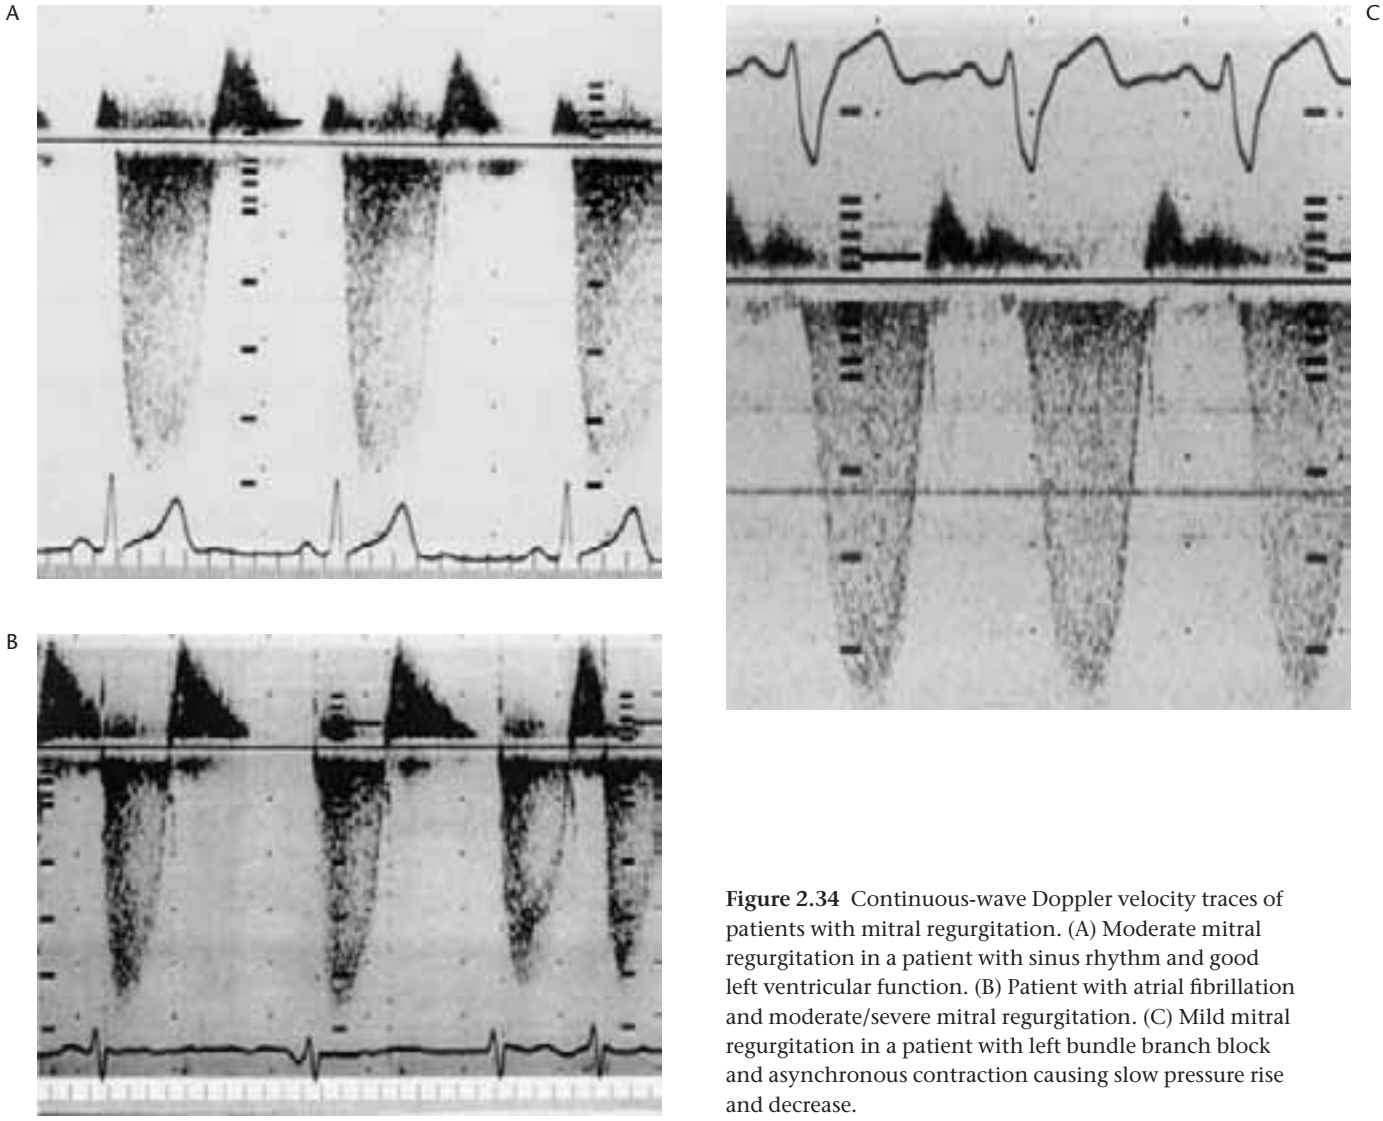

Figure 2.34 Continuous-wave Doppler velocity traces of patients with mitral regurgitation. (A) Moderate mitral regurgitation in a patient with sinus rhythm and good left ventricular function. (B) Patient with atrial fibrillation and moderate/severe mitral regurgitation. (C) Mild mitral regurgitation in a patient with left bundle branch block and asynchronous contraction causing slow pressure rise and decrease.

Table 2.4 Reference values (± 1SD) for transvalvular Doppler velocities (cm/s)

	Adults		Children	
	Mean	Range	Mean	Range
Mitral valve	90	60–130	100	80–130
Tricuspid valve	50	30–70	60	50–80
Pulmonic valve	75	60–90	90	70–110
Aortic valve	135	100–170	150	120–180
Left ventricular outflow tract	100	70–110	100	70–120

Reproduced with permission from Hatle and Angelsen [50].

Table 2.4 [52,53]. The transtricuspid flow velocity pattern is similar in morphology to the transmitral flow pattern but the velocities are lower (Table 2.4). The flow velocity patterns recorded proximal and distal to the pulmonary valve are similar to those obtained from the aortic valve but peak velocities are significantly lower.

Pulmonary vein velocity pattern

In most patients the flow velocity profile of the right upper pulmonary vein can be interrogated from a foreshortened apical cross-section with the Doppler sample volume placed just inside the vein. All pulmonary veins

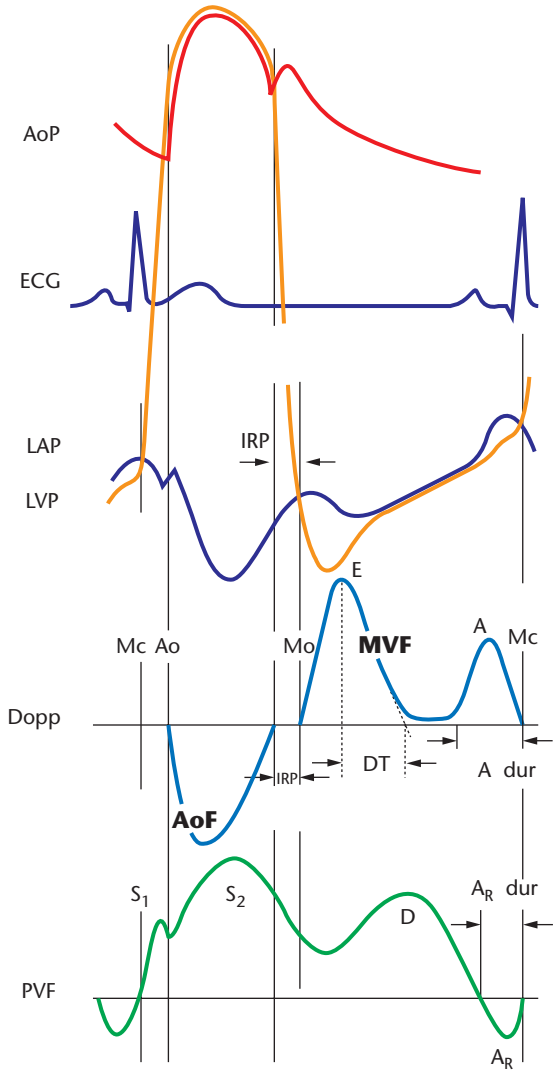

Figure 2.35 Intracardiac pressure tracings from the aorta (AoP), left ventricle (LVP) and left atrium (LAP) with the corresponding Doppler aortic (AoF), mitral (MVF) and pulmonary vein (PVF) flow velocity patterns. The isovolumic relaxation period (IRP) is the interval between aortic valve closure (Ac) and the onset of left ventricular (LV) filling at mitral valve opening (Mo) on the Doppler trace. Ac is best defined on a simultaneously recorded phonocardiogram but a more practical way is by positioning the sample volume of the pulsed-wave Doppler halfway between the anterior mitral leaflet and the outflow tract. AoF and MVF are both recorded as shown on the diagram. The time interval between the end of AoF (aortic valve closure, Ac) and the onset of MVF (mitral valve opening, Mo) represents IRP. During relaxation there is a pressure cross-over between left atrial and LV pressure, which causes the mitral valve to open and rapid filling to occur (E wave). In this part of the cardiac cycle LV relaxation is still ongoing, causing a continuing drop in LV pressure and reflects the speed of the initial part of myocardial relaxation. Prolonged IRP is a sensitive marker of abnormal myocardial relaxation. The area under the E wave is the velocity time integral and reflects the contribution of the rapid filling phase in LV diastolic filling. The deceleration time (DT) is a measure of how rapidly early diastolic filling stops. It is represented by the time interval between the E peak and the point on the baseline where the descending limb crosses the baseline. The A wave is associated with atrial contraction and is an important index of diastolic function. The area under the A wave is the velocity time integral and reflects the contribution of atrial contraction to LV diastolic filling. The normal PVF usually has a biphasic (occasionally triphasic with S_1 wave) flow with a slightly greater systolic (S_2) than diastolic (D) wave and a small retrograde flow wave during atrial contraction (A_R). The A_R wave may become larger with increasing age. A dur, A-wave duration; A_R dur, A_R duration; Ao, aortic valve opening; Mc, mitral valve closure.

are readily imaged via the transoesophageal approach. The normal pulmonary vein flow pattern is shown in Fig. 2.35. It is usually biphasic with a predominant systolic forward flow (S wave) and a less prominent diastolic forward flow wave (D wave). Occasionally, there may be a triphasic flow pattern with two distinct systolic flow waves, of which the initial flow into the LA results from atrial relaxation followed by a further inflow due to the increase in pulmonary venous pressure. The D wave occurs when there is an open conduit between the pulmonary vein, LA and LV and reflects the transmitral E wave. A retrograde flow wave into the pulmonary vein (A_R wave) occurs during atrial contraction and its amplitude and duration are related to LV diastolic pressure, LA compliance and heart rate [8]. In normal subjects, the amplitude of the A_R wave is generally less than 25 cm/s and its duration is shorter than that of the transmitral A wave.

Tissue Doppler velocity imaging

The normal heart shows synchronous contraction and relaxation, with maximum velocities at the base and decreasing towards the apex, which shows an opposite velocity direction. The centre towards contraction of the LV walls lies in an area which is situated 70% down in the LV cavity on a virtual line connecting the anterolateral aortic valve edge to the apex in end-systole [54]. This basic knowledge of the ventricular contraction pattern was obtained with endocardial markers implanted during open heart surgery and is now confirmed by tissue Doppler echocardiography. The maximum velocity is found during the first third of systole and is colour-coded in the four-chamber and five-chamber views in both LV walls [55].

Using M-mode recordings, the timing of contraction and relaxation, including the periods of isovolumic

contraction and relaxation, can be determined in order to assess global and regional wall function [56]. This has been confirmed with invasive measurements [57].

In the absence of gross LV shape abnormalities or severe regional wall motion abnormalities, mitral annulus motion reflects volume changes rather than pressure differences between the LA and the LV and is less load dependent than the transmitral inflow velocity pattern. Mitral annulus velocity can be measured by TDI. The normal mitral annulus velocity pattern is shown in Figs 2.46 and 2.47.

It should be noted that annulus velocities may differ around its circumference and that an average value of septal, anterior, lateral and posterior velocities should be used, especially in patients with regional wall motion abnormalities. In the systolic phase the annulus shows anterior motion, which starts after the isovolumic contraction. The diastolic phase includes the isovolumic relaxation period (IRP), early rapid diastolic filling (E′ wave) followed by diastasis and atrial contraction, which causes the late diastolic A′ wave. The E′ wave is larger than the A′ wave and mirrors the transmitral flow velocity pattern. Peak systolic mitral annulus velocity correlates with the peak rate of LV pressure rise (dP/dt). TDI annulus velocity measurements are used for differentiating pseudo-normal from normal transmitral inflow patterns since early diastolic velocity of the mitral annulus (E′ wave) is relatively preload independent and correlates with LV relaxation [58]. The peak transmitral E′ wave velocity ratio correlates with main pulmonary capillary wedge pressure.

Colour M-mode transmitral flow

The rate of flow propagation from the LA into the LV is determined by the rate of relaxation and diastolic LV suction and is also helpful in differentiating between normal and pseudo-normal transmitral velocity patterns [59]. The colour M-mode method offers a practical means to rapidly screen for a diastolic inflow abnormality during the examination procedure. In practice, an M-mode cursor is placed parallel to the mitral inflow and adjusted so that the longest column of colour flow from mitral valve to apex is recorded (see Figs 2.46 and 2.47). The propagation velocity is measured by the slope along a distinct isovelocity (aliasing) line during early filling from the mitral valve plane up to 4 cm into the LV cavity. The normal value is > 40 cm/s.

Doppler haemodynamics

Both M-mode and two-dimensional echocardiography provide indirect qualitative information on haemodynamic abnormalities (Table 2.5). However, Doppler echocardiography allows accurate quantitative assessment of intracardiac haemodynamics and is currently the preferred method.

Volume flow

Stroke volume and cardiac output

Volume flow across an orifice is the product of its cross-sectional area (CSA) and the blood flow velocity (V). The flow velocity varies during ejection. Therefore, in order to obtain the total volume, the individual velocities during a given ejection period must be integrated (the sum of the individual velocities), i.e. the

Table 2.5 Indirect M-mode and two-dimensional echocardiographic signs of haemodynamic abnormalities

Sign	Abnormality
Mitral valve flutter	Aortic regurgitation
'B' notch on mitral or tricuspid valve	Elevated LA or RA end-diastolic pressure
Systolic anterior motion of mitral valve	Dynamic LVOT obstruction, pseudo-obstruction
Premature mitral valve closure	High LV pressure
Premature aortic valve closure	Fixed (membranous) subaortic stenosis
Mid-systolic aortic valve closure	Dynamic LVOT obstruction
Dilated inferior vena cava: non-collapsing during inspiration	High RA pressure
Absent A wave and systolic W-shape of (mid-systolic closure) pulmonary valve tracing	Pulmonary hypertension
Diastolic RA and RV wall collapse	Cardiac tamponade
Abnormal paradoxical septal motion	See Table 2.7

LA, left atrium; RA, right atrium; RV, right ventricle; LV, left ventricle; LVOT, left ventricular outflow tract.

velocity time integral (VTI). Stroke volume (SV) is then calculated as:

$$SV = CSA \cdot VTI$$

Built-in software allows Doppler velocity waveforms to be traced directly from the screen to obtain VTI. The CSA of the LVOT is most commonly used but can also be measured at other orifices. For practical reasons these are assumed to be circular and only the diameter (D) is measured. CSA is calculated as follows:

$$CSA = \pi(D/2)^2 = 0.785D^2$$

$$SV = 0.785D^2 \cdot VTI$$

Cardiac output (CO) is obtained by the product of SV and heart rate. The cardiac index is CO divided by body surface area.

Regurgitant volume

Two methods can be used: the volumetric and the PISA methods.

VOLUMETRIC METHOD

Total forward flow (Q) across a leaking valve is the sum of SV and regurgitant volume. Consequently:

$$\text{Regurgitant volume} = Q - SV$$

In aortic regurgitation, the regurgitant volume is calculated by subtracting the mitral inflow volume, which in the absence of mitral regurgitation equals SV, from the LVOT (or aortic) forward flow (Q_{Ao}). In mitral regurgitation, the regurgitant volume is calculated as the mitral inflow volume (Q_{MR}) minus the LVOT forward flow, which in the absence of aortic regurgitation equals SV. Mitral inflow volume is calculated from the mitral VTI and its CSA.

Regurgitant fraction is the percentage regurgitant volume of the total flow through the regurgitant valve.

$$\text{Regurgitant fraction (\%)} = (Q - SV/Q) \times 100$$

PISA METHOD

The total volume through a leaking valve is estimated by the product of the effective regurgitant orifice area (EROA) and regurgitant VTI (VTI_{reg}) [60].

$$\text{Regurgitant volume} = EROA \cdot VTI_{reg}$$

EROA is estimated using the PISA method (Fig. 2.36) [61]. On colour Doppler flow images, the region proximal to the regurgitant orifice shows smoothly accelerating blood flow as it rushes into the EROA and forms a series of hemispherically shaped isovelocity contours of decreasing surface area and increasing velocities. All the blood passing through these isovelocity contours must also pass through the EROA (conservation of mass). Flow is estimated by measuring the radial distance (r) from the

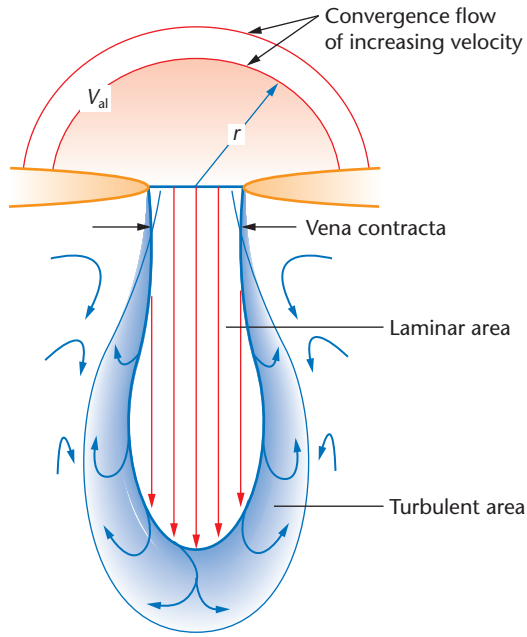

Figure 2.36 The principle of the proximal isovelocity surface area (PISA) method and vena contracta measurement for regurgitant volume measurement. The vena contracta or narrowest extent of the regurgitant jet as it passes through the effective regurgitant orifice correlates well with the severity of mitral regurgitation. This method assumes that the regurgitant orifice does not alter in shape or size during septole and should therefore not be applied to initial valve prolapse. As blood flow accelerates towards the regurgitant orifice, concentric rings of isovelocity regions are produced and are visualized as concentric isovelocity hemispheres with colour Doppler. The smallest hemisphere nearest the regurgitant orifice has the highest velocity. The PISA radius (r) is the radial distance between this nearest aliasing contour (V_{al}) and the centre of the regurgitant orifice. The regurgitant jet area consists of the laminar area with the highest velocities and a turbulent area caused by the high laminar flow jet in the stagnant blood volume.

EROA to the PISA and calculating the surface area of this isovelocity hemisphere or PISA ($2\pi r^2$). The product of that surface area and the aliasing velocity (V_{al}) gives the instantaneous volume flow through the PISA, which equals the flow rate through the EROA.

$$\text{Volume flow} = 2\pi r^2 V_{al}$$

EROA can now be estimated by dividing the volume flow by the regurgitant velocity. For example, in mitral regurgitation the EROA is estimated as follows:

$$EROA = \frac{\text{Volume flow}}{V_{MR}} = 2\pi r^2 \times \frac{V_{al}}{V_{MR}}$$

$$\text{Regurgitant volume} = 2\pi r^2 \frac{V_{al}}{V_{MR}} \times VTI_{MR}$$

The same principle can be used in aortic regurgitation.

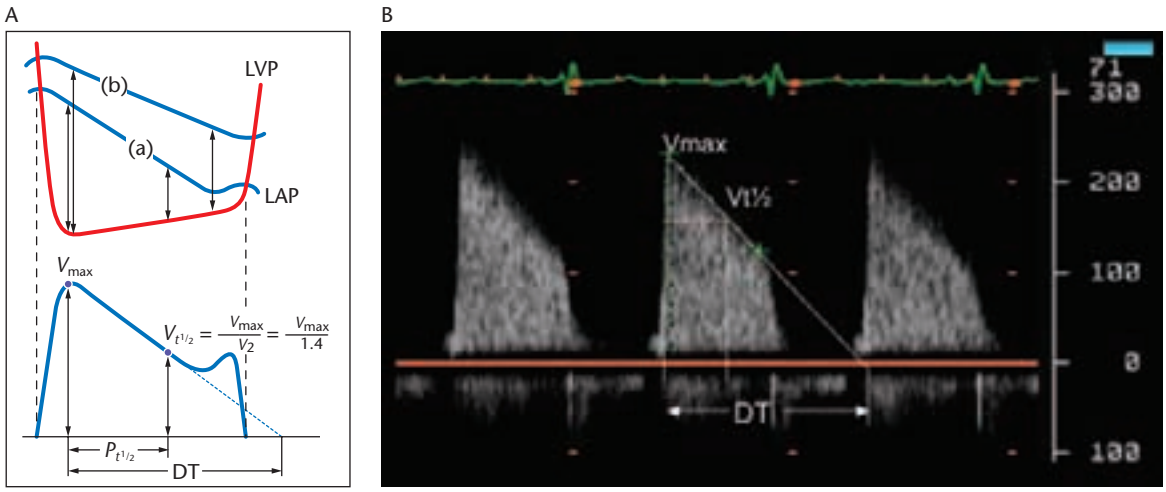

Figure 2.37 Calculation of pressure half-time in mitral stenosis. (A) Diastolic left ventricular (LVP) and left atrial (LAP) pressures are shown with the Doppler velocity trace. The pressure gradient linearly decreases during diastole (a) resulting in a linear decrease of transmitral velocities. In more severe mitral stenosis (b) the transmitral peak gradient is higher, its fall slower and the interval to reach the half-value is prolonged (see arrows). (B) Recording of a patient with mitral stenosis. V_{max} is 2.3 m/s; using the equations in the text $V_{t^1/_2}$ is 2.3/1.4 = 1.64 m/s. The time interval between V_{max} and $V_{t^1/_2}$ on the Doppler trace is 135 ms. The deceleration time (DT) can also be measured and is 480 ms. Using the equations in the text $P_{t^1/_2}$ is 0.29 × 480 = 139 ms. The valve surface area is 220/135 (or 220/139) or 1.63 cm^2 (1.58 cm^2).

Shunts

The magnitude of an intracardiac shunt is expressed as the flow ratio between the pulmonary (Q_p) and systemic (Q_s) circulation. Q_p is measured in the right ventricular outflow tract, i.e. $(CSA \cdot VTI)_{RVOT}$, and Q_s in the left ventricular outflow tract, i.e. $(CSA \cdot VTI)_{LVOT}$.

$$Q_p/Q_s = (CSA \cdot VTI)_{RVOT}/(CSA \cdot VTI)_{LVOT}$$

Pressure gradient

Doppler velocities allow measurement of the instantaneous pressure drop (gradient) across stenotic orifices or restrictive defects. These are calculated by applying the simplified Bernoulli equation, which is based on the principle of conservation of energy (pressure energy vs. kinetic energy) [50].

$$\text{Pressure gradient (in mmHg)} = 4V^2$$

where V is the peak blood flow velocity (m/s) at the stenotic valve (or restrictive defect) measured with continuous-wave Doppler. The Doppler-derived pressure gradient is the maximal instantaneous pressure difference and is always larger than the pressure gradient measured at cardiac catheterization. The mean pressure gradient is an average of the instantaneous pressure gradients during the total flow period and correlates better with catheter measurements.

The Doppler velocity waveforms are interactively traced from the display screen and peak velocity, maximal pressure gradient and mean pressure gradient are calculated by integrated software.

Valve surface area

Three methods can be used: the pressure half-time, the continuity equation and the PISA method.

Pressure half-time

In mitral stenosis, the pressure difference between the LA and LV is maximal at the onset of diastole and decreases linearly after valve opening. The time course of the decrease of pressure fall can be expressed as the time needed to reach half-maximal pressure difference ($P_{t^1/_2}$) and is the same as the time for peak velocity (V_{max}) to fall to a value that equals V_{max} divided by 1.4 (Fig. 2.37).

$$P_{t^1/_2} = {}^1/_2 P_{max} = 4(V_{t^1/_2})^2 - {}^1/_2 4(V_{max})^2$$

$$V_{t^1/_2} = V_{max}/\sqrt{2} \quad \text{or} \quad V_{max}/1.4$$

Pressure half-time (PHT) is also calculated from DT (the time interval for peak velocity to reach zero baseline) and is always 0.29DT (0.29 is an algebraic constant that converts velocity to pressure) (Fig. 2.37). Mitral valve area (MVA) is then estimated using the empiric constant 220.

$$\text{MVA} = 220/\text{PHT} \quad \text{or} \quad 220/0.29\text{DT}$$

In severe aortic regurgitation, the diastolic pressure difference between the aorta and LV decreases rapidly with shortening of the deceleration time. The PHT of the regurgitant jet can be used to estimate the severity of the regurgitation (Fig. 2.38) (see also Chapter 21).

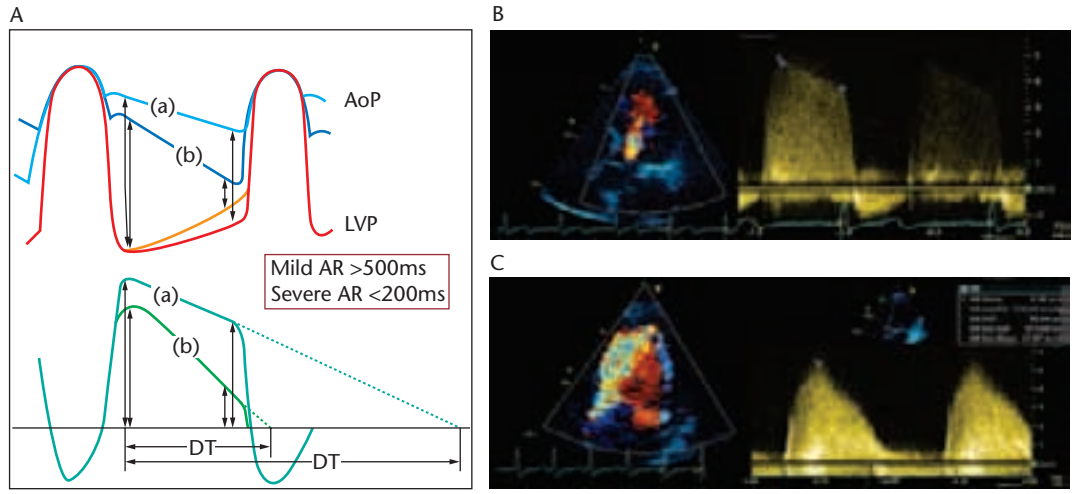

Figure 2.38 (A) In aortic regurgitation (AR) the pressure half-time becomes progressively shorter with severity of disease. The left ventricular (LVP) and aortic (AoP) pressure traces are shown with the corresponding Doppler velocity traces. With more severe AR (b) the pressure decreases more rapidly and is associated with a rapid rise in diastolic LVP. The pressure gradient rapidly becomes lower and the velocity rapidly decreases resulting in a shorter deceleration time (DT) than in mild AR (a). (B) Velocity recording of a patient with a pressure half-time of 470 ms indicating mild/moderate AR. (C) Patient with a pressure half-time of 90 ms indicating severe AR. Pressure half-time is automatically calculated by machine software after marking two points on the slope of velocity trace. The colour Doppler flow images show the moderate jet and the larger jet reaching the apex in severe aortic regurgitation.

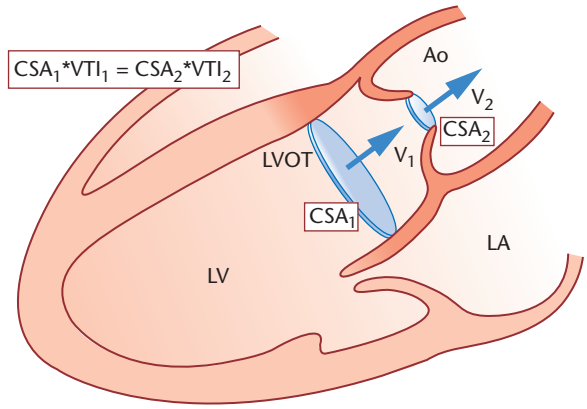

Figure 2.39 Principle of stenotic orifice area calculation based on the continuity equation (see text).

Continuity equation

This is based on the principle of conservation of mass, which states that flow proximal to the stenosis is equal to the flow across the stenosis.

$$CSA_1 \cdot VTI_1 = CSA_2 \cdot VTI_2$$

The flow velocity integral proximal to the stenosis and in the stenosis and the CSA proximal to the stenosis or regurgitant orifice can be calculated (Fig. 2.39). Consequently:

$$CSA_2\ (cm^2) = CSA_1 \cdot VTI_1 / VTI_2 = SV / VTI_2$$

For aortic stenosis, the valve area equals SV/VTI_{Ao} and for mitral stenosis SV/VTI_{MS}. (These equations cannot be used in the presence of aortic and mitral regurgitation.)

PISA method

By measuring the volume flow using the PISA method through the stenotic mitral valve, its surface area (MVA) can be calculated using the continuity equation:

$$MVA = 2\pi r^2 \times \frac{V_{al}}{Peak\ V_{mitr}} \times \alpha/180^\circ$$

When the angle (α) of the mitral leaflets relative to the inflow direction is different, a correction factor (α/180°) should be used.

Intracardiac pressures

Doppler is a reliable alternative to cardiac catheterization for the assessment of intracardiac haemodynamics in most clinical conditions. As shown above, Doppler echocardiography allows non-invasive measurement of pressure gradients across valves or chamber defects. It is fortunate that (trivial) valvular closure-associated regurgitation is commonly present in the normal condition (physiological) and even more so in cardiac disease so that these measurements are possible. Accurate beam alignment is necessary in order to minimize velocity underestimation related to non-parallel beam angles.

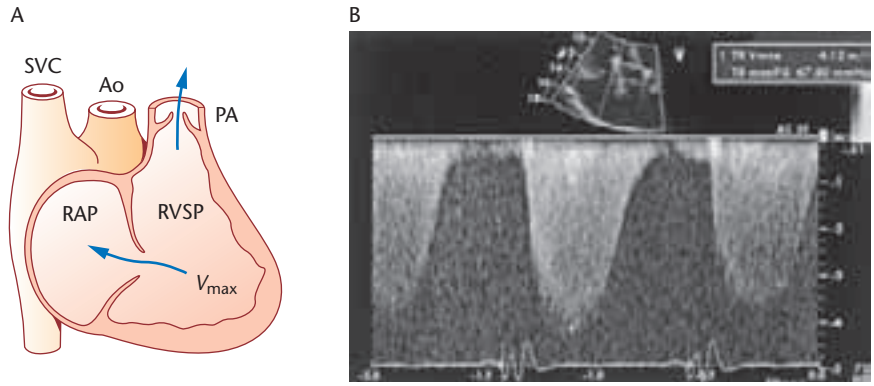

Figure 2.40 Basic principle involved in measuring intracardiac pressures and gradients. (A) This diagram shows the principle of right ventricular systolic pressure (RVSP) measurement. Right atrial pressure (RAP) is estimated from the central venous pressure or imaging of the inferior vena cava and its diameter change during respiration. From V_{max}, the pressure gradient between RV and RA is calculated. (B) Doppler velocity trace of a tricuspid regurgitant jet of 4.12 m/s. The instantaneous pressure gradient is thus 67.8 mmHg. Adding RAP gives an RVSP of 77.8 mmHg.

Table 2.6 Estimation of right atrial pressure (RAP)

Inferior vena cava diameter (cm)	Respiratory change (%)	Estimated RAP (mmHg)
< 1.5	Collapse	0–5
Nl (1.5–2.5)	Decrease > 50	5–10
Nl (1.5–2.5)	< 50	11–15
> 2.5	Decrease < 50	16–20
> 2.5	No change	> 20

Reproduced with permission from Otto [62].

M-mode and two-dimensional echocardiographic signs may provide indirect qualitative evidence of abnormal haemodynamics (see Table 2.5).

Right ventricular systolic pressure (RVSP) is calculated by interrogating the tricuspid regurgitant jet which is commonly present. Its maximal (peak) velocity (V_{max}) is converted to a pressure gradient with the simplified Bernoulli equation. By adding the pressure of the receiving chamber, in this case right atrial pressure (RAP), the RVSP is obtained (Fig. 2.40):

$$RVSP = 4(V_{max})^2 + RAP$$

RAP can be estimated by measuring the diameter of the inferior vena cava and its percentage collapse during respiration (Table 2.6).

This principle is the basis of measuring intracardiac pressures. Echo contrast injection for Doppler signal enhancement may allow more accurate peak velocity measurements in patients with poor Doppler signals. Similarly, in mitral regurgitation, the velocity reflects the pressure difference between the LV and LA. In the absence of LVOT obstruction, the cuff-measured systolic brachial artery pressure (SBP_{cuff}) equals LV systolic pressure. Consequently, left atrial pressure (LAP) is calculated as follows:

$$LAP = SBP_{cuff} - 4(V_{MR})^2$$

In mitral stenosis:

$$LAP = LVEDP + \text{mitral gradient}$$

where LVEDP denotes LV end-diastolic pressure. In aortic regurgitation, the regurgitant velocity reflects the diastolic pressure difference between the aorta and LV. Therefore:

$$LVEDP = SBP_{cuff} - 4(V_{ARend\text{-}diastole})^2$$

In the presence of a ventricular septal defect, the colour Doppler flow identified shunt can be interrogated with continuous-wave Doppler and the LV-to-RV or ventricular septal defect pressure gradient measured from the velocity recordings. SBP_{cuff} represents LV peak systolic pressure in the absence of LVOT obstruction. Hence:

$$RVSP = SBP_{cuff} - 4(V_{LV\text{–}RV})^2$$

In patients with an LVOT outflow gradient:

$$LVSP = SBP_{cuff} + \text{LVOT gradient}$$

The RV diastolic pressure (RVDP) equals RAP in the absence of tricuspid stenosis but can also be estimated as:

$$RVDP = LVEDP - 4(V_{LV\text{–}RV})^2_{diast}$$

When right ventricular outflow tract (RVOT) obstruction is absent, the pulmonary artery systolic pressure (PASP) equals RVSP. Both RVOT and pulmonary valve velocities should always be measured in the presence of elevated RVSP in order to exclude RVOT obstruction. In the presence of pulmonary stenosis (PS):

$$PASP = RVSP - PS_{gradient}$$

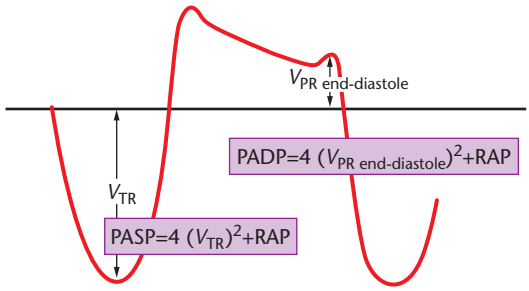

Figure 2.41 The principle involved in measuring systolic (PASP) and end-diastolic pulmonary artery (PADP) pressure. V_{PR} is the end-diastolic regurgitant PA jet velocity and V_{TR} is the systolic tricuspid regurgitant jet velocity. RAP, right atrial pressure.

Pulmonary regurgitation (PR) is common in pulmonary hypertension and allows estimation of the pulmonary artery (PA)-to-RV pressure gradient and pulmonary artery diastolic pressure (PADP). This principle is shown in Fig. 2.41. The end-diastolic PR velocity is measured and the pressure difference between PA and RV is calculated:

$$PADP = 4(V_{PRend\text{-}diastole})^2 + RAP$$

where RAP (right atrial pressure) equals RV end-diastolic pressure. The early (peak PR velocity) diastolic pressure difference between PA and RV closely corresponds to the mean PA pressure and is estimated using the same formula as for PADP. (For estimating LV filling pressures, see Assessment of left ventricular diastolic function, below.)

Assessment of left ventricular systolic function

Assessment of both systolic and diastolic left ventricular function is the most common request for, and an essential part of, the echocardiographic examination. Global systolic function assessment is based on size and volume changes, while the diagnosis of ischaemic myocardial disease is based on segmental wall motion analysis.

Global left ventricular systolic function

M-mode echocardiography: dimensions

Simple M-mode-derived parameters indicating impaired LV function include mitral E point–septal separation (EPSS) greater than 7 mm (dilated left ventricle) (see Fig. 2.6), 'B' bump or AC notch on the mitral valve trace (elevated end-diastolic pressure) and decreased systolic anterior motion of the aortic root (low SV).

LV dimensions are measured in end-systole (ESD) and end-diastole (EDD) at chordal level from two-dimensional guided M-mode tracings in the parasternal long-axis and short-axis views (see Fig. 2.22). Linear cavity dimensions are useful for detecting LV dilatation and can be used for follow-up of patients and for calculating the percentage change in LV dimension during systolic contraction (fractional shortening).

$$\text{Fractional shortening (in \%)} = \frac{EDD - ESD}{EDD} \times 100$$

Interventricular and posterior wall thickness in end-systole (TES) and end-diastole (TED) are used to calculate their systolic thickening.

$$\text{Systolic thickening (in \%)} = \frac{TES - TED}{TES} \times 100$$

For LV mass calculation, see p. 53.

Two-dimensional echocardiography: areas and volumes

When end-diastolic surface area (EDA) and end-systolic surface area (ESA) are measured using planimetry of two-dimensional views of the LV, the fractional area change can be calculated.

$$\text{Fractional area change (in \%)} = \frac{EDA - ASA}{EDA} \times 100$$

Acoustic quantification (see above) allows online computation of LV cavity area changes from the automatically generated endocardial boundaries. These can be displayed as an area vs. time curve synchronized with the ECG.

For determination of ejection fraction one has to calculate both end-diastolic volume (EDV) and end-systolic volume (ESV) (see p. 56). Manual tracing of LV endocardial borders from two-dimensional echocardiograms is time-consuming and tedious. Currently, real-time semi-automated border detection systems (acoustic quantification) are integrated into most ultrasound systems and allow rapid calculation of volumes and ejection fraction.

$$\text{Ejection fraction (in \%)} = \frac{EDV - ESV}{EDV} \times 100$$

Doppler-derived systolic indices

Several Doppler indices have been proposed for assessment of LV systolic function. SV and CO (see p. 64), ejec-

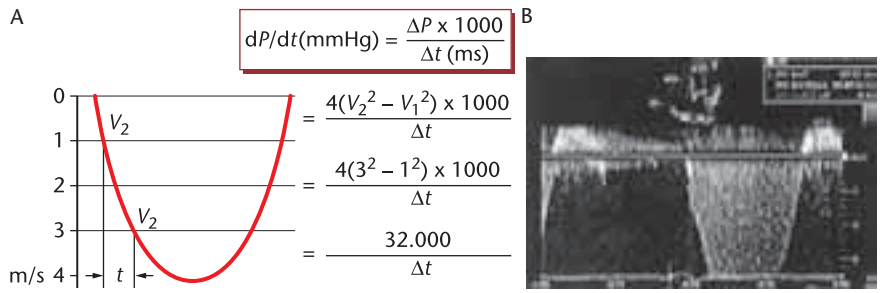

Figure 2.42 Measurement of left ventricular d*P*/d*t* from the mitral regurgitant velocity trace. (A) d*P*/d*t* can be estimated from the rate of rise of velocity of the mitral regurgitant jet. The time interval (d*t* in ms) between regurgitant velocities of 1 and 3 m/s is measured from the velocity waveform (recording speed of 100 mm/s must be used). It is assumed that left atrial pressure does not change significantly in this time interval. (B) In most systems the acceleration slope is automatically calculated after marking the velocity waveform at 1 and 3 m/s. In this patient d*P*/d*t* is 400 mmHg/s.

tion time, myocardial performance index and d*P*/d*t* are used. Peak aortic flow velocity has also been proposed but this index is highly load dependent.

GLOBAL LEFT VENTRICULAR PERFORMANCE

A Doppler-derived myocardial performance index (MPI) or time ejection index, which combines systolic and diastolic time intervals, can be used for the assessment of overall cardiac function. This index is the sum of isovolumic contraction and relaxation time divided by the ejection time [63]. These time intervals are readily obtained with Doppler echocardiography from the mitral closure–mitral opening interval minus ejection time, divided by the ejection time (see Fig. 2.35). This index can also be used for RV function assessment [63,64]. The normal value is 0.40 ± 0.05. It is also helpful in valvular heart disease for discriminating between normal and impaired ventricular function, and for the prediction of prognosis [65–67].

LEFT VENTRICULAR CONTRACTILE FUNCTION (d*P*/d*t*)

d*P*/d*t* represents the rate of rise of LV pressure and reflects systolic contractile function. d*P*/d*t* can be estimated from the rate of rise of velocity of the mitral regurgitant jet [68] (Figs 2.42 and 2.49). The time interval (d*t* in ms) between regurgitant velocities of 1 and 3 m/s is measured from the velocity waveform (recording speed of 100 mm/s must be used). The Bernoulli equation allows calculation of the pressure change during that period, i.e. $4(3^2 - 1^2) = 32$ mmHg. Hence:

$$dP/dt\ (mmHg/s) = 32 \times 1000/dt$$

The normal value is > 1200 mmHg/s.

Similarly, RV contractile function can be estimated from tricuspid velocity signals. The negative d*P*/d*t* is estimated from the dowstroke of the regurgitant velocity waveform.

Table 2.7 Differential diagnosis of paradoxical motion of the interventricular septum (IVS)

Increased right ventricular internal dimension (> 30 mm)
Normal IVS thickening (> 30%)
Right ventricular volume overload
Primary pulmonary hypertension
Reduced IVS thickening (< 30%)
Coronary artery disease
Dilated cardiomyopathy
Normal right ventricular internal dimension (< 30 mm)
Normal IVS thickening (> 30%)
Postoperative patients
Acute right ventricular volume overload
Constrictive pericarditis
Pericardial effusion (large)
Intraventricular conduction abnormalities
Reduced IVS thickening (< 30%)
Coronary artery disease
Left bundle branch block (typical early systolic notch)
Hypertrophic cardiomyopathy (septal hypertrophy)

Segmental left ventricular function

Detailed motion analysis of the interventricular septum from M-mode echocardiography may allow a specific diagnosis (Table 2.7 and Fig. 2.43). For two-dimensional echocardiographic analysis the LV is divided into three levels (basal, mid and apical) and 16 segments for standardized analysis from multiple parasternal and apical views. LV wall function is graded using a scoring scale in which 1 denotes normal function, 2 hypokinesis, 3 akinesis and 4 aneurysmal dyskinesis for each individual segment (Figs 2.16 and 2.44). For quantitative analysis, colour kinesis can be used (see Fig. 2.16). Recently, analytical software has become available for rapid segmental analysis.

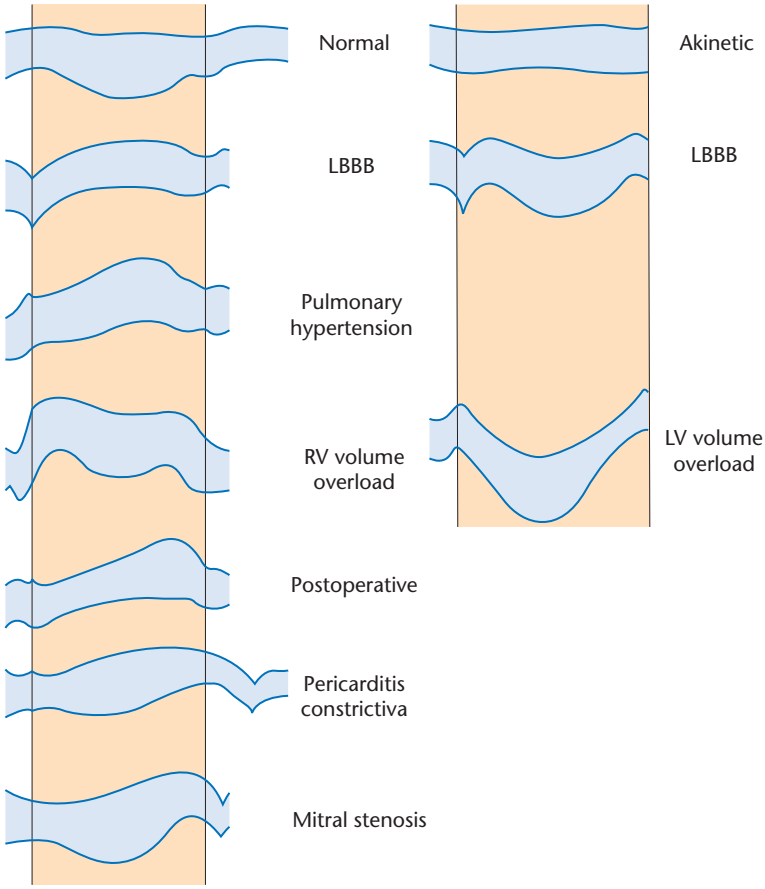

Figure 2.43 Specific diagnostic motion patterns of the interventricular septum on M-mode echocardiography. LBBB, left bundle branch block; LV, left ventricle; RV, right ventricle.

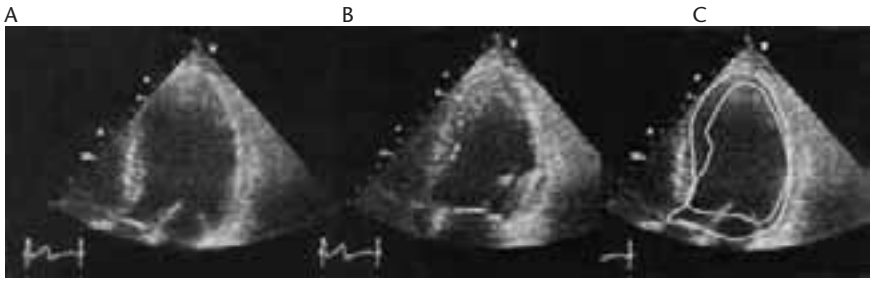

Figure 2.44 Segmental wall function analysis: postinfarct lateral wall hypokinesis shown in the AP4C view. The left ventricle is dilated. Superposition of the traced endocardial contours at end-diastole (A) and end-systole (B) shows the hypokinesis and compensatory hyperkinesis of the interventricular septum. (C) shows the superimposed end-diastolic and end-systolic contours.

Tissue Doppler velocity imaging is now also used for segmental wall function analysis (see Principles of Doppler echocardiography, above).

Right ventricular function

Measurement of RV volume and mass by M-mode and two-dimensional echocardiography remains problematic because the assumptions used for LV volume calculation do not apply (see p. 54). The MPI index can be used to detect RV global dysfunction. Three-dimensional echocardiography provides excellent estimations and will rapidly become the method of choice for volume-based RV function assessment.

Assessment of left ventricular diastolic (dys)function and filling pressure

Assessment of diastolic LV function and estimation of filling pressures is an important part of the management of patients with heart disease. It is well known that symptoms and prognosis are better related to diastolic than systolic function and that physical signs provide limited information. Recent studies have validated Doppler flow and tissue velocity measurements for reliable and non-invasive evaluation of filling dynamics in patients with LV dysfunction and heart failure [69].

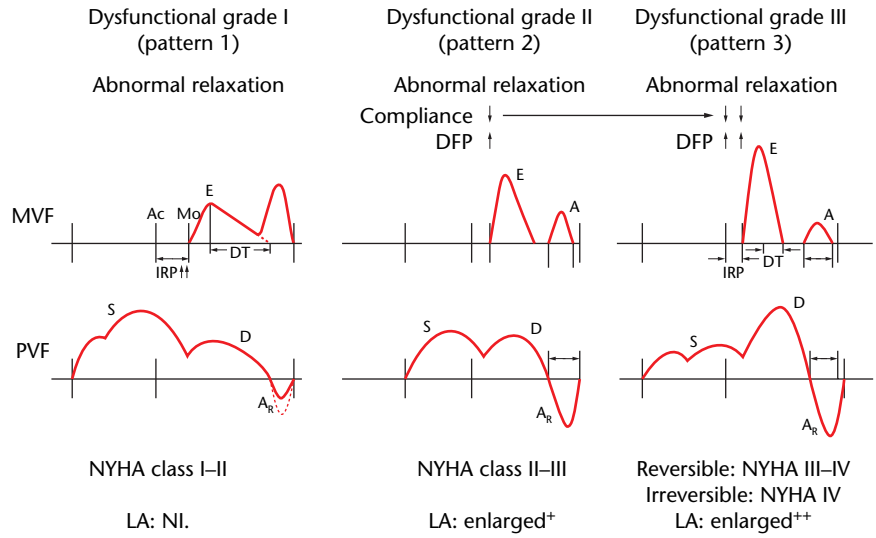

Figure 2.45 Basic abnormal mitral valve (MVF) and pulmonary vein (PVF) Doppler flow velocity patterns corresponding to different grades of left ventricular (LV) dysfunction. Pattern 1 is seen in patients with abnormal relaxation. The isovolumic relaxation period (IRP) is prolonged, the E wave decreased, deceleration time (DT) prolonged and the A wave increased as a result of increased atrial contribution to LV filling. The E/A ratio is < 1 and the D wave on the PVF becomes smaller in proportion to the reduction of the E wave. Pattern 2 shows pseudo-normalization when the decreased LV compliance causes increased diastolic filling pressure (DFP). In these patients, there is increased flow reversal into the pulmonary veins and the amplitude of the A_R wave increases, as well as its duration. Pattern 3 is the typical waveform of restrictive LV filling, when LV compliance further deteriorates causing increased E-wave velocity, shortened DT and low A-wave velocity. Most of the atrial contraction results in flow reversal into the pulmonary veins and A_R duration is much longer than the transmitral A duration.

Table 2.8 Assessment of diastolic (dys)function: transmitral Doppler velocities

		Normal	Abnormal relaxation	Restrictive filling
Isovolumic relaxation period	< 40 years	70 ± 12 ms	> 110 ms	< 60 ms
	> 40 years	80 ± 12 ms	> 110 ms	< 60 ms
Deceleration time		200 ± 32 ms	> 240 ms	< 150 ms
E wave		0.85 ± 0.15 m/s	< 0.50 m/s	> 1.20 m/s
A wave		0.55 ± 0.15 m/s	< 0.80 m/s	30 m/s
E/A ratio		> 1	< 1	> 2

Assessment of left ventricular diastolic dysfunction

Different grades of LV diastolic dysfunction result in different flow velocity patterns. The basic patterns of abnormal transmitral and pulmonary vein Doppler flow velocities are shown diagrammatically in Fig. 2.45 and the transmitral Doppler velocities in Table 2.8.

Pattern 1 is seen in patients with impaired myocardial relaxation and normal diastolic LA and LV pressures. This pattern is characterized by a prolonged IRP, a decrease in E-wave amplitude, prolonged DT and an increase in A-wave amplitude, the latter being a reflection of compensatory increase in atrial contraction to diastolic filling. The E/A ratio is < 1. The pulmonary venous flow velocity pattern may show a diminished D wave as a result of reduced early diastolic filling and an increased A_R wave when LVEDP is elevated. The E' wave on TDI is decreased and the rate of flow propagation in the LV on colour M-mode is decreased. An abnormal relaxation pattern is common in the elderly but represents the earliest manifestation of diastolic dysfunction in younger individuals.

Patients with an abnormal relaxation pattern (grade I diastolic dysfunction) usually do not have symptoms at rest but may experience mild functional impairment (NYHA class I–IIa)

When diastolic function deteriorates, LV compliance progressively decreases with an increase in LA pressure and size. In fact, LA size is a key indicator of LV diastolic dysfunction. The transmitral flow pattern and more particularly the E wave normalize. This pseudo-normal pattern (pattern 2) is a transition pattern from impaired

relaxation to restrictive filling. In certain clinical conditions this pattern may be confusing and must be distinguished from the normal pattern. In patients who are regularly followed, progression of disease and pseudo-normalization is usually recognized. However, it may be a problem in the patient with minimal symptoms who presents with a normal transmitral velocity pattern. A pseudo-normal pattern can be identified as follows.

- The LA is (moderately) enlarged (a normal LA size makes diastolic dysfunction unlikely) [70].
- The A_R wave on the pulmonary venous flow trace has an amplitude > 25 cm/s and its duration is longer than the transmitral A wave [70].
- The E′ wave on TDI is diminished and the transmitral E/E′ ratio is > 15 [54].
- Colour M-mode shows a reduced flow propagation rate (< 40 cm/s) [71].
- Altering loading conditions (induced, for example, by nitroglycerin, nitroprusside or Valsalva manoeuvre) reveals an impaired relaxation pattern.
- The rate of fall of mitral and/or aortic regurgitation velocity (negative d*P*/d*t*) measured from continuous-wave Doppler velocity recordings provides a direct measurement of LV relaxation rate and is decreased [69].

Patients with a pseudo-normal filling pattern (grade II diastolic dysfunction) experience exertional dyspnoea and have moderate functional impairment (NYHA class IIb–III)

With further decrease of LV compliance as a result of the deterioration of diastolic LV function, LAP increases and a restrictive filling pattern develops (pattern 3). The higher LAP causes an earlier opening of the mitral valve and a shortened IRP, and the low compliance of the LV causes a rapid increase in early LV pressure and a shortened inflow and DT. The E/A ratio is > 2. Forward diastolic pulmonary vein flow stops in mid–late diastole and there is a significant flow reversal in the pulmonary veins during atrial contraction resulting in a prolonged A_R. DTI shows a diminished E′ wave and colour M-mode a low flow propagation rate.

Patients with a restrictive filling pattern (grade III dysfunction) have dyspnoea with minimal exertion and severe functional impairment (NYHA class IV)

Patients with restrictive filling can be further classified into those with reversible and those with irreversible restrictive pattern by altering the loading conditions. Decreasing preload with nitroglycerin or nitroprusside will change reversible restriction to an impaired relaxation pattern, whereas the irreversible pattern remains unchanged [71]. The distinction is important for prognostication and management of patients with advanced heart failure. Those with a reversible pattern can still benefit from medical therapy while those with an irreversible pattern are candidates for a device to assist LV function or for cardiac transplantation. Studies have shown that patients with a mitral annulus A′ wave > 5 cm/s on TDI have a reversible restrictive physiology.

Estimation of left ventricular filling pressure

Several parameters, alone or in combination, can be used to identify patients with an elevated LV filling pressure (Figs 2.45, 2.46 and 2.47 and Table 2.9). However, these parameters must be interpreted in the clinical context considering age, symptoms and functional status.

The initial E-wave velocity is mainly determined by LAP at mitral valve opening and its peak acceleration rate correlates with LV filling pressure. In general, a high E-wave amplitude indicates a high mean LAP and a low E-wave amplitude a low mean LAP. In the presence of systolic dysfunction, an E/A ratio > 2 indicates a high LAP, while a low E/A ratio indicates a low LAP. When the mean LAP is high as a result of a diseased non-compliant LV, DT is shortened. A DT of less than 150 ms represents a mean LAP of 20 mmHg. It should be noted that young subjects with fast relaxation, rapid LV suction and a highly compliant LV may have a high E wave and a short DT (they have no symptoms and good exercise tolerance). The TDI mitral annulus velocity in these subjects is elevated whereas it is decreased in patients with diastolic dysfunction. On the other hand, patients with a dilated LA and LV will always have symptoms and an increased filling pressure.

The difficult patient is the one with mild functional impairment and LV systolic dysfunction who has a pseudo-normal transmitral velocity pattern. Indices derived from the pulmonary vein velocity pattern are then helpful for identifying a pseudo-normal pattern. The S/D ratio or the systolic forward flow fraction (in percent) decreases, and when less than 40% indicates a pulmonary artery wedge pressure higher than 18 mmHg [72]. Other parameters are the amplitude and duration of the A_R wave. When the LV becomes more diseased and non-compliant, transmitral flow after atrial contraction rapidly stops and the flow reversal in the pulmonary veins will increase. An A_R-wave velocity > 25 cm/s and an A_R duration 30 ms longer than that of the transmitral A wave indicate an LVEDP of > 15 mmHg. However, pulmonary vein flow parameters are often difficult to measure especially at faster heart rates.

Two indices that aim at correcting the E-wave velocities for the confounding relaxation rate are the mitral annulus velocity (E′ wave) and the colour M-mode LV

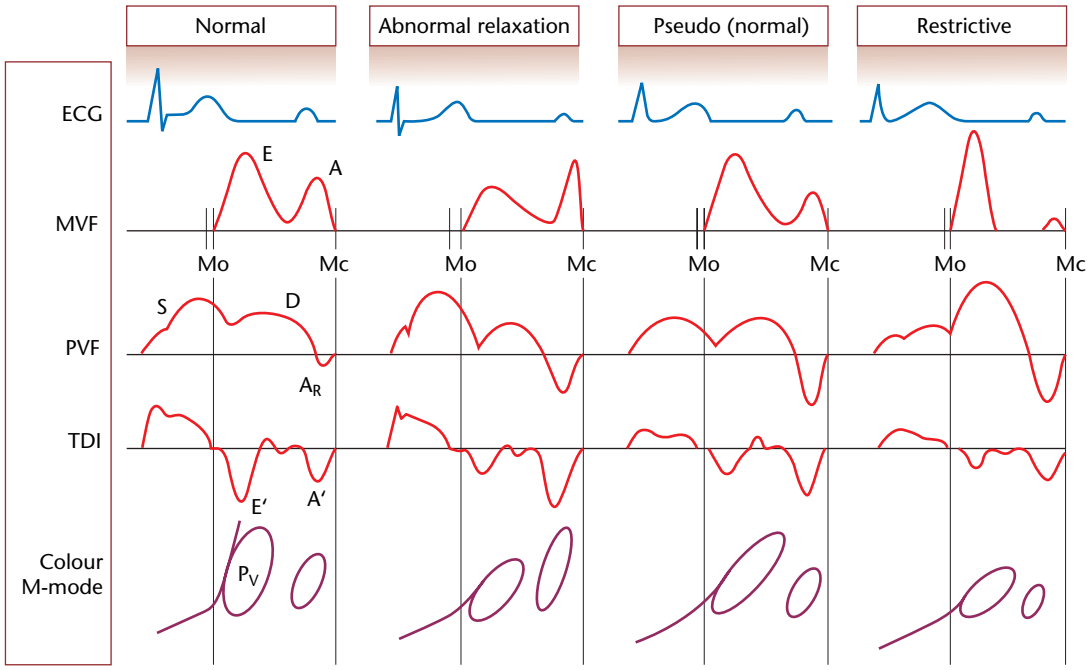

Figure 2.46 Typical mitral valve flow (MVF), pulmonary vein flow (PVF), tissue Doppler mitral annulus velocity (TDI, tissue Doppler imaging) and colour M-mode patterns of the various stages of diastolic dysfunction. propagation velocity (PV). The E/E′ ratio is a practical index that can be calculated in most patients. A ratio < 8 indicates a normal filling pressure, whereas a ratio > 15 corresponds to a filling pressure in excess of 15 mmHg [73]. The ratio can also be used in patients with sinus tachycardia (fused mitral E and A waves) and atrial fibrillation.

An E/PV ratio < 2 suggests an elevated LV filling pressure. Several formulae that allow the estimation of LV filling pressures have been proposed and are presented in Table 2.10.

Specific conditions

Atrial fibrillation

In atrial fibrillation there is no atrial contraction and consequently no A wave on the transmitral flow velocity pattern, no A_R wave on the pulmonary vein flow and no A′ wave on the TDI mitral annulus velocity recordings. Nonetheless, some parameters can be used to identify patients with an elevated LV filling pressure (Table 2.9). Peak E-wave velocity and DT vary with the length of the cardiac cycle. Peak E-wave acceleration rate correlates with LV filling pressure but is often difficult to measure. DT is shortened when LV filling pressure is elevated but should not be measured from short RR interval cycles because filling stops very early and the DT may become artificially short. Therefore it is practical to select cardiac cycles corresponding to a heart rate of 60–80 b.p.m. The S wave on the pulmonary vein flow is low in amplitude since forward flow to the LA is predominantly diastolic. The E/E′ ratio is a practical parameter for estimating LV filling pressure (Table 2.10). The initial deceleration rate of the D wave and the flow propagation velocity can also be used.

Constrictive pericarditis

This condition can mimic the manifestations of restrictive cardiomyopathy, which are clinically difficult to distinguish. In patients with constrictive pericarditis, an increase in respiratory variation of the early mitral inflow velocity is seen whereas this is not present in restrictive cardiomyopathy. These phasic changes result from exaggerated ventricular interdependence [74]. TDI shows a decreased mitral annulus velocity in restrictive cardiomyopathy whereas the velocity is normal in constrictive pericarditis.

Hypertrophic cardiomyopathy

Prolonged relaxation is the predominant diastolic abnormality in hypertrophic cardiomyopathy (prolonged IRP, low E wave, slow DT and increased A wave). Relaxation can be markedly delayed in some myocardial areas, resulting in a triphasic mitral inflow pattern. When the disease progresses and LAP increases, the early E-wave velocity increases and the DT shortens as a result of diminishing LV compliance. In some patients an intracavitary reversed gradient can be produced by apical relaxation during the IRP, producing flow from base to apex. A formula to estimate the pre A-wave diastolic pressure has been proposed by Nagueh *et al*. [75].

Echocardiography/Doppler in specific cardiac conditions

Echocardiographic/Doppler techniques play an invaluable role in the diagnosis and management of patients with virtually any form of cardiac disease. The relative

Table 2.11 Relative diagnostic information obtained with various echocardiographic/Dopper modalities*

*Use of echo contrast helps to enhance both image quality and Doppler signals. Qualitative information on myocardial perfusion can also be obtained.

diagnostic information obtained with echocardiographic/Doppler modalities in the different aspects and presentation of cardiac disease are presented in Table 2.11.

It is impossible to describe in detail the salient features and the diagnostic echocardiographic/Doppler criteria of all cardiac conditions in this limited chapter. Some are presented in their respective chapters and are extensively available in specific textbooks [1,30,38,62] and in the ACC/AHA guidelines for the clinical application of echocardiography [76]. The most important referral questions for echo/Doppler examination are for the evaluation and follow-up of cardiac function (heart failure), ischaemic heart disease, myocardial disease (cardiomyopathies), valvular disease, pericardial disease, mass lesions and congenital heart disease. Patients are also often referred for the evaluation of cardiac symptoms, physical signs or abnormal laboratory tests. A diagnostic clue and, more often, a definitive diagnosis is provided (Table 2.12).

The cardiomyopathies (myocardial diseases)

Echocardiography combined with Doppler allows the detection of structural, functional and intracardiac flow abnormalities for the accurate diagnosis and classification of cardiomyopathy [77] (see Chapter 16).

Dilated cardiomyopathy

Dilated cardiomyopathy is characterized by dilatation of the LV (or both LV and RV) without increased wall thickness and a widened outflow tract (increased EPSS) (see Figs 2.6, 2.31 and 2.49). Systolic as well as diastolic function and CO parameters are all decreased (see Assessment of left ventricular systolic function and Assessment of left ventricular diastolic (dys)function and filling pressure, above). Both the amplitude of wall motion (hypokinesis) and its thickening are globally decreased. Doppler techniques provide information about the presence of associated mitral regurgitation (as a result of annulus dilatation and incomplete mitral leaflet coaptation), pulmonary artery pressure and diastolic LV dysfunction (elevated filling pressures).

Hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy is characterized by LV hypertrophy (or both LV and RV) in the absence of other causes. The pattern of hypertrophy is often asymmetric (most often in the interventricular septum, while isolated apical hypertrophy is a rare variant) and its distribution is readily visualized by echocardiography (Fig. 2.50). Subsets of patients have a dynamic LVOT obstruction (hypertrophic obstructive cardiomyopathy) caused by systolic anterior motion of the anterior mitral leaflet produced by a Venturi effect or an intraventricular (mid-cavity) obstruction that causes typical Doppler patterns (Figs 2.51 and 2.52). Systolic function is normal or increased and diastolic filling is always impaired with a characteristic inflow pattern. Patients with dynamic LVOT obstruction have mitral regurgitation (Fig. 2.51).

Restrictive cardiomyopathy

Restrictive cardiomyopathy results from deposition of substances between the myocytes (haemochromatosis, glycogenosis) or within the myocytes (infiltrative, e.g. amyloidosis). It is typically characterized by impaired diastolic filling of either or both ventricles [74]. This causes atrial dilatation. LV size and systolic function may be normal but wall thickness is increased. Restrictive physiology is found in patients with endomyocardial disease (hypereosinophilic syndrome, endomyocardial fibrosis) (Fig. 2.53).

Hypertensive hypertrophic cardiomyopathy

Hypertensive heart disease results from arterial hypertension and manifests with concentric LV hypertrophy and

Table 2.12 Common referral symptoms, signs or laboratory abnormalities for echocardiographic/Doppler evaluation

Referral questions	Differential diagnosis (or exclusion)
Chest pain	Regional wall motion abnormality: ischaemia or infarction? Left ventricular outflow obstruction: aortic stenosis, HOCM? Aortic disease: intramural haematoma, aortic dissection? Pulmonary embolism (Pericarditis)
Dyspnoea	Left ventricular systolic and/or diastolic dysfunction: heart failure? Valvular disease Cardiomyopathy Pulmonary artery pressure: pulmonary hypertension
Heart murmur	No structural abnormality: flow murmur Valvular disease Dynamic left ventricular outflow obstruction Shunt (mainly right-to-left shunt)
Palpitations	Structural cardiac abnormality?
Syncope	Aortic stenosis, cardiomyopathy, intracardiac mass (myxoma)
Hypotension/shock	See Emergency echocardiography
Chest radiography	Enlarged heart shadow: cardiomyopathy, left ventricular dysfunction, pericardial effusion, specific chamber enlargement?
Abnormal ECG	Non-specific ECG changes: regional wall motion abnormality (old silent myocardial infarction, chronic ischaemia), left ventricular hypertrophy, structural heart disease Signs of hypertrophy: specific chamber enlargement, increased mass
Suspicion of endocarditis	See Infective endocarditis
Embolic event(common indication for TOE)	Intracardiac mass lesion Structural and functional abnormalities predisposing to embolic events: atrial septal defect, patent foramen ovale, interatrial septal aneurysm (Fig. 2.48), low LAA velocities Atheroma in aorta

HOCM, hypertrophic obstructive cardiomyopathy; LAA, left atrial appendage; TOE, transoesophageal echocardiography.

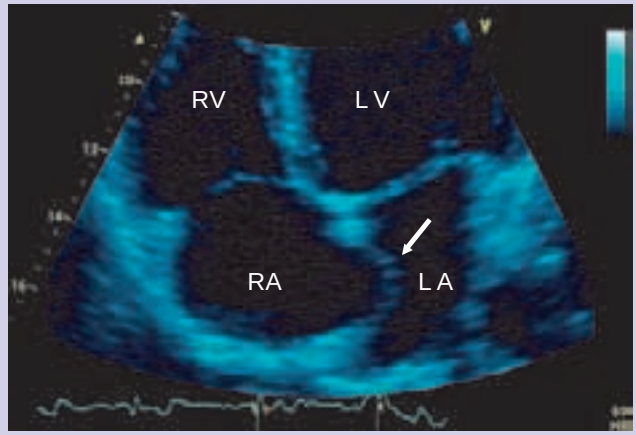

Figure 2.48 Apical four-chamber view showing an interatrial septal (IAS) aneurysm (arrow) with a width and fixed depth of > 2 cm (normal < 1 cm depth deviation). This represents a type I IAS aneurysm and these patients do not usually have an interatrial shunt. In type II IAS aneurysm, there is motion of the interatrial septum in both directions of > 10 mm. These patients often have an interatrial shunt. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

diastolic dysfunction. Both the aortic root and the LA are often dilated and there is a high incidence of aortic valve sclerosis and mitral annulus calcification. Hypertensive hypertrophic cardiomyopathy represents an extreme manifestation of LV hypertrophy, with normal systolic function and signs of heart failure. When long-standing hypertension leads to systolic LV dysfunction, the LV becomes dilated.

Ventricular non-compaction

Non-compaction of the LV myocardium is a rare cardiomyopathy that manifests with typical echocardiographic features. Presence of thin compacted myocardium on the epicardial and a non-compacted myocardium on the endocardial side with prominent trabeculae in the absence of acquired or congenital heart disease are diagnostic (ratio

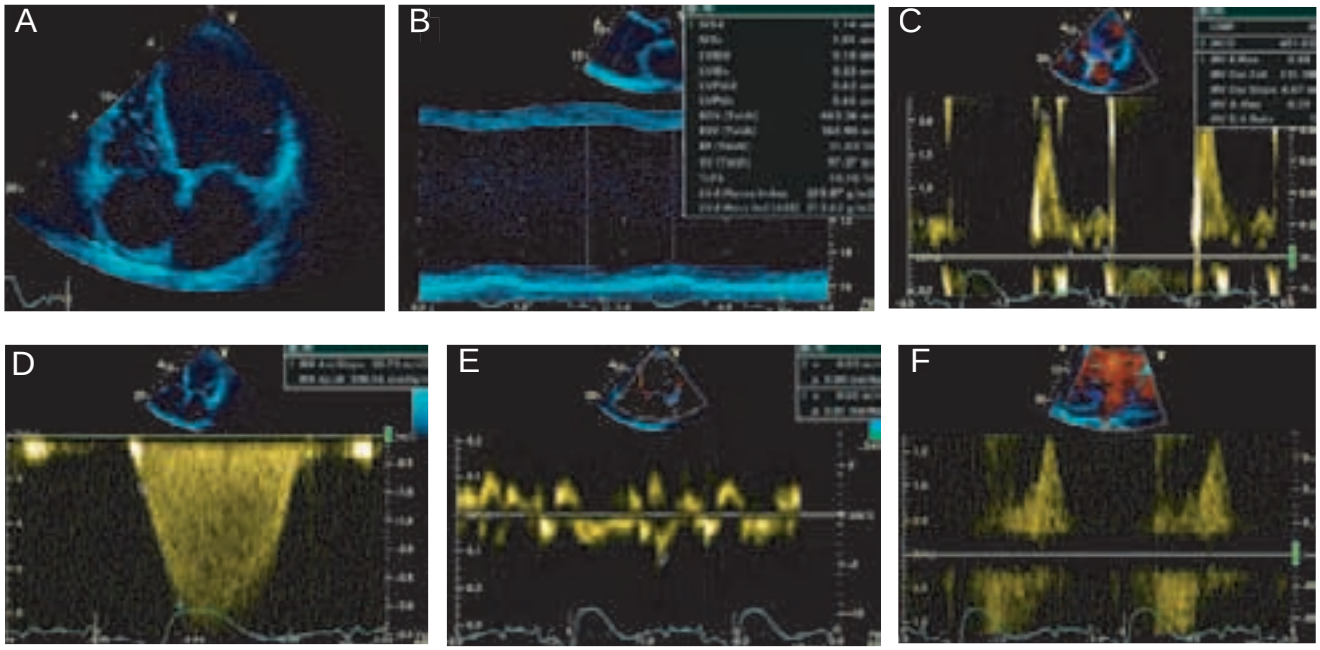

Figure 2.49 A patient with severe dilated cardiomyopathy. (A) Apical four-chamber view shows a severely dilated left ventricle and left atrium. (B) M-mode shows the extremely dilated left ventricle (end-diastolic dimension of 9.14 cm) with a fractional shortening of 10% on the dynamic images. There is also global wall hypokinesis. (C) Transmitral inflow Doppler trace shows a restrictive left ventricular filling pattern (grade 3). (D) Left ventricular d*P*/d*t* is 330 mmHg/s, which is extremely low. (E) Mitral annulus velocities are also very low. (F) Pulmonary vein flow has a high D wave and low S wave, consistent with grade 3 diastolic dysfunction (see Fig. 2.45).

of non-compacted/compacted layers > 2 at end-systole at the thickest LV wall). Deep recesses communicating with the LV cavity are best visualized with colour Doppler or echocardiographic contrast (Fig. 2.54).

Arrhythmogenetic right ventricular cardiomyopathy

In this myopathy the RV myocardium is progressively replaced by fatty and fibrous tissue with outpouching of the free wall. The RV becomes dilated with poor contractility and visible on the echo study. It is one of the most common causes of sudden death in young adults. The limited spatial information of echocardiographic images is a problem for accurate analysis of this cardiomyopathy and is the domain of magnetic resonance imaging (MRI).

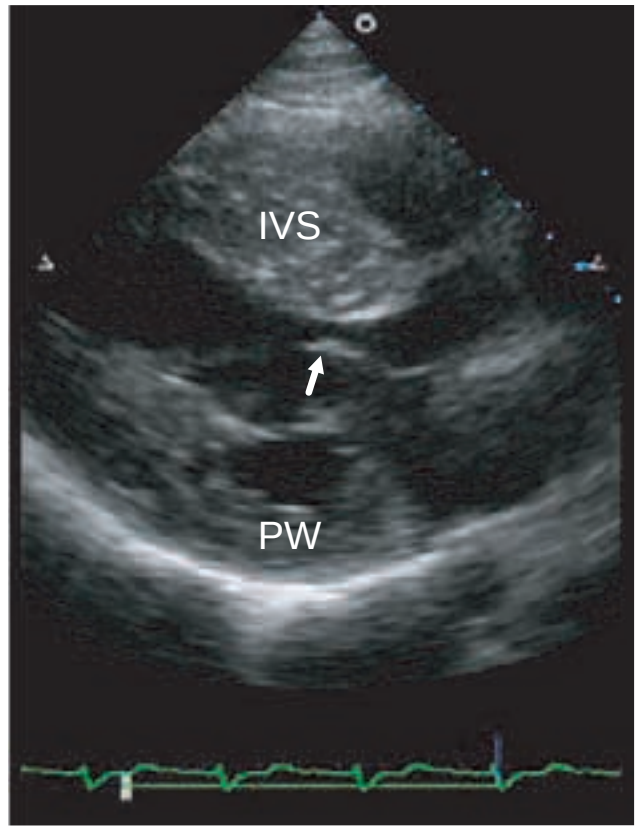

Figure 2.50 Hypertrophic obstructive cardiomyopathy (parasternal long-axis view). The interventricular septum (IVS) is extremely hypertrophic. The posterior wall (PW) is also thickened. The systolic anterior position of the anterior mitral leaflet is nicely shown (arrow) and causes the dynamic obstruction of the left ventricular outflow tract and mitral regurgitation.

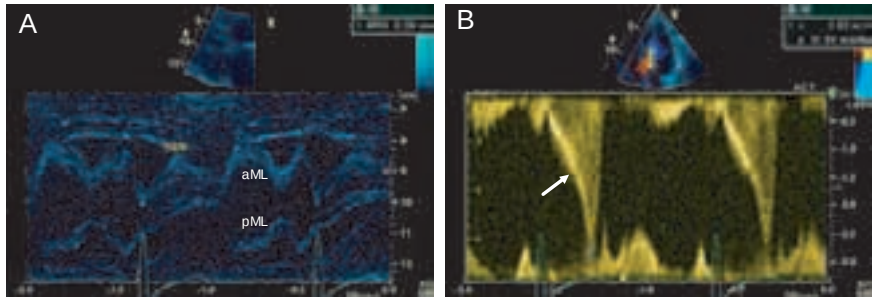

Figure 2.51 Hypertrophic obstructive cardiomyopathy. (A) M-mode echocardiogram showing systolic anterior motion (SAM) of the anterior mitral valve leaflet (aML). pML, posterior mitral valve leaflet. (B) Continuous-wave Doppler velocity recording showing the typical 'dagger-shape' pattern of the outflow obstruction (arrow). The maximum velocity is 2.8 m/s, corresponding to a gradient of 31 mmHg.

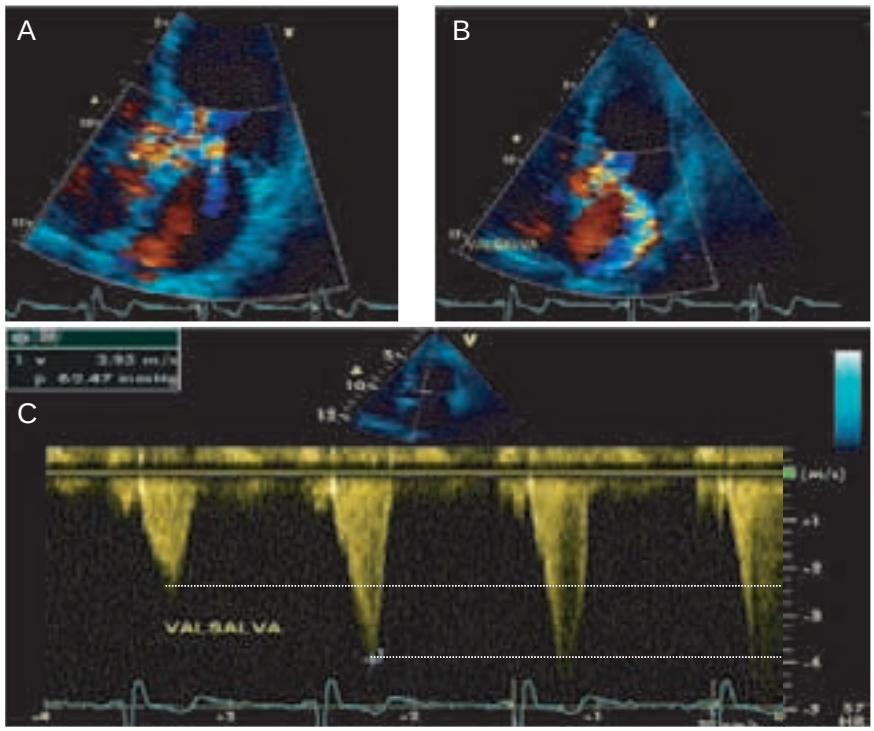

Figure 2.52 Hypertrophic obstructive cardiomyopathy. (A) Colour flow Doppler apical long-axis systolic view shows turbulence in the outflow tract and trivial mitral regurgitation. (B) During the Valsalva manoeuvre the outflow obstruction increases and the mitral regurgitation jet increases. (C) The dynamics of the outflow obstruction is better demonstrated in the spectral Doppler recording during the Valsalva manoeuvre. The peak velocity increases from 2.4 to 3.9 m/s.

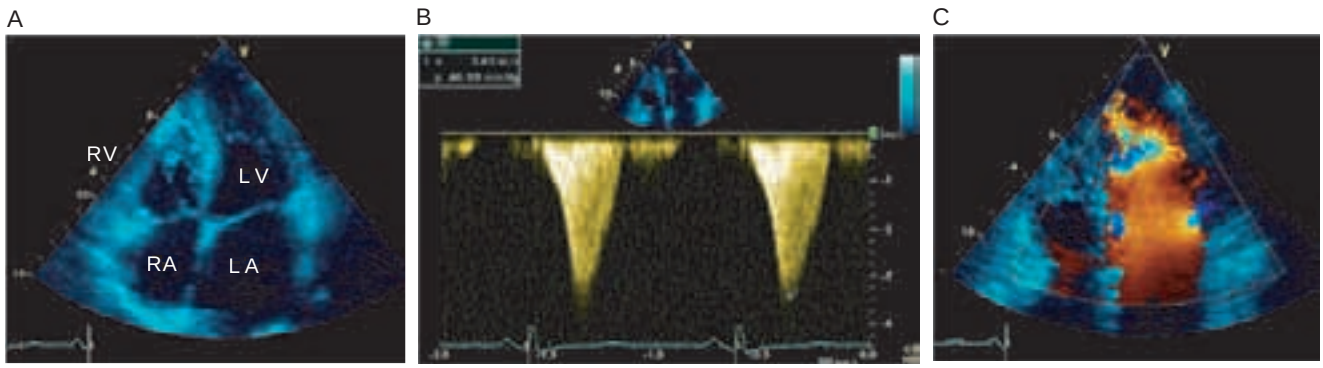

Figure 2.53 Endomyocardial fibrosis. (A) There is apical obliteration of the right ventricle (RV) and involvement of the left ventricle (LV) mid-ventricular endocardium. Both the right atrium (RA) and left atrium (LA) are dilated. (B) This mid-ventricular involvement causes a dynamic mid-cavitary obstruction with a peak pressure gradient of 47 mmHg (see the sample volume in the middle of LV). (C) Colour Doppler inflow shows turbulence in the middle/apical areas of the LV.

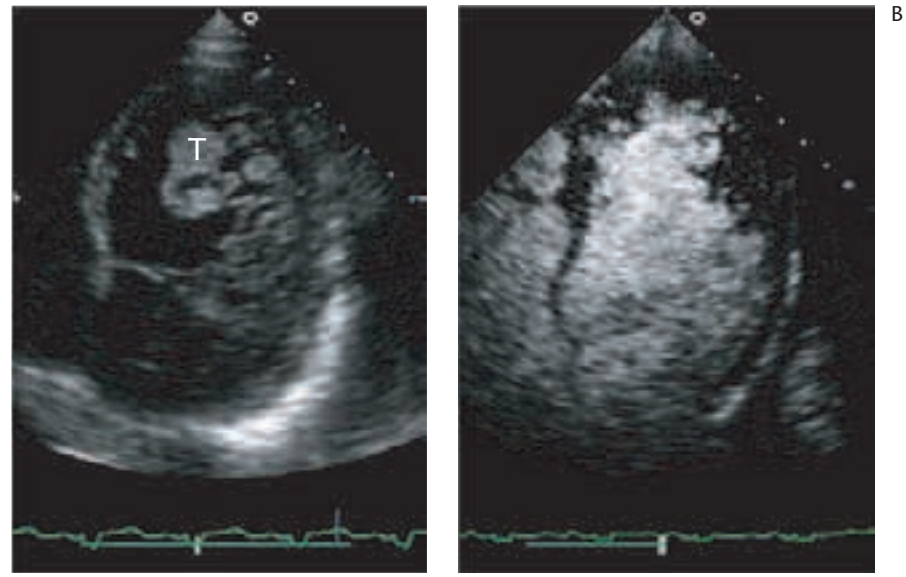

Figure 2.54 Left ventricular non-compaction. Apical four-chamber views (A) without and (B) with left ventricular echo-contrast opacification. Excessive and prominent trabeculation of the left ventricle is visualized. The echo contrast nicely shows the communication between the recesses and left ventricular cavity. A thrombus (T) is present in the apex.

Ischaemic heart disease

Reduction in myocardial blood flow causes ischaemia with decreased wall thickening/function followed by ECG changes and chest pain (see Chapter 12). Echocardiography allows detection of transient regional wall motion abnormalities during episodes of chest pain and has been shown to be extremely helpful for the assessment of patients presenting with chest pain and acute coronary syndrome (see Fig. 2.17). Demonstration of completely normal wall function/motion during such an episode virtually excludes myocardial ischaemia or myocardial infarction. This wall-motion assessment is very useful in patients presenting with chest pain and a non-diagnostic ECG. In addition, echocardiography/Doppler allows diagnosis of most diseases that can mimic ischaemic episodes.

Unstable angina is characterized by transient or permanent wall motion abnormalities. Myocardial infarction results in a permanent reduction in wall thickness (< 6 mm), which is replaced by fibrotic/scar tissue (Fig. 2.55).

Outward systolic motion or bulging results in an abnormal ventricular shape and indicates aneurysm formation. Free-wall rupture after pericarditis with epicardial and pericardial adhesion results in a pseudo or false aneurysm (Fig. 2.56). Both types of aneurysm contain thrombus but a true aneurysm leads more often to systemic embolization. RV infarct involvement is also readily detected (RV dilatation). The detection of complications of a myocardial infarction is the domain of

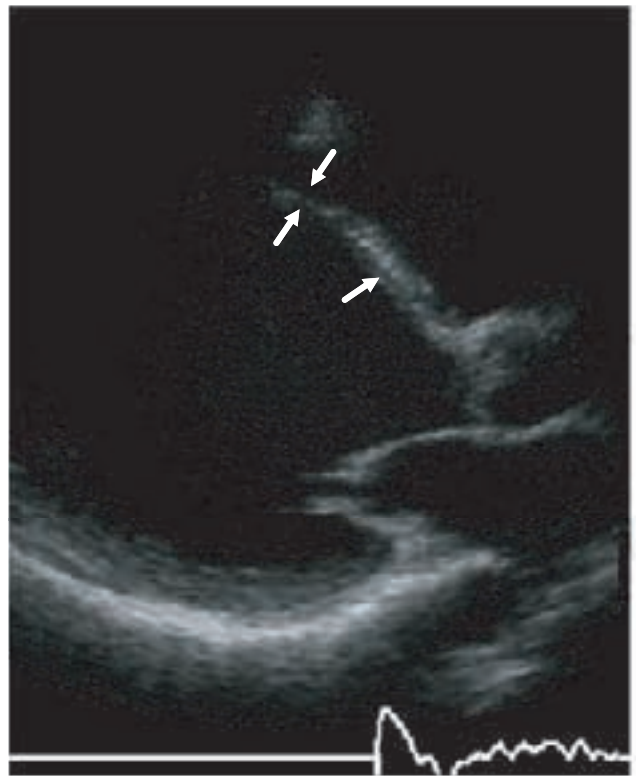

Figure 2.55 Ischaemic cardiomyopathy. The left ventricle is extremely dilated after a large anteroseptal myocardial infarction, which shows outward bulging (aneurysm). The septal myocardium is replaced by scar tissue which is < 6 mm in thickness (see arrows).

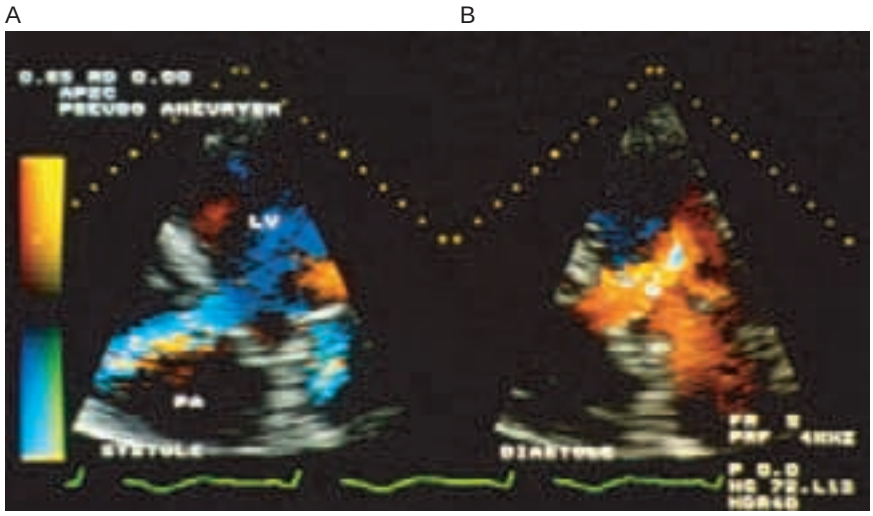

Figure 2.56 Pseudo-aneurysm of the left ventricle. (A) Systolic frame with a jet from the left ventricle into the pseudo-aneurysm. There is also a jet of mitral regurgitation into the left atrium. (B) Diastolic frame: the blood passes from the pseudo-aneurysm into the left ventricle. Note the normal diastolic transmitral and the mild aortic regurgitation jet.

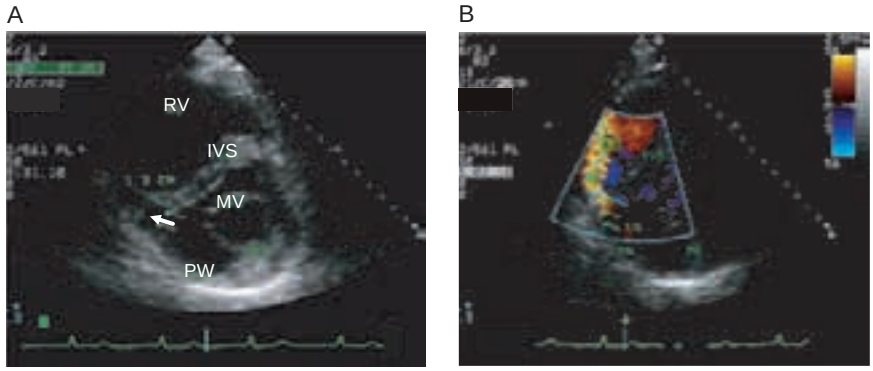

Figure 2.57 Postinfarction interventricular septal (IVS) rupture. (A) Short-axis view at the level of the mitral valve (MV) and the posteriorly located rupture (arrow). Note the dilated right ventricle (RV), flattened IVS and the 'D-shaped' left ventricle (LV) cavity indicating acute RV pressure and volume overload. PW, posterior wall. (B) Colour flow image demonstrates the turbulent shunting blood flow from LV to RV.

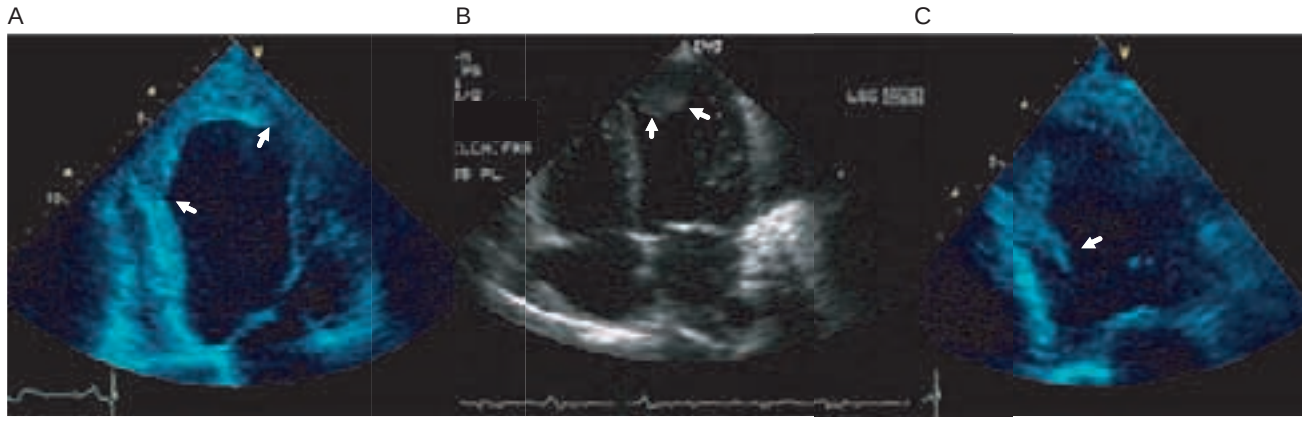

Figure 2.58 (A) Large aneurysm and thrombus formation in a patient after antero-apical myocardial infarction. The thrombus is laminated and smooth. The risk of embolization is low. (B) Protruding thrombus in a patient with antero-apical myocardial infarction. (C) Pedunculated mobile thrombus after anteroseptal infarction. The risk of embolization is high.

bedside echocardiography. Ventricular septal rupture (Fig. 2.57) and papillary muscle rupture are readily diagnosed. Signs of pericardial effusion in the acute phase are a warning sign for rupture of the myocardium and require urgent surgery. Chronic complications include thrombosis (Fig. 2.58), aneurysm formation and remodelling with heart failure, all of which are readily diagnosed by echocardiography.

Heart failure

Echocardiographic/Doppler examination has a crucial role in patients presenting with complaints (dyspnoea, reduced exercise tolerance) and signs (hypervolaemia) suggesting heart failure and is recognized by the European Society of Cardiology as the most important diagnostic test [78].

Evaluation of pericardial and valvular structure and myocardial function can accurately establish the diagnosis and the aetiology of heart failure and identify concomitant relevant disease. In the absence of such abnormalities, a non-cardiac cause mimicking a heart failure syndrome should be investigated. The classification of heart failure as systolic, diastolic [79] (or both) or high-output failure must be made (see Assessment of left ventricular systolic function and Assessment of left ventricular diastolic (dys)-function and filling pressure, above). Quantification of LV systolic and diastolic function is also the basic step in effective management and prognosis (remodelling, ejection fraction). Echocardiographic/Doppler techniques have an important role in resynchronization procedures of the LV (Fig. 2.59) and in guiding and monitoring novel therapies (e.g. LV assist devices, ACORN and Myosplint devices, DOR and Maze procedures, cardiac resynchronization therapy). Stress echocardiography should be considered when the symptoms are suggestive of angina pectoris rather than heart failure.

Valvular heart disease (see Chapter 21)

Native valves

The diagnosis, differentiation and grading of valvular heart disease is one of the important tasks of echocardiographic laboratories. With the addition of colour Doppler echocardiography, not only the diagnosis but also the aetiology and the underlying patho-anatomy of the disease can be described (Fig. 2.60). Only rarely is cardiac catheterization necessary in order to establish cardiac haemodynamics and select the appropriate form of therapy. Using the different algorithms, valvular gradients, orifice areas and regurgitation fraction can be assessed for the four heart valves (see Principles of Doppler echocardiography and Doppler haemodynamics, above) [62,80,81]. Many patients have to be studied by TOE in order to obtain exact information about the valve pathology and to exclude thrombus in patients selected for intervention or valve repair. Echocardiography/Doppler is particularly useful in patients with low gradients and LV dysfunction in which the gradient response to dobutamine helps in the decision-making. If reconstructive methods during surgery are used, intraoperative echocardiography is widely used to monitor the procedure and to prove its success.

Prosthetic valves

Another domain is the follow-up of prosthetic valves (bioprosthesis, homografts and mechanical valves) after surgery. TOE is often necessary because of acoustic shadowing and reverberations. Transvalvular gradients and valve areas can be determined (estimates of these parameters for most common prosthetic valves can be found in ref. 82). Virtually all early and late complications are detected, including vegetative endocarditis (Figs 2.32 and 2.61), paraprosthetic regurgitation (Fig. 2.62), abscess formation, mycotic aneurysm (Fig. 2.63), fistula (Fig. 2.64) and thrombus formation interfering with valve mechanics. Each prosthetic valve has its own haemodynamic characteristics, and these should be established by each echo laboratory based on the product information and the surgeon's information after valve implantation. A discharge echo/Doppler study should always be available after surgery. Also the degenerative process, which often

A

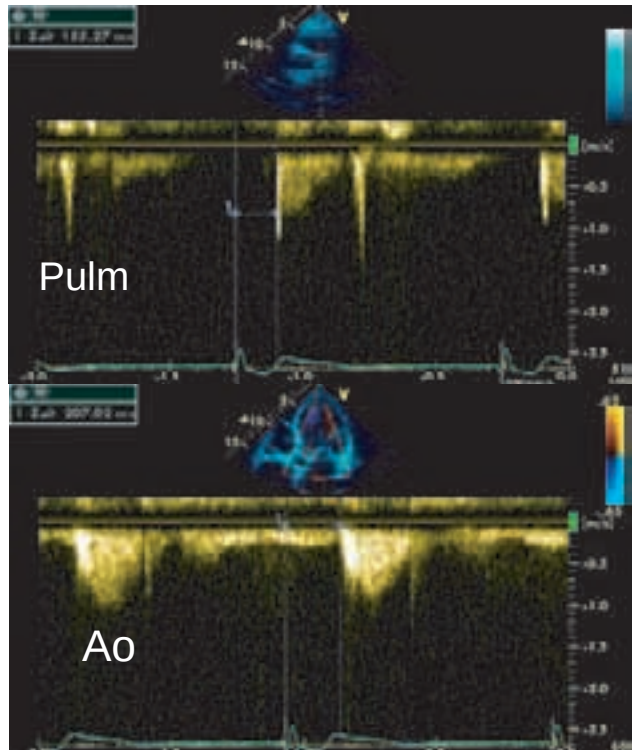

Figure 2.59 (A) Principle of measurement of the interventricular delay of contraction by Doppler echocardiography. The pre-ejection period (PEP) of the right ventricle (RV) is measured from the onset of QRS to the onset of pulmonary outflow (Pulm), and for the left ventricle (LV) from the onset of QRSD to the onset of aortic outflow (Ao). Subtracting RV-PEP from LV-PEP gives the mechanical/contraction delay. In this example the interventricular contraction delay is 52 ms (delay > 40 ms indicates interventricular dyssynchrony). (*Continued* p. 82.)

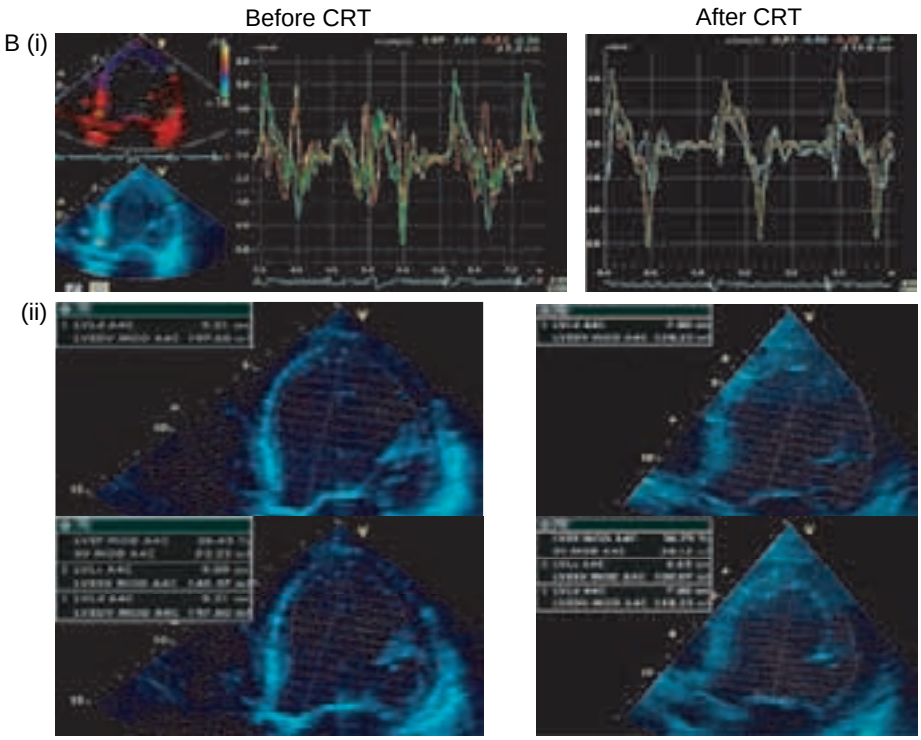

Figure 2.59 (Continued) (B) Tissue Doppler imaging (i) obtained in the basal and middle segments of the interventricular septum and the posterolateral wall of a patient with interventricular dyssynchrony before and after cardiac resynchronisation therapy (CRT). Note the severe dyssynchrony before CRT tracings and normalization of contraction synchrony after implantation of a CRT device. Note also that LV end-diastolic volume has decreased from 197 to 158 ml and that ejection fraction has increased from 20 to 37% (ii).

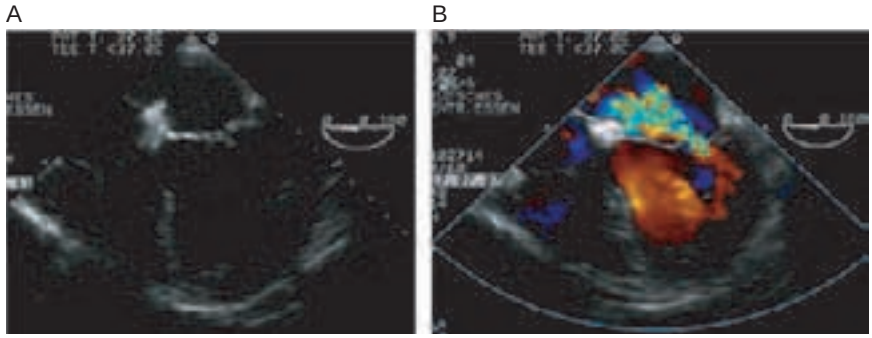

Figure 2.60 (A) Transoesophageal echocardiography obtained at 0° in a patient with mitral valve prolapse of the posterior leaflet. (B) Colour flow Doppler shows the turbulent jet directed towards the interatrial septum indicating severe mitral regurgitation.

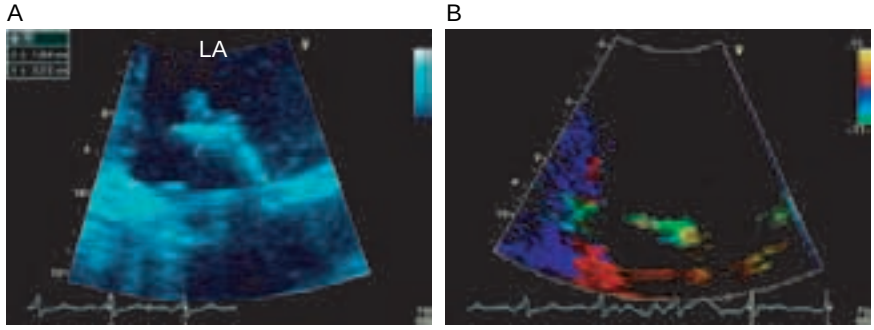

Figure 2.61 (A) Patient with endocarditis and a vegetation on a mitral prosthesis. (B) Tissue Doppler imaging shows incoherent motion of the vegetation (see Fig. 2.32).

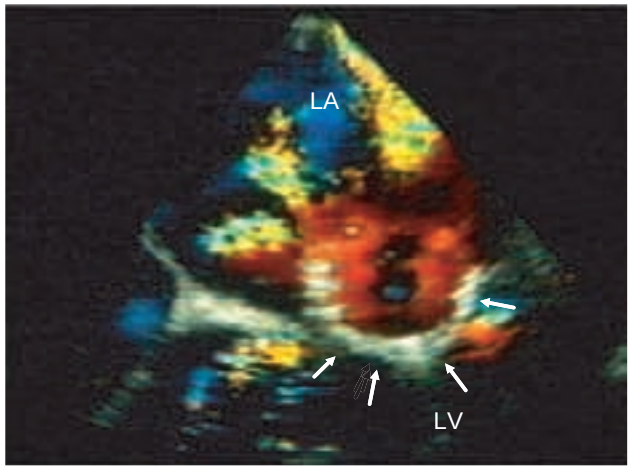

Figure 2.62 Transoesophageal echocardiography colour Doppler flow image of a patient with a mitral Björk–Shiley prosthesis (arrows) and infective endocarditis. Several paraprosthetic regurgitant turbulent jets are seen in the dilated atrium (LA). LV, left ventricle.

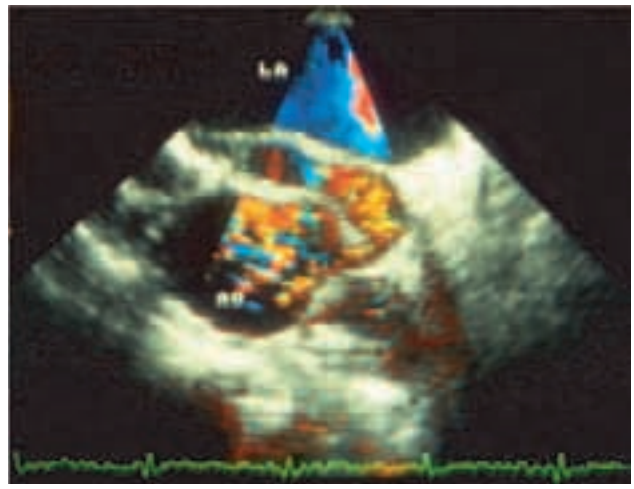

Figure 2.63 Transoesophageal echocardiography colour Doppler flow image of a patient with infective endocarditis and an abscess between the aorta (Ao) and left atrium (LA), which is septated by interconnected compartments. The turbulence in one of the compartments indicates a connection with the intravascular/intracardiac space and therefore represents a mycotic aneurysm.

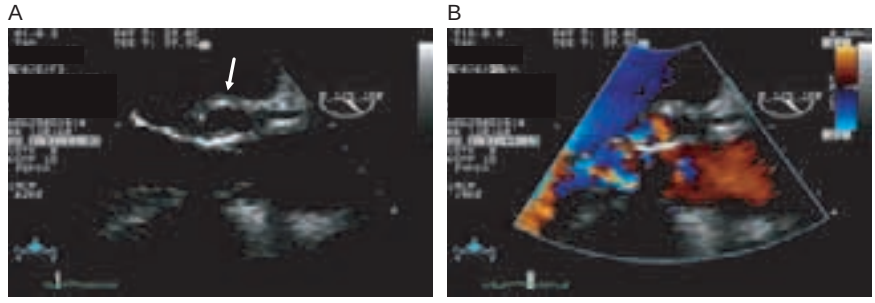

Figure 2.64 Infective endocarditis of the aortic valve. (A) There is a cavity at the base of the aorta (arrow). (B) Colour Doppler flow image shows turbulence in the cavity and diastolic regurgitation from the aorta into the left ventricle, indicating fistula formation between aorta and left ventricle.

involves bioprostheses, can be imaged and graded in order to guide reoperation in an appropriate time scale.

Infective endocarditis

In patients studied for suspected or proven infective endocarditis, transthoracic and transoesophageal echocardiography play an important role because, in addition to the history, clinical features and blood culture, they provide morphological information that was previously not available or only obtained at surgery or autopsy. Transthoracic echocardiography is less sensitive and specific than TOE. The diagnosis of endocarditis is based on clinical laboratory (bacteriological) and echocardiographic findings (Duke criteria) [83]. Echocardiography is the best diagnostic method for diagnosing the complications of infective endocarditis (Figs 2.61–2.65).

Echocardiography has changed the textbooks with regard to this severe disease, because the diagnosis can now be confirmed before valve destruction results in lesions that previously were only detected by auscultation. Infective endocarditis can now be diagnosed in the absence of heart murmurs. In addition, complications of the disease can be imaged (e.g. abscess formation). Follow-up studies are used in order to control medical or surgical therapy.

Pericardial disease (see Chapter 17)

The diagnosis of pericardial and pleural effusion was one of the major applications of M-mode echocardiography. Two-dimensional echocardiography has significantly improved the diagnosis and even allows quantification of pericardial effusion [84].

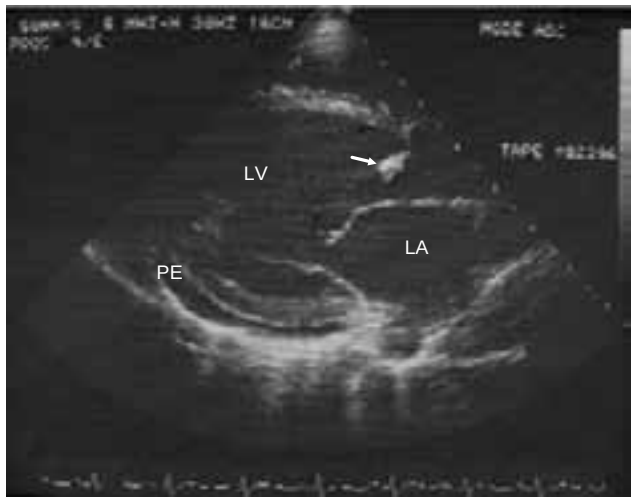

Figure 2.65 Parasternal long-axis view of a patient with infective endocarditis on the aortic valve (arrow) and vegetation. There is massive aortic regurgitation, the left ventricle (LV) is extremely dilated and the left atrium (LA) is enlarged. The patient had acute heart failure. There is also moderate pericardial effusion (PE). These findings are an indication for acute surgery.

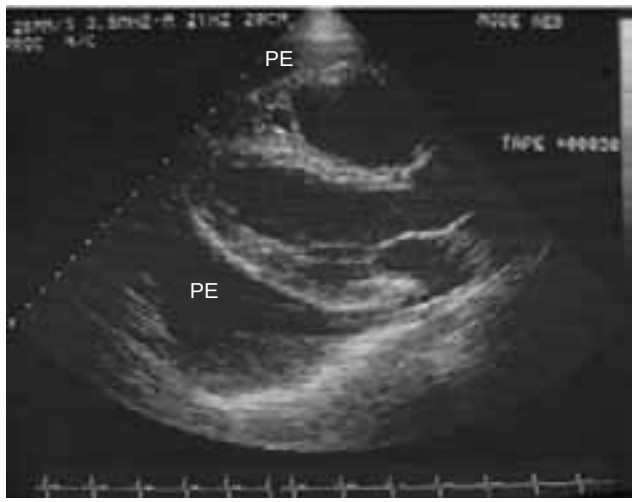

Figure 2.66 Large pericardial effusion (PE) seen as an echolucent area around the heart.

Pericarditis

This is a clinical diagnosis (pain, pericardial rub and ST changes) and pericardial effusion is not a necessary echocardiographic criterion as there is no correlation between its presence or absence and the diagnosis.

Pericardial effusion

Separation between epicardial and pericardial layers occurs when the pericardial fluid exceeds the normal level of 15–35 ml. Using M-mode echocardiography, different degrees of pericardial and epicardial separation have been distinguished (Figs 2.65 and 2.66). Also, pericardial thickening can be detected and is present when the signal exceeds 6 mm.

Two-dimensional echocardiography of pericardial effusion is best imaged using various scanning locations, including the subcostal, transthoracic, suprasternal and paravertebral. Whereas in acute pericardial effusion the pericardial space is free of masses, patients in the chronic stages of pericardial effusion or with acute inflammation can present with bands and masses that are free-floating or attached to the epicardium and pericardium, indicating fibrotic or thrombotic structures. Rarely, tumour masses are found within or adjacent to the pericardium.

Echolucent zones represent fluid between the epicardium and pericardium. The effusion appears first in the posterior part of the pericardial cavity, the posterior atrioventricular groove. An effusion appears behind the left atrium up to the oblique sinus only when there are very large collections. The differentiation between pericardial effusion and mediastinal fat may be misleading to pericardiocentesis because of similar appearance on the display. Accurate gain-setting, proper transducer location, and direction are the best ways to avoid potential pitfalls.

Localization of the pericardial effusion relative to the chest wall allows safe pericardiocentesis, especially for smaller and/or localized effusions. Some findings on M-mode and two-dimensional echocardiography are suggestive of cardiac tamponade. A greater than normal increase in RV dimension during inspiration and a reciprocal decrease in LV dimension is suggestive. Right atrial collapse on two-dimensional echocardiography may be seen in small effusions but is not specific. RV diastolic collapse is fairly specific and commonly observed during tamponade (Fig. 2.67).

After open heart surgery, even with the pericardium left open, localized effusion at the posterior wall can be found, with complete compression of the right atrium leading to cardiac tamponade. These images may be misinterepreted as cardiac tumours or atrial myxoma. A potential pitfall to be avoided is when bleeding into the pericardium occurs and complete or incompete thrombosis develops. This may be aggravated when thrombin is injected in order to stop acute iatrogenic-induced bleeding. The typical echolucent areas may disappear so that epicardial effusion and development of cardiac tamponade are overlooked if haemodynamics are not carefully monitored.

Quantification of pericardial effusion

Because cardiac tamponade is related to the amount of

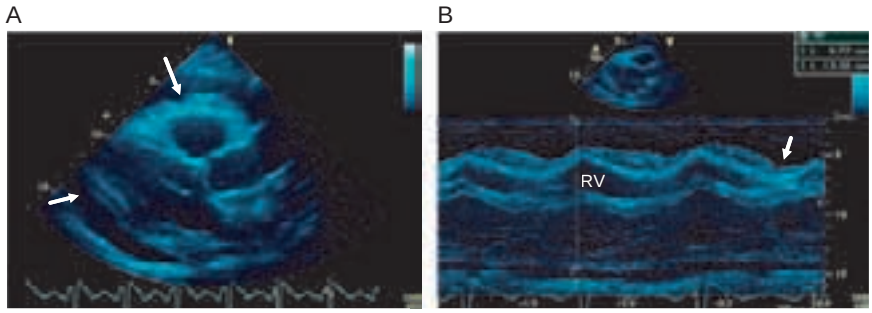

Figure 2.67 Patient with large pericardial effusion and cardiac tamponade. (A) Circumferential effusion (arrows). (B) M-mode recording showing right ventricular (RV) diastolic cavity collapse, which is accentuated during expiration (arrow).

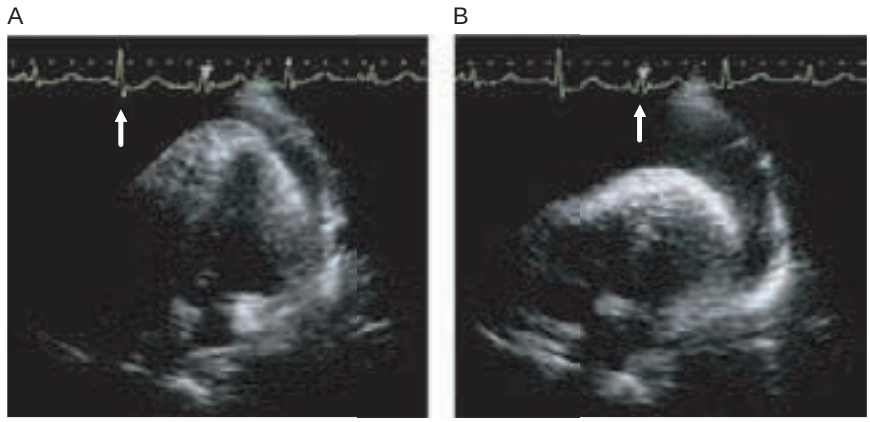

Figure 2.68 In the presence of a large pericardial effusion, the heart shows a 'swinging motion' in the pericardial sac. When the heart is close to the chest wall (A), the QRS voltage is increased; when the heart is away from the chest wall, the QRS voltage is decreased (B). This explains the electrical alternans on the ECG.

fluid, quantification of pericardial effusion has been attempted. Assuming that the pericardial sac approximates the shape of a barrel, the following formula has been developed:

$$V = {}^1\!/_6\pi(D_p^3 - D_v^3)$$

where V represents pericardial effusion volume, D_p the diameter of the parietal pericardium and D_v the diameter of the visceral pericardium at the centre of the heart just below the mitral valve. This method has been validated first with M-mode and subsequently with two-dimensional echocardiography. Stepwise reduction of pericardial effusion can be performed. A linear relationship has been demonstrated between 250 and 600 ml; for two-dimensional echocardiography the correlation coefficient is 0.97 and the regression equation is $y = 9.95x + 21.3$.

Pericardial tamponade is rarely found in patients with an effusion of less than 100 ml, although pericardial effusion of up to 400 ml has been found in 13% and > 400 ml in 39% of all patients. A semi-quantitative approach for effusion sizing has been proposed: small, < 10 mm in systole and diastole; moderate, 11–20 mm; large, > 20 mm. However, using these assumptions may lead to underestimation of the severity of the condition: a 10-mm effusion in a normal heart is less serious than a similar-sized effusion in an enlarged diseased heart. This underestimation also occurs when tangential subcostal scan planes are used.

In large pericardial effusions, the heart may move freely within the pericardial cavity, giving the typical phenomenon of the 'swinging heart'; this results in a voltage change on the ECG (electrical alternans) (Fig. 2.68).

Constrictive pericarditis

If pericardial thickening develops, typical echocardiographic images are obtained (Fig. 2.69). An increase in the size of left and right atrium is a typical consequence of constrictive pericarditis, which can be imaged by echocardiography. The visualization of pericardial thickening and the detection of calcification are better done with MRI or computed tomography (CT). If calcification is present, the thickening is accompanied by ultrasound shadowing, which is highly specific.

Indirect signs of constriction are enlargement of the left and right atrium with a normal left and right ventricle and normal systolic function. This is often a first clue to the diagnosis of constrictive pericarditis. Using M-mode echocardiography and careful observation of the two-dimensional images, an early pathological outward and inward movement of the interventricular septum can be observed, corresponding to the dip-plateau

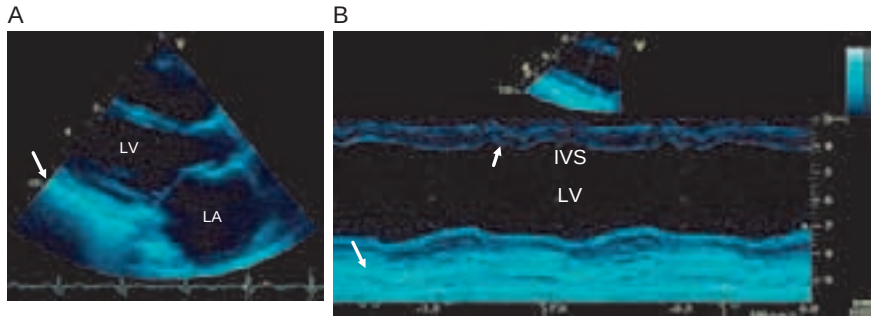

Figure 2.69 Patient with constrictive pericarditis. (A) Arrow indicates the thickened pericardium. Note the enlarged left atrium (LA). (B) M-mode recording of the left ventricle (LV). Note the flat diastolic posterior wall motion and the typical motion pattern of the interventricular septum (IVS) (see also Fig. 2.43). The recording shows an early diastolic notch with forward motion followed by a backward movement as a sign of the early diastolic filling abnormality and corresponds to the dip–plateau phenomenon seen on pressure recordings.

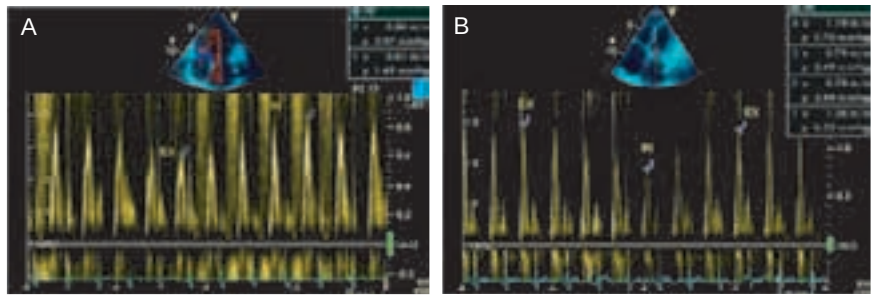

Figure 2.70 Same patient as in Fig. 2.69. (A) Transtricuspid and (B) transmitral Doppler flow patterns show opposite increase/decrease of flow velocities (note position of sample volume in the two-dimensional reference images). In the right heart the velocity increases during inspiration while it decreases in the left heart. This results from the fact that the total heart is constrained and reciprocal volume changes are influenced by the septal displacement during respiration.

phenomenon found by pressure recordings. This is reflected by M-mode echocardiography as an early diastolic notch within forward motion followed by a backward movement of the interventricular septum coinciding with the early diastolic abnormality (Figs 2.43 and 2.69). The diameter of the LV does not increase after the early rapid filling phase. Thus, M-mode shows a horizontal shape with no further increase in LV diameter during diastole and atrial contraction.

Two-dimensional echocardiography visualizes the bright and thickened pericardium (Fig. 2.69). The inferior vena cava is dilated as are the hepatic veins, with restricted respiratory fluctuations. Doppler echocardiography is necessary in order to differentiate constrictive from restrictive physiology [74].

Differential diagnosis has to include acute dilatation of the heart, pulmonary embolism, RV infarction, pleural effusion and chronic obstructive lung diseases. However, the most important differential diagnosis is chronic obstructive lung disease. In this situation, mitral inflow velocity usually decreases during inspiration and increases during expiration, with up to 100% change in velocity (Fig. 2.70). The highest mitral E-velocity occurs at the end of expiration, unlike in constrictive pericarditis where it occurs immediately after the start of expiration. The most reliable differentiation can be performed by measuring flow velocity in the superior vena cava. In chronic obstructive lung disease, superior vena cava flow increases with inspiration, whereas it does not change significantly with respiration in constrictive pericarditis. The difference is rarely more than 20 cm/s. In atrial fibrillation, the differentiation and diagnosis of constrictive pericarditis may be difficult. Diastolic flow reversal in the hepatic vein with expiration can be observed even when the pattern of flow velocity is not diagnostic.

After pericardectomy, the clinical status improves. The degree of reduction of respiratory variation in mitral inflow E wave and peak velocity of pulmonary vein D and S waves correlates with the improvement. After the procedure asymptomatic patients have less variation in both mitral and pulmonary venous flow than symptomatic patients. In addition, DT is prolonged. The persistence of postoperative respiratory variation is found in 9–25%. The percentage change of the peak mitral flow E wave decreases by up to 50%. As a result, ejection fraction determined by echocardiography increases because better LV but also RV filling is induced. Consistent changes in left and right atrial sizes are not reported.

Table 2.13 Thoracic aortic disease

Acute
Traumatic aortic injury
Intramural haematoma
Penetrating aortic ulcer
Aortic dissection
Chronic
Atherosclerotic aortic disease
Aortic aneurysm
Aortic pseudo-aneurysm
Congenital malformations (e.g. Marfan's syndrome)

Aortic diseases (see Chapter 34)

TOE has a prominent role in the detection of chronic aortic disease and in the emergency diagnosis of an acute aortic syndrome (Table 2.13) [23]. Nonetheless, the most important factor leading to a successful and rapid diagnosis remains a high index of suspicion by the clinician in the emergency room. CT and MRI have better spatial resolution and also better identify the extent and side-branch involvement. These techniques are important for detecting early progression and for follow-up studies. The TOE examination procedure for assessing aortic disease can be found in textbooks [33–35].

Atheromatous disease of the thoracic aorta is common and increases with age. It manifests as intimal thickening and protruding or mobile lesions. They can be complicated by erosion, superimposed mobile thrombi, penetrating ulcers and intramural haematoma, which may lead to an acute aortic syndrome. Mobile atheromas represent the greatest risk of an embolic event.

Aneurysm of the aorta is defined as an enlarged aortic diameter without evidence of an intimal flap, tear or intramural haematoma. The upper diameter limit of the ascending aorta is 2.1 cm/m^2 and of the descending aorta 1.6 cm/m^2. All diseases that weaken the aorta can lead to an aneurysm, classified as localized (saccular) or diffuse (fusiform) and true (intact aortic wall) or false (result from penetrating ulcer). An aortic diameter greater than 5 cm is a predictor of risk of rupture.

The increasing knowledge that intramural haematoma and penetrating ulcer are subtypes of aortic dissection has led to a new classification (Svensson classification) of aortic dissection, which may be localized in the ascending or descending aorta (or both) (Fig. 2.71). The echocardiographic criteria for diagnosing aortic dissection are well described [85]. The demonstration of an intimal flap and a false lumen with or without an entry are the hallmarks (Fig. 2.72). Additional findings are aortic regurgitation and pericardial effusion (Fig. 2.73).

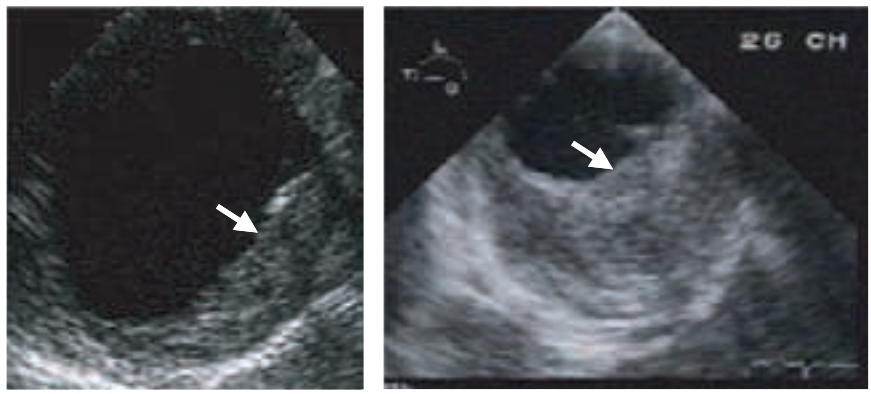

Figure 2.71 Intramural haematoma, a precursor of aortic dissection, is seen as an increased echodensity along the aortic wall as a result of thrombus formation between the intima (which has a smooth appearance, see arrows) and adventitia.

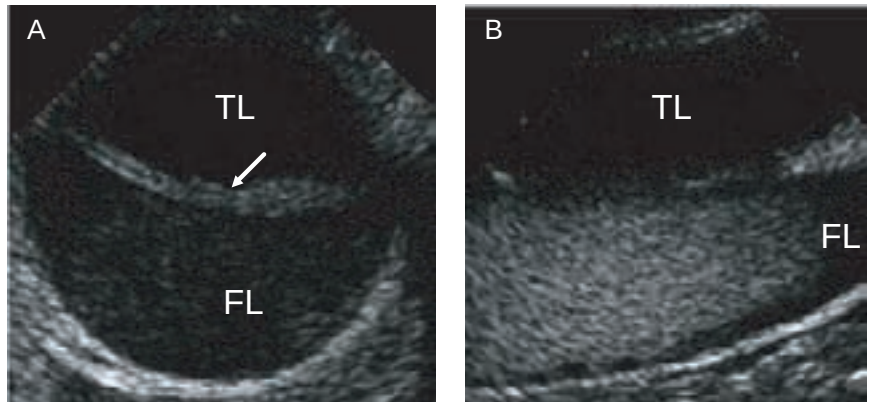

Figure 2.72 Transoesophageal echocardiography of aortic dissection. (A) Short-axis view of the aorta shows the intimal flap (arrow) separating the true lumen (TL) from the false lumen (FL). The slow/stagnant blood in the FL makes it echogenic. (B) Long-axis view shows the aortic dissection in the same area.

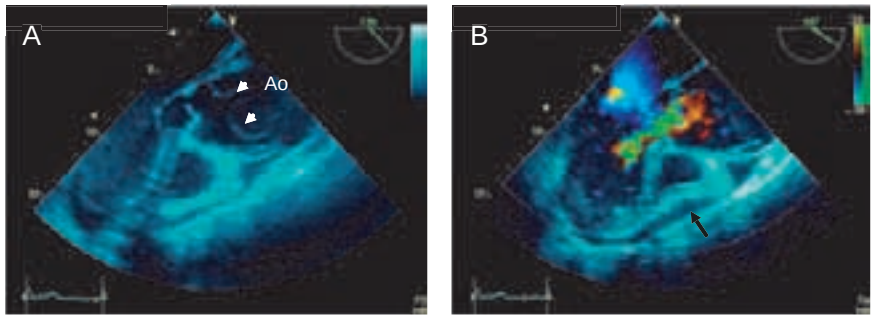

Figure 2.73 Transoesophageal echocardiography of a patient with type A, class 1 (Svensson classification) aortic dissection. (A) Note the dissected flap in the aorta (Ao) (arrows). (B) There is massive aortic regurgitation from the true lumen and a small pericardial effusion (arrow).

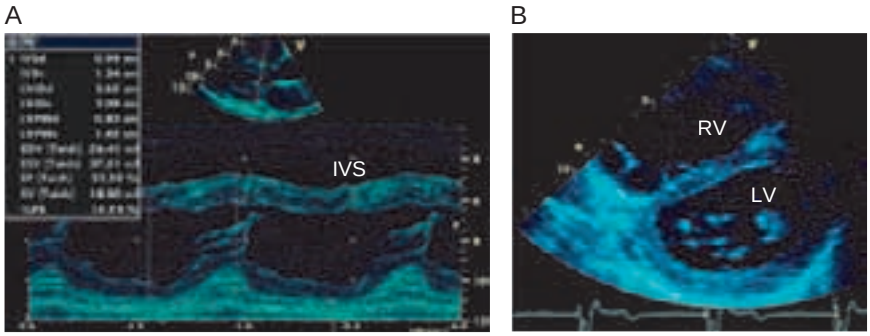

Figure 2.74 Chronic pulmonary hypertension. (A) The interventricular septum (IVS) has a typical paradoxical motion pattern (see Fig. 2.43). (B) Two-dimensional parasternal short-axis view shows the dilated right ventricle (RV) and flattened IVS resulting in the typical 'D-shaped' left ventricle (LV).

An acute aortic syndrome has to be included in the differential diagnosis of acute coronary syndrome in the emergency room. Rapid confirmation and patient management has to be organized in order to avoid deleterious events. Close cooperation between internal medicine, cardiology, radiology and cardiovascular surgeons is essential and the development of standard operating procedures (SOPs) is suggested. The most experienced physicians have to be included in decision-making.

Acute and chronic pulmonary disease

RV pressure overload may occur acutely or in a chronic fashion. Echocardiography is an ideal method for detecting right atrial and ventricular enlargement, which are usually accompanied by tricuspid insufficiency and distension of the inferior vena cava with reduced inspiratory collapse. Quantification of RV volumes remains a challenge. Three-dimensional echocardiography eliminates the need for standardized views and the use of geometric assumptions. It is therefore the optimal method for calculation of RV volume and function.

Pulmonary embolism results in pressure overload depending on the extent. In the case of small emboli no changes in haemodynamics occur. The first sign may be an increase in plasma levels of brain natriuretic peptide. In cases of moderate to severe pulmonary embolism, acute RV pressure overload occurs, characterized not only by ventricular enlargement but also by hypokinesia or akinesia of the RV free wall. In addition, the pulmonary diameter is distended (> 2 cm) as well as the inferior vena cava, with reduced inspiratory collapse. The pressure gradient rarely exceeds 45–50 mmHg, calculated with the Bernoulli equation from the tricuspidal regurgitant jet.

Thrombi within the right atrium and ventricle may be present but can be transient, disappearing in the pulmonary tree. Rarely with suprasternal scanning, but in up to 60% of patients scanned using TOE, emboli within the right, less often the left, pulmonary artery can be visualized when pressure overload is present. In type 1, the emboli are free-floating, whereas in type 2, which occur in acute recurrent events, emboli adherent to the vessel wall are found.

In chronic pulmonary hypertension, pressure overload results not only in right atrial and ventricular enlargement but also in hypertrophy (> 4 mm), which almost never exceeds 8 mm in the RV free wall. In addition, paradoxical interventricular septal motion is present and the size of the RV may exceed that of the LV in a very characteristic way (Figs 2.43 and 2.74). The Bernoulli equation allows estimation of pulmonary systolic as

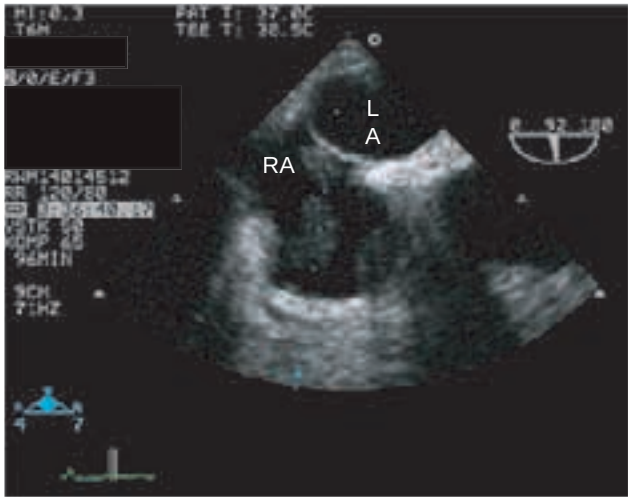

Figure 2.75 Transoesophageal echocardiography of patient with heparin-induced thrombocytosis (HIT). Multiple thrombi are seen in the right atrium (RA). LA, left atrium.

well as diastolic pressure (see Figs 2.40 and 2.41). This helps the clinician to follow the effects of medical treatment or surgery, when thrombectomy is performed. The prerequisite for surgery is the visualization of mural thrombus formation and wall thickening. Careful transoesophageal or intravascular ultrasound can be used for screening.

Intracardiac mass lesions (see Chapter 18)

Both transthoracic and transoesophageal echocardiography are highly accurate methods for detection and localization of mass lesions within the heart. These include primary and secondary tumours (metastatic tumours, hypernephroma, melanoma, sarcoma), thrombus and vegetations (Figs 2.58, 2.61, 2.65 and 2.75). Myxomas are the most common primary tumours in adults and are often located in the left atrium (Fig. 2.76). They are endocardial in origin while ventricular tumours are mostly myogenic and more often occur in children (rhabdomyosarcoma, fibroma, fibrosarcoma).

Echocardiography is the primary diagnostic tool in patients with clinical signs and/or symptoms suggesting an intracardiac mass or in patients with a cardiac disorder that predisposes to intracardiac mass formation. Not uncommonly, a mass lesion is detected during a routine echocardiographic examination. A histological diagnosis cannot be made by echocardiography however.

The differential diagnosis is with ultrasound artefacts and normal or variants of normal intracardiac structures (rete Chiari, Eustachian valve, hiatal hernia, lipomatous atrial septal hypertrophy, mitral annulus calcification, moderator band, Lambl's excrescences on valve cusps, false chordae in the LV).

Extracardiac masses may compress cardiac structures and mimic an intracardiac mass (mediastinal tumour).

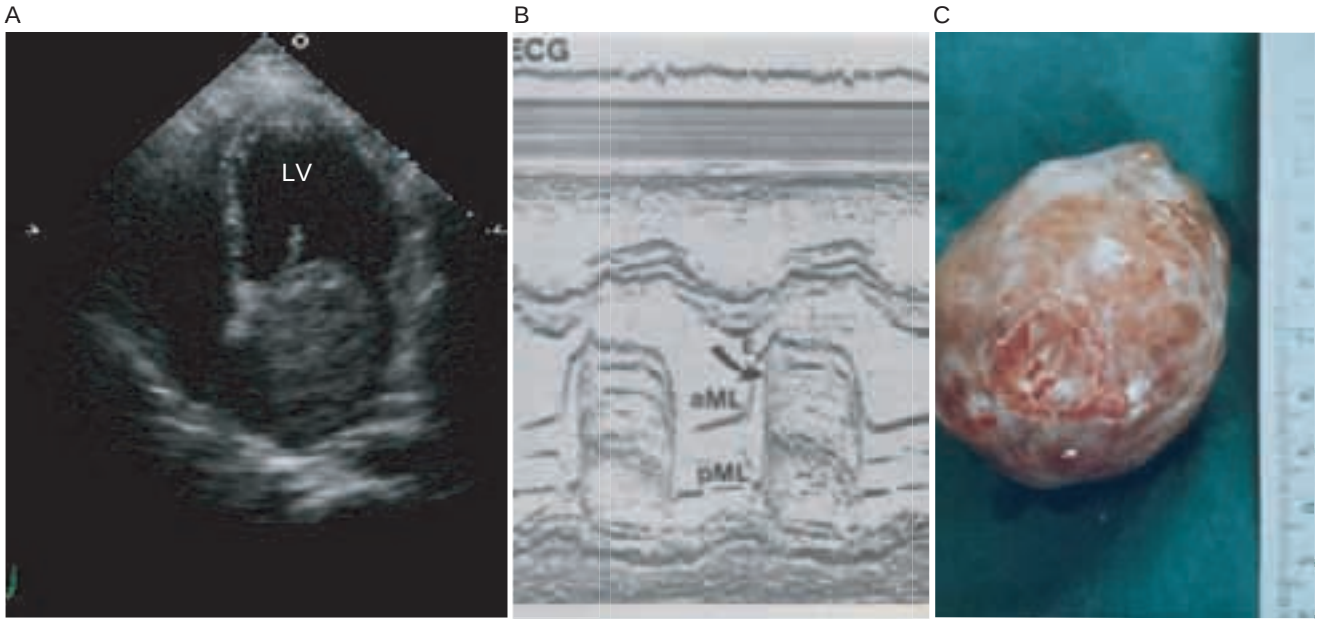

Figure 2.76 (A) Apical four-chamber view shows a large myxoma prolapsing into the mitral orifice in diastole. LV, left ventricle. (B) M-mode recording shows the tumour in the mitral orifice (arrow). Note that there is an interval between mitral valve (aML and pML) opening and diastolic prolapse of the tumour corresponding to the tumour plop heard on auscultation. Ventricular filling takes place during this short interval. (C) Anatomical specimen showing the excised attachment of the tumour to the interatrial septum.

Hydatid cysts are rare and are found in the heart or pericardium.

Embolic stroke

Source of embolism is one of the most common referral questions for TOE in patients with a transient ischaemic attack or stroke. Identification of an embolic source does not necessarily prove the causal relationship but is likely in patients who are < 45 years old and in whom vascular disease is likely to be absent. The detection of heart disease is also likely to be absent. The detection of heart disease makes the cardiac origin more likely: atrial fibrillation, mitral stenosis, endocarditis, prosthetic valve, thrombus and left atrial myxoma. Other potential sources of cardioembolic events are less clear because these are equally found in stroke victims and controls (mitral valve prolapse, annular calcification, septal aneurysm and patent foramen ovale). Contrast echocardiography demonstrating right-to-left shunting of blood flow increases the likelihood.

Emergency echocardiography

New technologies are continuously changing the way intensive-care physicians diagnose and treat their patients. Echocardiographic/Doppler examinations have numerous diagnostic applications in critically ill patients, especially when there is sudden haemodynamic deterioration. Acute circulatory failure and the haemodynamically unstable patient in both the intensive care unit and the emergency room are the most frequent indications. Obstructive shock (tamponade, pulmonary embolism) and hypovolaemic shock are readily diagnosed (or excluded). Expeditious diagnosis of acute cardiac problems requires rapid bedside imaging technology to assess patients with acute dyspnoea (atypical), chest pain and hypotension, syncope, shock and vascular (aortic) trauma. Many patients in the emergency room cannot be appropriately positioned for transthoracic echocardiography and patients in intensive care are often intubated for mechanical ventilation. Postoperative patients in intensive care have precordial dressings/tubes. All of these make TOE the first-line imaging approach [85] (see also p. 49—Substernal echocardiography).

Echocardiography/Doppler can detect acute or chronic mechanical problems, indeed all non-ventricular causes of low cardiac output (valve regurgitation or stenosis, pulmonary embolism, tamponade, constrictive pericarditis), hypovolaemia and low ventricular vascular resistance, as in anaphylactic shock, septic shock and acute failure.

Conclusion

This chapter has provided the physical and theoretical background of ultrasound applications in the heart. A few of its prominent clinical applications are also presented. It is obvious that the availability of smaller and faster microprocessors will further expand the potential and clinical applications of this non-invasive diagnostic method.

Personal perspective

In daily practice, echocardiographic/Doppler assessment is currently the first diagnostic test ordered whenever cardiac disease is suspected. In most instances a definitive diagnosis is made and further invasive procedures can be avoided. The application has recently extended into a variety of clinical scenarios including the emergency room, intensive care and both the operation and interventional suites where it is increasingly used as a routine method for guiding procedures and assessment of results.

As a result of advances in miniaturization and computer technology, newer modalities with increasing diagnostic functions and performance will continue to be developed. These will further increase the clinical questions that can be answered and the clinical scenarios in which echo/Doppler techniques are used.

3 Cardiovascular Magnetic Resonance

Dudley J. Pennell, Frank E. Rademakers and Udo P. Sechtem

Summary

This chapter summarizes the contemporary clinical role of cardiovascular magnetic resonance (CMR) in clinical cardiology. A number of techniques are described which can be applied widely in the cardiovascular system, and these include assessment of morphology and dynamic function, blood flow, ventricular volumes and mass, myocardial interstitial abnormality, and the response to stress.

The best established indications for CMR are anatomical, with typical examples being assessment of the great vessels and congenital heart disease, pericardium and cardiac masses. More recently, assessment of morphology has started to include interstitial myocardial abnormalities, which include acute and chronic infarction, myocardial fibrosis and myocardial infiltration. This has opened up the fields of infarction and viability assessment in coronary artery disease, and phenotyping in cardiomyopathy where distinct distribution patterns of abnormality are associated with various pathologies. The prognostic value of myocardial fibrosis in these settings is now under investigation.

Basic principles

This technical introduction to cardiovascular magnetic resonance (CMR) aims to facilitate understanding but greater detail is available elsewhere [1]. MR depends on the interaction between some atomic nuclei and radio waves in the presence of a magnetic field. In clinical practice, imaging is almost exclusively performed using hydrogen-1, which is abundant in water and fat. A small excess number of hydrogen nuclei align to the magnetic field and can be excited by a radiowave at a resonant frequency (63 MHz with a 1.5 Tesla scanner). After the excitation pulse, the net magnetization decays (*relaxation*) and releases energy as a radio signal (used to form an *echo*). Sophisticated techniques convert these echoes into images that therefore represent a spatially resolved map of radio signals. Tissue contrast depends on the delay from excitation to signal read-out (*echo time*; *TE*) and the time between radiowave pulses (*repeat time*; *TR*). Two relaxation processes occur and are known as *T1* and *T2*, and these vary widely between different tissues. A CMR scanner has a magnet that is superconducting, *gradients* that are driven by pulses of electricity and which provide extra temporary magnetic fields, a *radiofrequency transmitter and receiver* connected to *radio coils* to transmit and receive the radio signals, and a *computer*. Images are formed using the electrocardiogram (ECG) as a trigger.

A scanner requires coordination of action of many individual processes to produce images and the controlling 'orchestral score' is known as a scanning *sequence*. Sequence components include *preparation pulses* (generates contrast between tissues), *excitation pulses* (localizes the excitation area), *gradient and magnetic field pulses* (formation of the imaging echo) and *signal read-out* (data collection). *Spin echo* sequences give anatomical images with black blood, and *gradient echo* sequences give cines. The *inversion recovery* pre-pulse is valuable for infarct imaging by yielding high T1 contrast. The signal read-out for CMR is usually fast to allow breath-hold imaging, and the faster schemes include fast low angle shot (FLASH), steady state with free precession (SSFP), spiral and echo-planar imaging (EPI). *Velocity mapping* displays

each pixel in the image as a velocity rather than a signal magnitude, and this is used to measure velocity and flow by integration over time of the product of mean velocity in a vessel and its cross-sectional area. For coronary CMR, *navigator echoes* are used to correct respiratory motion during long acquisitions by diaphragm monitoring. CMR *angiography* visualizes the vessel lumen after intravenous injection of a *gadolinium*-based MR contrast agent. A sequence called *tagging* measures myocardial contraction from the distortion of a magnetic grid laid across the image in diastole.

The safety of CMR is excellent and clearly advantageous compared with X-ray techniques. However, problems can occur with MR. Items that are ferromagnetic may be strongly attracted to the magnet, become projectile and have the potential to strike the patient. The more obvious problem items include scissors, injection pumps and oxygen cylinders, and strict safety protocols must be followed. A second issue is medical implants and electronic devices. Most metallic implants are MR compatible, including all prosthetic cardiac valves, coronary stents [2] and orthopaedic implants. Some cerebrovascular clips can be problematic, and specialist neurological advice is required in these patients. The high magnetic field may interfere with electronics devices such as pacemakers and cardioverter-defibrillators. In addition, the pacing wires can couple to the radiofrequency waves and heat significantly. These devices are a strong relative contraindication for CMR, although recent reports have shown MR to be safe under special circumstances [3].

Volumes and function

CMR is highly accurate and reproducible to determine the basic parameters used to characterize cardiac function such as ventricular volumes, ejection fraction and ventricular mass. CMR is independent of acoustic windows that may limit echocardiography. The high reproducibility of CMR is significantly better than that of echocardiography, which makes it the ideal tool for serial examination of patients over time [4,5]. Although it is possible to determine ventricular volumes with CMR, using the area length technique that is known from echocardiography, the more commonly used three-dimensional technique is preferred because geometric assumptions are not necessary. From the stack of short-axis images, the volumes and left-ventricular mass are determined using Simpson's rule. Semiautomatic techniques are available, which minimize the analysis time. As quantitative information on the functional capacity of both ventricles is necessary in most patients, the short-axis approach is routinely used in most CMR centres. As the right ventricle has a more irregular shape than the left ventricle, Simpson's rule calculations are the only reasonable approach for quantifying right ventricular volumes. In patients with diseases mainly related to the right ventricle therefore, CMR is often very useful.

Assessment of regional wall motion is greatly facilitated by the high-quality images acquired in most patients using SSFP cines. Wall-motion abnormalities are better seen and with greater confidence than with echocardiography [6]. Important parameters such as regional wall thickness and regional wall thickening can be derived. Nevertheless, image quality depends on the ability of the patient to breath hold, and the absence of poorly controlled cardiac rhythms. Using myocardial tagging techniques, the deformation of the tagging grid provides estimates of myocardial strain, torsion and shear. It has been suggested that a two-dimensional strain analysis may be better than measuring wall thickening to distinguish between dysfunctional and normal myocardium. Although myocardial tagging provides new ways of looking at cardiac physiology, it is rarely used at present in the clinical environment. CMR assessment of myocardial function should be used when the quality of echocardiography is reduced owing to patient-related factors [7]. Moreover, because of its superior image quality, CMR should be used when there is a discrepancy between echocardiographic findings and the overall clinical picture.

Myocardial infarction

Myocardial infarction can be detected with very high sensitivity using a CMR technique known as *late gadolinium enhancement* (Fig. 3.1). This is performed 10 minutes or more after the intravenous injection of a gadolinium MR contrast agent. These contrast agents enter the extracellular space and, owing to kinetic and partition effects, are concentrated in infarcted myocardium late after injection, where the extracellular space is expanded as a result of cell necrosis (acute infarction) or fibrotic replacement (chronic infarction) [8]. Using an inversion recovery sequence, the signal intensity of normal myocardium is driven to zero by adjusting the inversion time, and this leads to intense signal in infarcted areas that have a shorter T1 as a result of gadolinium accumulation. Thus CMR gives an almost histological depiction of myocardial

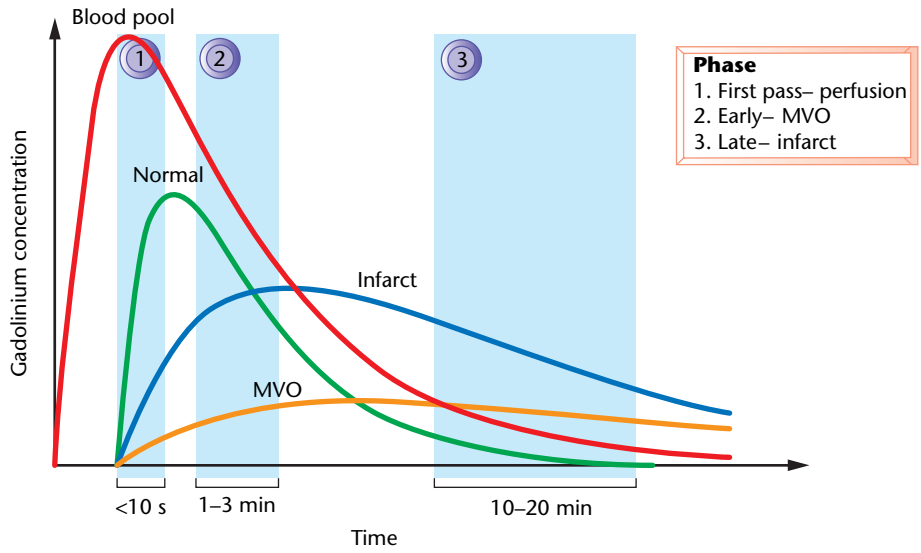

Figure 3.1 The use of intravenous gadolinium for CMR in detecting pathology depends on the time after injection that the images are taken. The bolus of gadolinium is given at time point 0, and the red line indicates gadolinium concentration in the blood (for clarity recirculation has been omitted). After a short delay, gadolinium enters the coronary arteries and the first pass through the myocardium is shown as the green line. At this time, ultrafast CMR can be used to measure myocardial perfusion (phase 1). After 1–3 min, early gadolinium enhancement imaging can be performed: at this time, the lowest gadolinium concentration is in avascular areas, such as in microvascular obstruction (MVO, orange line) in acute infarction; however, thrombus is also very well shown by this technique, and both appear very dark on the images (phase 2). When an MVO is present, it is surrounded by infarction, which is bright on the late gadolinium enhancement images taken after 10–20 min, when gadolinium is in highest concentration in infarcted areas (blue line, phase 3), or in cardiomyopathies in those areas of expanded extracellular space due to fibrosis or infiltration. The times given are for illustration of the principles and are dependent on the dose of gadolinium given and other factors.

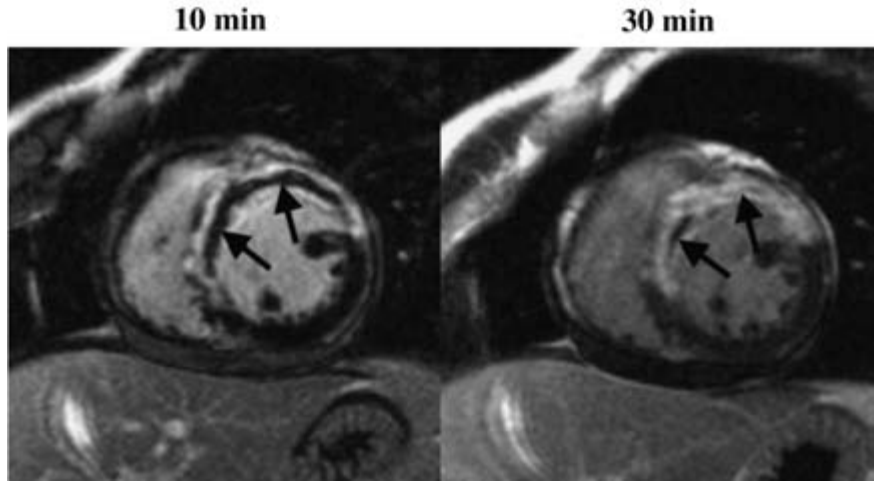

Figure 3.2 Large anterior myocardial infarction despite early reperfusion by percutaneous coronary intervention (PCI) and stenting. Left: At 10 min after the injection of contrast media (normal timing for assessment of enhancement) there is a central area of low signal intensity representing microvascular obstruction (arrows). This zone is surrounded by high signal intensity necrosis. Right: At 30 min after contrast injection the agent has also reached this central zone, leading to high signal intensity also in this portion of the infarct.

abnormality. Regions within the perfusion bed of an occluded coronary artery, which are underperfused but not necrotic, do not enhance. Some acute infarcts have a central dark zone in the area of late gadolinium enhancement, which represents microvascular obstruction, where it is difficult for gadolinium to penetrate (Fig. 3.2). These infarcts are associated with a poorer prognosis, as an independent predictor from the ejection fraction [9]. The area of microvascular obstruction slowly shrinks over weeks. In addition, the area of late gadolinium enhancement also shrinks substantially over time, both in volume and transmural extent, owing to scar formation with involution, and hypertrophy of adjacent and overlying myocardium. As CMR provides high spatial resolution,

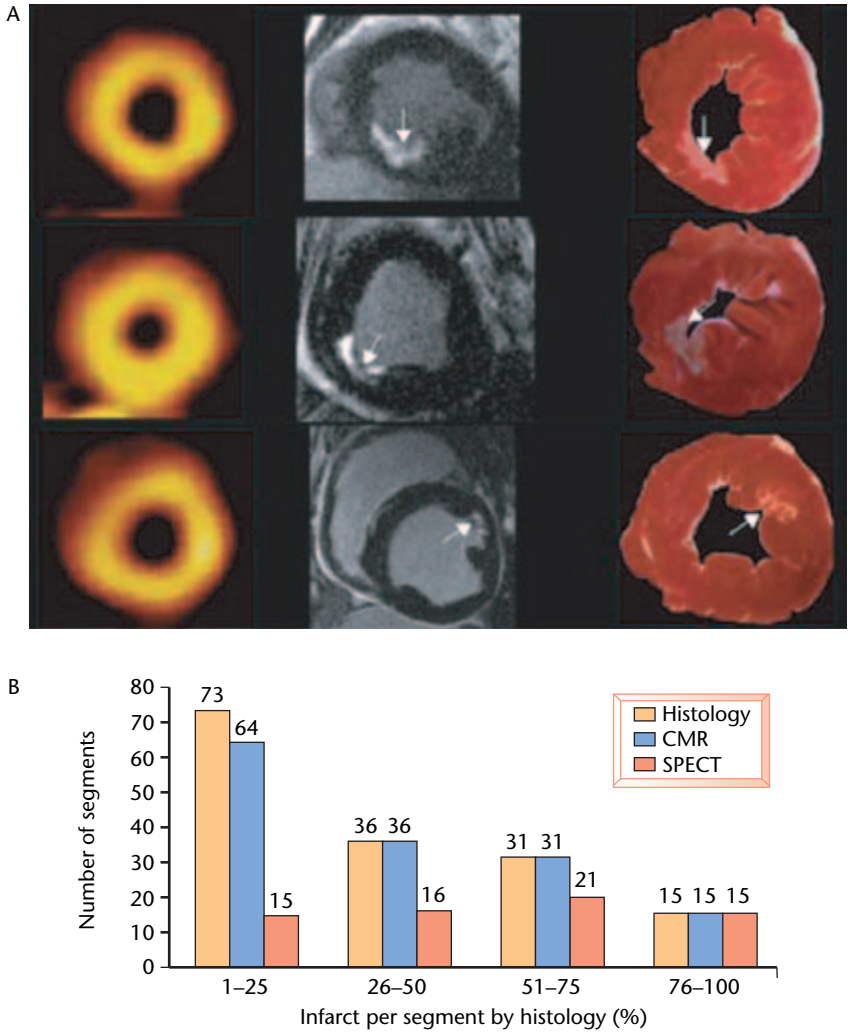

Figure 3.3 (A) Comparison of CMR and scintigraphy for detection of myocardial infarction in animals. The right column shows three experimentally induced infarcts with TTC staining as indicated by arrows. The *ex vivo* gadolinium images (middle column) show excellent correspondence, but the perfusion scintigraphy (left column) fails to resolve these small infarcts. (B) The graph relates the number of segments seen by each technique against the transmural extent of the infarction in quartiles. The light orange bar shows the results of histology, and comparison with the CMR (blue bar) is excellent. However, the proportion of missed infarct segments by scintigraphy (dark orange bar) increases as the infarcted segments become progressively more subendocardial. Reproduced with permission from Wagner *et al.*, *Lancet* 2003, **361**: 374–379.

has a high inter-study reproducibility and is completely non-invasive, it is the ideal tool to study acute infarction, healing and remodelling in man. In the chronic stage of myocardial infarction, the scar is still clearly visualized by late gadolinium enhancement. Late gadolinium enhancement CMR is significantly more sensitive for infarction detection than perfusion SPECT (Fig. 3.3) [10].

CMR can also depict the regional reduction in wall thickness and wall thickening associated with myocardial infarcts. However, the degree of abnormal systolic function is only a poor indicator of the degree of infarct transmurality. Myocardial stunning contributes to the observed loss of regional systolic function and it is not possible to distinguish this influence from the contractile dysfunction caused by infarct scar when using deformation imaging alone.

Viability

Accurate prediction of recovery of function following revascularization has been achieved with low-dose dobutamine CMR, with similar results to positron emission tomography (PET). However, late gadolinium enhancement CMR also allows the assessment of viable myocardium. Areas surrounding an infarct, which do not enhance, are composed of viable myocardium. The transmural extent of scarring is closely related to the likelihood of recovery of function after revascularization and also to recovery of ejection fraction [11]. However, low-dose dobutamine CMR may be more sensitive in predicting recovery of function [12]. This is not surprising as the

dobutamine-assisted test simulates the effects of revascularization. The main problem with late gadolinium-enhanced CMR is its reduced specificity in predicting the absence of recovery in non-transmural scars. The inability of non-transmural scar to recover function after adequate revascularization is poorly understood. One of the factors involved may be that recovery of function may require more time than the usual 3 months, which is the normal period after revascularization at which recovery function is studied. Moreover, coronary revascularization may be incomplete particularly in patients with extensive atherosclerosis and diffuse disease. Whatever CMR technique is used for assessing myocardial viability, it is appropriate to view viability as a continuum and not use a single threshold value for predicting functional improvement. Instead, one should base the clinical expectation of recovery on the extent of transmurality of the infarcts in a particular region. If more than 50% of the myocardium is infarcted, the probability of no recovery following revascularization is approximately 90% (negative predictive value) [11]. On the other hand, segments without scar have a 80% likelihood (positive predictive value) of recovery [12]. Late gadolinium enhancement CMR can also predict the effect of beta-receptor blocking agents in patients with severely reduced left-ventricular function. For larger scars, the improvement achieved by beta-blockade diminishes [13].

Stress ventriculography

Dobutamine stress CMR is now well established for diagnosing obstructive coronary artery disease (CAD) through induction of new wall motion abnormalities, and is superior overall to stress echocardiography because of better image quality [6]. Stress CMR is useful in patients who are unsuitable for dobutamine echocardiography. Normal stress CMR indicates a low event rate, and risk increases with ischaemia [14,15]. Ischaemia by stress CMR has been used for assessment of increased preoperative risk [14]. Ideally, stress CMR would allow quantification of wall motion assessment to reduce the high observer variability of dobutamine echocardiography. The most advanced, clinically, is tagging, which allows the measurement of myocardial strain, thus yielding increased sensitivity [15], but larger trials and faster post-processing are needed for clinical application. CMR stress ventriculography has been shown to be safe in large patient cohorts.

Myocardial perfusion

Myocardial perfusion CMR is the early phase of clinical adoption but it is attractive because when compared with scintigraphy, CMR has significantly enhanced in-plane spatial resolution with no ionizing radiation. A fast bolus of gadolinium contrast agent is given intravenously with a power injector and the first-pass signal changes in the myocardium are measured. At the current stage of development, perfusion CMR sequences typically image three or more slices per cardiac cycle, allowing a full segmental perfusion analysis. Areas of reduced perfusion are visualized as having persistent low signal, and in CAD appear to always involve the subendocardium with variable transmural extension. A rest study is not needed in principle, but it has been found useful for two reasons: first, to assist with the differentiation of endocardial artefacts from true ischaemic defects and second when the myocardial perfusion reserve is required for quantification. Late gadolinium enhancement is performed after 10 min and areas of infarction can be detected and compared with the stress perfusion images to determine whether peri-infarct ischaemia is present. The optimal imaging sequence for perfusion CMR is not yet determined. At least three fast sequences are being evaluated and these can be accelerated using parallel imaging and line-sharing techniques; however, it seems clear that faster and higher spatial resolution reduces artefacts. Perfusion CMR can also be analysed quantitatively using parameters such as the signal upslope. This allows the generation of parametric perfusion maps, indices of perfusion at rest and stress, and myocardial perfusion reserve [16]. More complex computer analysis may also be used with deconvolution of the myocardial signal curve with the input function taken from the left-ventricular blood pool, and this approach has been validated in animals. A CMR technique that does not require gadolinium contrast or ultra-fast imaging has also been described and this is called T2* blood oxygen level dependent (BOLD) [17]. However, the sensitivity of T2* to perfusion change may be quite low and its clinical role is not yet defined.

The results for the detection of CAD by myocardial perfusion CMR are very good in direct comparisons with coronary angiography, PET and single-photon emission computerized tomography (SPECT) [18]. Using perfusion CMR, the myocardial perfusion reserve has been shown to improve with coronary angioplasty, and the high resolution has allowed visualization of subendocardial perfusion abnormality in conditions such as cardiac syndrome X [16]. Perfusion CMR is likely to improve our

understanding of the pathophysiology of these types of conditions and have significant clinical application if the technique can be shown to have diagnostic and prognostic value.

Acute coronary syndromes

In an attempt to better and faster identify those patients with chest pain who present with true unstable coronary syndromes to the emergency room, CMR has been used to depict the abnormalities in wall motion, perfusion and infarct enhancement potentially associated with acute coronary chest pain. When performed at rest within 12 h of presentation, the sensitivity and specificity for detecting acute coronary syndromes was 84% and 85% by CMR, which was more sensitive than when ECG criteria for ischaemia, peak troponin I or the TIMI risk score were used [19]. CMR was also more specific than an abnormal ECG [19]. Whether CMR will be more useful than radionuclide imaging needs to be evaluated in a direct comparison trial.

CMR is helpful in detecting small acute myocardial infarctions such as those associated with coronary interventions. CMR shows areas of high signal intensity that are compatible with acute myocardial necrosis in the immediate vicinity of the intervention site or further downstream when embolization from the intervention site was the cause of the acute event [9]. After more extensive acute infarctions, CMR can depict large aneurysms and pseudo-aneurysms well, and ventricular thrombi are detected with higher accuracy than by echocardiography using an early gadolinium enhancement technique [20]. This has consequences in patients after myocardial infarction because thrombi mandate oral anticoagulation therapy for several months.

Coronary arteries

Although CMR angiography is an accepted technique for the visualization of arteries and veins throughout the body, its use in the coronary circulation is hampered by the inherent technical difficulties associated with imaging small, tortuous vessels on the curved surface of a continuously moving heart. The optimal spatial and temporal resolution for the visualization of coronary vessels cannot directly be achieved by conventional CMR sequences, so a number of special techniques are used (Fig. 3.4). To reduce blurring, coronary imaging is performed during cardiac diastasis in diastole when motion is limited; to image the tortuous vessels, a three-dimensional volume is acquired; to minimize cardiac displacement from respiratory movement, a breath-holding technique or diaphragmatic monitoring (called navigator echoes) is used; and to improve contrast, pre-pulses are used to suppress fat and non-coronary artery tissues (T2 preparation). At present, therefore, the most widely used technique is to combine a gradient echo or SSFP three-dimensional sequence with navigator diaphragm monitoring, T2 preparation and fat suppression. In the future, MR contrast agents may contribute to improved signal from the coronary lumen, and higher field magnets may also be useful.

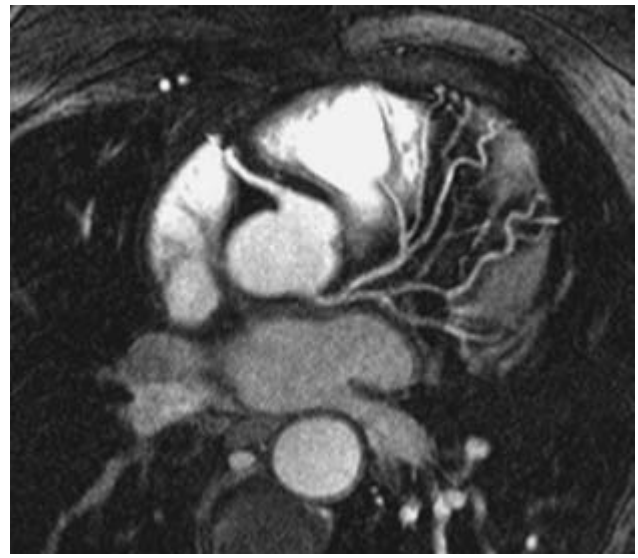

Figure 3.4 Coronary CMR showing a projection of a three-dimensional dataset into a single image. All three coronary arteries are visualized, as well as branch vessels.

With the current limitations, coronary CMR cannot replace conventional invasive coronary angiography. There are encouraging clinical results showing a high negative predictive value for left main stem or three-vessel disease [21], but the technique is not robust for routine use. Where coronary CMR has proven clinically valuable is in congenital abnormalities of the coronary tree with abnormal origin and course of the proximal artery. Here, the three-dimensional tomographic nature of coronary CMR gives superior results to projection conventional coronary angiography for the relation of the proximal coronary artery to the aortic root and pulmonary trunk (Fig. 3.5) [22]. The malign variants have an interarterial course. Bypass grafts can also be visualized confidently with CMR, allowing the exclusion of graft

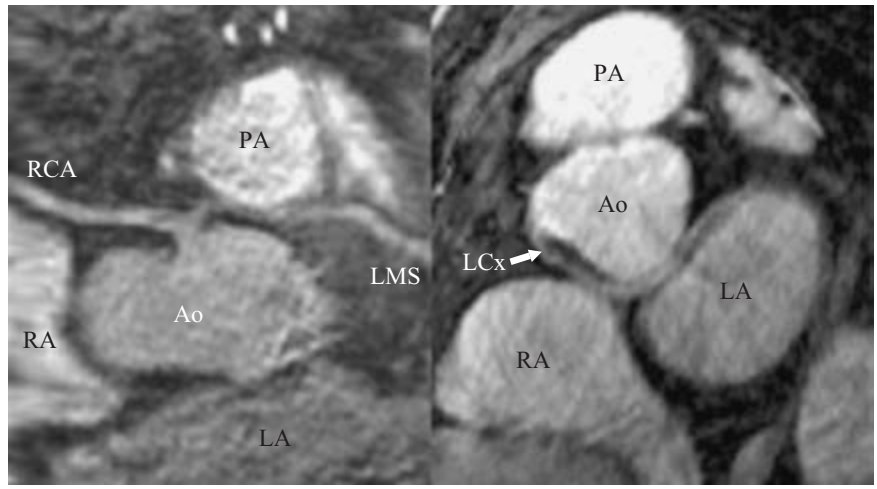

Figure 3.5 Coronary CMR of coronary anomalies. (A) The right coronary artery (RCA) and the left main stem (LMS) both arise from the anterior coronary sinus. The left main stem passes between the aorta (Ao) and the pulmonary artery (PA), and is considered a malignant course because of the risks of compression between the great vessels. (B) A benign anomaly with a left circumflex (LCx) arising from the anterior coronary sinus and passing posteriorly behind the aorta, in front of the right atrium (RA) and left atrium (LA), to reach the posterior atrioventricular groove. This variant is considered benign.

occlusion but the exact morphology of the connection with the native circulation (often the location of pathology) is frequently difficult to visualize accurately. Here the use of flow reserve measurements can be helpful [23]. Inflammatory diseases of the coronary arteries giving rise to aneurysm formation can be visualized and followed over time to judge evolution with treatment [24]. Currently, the performance of multislice CT is better than coronary CMR, but it too is not yet ready for routine clinical practice and carries a significant radiation burden, contrast hazards, and artefacts from calcium, which can obscure luminal interpretation.

Vessel wall

A new application of CMR is the direct assessment of atherosclerotic plaque. This is currently most easily accomplished in the carotid arteries, because the artery is superficial and surface coils allow high spatial resolution. Arterial wall CMR can be used to measure total plaque burden within an imaging volume by using T1-weighted images with blood signal suppression, and summing the difference in each image slice between the outer and inner vessel boundary to obtain the total vessel volume. This is highly reproducible and allows the demonstration of plaque regressions with statins [25]. The technique can also image coronary plaque. Plaque characterization is also possible with identification of features of plaque inflammation, cholesterol pools and the thickness of the fibrous cap using a combination of T1-, T2- and proton density-weighted images [26]. Thin or disrupted caps on CMR have been strongly linked with cerebrovascular events [27]. Arterial sclerosis can also be assessed using CMR including the measurement of compliance in the ascending aorta (change of aortic volume in a slice normalized to pulse pressure) and pulse wave velocity (rate of propagation of the flow wave around the aortic arch in metres per second). These age-dependent measures are abnormal in early atherosclerosis and predict cardiac events.

Endothelial function can also be measured reproducibly by CMR using stimuli that cause arterial vasodilatation, such as flow-mediated dilatation (endothelium dependent) and glyceryl trinitrate (endothelium independent). Flow-mediated dilatation of the brachial artery is assessed by forearm cuff occlusion for a standard time period, followed by release, which induces increased endothelial shear, the release of nitric oxide and arterial dilatation [28]. The use of CMR allows area measurement of the vessel, which has advantages over the diameter measurement made by ultrasound. Validation studies have been performed in humans using invasive techniques, and repeated measurements by CMR appear to have greater reproducibility than by ultrasound, suggesting smaller sample sizes for trials using CMR [28]. An additional advantage of CMR is that flow changes can also be measured directly in response to the standard stimuli.

Cardiomyopathy

Hypertrophic cardiomyopathy

The diagnosis of hypertrophic cardiomyopathy (HCM) is usually made by echocardiography, but CMR has

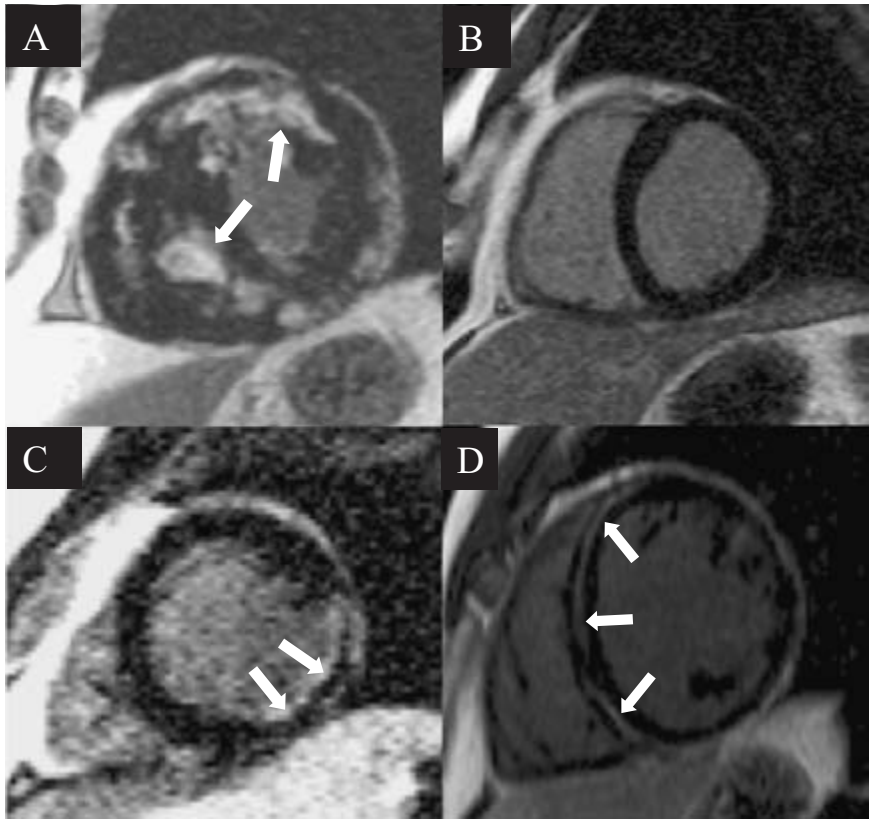

Figure 3.6 Late gadolinium enhancement CMR in cardiomyopathy. (A) A patient with hypertrophic cardiomyopathy (HCM) and the arrows depict areas of fibrosis that are discrete, of variable distribution across the thickness of the myocardial wall and not distributed in coronary territories. (B) A patient with dilated cardiomyopathy (DCM) and no late gadolinium enhancement is seen. (C) A patient who had been diagnosed as having DCM on the basis of normal coronary arteries; however, late gadolinium CMR clearly showed an inferolateral infarction (arrows), suggesting that the infarct-related artery had recanalized by the time of coronary angiography, and therefore that DCM was not the correct diagnosis. (D) Another patient with DCM is shown, in whom there is mid-wall enhancement (arrows), which is clearly different from HCM or infarction.

advantages in some clinical scenarios because of its excellent image quality with comprehensive ventricular coverage for identification of regional hypertrophy. Thus CMR is mainly used diagnostically when the results from echocardiography are inconclusive, such as in apical hypertrophy [29]. Other features of HCM can also be shown including obstruction in the outflow tract, and systolic anterior motion of the mitral valve. The accuracy of CMR for the phenotypic determination of HCM may also be helpful for screening of relatives of probands.

A number of other CMR techniques may also be helpful, although their place in clinical practice is not yet established. One feature of myopathic hypertrophy is impaired contraction and this can be quantified using CMR tagging. In HCM, tagging shows abnormal strain, shear and torsion in dysfunctional hypertrophic areas. This may prove to have value in differentiating HCM from hypertrophy as a result of exercise or hypertension. Another feature of myopathic heart is a bioenergetic defect in high-energy phosphate compounds such as ATP, which can be detected using complex CMR spectroscopic methods in patients with HCM who have varying genetic mutations. This suggests the hypothesis that inefficient energy utilization may be the underlying substrate for HCM [30]. Finally, late gadolinium enhancement CMR occurs in HCM, and this has been shown to represent myocardial fibrosis (Fig. 3.6) [31]. A common benign pattern of enhancement occurs at the insertion points of the right ventricle into the left ventricle. However, some patients have extensive late gadolinium enhancement. A link has been shown between the extent of late gadolinium enhancement and the risk of heart failure or sudden death (Fig. 3.7) [32]. This is thought to reflect the risk of re-entrant tachycardia and systolic failure from scar formation. It is not yet known whether late gadolinium enhancement in HCM is an independent risk factor in comparison with other established parameters. Late gadolinium enhancement also occurs in therapeutic septal myocardial infarction. This is useful for localizing and assessing the transmural extent of the infarction to assess procedural success.

CMR has also proved useful in other causes of hypertrophy, which form a differential diagnosis in HCM. About 4% of HCM patients have Fabry's disease, in which α-galactosidase is deficient which causes accumulation of glycosphingolipid GB3 in myocytes and endothelium. CMR typically shows lateral wall late gadolinium enhancement in these patients (Fig. 3.8) [33], which has been

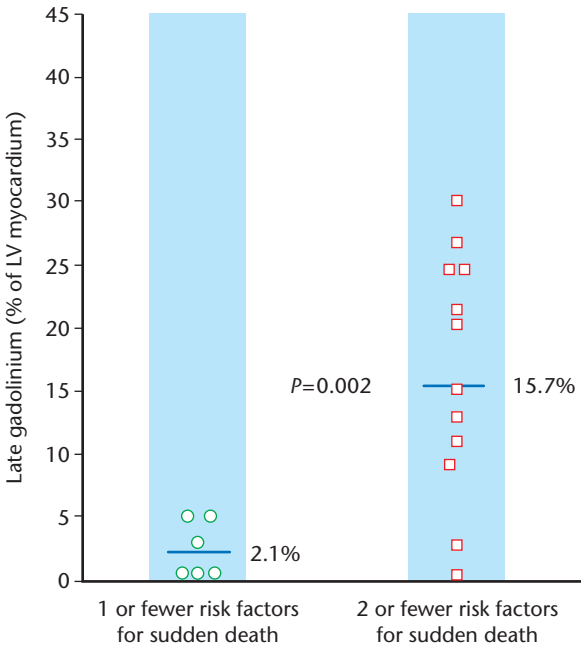

Figure 3.7 In hypertrophic cardiomyopathy, the extent of late gadolinium enhancement is related to the presence of risk factors for sudden death. These findings suggest that the extent of fibrosis may be a useful clinical marker of risk.

related to fibrosis, although the cause for this distribution is not known. It is, however, useful diagnostically. Another differential diagnosis is cardiac amyloidosis, which shows a different pattern again, with global subendocardial late gadolinium enhancement due to preferential endocardial amyloid deposition.

Dilated cardiomyopathy

CMR shows and quantifies the functional abnormalities in dilated cardiomyopathy (DCM) for both ventricles. Because CMR has excellent reproducibility, changes over time can be used for serial monitoring of function. However, the main clinical question in DCM is the differentiation from coronary artery disease (CAD). This may not be straightforward and many centres routinely perform coronary angiography as a gold standard. Late gadolinium enhancement CMR has been shown to be useful as a non-invasive alternative [34]. In a study of patients labelled with DCM following normal coronary angiography, 59% showed no late gadolinium enhancement and 28% presented with patchy or longitudinal striae of mid-wall enhancement sparing the subendocardium (Fig. 3.6). In all of these cases, CMR correctly identified

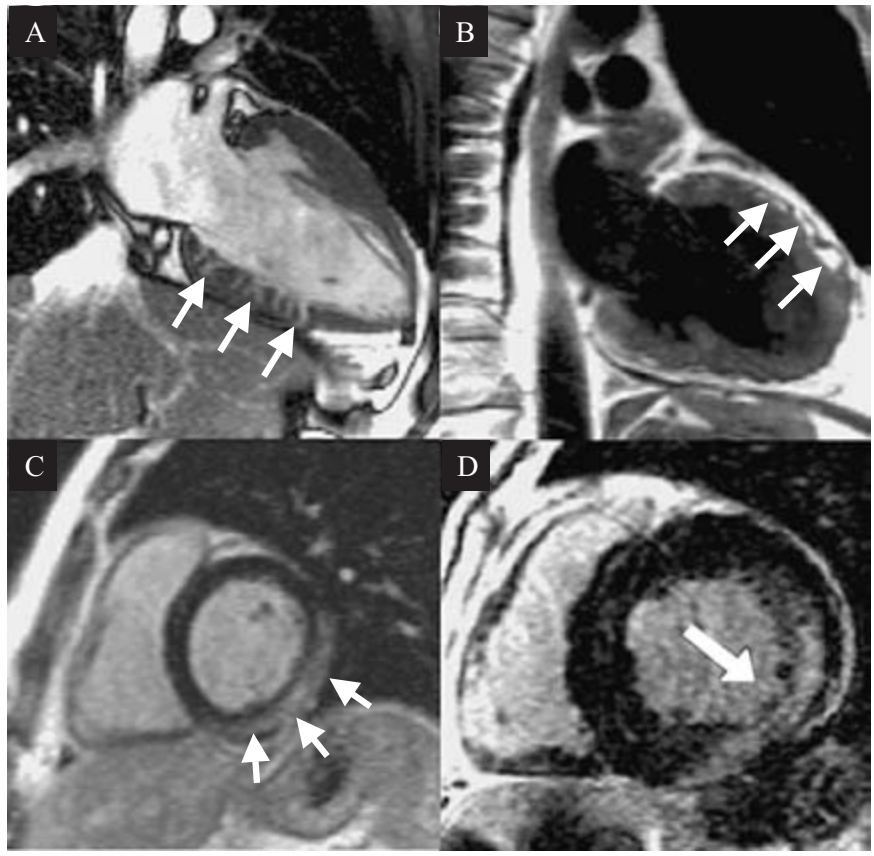

Figure 3.8 CMR in other myocardial conditions. The inferior wall in (A) shows deep recesses (arrows) diagnostic of non-compaction. The anterior wall in (B) shows high signal areas that were shown to be fat using fat-suppression sequences in a patient with left-ventricular involvement in ARVC. In (C), the inferolateral wall shows epicardial late gadolinium enhancement in a patient with myocarditis. In (D), there is mid-wall late gadolinium enhancement in the typical location for Fabry's disease.

that myocardial infarction was not the cause of ventricular dysfunction. Also of significant interest was the final group of 13% of patients in whom late gadolinium enhancement was present, which was indistinguishable from infarction. This suggests that these patients were incorrectly assigned the clinical label of DCM following 'normal' coronary angiography, probably as a result of coronary recanalization post infarction and untreated ventricular remodelling. When it is also considered that incidental coronary stenosis may occur in patients with true DCM that has not resulted in infarction, the use of coronary angiography as a gold standard for diagnosis of DCM appears flawed. If these results are confirmed in further studies, CMR may become established as an alternative to coronary angiography in the diagnostic work-up of DCM.

The mid-wall late gadolinium enhancement identified in patients with DCM is similar to the fibrosis found in these patients at post-mortem. This has not previously been identified *in vivo*, and studies are under way to determine whether the presence of such scars has prognostic importance as a source of re-entrant arrhythmias or accelerated ventricular dysfunction. The prognosis in DCM has also been assessed using CMR spectroscopy, with which a low phosphocreatine–ATP ratio predicts an adverse outcome [35].

Iron overload (siderotic) cardiomyopathy

Siderotic cardiomyopathy occurs in patients who require regular blood transfusions. The body has no mechanism for the excretion of iron, which therefore accumulates in the tissues, causing organ dysfunction and oxidative cellular damage. The most frequent condition associated with siderotic cardiomyopathy is β-thalassaemia major, in which heart failure occurs at a young age and is the cause of death in 71% of patients. Approximately 60 000 children are born annually with this condition, and all require lifelong treatment. In view of the high mortality rate from heart disease, protocols have been developed for clinical management, which are based on measurements of blood ferritin and liver iron levels. These are not ideal because they are surrogate measures for the target lethal organ, which is the heart. The measurement of cardiac iron clinically has been difficult, and myocardial biopsy has been rarely used because of the risk of complications and sampling error because of non-homogeneous myocardial iron distribution. Recently, however, it was shown that the myocardial relaxation parameter T2* measured by CMR can be used to assess iron in the heart [36]. Normal myocardial T2* is > 20 milliseconds (ms), and values lower than this indicate iron overload, which has been linked with left-ventricular dysfunction (Fig. 3.9),

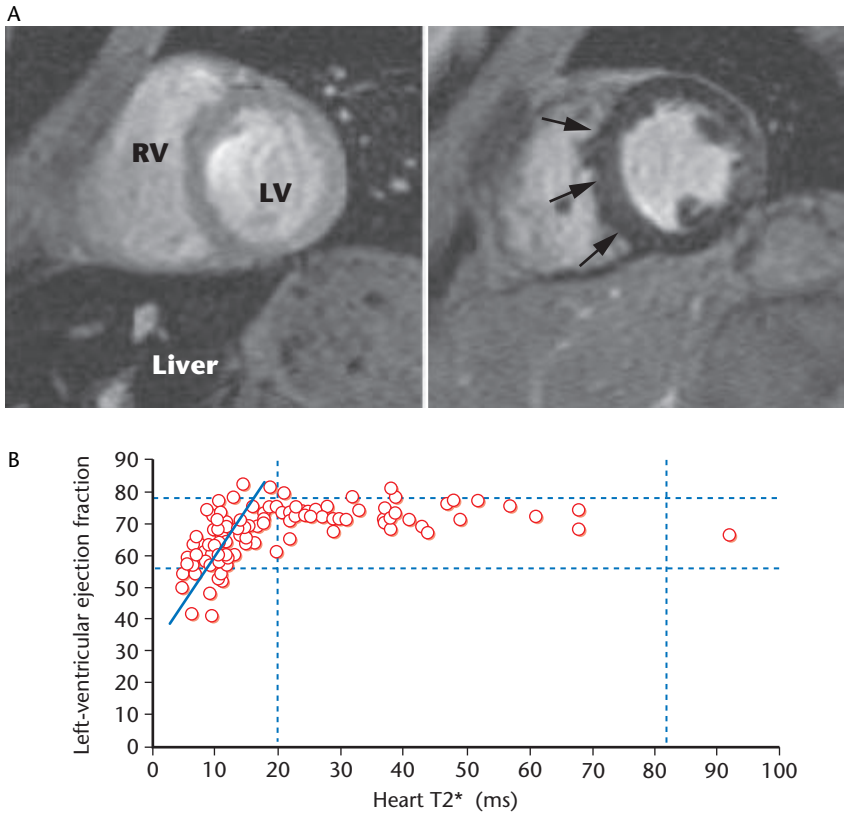

Figure 3.9 (A) T2* CMR in iron overload cardiomyopathy. The left panel shows an iron-loaded liver (dark) but normal myocardial signal. If a liver biopsy was performed, this would suggest iron loading, and chelation therapy might be increased with the risk of significant side-effects. The right panel shows a counter example, where the liver is normal but the heart is iron loaded (arrows). If a liver biopsy were performed on this patient, it would be falsely reassuring and the patient would be at risk of cardiac complications. The inter-organ disparity in iron loading explains why heart failure is the biggest cause of mortality in thalassaemia patients. (B) The relation between myocardial T2* and the ejection fraction. The normal myocardial T2* is > 20 ms, and this is associated with a normal ejection fraction but below this the ejection fraction falls with iron toxicity. Reproduced from Anderson *et al.*, *Eur Heart J* 2001, **22**: 2171–2179.

and increased volumes and mass typical of remodelling in heart failure [36]. Liver and heart iron can be at wide variance making clinical management using heart iron essential (Fig. 3.9). Myocardial T2* increases in thalassaemia patients undergoing intensive iron chelation treatment for heart failure as the heart function improves. The technique can now be completed in a single breathhold, making it cost-effective in countries with large patient numbers. In addition, early results suggest oral chelators may have preferential effects on myocardial iron compared with the established subcutaneous injected therapy.

Arrhythmogenic right ventricular cardiomyopathy

Structural and functional abnormalities of the right ventricle are well seen by CMR and therefore it is used in expert centres for the investigation of arrhythmogenic right ventricular cardiomyopathy (ARVC). CMR assists in locating diagnostic criteria for ARVC including the presence of regional wall motion abnormalities, increased volumes, morphological abnormalities, fatty infiltration and left-ventricular involvement (Fig. 3.8). Follow-up of right ventricular volumes over time can be helpful, as the condition is progressive and it can present in the early concealed phase. Scan interpretation is not straightforward, however, because the right ventricle has significant variation of normality, including hypokinesia at the moderator band insertion, variable trabeculation, and epicardial fat deposits that may mask the normal thin right ventricular myocardium, except in the best quality images. Fatty infiltration can also occur in circumstances other than ARVC. Recent work suggests that late gadolinium enhancement may be useful to demonstrate the fibrous replacement in the right ventricle that occurs in ARVC. Another protocol of interest is use of fat suppression imaging, which allows signal from fat to be reduced, which leaves the normal right ventricular myocardium better seen and fatty infiltration as dark areas. More work needs to be done in the use of CMR in ARVC. There is no doubt about its value, but no technique is ideal in investigating this difficult condition at present.

Myocardial sarcoidosis

Sarcoidosis of the heart is uncommon, but is a well-recognized cause of sudden death. The clinical diagnosis is difficult, although changes in the ECG can be indicative. Late gadolinium enhancement CMR has been used to show myocardial abnormalities in presumed areas of fibrosis in sarcoidosis [37], but more experience is needed. T2-weighted sequences may also be abnormal in active myocardial inflammation.

Myocardial amyloidosis

CMR can show the features of restrictive cardiomyopathy such as in amyloidosis, with diastolic dysfunction, ventricular hypertrophy and interatrial septum thickening. Recently, amyloid infiltration has been shown using late gadolinium enhancement, with a global subendocardial pattern that results from dominant interstitial expansion of the endocardial layer with amyloid protein.

Myocardial non-compaction

Non-compaction is a congenital disorder of endomyocardial embryogenesis in which the myocardium fails to compact properly and deep clefts occur in the left ventricle. It is associated with progressive dysfunction, arrhythmias and systemic embolism. The diagnosis can be made by echocardiography but CMR depicts the abnormality well, with comprehensive ventricular coverage if there is limited involvement (Fig. 3.8), and underlying fibrosis can be shown with late gadolinium enhancement.

Myocarditis

The clinical diagnosis of myocarditis is often difficult and may mimic infarction. A number of reports indicate that CMR may be useful in this diagnosis. Focal increase of myocardial signal is seen in acute myocarditis with gadolinium-enhanced T1-weighted spin-echo imaging at 1-2 min after injection, and myocardial enhancement relative to skeletal muscle may be increased [38]. The relative enhancement falls over time and is predictive of long-term ventricular function. T2-weighted spin-echo imaging may also show high signal. Late gadolinium enhancement CMR has also been shown to be abnormal in the acute phase, particularly in the epicardial portion of the lateral wall (Fig. 3.8) [39].

Valvular heart disease

Although echo Doppler is widely used for the diagnosis and follow-up of valvular disorders, it can be difficult in the individual patient to quantify the severity of the lesion, to judge the impact on ventricular morphology and function, and to evaluate prognosis with respect to timing of surgical vs. pharmacological treatment. CMR,

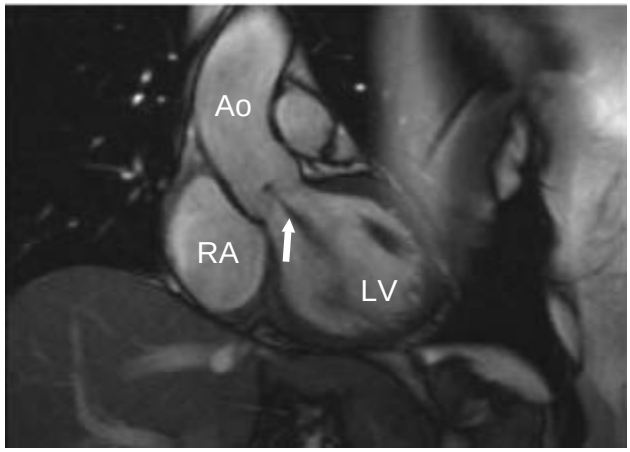

Figure 3.10 Coronal image in mid-diastole from an SSFP cine acquisition. There is a jet of aortic regurgitation (arrow). Ao, aorta; LV, left ventricle; RA, right atrium.

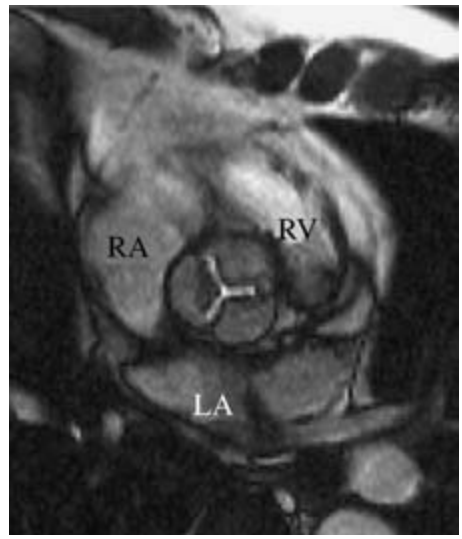

Figure 3.11 Planimetry of the aortic valve area in aortic stenosis. The tight tri-foil shape of the aortic valve can be seen, and the valve area can be planimetered directly. Good correlation of this technique with other investigations has been shown (RA, right atrium; RV, right ventricle; LA, left atrium). Reproduced with permission from Kupfahl *et al.*, *Heart* 2004, **90**: 893–901.

although presently underused for this indication, is useful in this area [40]. Breath-hold spin-echo sequences (for morphology) and the SSFP cine sequences (for dynamic visualization) can reliably study normal and abnormal valves. Turbulence of flow resulting from stenosis or regurgitation causes signal loss on cine sequences allowing ready identification of the abnormality (Fig. 3.10). The size and extension of the signal loss, however, is only a semi-quantitative measure for lesion severity because of the influence of haemodynamics, shape of the valve and parameters of the sequence, just as in colour flow mapping in echo Doppler. Imaging perpendicular to the stenotic valve with thin, adjacent slices enables the planimetry of the stenotic area (Fig. 3.11) [41]. Through plane motion, signal voids because of turbulence or calcification and distorted valve morphology may interfere with this measurement but good results have been reported. Velocity mapping permits the quantification of peak and mean flow velocities (m/s) (as with Doppler) as well as volume flow (ml/s) at multiple sites in the heart. Short TE sequences are needed to avoid loss of velocity information with turbulence. Integration over time of volume flow provides stroke volume, as well as antegrade and retrograde flow volumes. Combining such measurements with each other and with the stroke volumes from the left and right ventricles enables the calculation of gradients, resistance, valve area, regurgitant volumes and fraction. The impact of valvular dysfunction can be reliably and reproducibly followed over time by measuring myocardial mass, cavity volumes and shape. End systolic volume (among others) has been shown to be an important prognostic factor. Automated tracking of valve through plane motion may in the future improve the reliability of velocity-encoded measurements and make CMR the optimal technique to quantify valvular dysfunction.

Aortic regurgitation can be quantified by measuring retrograde diastolic flow immediately above the valve and below the coronary ostia. By dividing retrograde by antegrade flow volume, the regurgitant fraction is obtained. A similar approach is less obvious for mitral insufficiency because of the larger, less circular mitral ring area and the three-dimensional motion of the valve. Eccentric jets can also cause problems. The difference measurement between stroke volume obtained from cavity measurements and antegrade flow in the aorta is therefore a more reliable technique. For stenosis assessment, both in- and through-plane velocity measurements can be used, but in both instances multiple parallel planes are required to optimize alignment and to obtain true maximal velocities, which can be inserted in the modified Bernoulli's equation for calculation of gradients and valve area with the continuity equation [42].

It is safe to perform CMR in all prosthetic valves, although the metal in the prostheses causes focal artefacts that can obscure small jets. Quantification of valvular regurgitation remains possible, but even more care has to be taken to adjust the acquisition plane to the motion of the valve. Endocarditis lesions can be visualized if they do not show a rapid, erratic motion pattern that makes them 'invisible' on gated sequences but, typically, echocardiography is preferred. Real-time CMR may make

imaging of endocarditis lesions more reliable. Overall, in valve disease, CMR is a valid alternative when echocardiographic quality is suboptimal and is the technique of choice for individual patient follow-up with respect to volumes and mass.

Congenital heart disease

Congenital heart disease is a major indication for CMR. The three-dimensional character of CMR, together with the ability to quantify local flow and therefore shunts, the absence of radiation and the difficulties of using echocardiography post surgery, have all contributed to the successful use in this indication [43]. The full spectrum of CMR sequences is used in congenital heart disease: SSFP sequences for overall anatomy and function (left-ventricular, right ventricular and atrial volumes, stroke volumes and ejection fraction, myocardial mass); spin echo for morphological details, T2 imaging for tissue characterization; velocity mapping of local flow and for valvular function (aorta, pulmonary artery, caval veins, pulmonary veins, grafts and conduits, valve planes) and gadolinium angiography for three-dimensional representation of the great vessels and complex anatomy.

Viscero-atrial situs

The viscero-atrial situs (situs, solitus, inversus, ambiguous) and the malposition of the heart (dextrocardia) can be more easily obtained with CMR, as the technique offers a large field of view which includes the surrounding structures, including the abdomen, and identification of the different chambers from morphological and functional characteristics. A full set of images in the three orthogonal planes (transverse, sagittal, coronal) is the basis for this analysis. Depending on the anomalies observed, further images, taken in oblique planes, can be combined with functional imaging.

Atria and veins

Atrial septal defect can usually be visualized with echocardiography (especially transoesophageal echo), but the impact on the circulation (shunt quantification [44], right ventricular dilatation and function) is better evaluated with CMR. By measuring the flow in the ascending aorta and in the pulmonary artery the shunt flow and fraction can easily be determined. Right ventricular dimensions and function are notoriously difficult to evaluate with echo; CMR can quantify volumes, ejection fraction and pulmonary valve flow. Partial anomalous pulmonary venous return can be difficult to detect even with transoesophageal echocardiography. CMR visualizes well the (sometimes very variable) morphology of the pulmonary veins, but can also measure the flow in the aberrant vein, calculate the shunt fraction and show the abnormal connection [45]. Systemic venous abnormalities or variants can be visualized with contiguous two-dimensional scanning or three-dimensional volume acquisitions (left superior vena cava, interrupted inferior vena cava). After surgery, for example repair for transposition of the great arteries, the reconstructed venous conduits and baffles may become obstructed and stenotic, and the morphology and degree of stenosis can be measured from cine and flow imaging.

Atrioventricular connections

CMR can be used to identify atria and ventricles using characteristic morphological features, allowing the demonstration of discordant atrioventricular connections. Abnormal morphology or function of the valves (straddling, atresia, regurgitation, stenosis) can be visualized. A reliable quantification of ventricular volumes and function can be used for surgical decisions (repair vs. Fontan).

Ventricles

Complex ventricular anomalies (tetralogy of Fallot, univentricular hearts, valve atresia) can be depicted with CMR and the shunt fraction and morphological and haemodynamic consequences can be quantified. This can help in treatment decisions. Ventricular septal defects can be visualized (jet on cine images) and the shunt quantified, but it is mainly in complex lesions (double outlet) that CMR proves superior to echocardiography.

Valves

Although direct depiction of valves is less good with CMR than echocardiography, its main importance lies in the quantification of regurgitation and the impact on the receiving chamber, especially for the right ventricle. An example is pulmonary regurgitation after patch surgery for tetralogy of Fallot, where it is clinically difficult to decide on the appropriate timing for valve replacement.

Great arteries and conduits

Coarctation of the aorta is the most common anomaly of the thoracic aorta. CMR can visualize the lesion itself but also the collateral circulation. By comparing flow

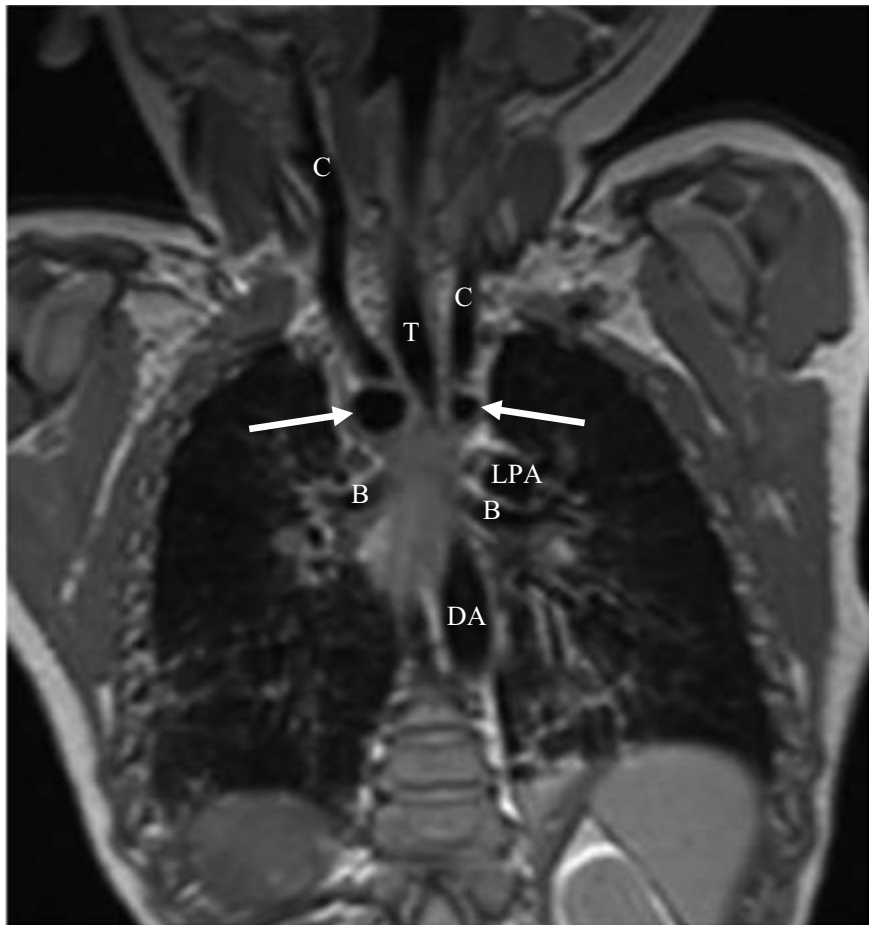

Figure 3.12 CMR in the posterior coronal plane (close to the spine) in a patient with double aortic arch seen in cross-section (arrows). B, bronchus; C, carotid artery; DA, descending aorta; LPA, left pulmonary artery; T, trachea.

before the coarctation and at the level of the diaphragm, the collateral circulation can be quantified and used to judge the success of invasive treatment. Other abnormalities of the aorta (double aortic arch, aneurysm of the sinus of Valsalva, dilatation in Marfan's and Ehlers–Danlos syndromes) can be followed over time (Fig. 3.12). Patent ductus arteriosus can be easily seen with echo in newborns, but in older patients CMR can be more reliable. Abnormalities of the pulmonary circulation in patients with reduced pulmonary artery flow or systemic to pulmonary collaterals, as well as pulmonary anomalies can be shown with CMR. Comparing flow in the right and left pulmonary artery, and comparing these to systemic return flow, can help in evaluating the severity of the lesions and the options for therapy. Also after intravascular or surgical treatment CMR can be useful to evaluate the effects and evolution (to stenosis) of the intervention.

Postoperative follow-up

CMR is very helpful after surgery for complex anomalies, as the echocardiographic quality is often degraded and a need exists for a quantitative technique that can reliably follow volumes, function and morphology over time. This is especially true for conduits and for the right ventricle, which is often overloaded as it functions as the systemic ventricle or due to pulmonary insufficiency.

Coronary arteries

CMR is the technique of choice for the diagnosis of congenital coronary abnormalities. It can show the abnormal origin of the artery but also the course with respect to aorta and pulmonary artery which is important for risk and surgical planning in congenital heart disease [22].

Comparison with other modalities

Echocardiography remains the technique of choice in newborns and young infants, as image quality is usually very good and CMR would require sedation or anaesthesia. On the other hand, in older infants, adolescents and adults, in complex pathology and after surgery, CMR is often useful. In the last two conditions, the full advant-

age of CMR becomes evident, offering unlimited image planes irrespective of scar or lung interposition and the capability of localized flow measurements for the evaluation of shunts, stenoses and valve lesions. The CMR information may allow cardiac catheterization to be avoided, significantly shortened or reserved for interventional procedures. For follow-up, CMR usually offers all the necessary information and cumulative radiation can be avoided.

Great vessels

CMR has become the primary imaging modality for assessment of great vessel disease. Gadolinium CMR angiography generates high-resolution three-dimensional angiograms, and velocity mapping provides reliable measurements of blood flow. The most common indications for performing CMR in aortic disease are to depict or follow aneurysms or dissections. Although CMR angiography shows the size, extent and shape of aneurysms, additional use of black-blood imaging is needed for depiction of the vascular wall and peri-aortic soft tissue. Image acquisition in at least two planes is helpful to identify inflammatory changes such as arteritis (Fig. 3.13), perivalvular abscesses and mycotic aneurysms or post-surgical infections. In dilated and especially dissected aortas, it is often necessary to identify the presence of thrombus and distinguish it from slow flow in a patent lumen.

CMR has a high accuracy in diagnosing and excluding aortic dissection [46], and the entire aorta can be imaged within 15 min. Therefore, even in cases with acute disease, CMR is competitive with more commonly used techniques such as CT and transoesophageal echocardiography. Patient monitoring in the magnet is straightforward, but full-time magnet availability with experienced operators may be problematic. The main feature of aortic dissection is the presence of an intraluminal intimal flap, which is easily demonstrated using transverse cine CMR. Gadolinium CMR angiography may provide additional information regarding branch vessel involvement. The presence of pericardial effusions and the function of the aortic valve can also be depicted and quantification of aortic regurgitation is possible using velocity mapping. In practice, CMR is often mostly used for follow-up or in patients with chronic disease. This is because CMR is free from ionizing radiation, MR contrast agents are not nephrotoxic and serial measurements at predefined landmarks are more reliably performed than from transoesophageal echocardiography.

Intramural haematoma is characterized by the presence of a false lumen without blood flow. The likely mechanism is intramural haemorrhage resulting from leaking vasa vasorum. Black-blood pulse sequences, such as spin-echo sequences with T1 weighting, are especially useful for depicting the bright crescentic thickening of the aortic wall. Another acute aortic syndrome is the penetrating aortic ulcer, which occurs predominantly in the

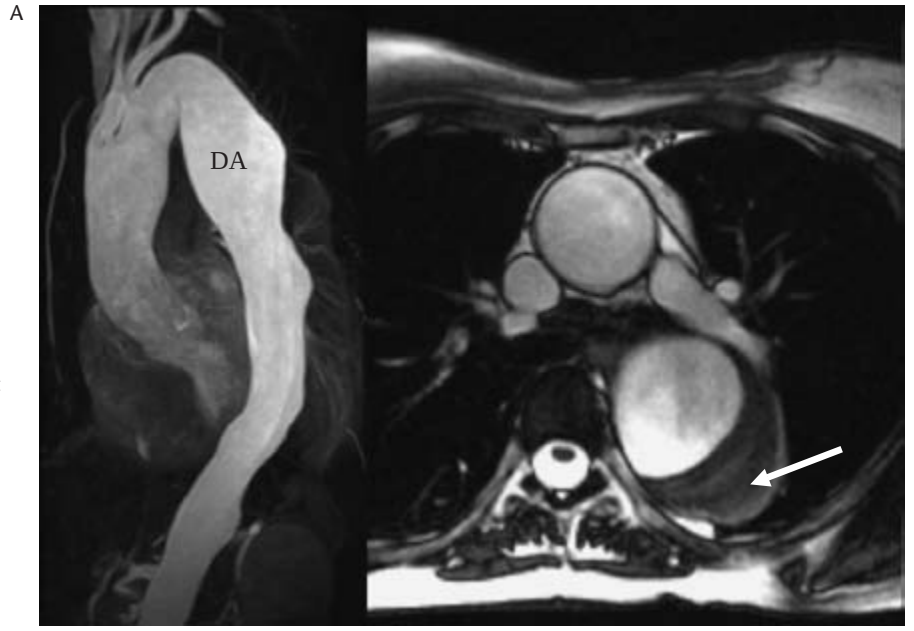

Figure 3.13 Aortic aneurysm in a patient with arteritis. (A) Three-dimensional MR angiogram shows grossly irregular contours of the descending aorta (DA) and vertical position of the aortic arch. (B) Transverse cine CMR image shows the large aneurysm of the descending aorta, which is filled to a large part by thrombus (arrow).

elderly with diffuse and severe forms of atherosclerosis. These ulcers can lead to large aneurysms, which may need placement of endovascular stent grafts. Such ulcers can be distinguished from small and benign ulcers by using both black-blood CMR and angiography.

CMR is also useful for depicting the pulmonary vasculature and may be a useful adjunct to functional CMR of right heart abnormalities. However, although the initial experience for pulmonary embolism is promising, pulmonary MR angiography requires long breath-holds, which may not be possible especially in this patient population. Consequently, CT remains the technique of choice for this clinical question.

Pericardium

CMR is able to depict the pericardium and the pericardial space with high spatial resolution. It is thus clinically helpful in patients with suspected pericardial disease in whom echocardiography may provide suboptimal image quality. Moreover, pericardial thickness can be accurately determined, which may be difficult with echocardiography. When compared with CT, CMR has the disadvantage of a longer examination time and inferior image quality in very sick patients who have poorly controlled atrial fibrillation or are unable to hold their breath for a longer period of time. CMR is also inferior in depicting pericardial calcification. However, CMR provides a functional assessment of the abnormalities associated with pericardial disease and this may make CMR the preferred technique in difficult cases.

As pericardial fluid is depicted as a high single intensity space between the epicardium and the fibrous pericardium, even small quantities of pericardial fluid can be reliably detected. This may be important in patients with infectious pericarditis and myocarditis with pericardial involvement (Fig. 3.14). Although systematic comparisons are lacking, the sensitivity and the confidence for detecting especially inferior localized diffusions may be better for CMR than for echocardiography. Acute pericardial inflammation is characterized by enhancement of the (thickened) pericardium following gadolinium MR contrast agent.

To distinguish between restrictive cardiomyopathy and constrictive pericarditis, reliable measurements of pericardial thickness are important. CMR is highly accurate in distinguishing between these two clinical entities, although it is limited in patients who develop constrictive pericarditis following cardiac surgery when the pericardium may have normal thickness [47]. Another helpful feature to distinguish restrictive cardiomyopathy from constrictive pericarditis is that CMR identifies amyloid heart disease, one of the most common causes of restrictive cardiomyopathy. CMR is also helpful to identify pericardial cysts and distinguish them from other tumours. It is also possible to identify a rare pericardial abnormality,

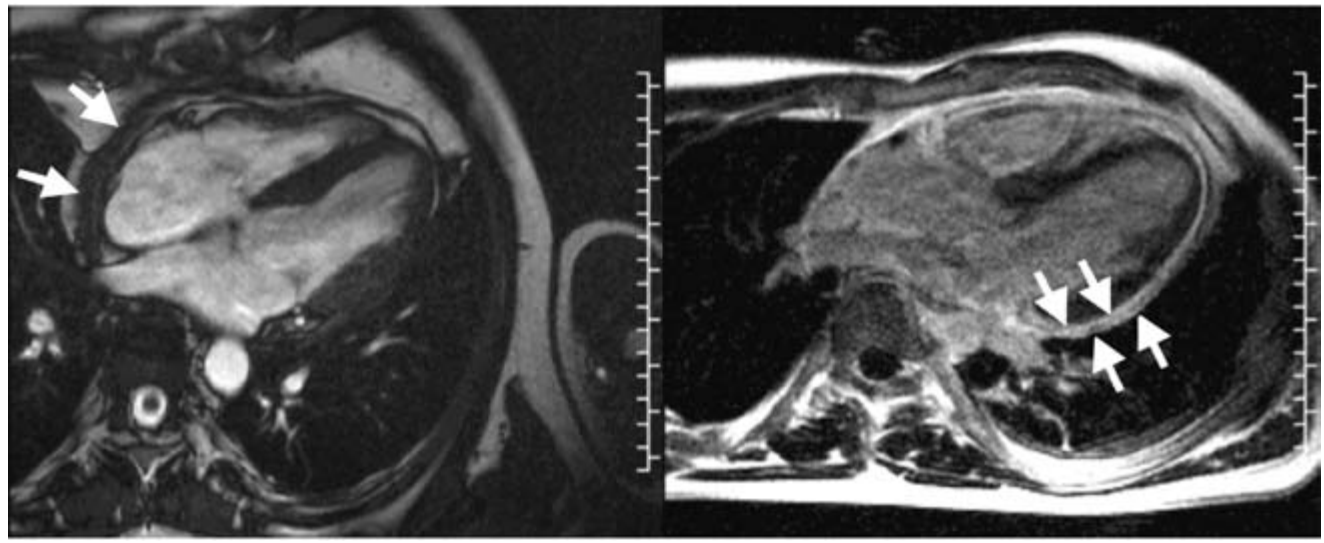

Figure 3.14 Patient with acute tuberculous pericarditis. (A) Cine image demonstrates pericardial thickening covering the right atrial surface (arrows). (B) Late gadolinium enhancement CMR shows that both layers of the pericardium are inflamed over the left ventricle with marked enhancement (arrows). The potential mechanism of tuberculous spread to the pericardium is suggested by the infiltration of the adjacent left lung.

absence of the pericardium or partial absence of the pericardium, by the unusual position of the heart.

Tumours and masses

Chest radiography and echocardiography are the first-line imaging techniques to visualize cardiac tumours and masses. CMR is useful to better obtain the relation with surrounding tissue and organs (extension, infiltration, vascular relation) and for tissue characterization, both of which can help to better plan treatment [48]. Simple visualization of a mass is usually carried out with the cine SSFP sequences, but tissue characterization requires T1- and T2-weighted spin-echo imaging, fat suppression and gadolinium studies including first pass, early enhancement and late enhancement for interpreting vascularity, necrosis or thrombus formation (Fig. 3.15) and fibrosis or expansion of the interstitial space. Together with the location of the tumour (right heart more malignant), its size, homogeneity and extension in surrounding tissues (malignancy), the presence of pleural and pericardial effusion (malignant, metastatic), this allows for a good but not perfect characterization of the mass. Furthermore the haemodynamic and functional effects of the tumour can be quantified. Cardiac tumours can be primary (benign or malignant) or metastatic. Malignant tumours of the heart often have a characteristic panoply of diagnostic features (Fig. 3.16).

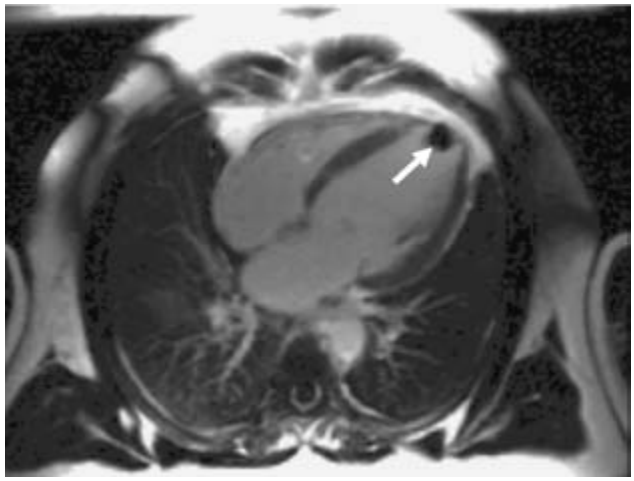

Figure 3.15 Ventricular thrombus. After gadolinium injection with early inversion recovery imaging at 2 min, the mass is well defined and the very low signal implies low penetration of gadolinium and low vascularity. This is compatible with thrombus in this patient with cardiomyopathy.

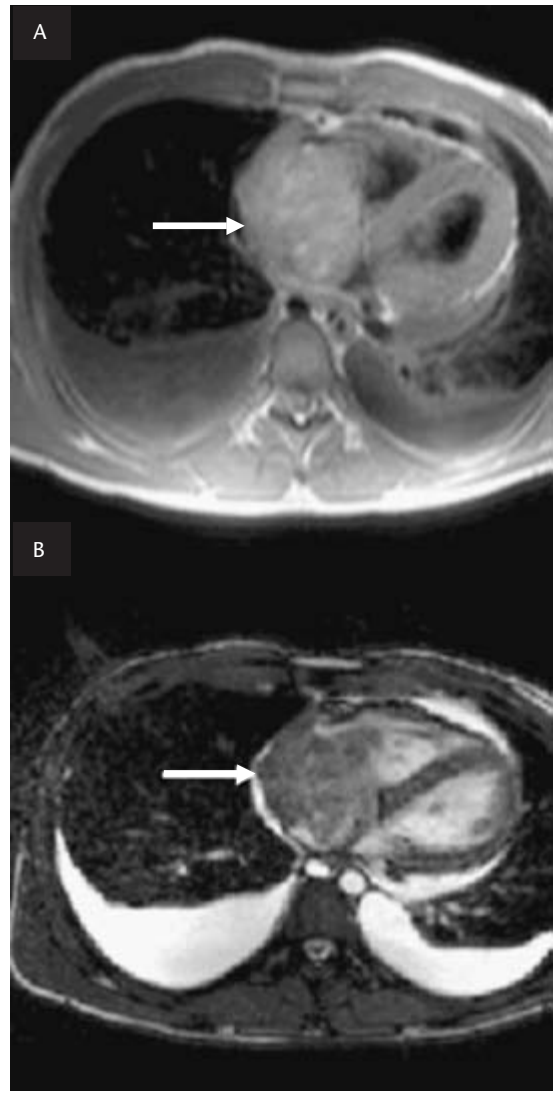

Figure 3.16 Sarcoma. The T1-weighted spin-echo image (A) in the transaxial plane shows a mass in the right atrium (arrow), which is irregular and of heterogeneous signal. The late gadolinium enhancement image (B) shows pericardial effusion with invasion and heterogeneity of signal suggesting patchy fibrosis. Many of these features suggest malignancy.

Interventional cardiovascular magnetic resonance

Interventional CMR is in its infancy, and clinical applications in the heart are only just starting to emerge. The technical innovations needed for interventional CMR are catheter tracking, real-time imaging, MR-compatible materials and devices and new imaging sequences. Two

main strategies exist for catheter tracking, passive and active, the former using regular sequences adapted to visualize the thin catheter, the latter using the catheter as an MR antenna allowing three-dimensional localization with superimposition of position on a morphological image. Clinical placement of devices has been greatly advanced by the development of robust real-time imaging, which is essential to allow interactive manipulation. Most catheters and devices contain metal that not only causes artefacts on the MR images, but also could induce electrical currents and heat at contact sites, which can be potentially harmful, and therefore MR-compatible devices such as catheters, stents and closure devices are now being developed.

The present areas of clinical use of interventional CMR are congenital heart disease, electrophysiology, peripheral vascular disease and stem cell work. In congenital disease, defects have been closed with interventional CMR [49], and implantation of stents and intravascular valves has been pursued. In some cases full CMR implantation and evaluation has been performed, and this area is expanding. In electrophysiology, CMR is used to guide the interventional cardiologist by supplying three-dimensional models of the chambers under investigation so that catheter manipulation is easier. Usually these CMR data are acquired separately at a previous occasion, but in an XMR suite (combined X-ray and CMR in joined rooms) the patient can be shifted between the modalities, allowing for a complete three-dimensional fusion of the CMR and catheterization data. It is also possible to directly visualize ablation lesions, showing their extent and continuity, which allows additional ablation in regions of discontinuity. In peripheral vascular atherosclerotic disease, interventional CMR has proved easier because of the larger vessel size and full diagnostic and therapeutic MR procedures are therefore feasible. Interventional CMR has also been used for direct injection of gene material or stem cells in the region of a previous infarct [50]. This requires a real-time sequence to visualize the infarction. By including iron particles in the cells, the location, extent and migration of the injected material can be followed *in vivo* over time.

Personal perspective

CMR has rapidly developed in recent years and now fulfils an indispensable role in major cardiac centres in the investigation and management of cardiovascular disease. Currently, the most frequent clinical referrals are in cardiomyopathy, arterial angiography (non-coronary), congenital heart disease and viability/infarction assessment. However, there are two other major sources of clinical referral, which can be given the generic titles of 'unusual or uncertain cardiovascular pathologies' and 'suboptimal results from other imaging techniques'.

However, the role of CMR in coronary artery disease is expanding relatively slowly for three main reasons: conventional techniques are well-entrenched clinically; there is limited availability of dedicated CMR scanners, CMR expertise and appropriate reimbursement; and publication of larger multicentre clinical trials with outcomes analysis is needed. The exception, as noted above, is the use of late gadolinium enhancement to identify infarction. This new high-resolution technique has made significant contributions to our understanding of infarction and viability because the circumferential and transmural extent of necrosis and scar can be imaged *in vivo* for the first time. Thus, not only is CMR now the most sensitive clinical method for detection of infarction other than cardiac enzymes in the acute phase, but also the presence of stunning and hibernation and therefore the likelihood of functional recovery can be directly determined. In CAD, the next likely area for significant clinical application by CMR will be perfusion imaging. The advantages include high resolution, lack of radiation burden, quantitative analysis of perfusion and a fast procedure time for the patient (approximately 30 min). The optimal imaging sequence and clinical protocol needs to be finalized but will come in the near future.

The future for CMR is bright. No other technology offers the combination of safety, image quality and versatility and the incorporation of CMR into cardiology training programmes recognizes the importance of this new technology for trainees and established cardiologists.

4 Cardiovascular Computerized Tomography

Pim J. de Feyter and Stephan Achenbach

Summary

The high prevalence of coronary artery disease with its associated high morbidity and mortality rates provides a strong stimulus for the development of a non-invasive diagnostic modality to image the coronary arteries. Contrast-enhanced computerized tomography (CT) coronary imaging has emerged as a reliable diagnostic modality to detect significant coronary stenoses in selected patients who have a slow (< 70 beats per minute) and stable heart rate. Severe calcifications and irregular heart rhythms significantly limit the clarity of CT coronary imaging, while the relatively high radiation exposure is of concern.

The cross-sectional nature of CT coronary imaging allows the non-invasive assessment of atherosclerotic changes in the coronary wall and has the potential for early detection of coronary atherosclerosis in asymptomatic individuals.

CT imaging for pulmonary embolism is highly accurate and may be considered the first-choice diagnostic option. CT imaging of the great thoracic vessels, for cardiac function, and of heart valves, cardiac tumours and thrombi or pericardial disease is feasible but the non-radiation diagnostic modalities echocardiography or magnetic resonance imaging should be considered the first diagnostic options.

Introduction

The development of X-ray computerized tomography (CT) in the 1970s is considered one of the greatest advances in diagnostic imaging because of its ability to image non-invasively the internal structures of the body with unprecedented accuracy. No other modality allows the scanning of large body regions with comparable spatial resolution and contrast within such a short time. The high spatial and tissue resolution of CT can be achieved because the collimated X-ray beam is transmitted selectively through a specific cross-section; this minimizes superimposition of structures above and below a specific cross-section (slice) while also reducing X-ray scatter and improving image contrast. Finally, CT makes use of refined detectors that can measure small differences in tissue contrast (to less than 0.1%).

The first commercially available CT system with an acquisition time fast enough to image dynamic cardiovascular structures was the electron-beam computerized tomography (EBCT) scanner. EBCT was initially developed in the late 1980s for functional analysis of the left ventricle (and was therefore originally called 'cine CT') [1] but soon thereafter became mainly used for the detection and quantification of coronary artery calcification. In 1995, contrast-enhanced EBCT coronary angiography was first described [2] and in subsequent evaluations was demonstrated to permit non-invasive detection of haemodynamically relevant coronary artery stenoses with moderate reliability.

'Spiral' or 'helical' CT—which combines continuous rotation of the X-ray tube with continuous movement of the patient table along the *Z*-axis—was introduced in the 1990s and, unlike EBCT, this technique has undergone such extremely rapid development in the past few years that it has now emerged as a very reliable, non-invasive

cardiovascular imaging technique that is able to create practically motion-free images of the heart and coronary arteries. Consequently, several studies have shown that spiral CT permits the detection of coronary stenoses and extraluminal coronary plaques.

Basics of computerized tomography

CT is an X-ray-based imaging technique. An X-ray source rotating around the patient emits a narrowly collimated fan-shaped beam of X-rays that passes through the body. Various tissue types (heart, lungs, etc.) have different absorption characteristics and the attenuation of the X-ray beam is recorded by detectors on the opposite side to the source. Based on the attenuation values measured at a multitude of projections, cross-sectional images are reconstructed (Fig. 4.1). To reconstruct one image, it is necessary to acquire data over an angle of at least 180° (one-half rotation).

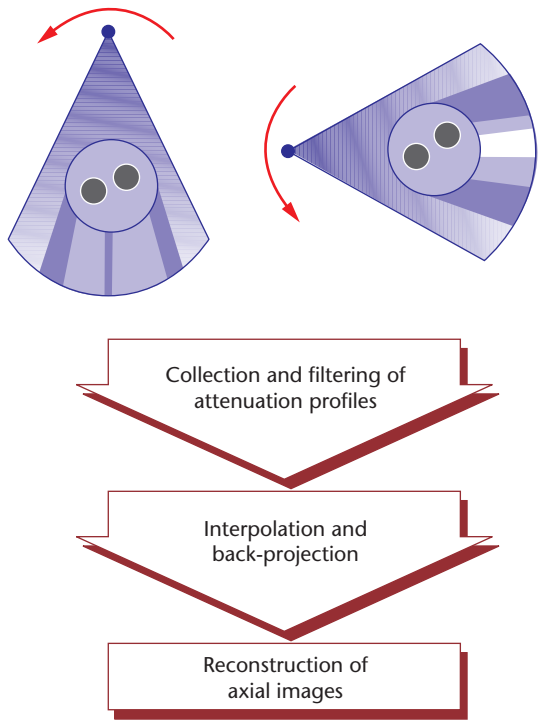

Figure 4.1 Principles of computerized tomography. Multiple attenuation profiles from different angles are acquired during a 180° rotation of the X-ray tube and detector system. After filtering of the data, the projection profiles are interpolated in the *Z*-axis (longitudinal axis), to create complete datasets (profiles) at each plane position. Using back-projection reconstruction algorithms, axial source images are created from the interpolated projection profiles.

After acquisition of the X-ray data, many parameters that can individually be chosen will influence the appearance of the reconstructed image. The size of the reconstructed image ('field of view') is usually adapted to encompass the target organ to be investigated. Images are reconstructed with a 1024×1024 or 512×512 matrix size so that the size of one image pixel will be:

$$\text{pixel size} = \text{field of view/matrix size}$$

The thickness of the reconstructed image can also be adjusted after the scan itself. It can be between 0.5 mm and several millimetres. Frequently, slice thickness will be set to a thickness somewhat larger than the collimation to reduce image noise. Usually, the reconstructed images have a distance ('reconstruction increment') that is lower than the slice thickness, so there is overlap between consecutive images (e.g. data are acquired with 0.6-mm collimation, and reconstructed with 0.75-mm thickness and 0.5-mm increment). Finally, appearance of the reconstructed image is influenced by the reconstruction kernel, a filter algorithm used in the reconstruction process which determines the relationship between resolution of the image ('sharpness') and image noise.

X-ray attenuation values measured by CT (also called ('CT number') are expressed in 'Hounsfield Units' (HU). The CT number of a given pixel is normalized to that of water:

$$\text{CT number (HU)} = [(\mu_{\text{tissue}} - \mu_{\text{water}})/\mu_{\text{water}}] \times 1000$$

where μ_{tissue} is the attenuation value of tissue and μ_{water} is the attenuation value of water. By definition, water has a CT number of 0 HU, air (no attenuation) has a CT number of –1000 HU. Bone (highly attenuating) usually has a CT number between + 1000 and + 3000 HU. Each pixel in the reconstructed CT image is assigned a brightness value in proportion to the determined CT attenuation, to create the digital reconstruction image. The digital reconstruction image is then converted into a grey-scale image (in which the shades of grey represent CT attenuation values) for display on a cathode ray tube, television monitor, or on film. However, the human eye can only distinguish a limited number of grey levels. Specific CT numbers within the image are therefore mapped to a smaller range of grey-scale levels. The 'window width' determines the range of grey levels to be displayed and allows the selective display of a restricted range of tissues. The centre of the range of CT numbers that are displayed is the window level. The tissue grey-scale ranges from white at one end of maximum attenuation (highest CT number in the range) to black at the other end where attenuation is minimal (lowest CT number in the range),

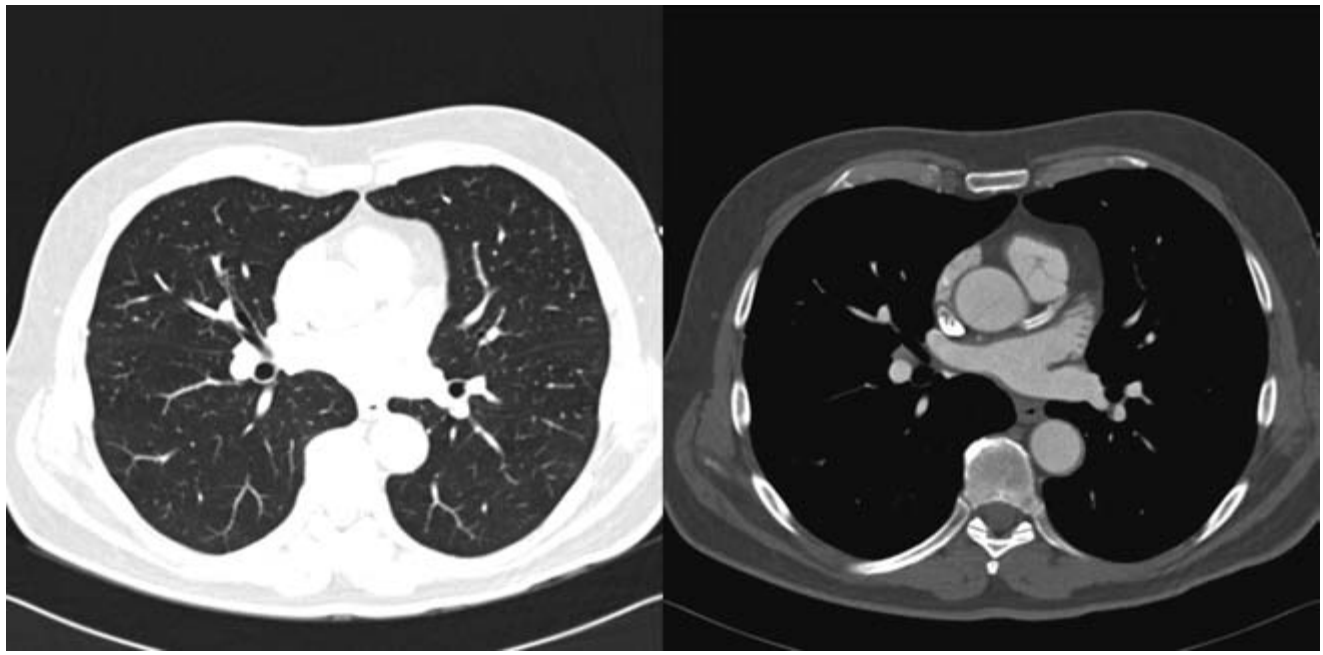

Figure 4.2 Axial CT image of the chest. Axial images of the thorax at the level of the origin of the left main coronary artery. The same image is displayed using (A) a 'lung' window (used for evaluation of lung parenchyma) and (B) a 'cardiac' window (used for evaluation of cardiac structures). The image is displayed as if looking from the patient's feet upwards.

with various shades of grey in between. The process of changing the CT imaging grey-scale is referred to as 'windowing'. Windowing is very useful because it is used to suit the needs of the observer reading the images. For instance, reading the heart and coronary arteries requires window settings in the CT range of soft tissue whereas reading pulmonary abnormalities or bone abnormalities would require window settings matched either to lung tissue or bone tissue (Fig. 4.2).

By convention, CT images are displayed as if looking upwards from the patient's feet.

Special considerations for computerized tomography imaging of the coronary arteries

Visualization of the coronary arteries and coronary stenoses, a major application of cardiac CT, is difficult because the coronary arteries are small, have low X-ray attenuation properties and are in constant, rapid motion during cardiac contraction and respiration. Thus, non-invasive CT coronary imaging requires high spatial and temporal resolution (i.e. time needed to acquire data for the reconstruction of one cross-section), superb low-contrast detectability and fast coverage of the entire heart within one breath-hold—which all have to be met at the same time.

Computerized tomography acquisition modes

Multidetector CT imaging is performed either in sequential mode or spiral mode. In the sequential mode ('slice by slice') the table, and thus the patient, is moved incrementally between successive rotations of the X-ray tube (Fig. 4.3). In the spiral mode, the patient is moved continuously during continuous rotation of the X-ray tube (Fig. 4.4). Because heart motion artefacts can be minimized by using image reconstruction data from the relatively motion-free diastolic phase of the heart cycle, the simultaneously recorded electrocardiogram (ECG) signal is

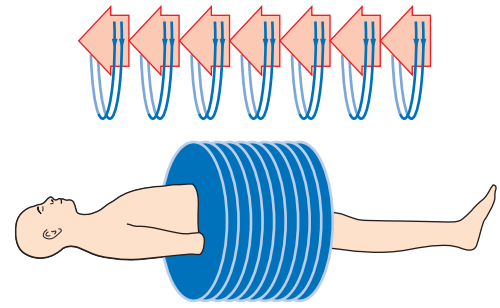

Figure 4.3 CT sequential acquisition mode. The table, and thus the patient, is moved incrementally between successive rotations of the X-ray tube.

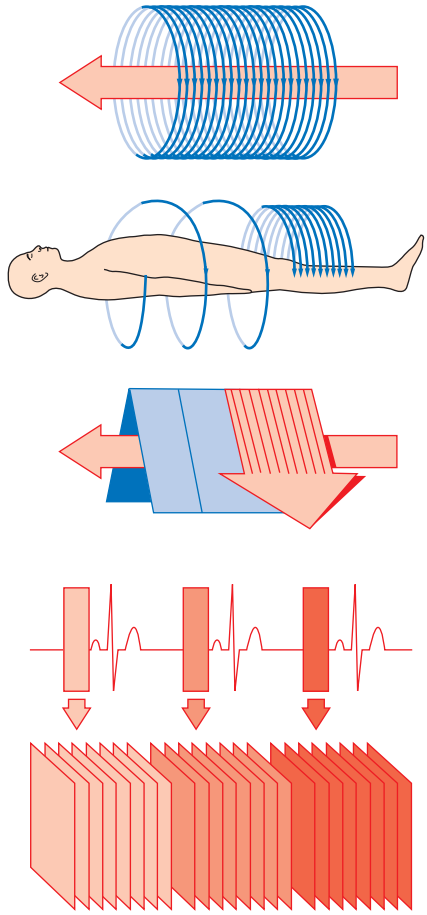

Figure 4.4 CT spiral acquisition mode. The X-ray tube and detectors in the spiral acquisition mode rotate constantly around the patient, while the table is advanced through the gantry. A collimated cone beam passes through the patient and data on X-ray attenuation are constantly collected by multiple rows of detectors. During table propagation, data are continuously acquired by 16–64 parallel detector rows, resulting in a spiral/helical data acquisition pattern from the patient's perspective. Overlapping sampling data, by applying a slow table feed per gantry rotation, are available during the entire cardiac cycle. Retrospectively, ECG-synchronized data from each cycle are extracted for reconstruction of the axial slices.

used to synchronize prospective data acquisition or retrospective data reconstruction in the diastolic phase.

Multidetector spiral computerized tomography

The geometry of the multidetector CT scanner is shown in Fig. 4.5. The most recent generations of multidetector spiral CT (MDCT) scanners are equipped with 16–64 detector rows and a rotation time between 330 ms and 500 ms, and allow high-resolution scanning of large sections in a short time.

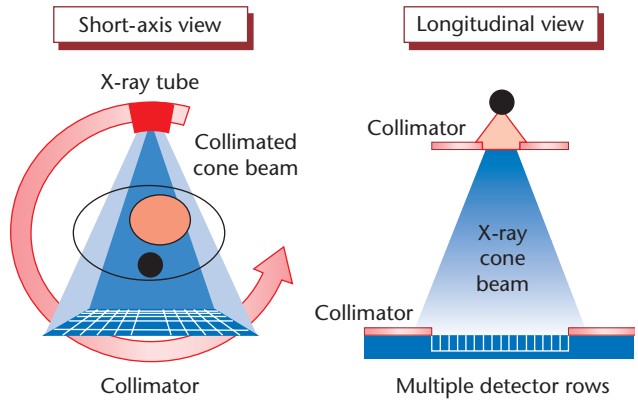

Figure 4.5 MDCT scanner geometry. The rotating X-ray tube produces a collimated cone beam which passes through the patient and the attenuated X-rays are collected on multiple detectors.

To acquire cardiac images during the same cardiac phase, images are reconstructed using retrospective ECG gating (Fig. 4.4). While X-ray data are acquired continuously throughout the cardiac cycle, the ECG is recorded simultaneously. Isophasic (raw) X-ray data are selected for image reconstruction based on the recorded ECG. Although images can be reconstructed at any cardiac time position within the R-to-R interval, reconstructions during the diastolic phase generally contain the fewest motion artefacts. To ensure availability of X-ray data from a sufficient number of projections at any cardiac phase, table feed is set to a speed low enough to assure that each plane position is sampled during an entire cardiac cycle (Fig. 4.6). The advantages of retrospective ECG-gating are the possibility to select the optimal (motion-sparse) reconstruction phase, the opportunity to deal with arrhythmias or faulty ECG signals after the scan, and the potential for functional studies. The disadvantage is the application of redundant radiation (X-ray data sampled during unsuitable cardiac phases and thus not actually used for image reconstruction) and therefore a considerable radiation dose.

Current CT scanners have X-ray tube rotation times of 330–500 ms. Because the first and second halves of the X-ray tube rotation provide comparable data, partial scan (180°) reconstruction algorithms are used that reduce the average temporal resolution down to 165–250 ms. Further improvement of the temporal resolution is possible by combining isophasic data from consecutive heart cycles (Fig. 4.7). If the same section is sampled during more than one cycle, data from several consecutive cardiac cycles can be combined to provide the necessary 180° of data. Thus, data acquisition windows of considerably less than one-half rotation can be used and the temporal resolution is improved. Despite the potential benefits, there are

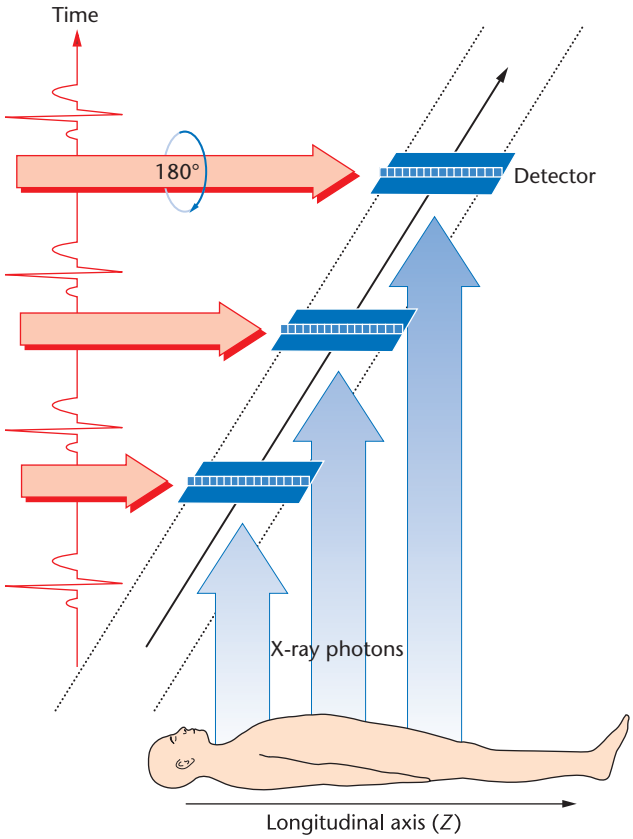

Figure 4.6 MDCT data acquisition. Graph depicting time (and ECG) on the vertical axis and the *Z*-position on the horizontal axis and detector position. Although data are acquired continuously, only data acquired during selectable intervals of approximately 200 ms (during which the gantry rotates 180°) are used for reconstruction. The *Z*-position of the detector rows during these instances needs to cover the entire heart to ensure gapless image reconstruction, which means that each plane position is sampled during at least one entire heart cycle by the consecutive detector rows. Because the position of each detector shifts in the *Z*-direction during these 200-ms periods, interpolation of the data is required to obtain a complete set of attenuation profiles at a given plane position.

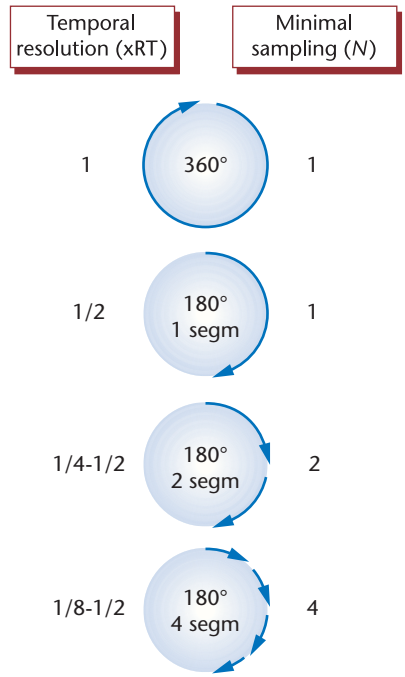

Figure 4.7 Temporal resolution and image reconstruction algorithms. Full scan (360°), monosegment (180°), bisegmental (180°) and quadrosegmental (180°) reconstruction algorithms and the temporal resolution for each as a ratio of the rotation time and required number of cycles during which the same position needs to be sampled.

disadvantages in terms of over-sampling and potentially excessive radiation, heart-rate-dependent effectiveness, and the fact that this approach assumes absolutely identical cardiac motion during each heart cycle.

The effective radiation dose of a four-slice MDCT is estimated to range from 1.0 to 4.1 mSv for calcium scanning and from 6.7 to 13.0 mSv for 'coronary angiography' [3,4], which is significantly higher than the dose of diagnostic coronary angiography reported to be between 2.1 and 5.6 mSv. The effective radiation doses of 16-slice or 64-slice CT scanners for coronary angiography are estimated to be between approximately 8 and 15 mSv. Reduction of radiation exposure can be achieved by using ECG-synchronized X-ray dose modulation which limits full tube current to a short time interval during diastole and reduced tube current during systole. This algorithm may reduce the total radiation dose by approximately 50% [5].

Image evaluation

The result of the reconstruction process is a large stack of overlapping slices, representing the contrast-enhanced heart and coronary arteries during a specific cardiac phase (Fig. 4.8). To optimize reconstructed images for visual analysis, 'windowing' is interactively performed by changing the grey-scale display of the CT values on the screen to improve delineation for the structures of interest.

Cross-sectional images in axial orientation are the source images and form the basis for all assessments. However, to facilitate analysis of the large number of cross-sectional images that is usually generated (200 or more), two-dimensional and three-dimensional image

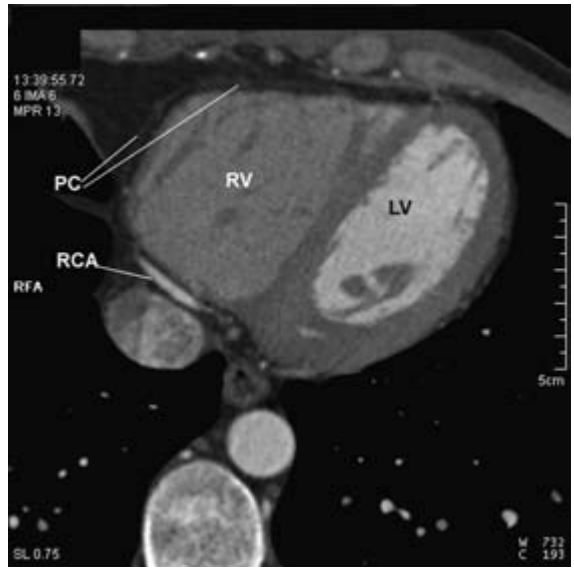

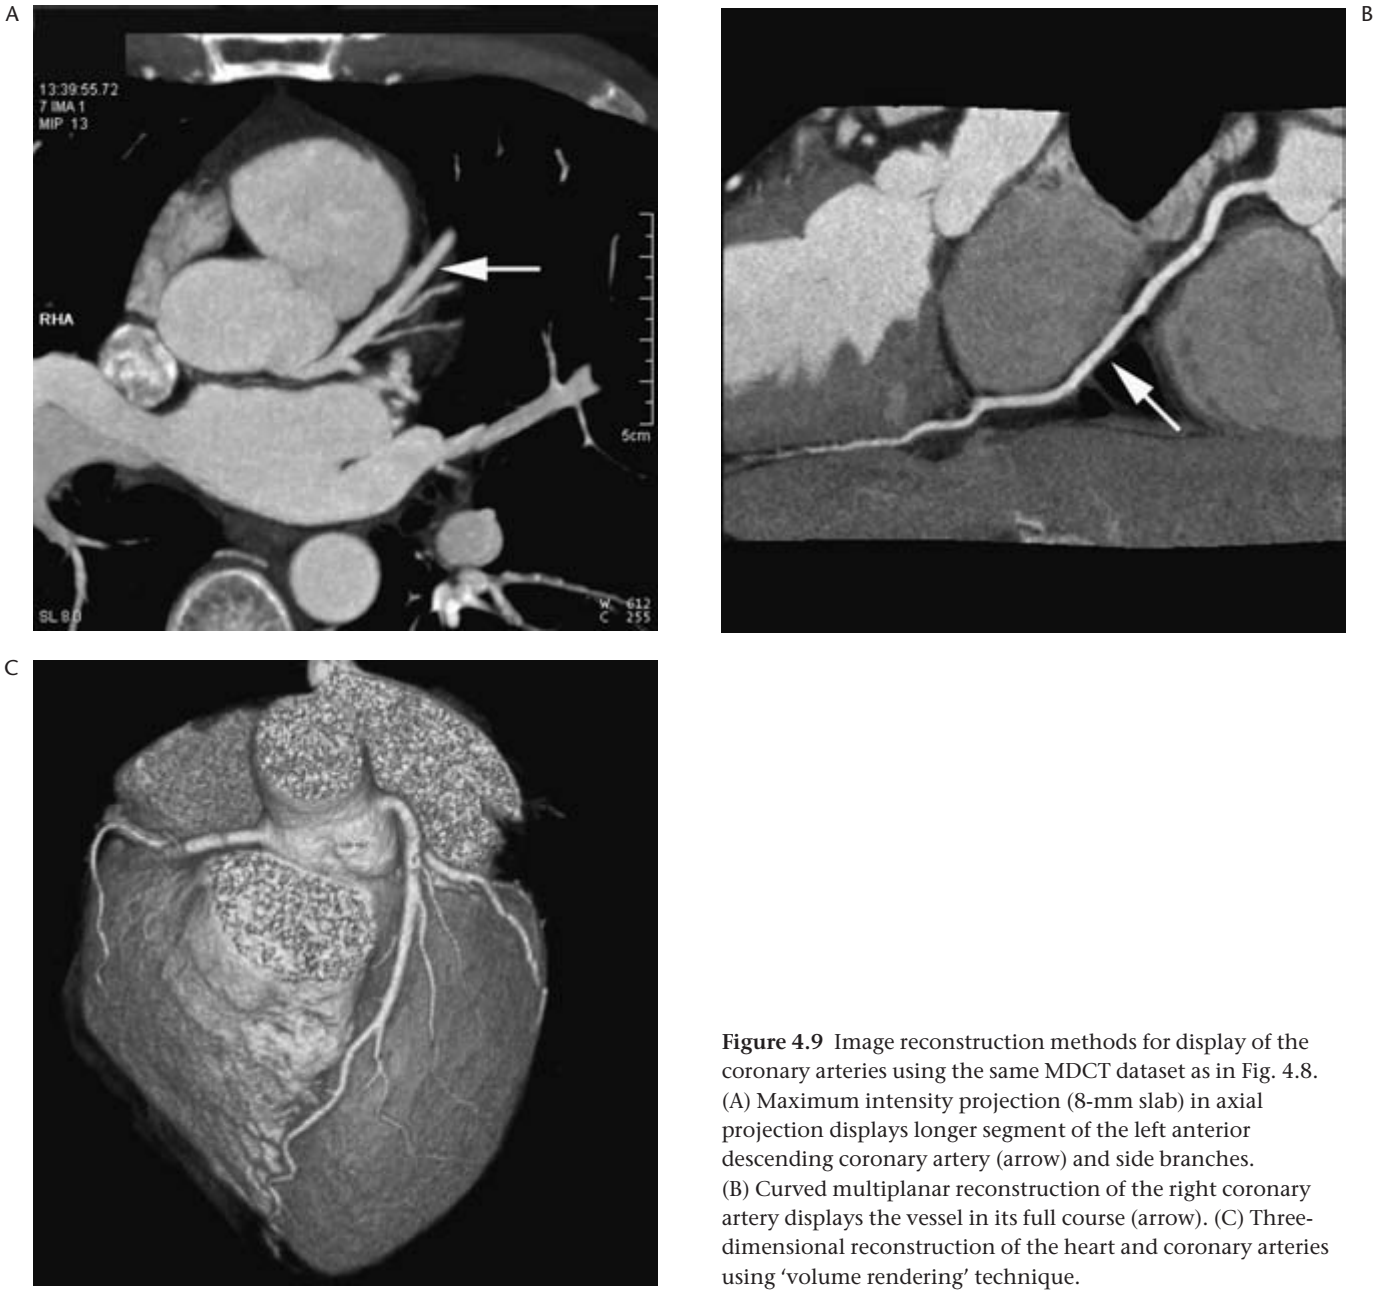

Figure 4.9 Image reconstruction methods for display of the coronary arteries using the same MDCT dataset as in Fig. 4.8. (A) Maximum intensity projection (8-mm slab) in axial projection displays longer segment of the left anterior descending coronary artery (arrow) and side branches. (B) Curved multiplanar reconstruction of the right coronary artery displays the vessel in its full course (arrow). (C) Three-dimensional reconstruction of the heart and coronary arteries using 'volume rendering' technique.

reconstruction methods, such as multiplanar reformation, (thin-slab) maximum intensity projection and volume rendering have been developed (Fig. 4.9). Thin-slab maximum intensity projections are selective two-dimensional displays of the highest densities (e.g. contrast medium, calcium or metal) within a given slab (typically with a thickness of 5–8 mm). In the analysis of 'CT coronary angiography' datasets, they allow for quick assessment

Figure 4.8 (*opposite*) Cross-sectional CT anatomy of the heart. Typical images of the heart acquired by 16-slice MDCT with 370-ms rotation time and retrospective ECG gating after intravenous injection of contrast agent. Reconstructed slice thickness 1.0 mm. Out of a dataset of approximately 250 axial images, six images at typical levels are selected to demonstrate typical cardiac anatomy in CT (A–F). Ao, ascending aorta; CS, coronary sinus; LA, left atrium; LAA, left atrial appendage; LAD, left anterior descending coronary artery; LCX, left circumflex coronary artery; LM, left main coronary artery; LV, left ventricle; PA, pulmonary artery; PC, pericardium; RA, right atrium; RCA, right coronary artery; RV, right ventricle; SVC, superior vena cava.

of luminal integrity, but are sensitive to overlap and less effective in the presence of severe coronary calcification or stents. In these situations, multiplanar reconstructions (two-dimensional cross-sections at freely selectable positions or angles) are more suitable. These cross-sections can be obtained in a two-dimensional plane, or curved along the course of a vessel of interest, to capture the vessel in a single image. Three-dimensional reconstruction of the coronary arteries allows an overview of coronary morphology and its relation to cardiac anatomy (Fig. 4.10). Three-dimensional volume rendering reconstructions are less suited for initial assessment of the coronary lumen, particularly in the presence of stents and calcified plaque tissue. However, a diagnostic advantage of these advanced image reconstruction techniques over evaluation of the axial source images has not been shown and, should a lesion be suspected based on two- or three-dimensional methods of image display, verification and confirmation on the original source images is always necessary.

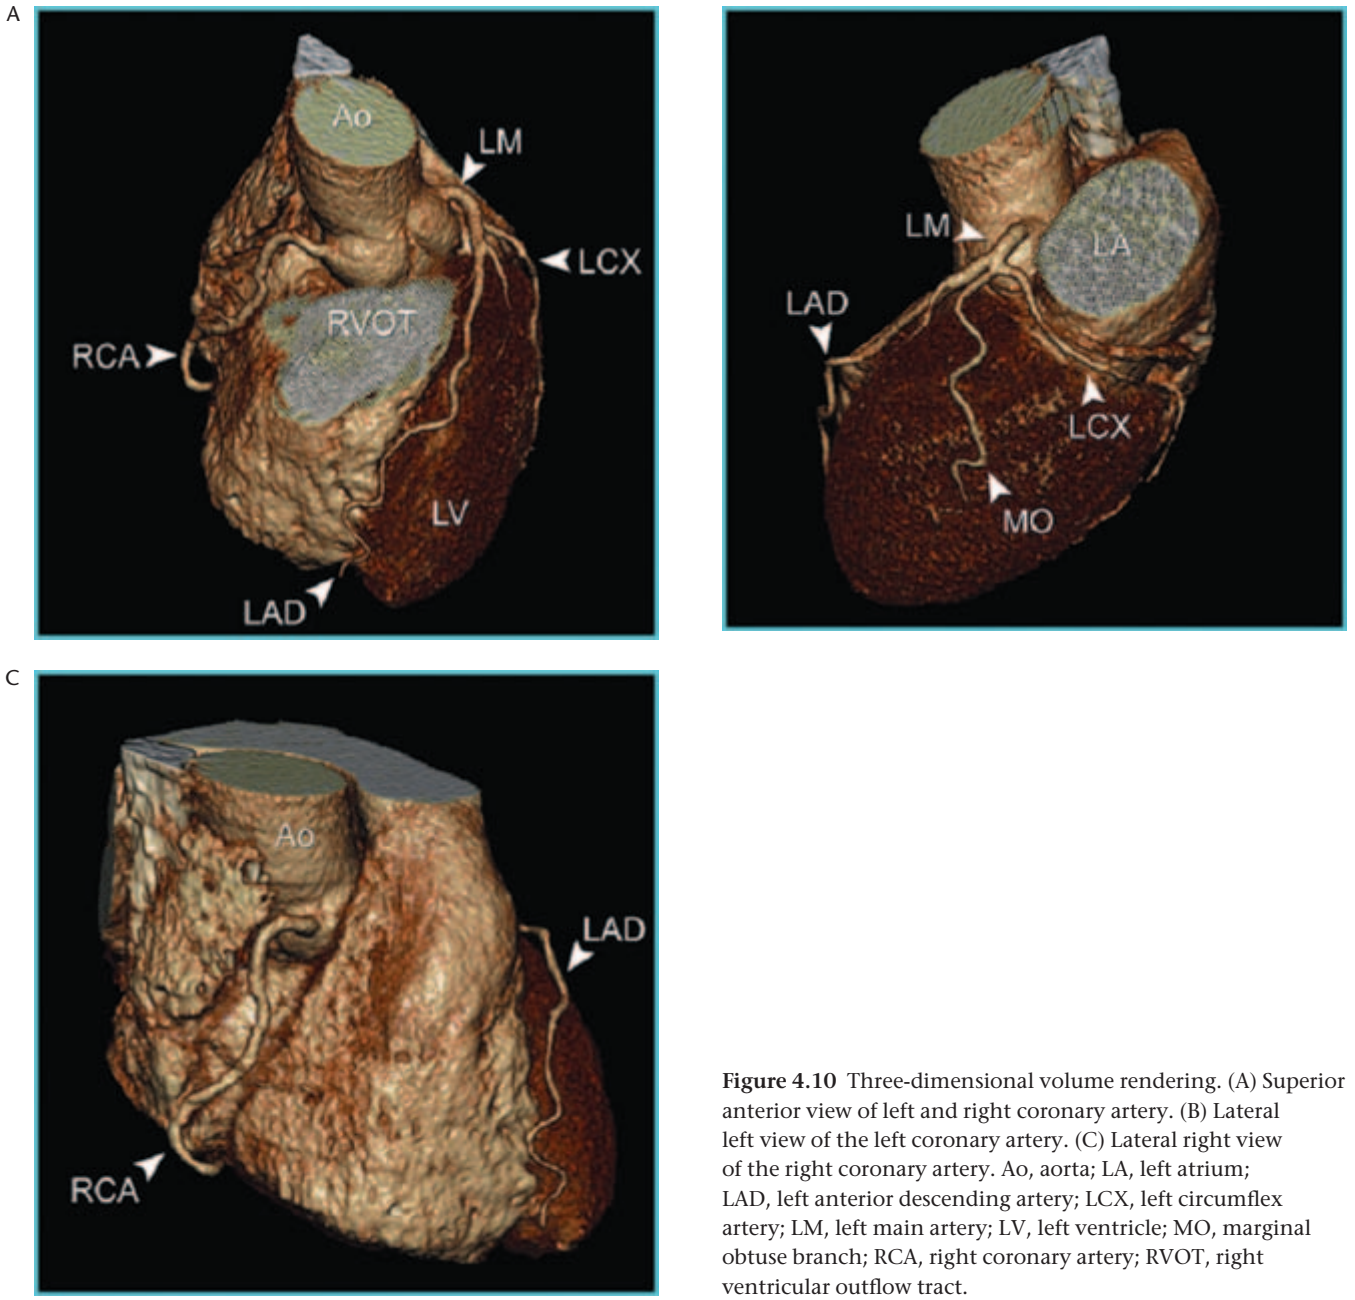

Figure 4.10 Three-dimensional volume rendering. (A) Superior anterior view of left and right coronary artery. (B) Lateral left view of the left coronary artery. (C) Lateral right view of the right coronary artery. Clinical applications of cardiac computerized tomography

Coronary artery calcification

CT provides a highly sensitive non-invasive diagnostic modality for the determination of the presence of coronary calcium because calcium has a high X-ray attenuation value (high CT number). Tissue within the vessel wall with a CT number of 130 HU or more is defined as calcified (Fig. 4.11).

Initially calcium detection has been performed with EBCT using a non-enhanced, ECG-triggered sequential CT technique [6]. Recently MDCT has emerged as an alternative modality by application of either the prospectively ECG-triggered sequential mode or the retrospectively ECG-gated spiral mode of the MDCT scanner.

The traditional method of quantifying coronary calcification is the 'Agatston score' [6]. This is derived from the area of a calcified lesion and the maximum CT attenuation within that lesion. Alternative quantification methods include assessment of the calcified volume (e.g. in mm^3) and of the mass of calcium (e.g. in mg) [7,8]. In spite of the potential advantages of these newer quantification methods, especially with regard to variability and independence from scanner type, no clinical studies of significant size have used these latter algorithms and all published studies demonstrating the predictive value of calcium are based on the 'Agatston score'.

With the possible exception of patients in chronic renal failure [9], the presence of coronary calcium is invariably associated with coronary atherosclerosis and the amount of coronary calcium correlates to the histological 'total coronary plaque burden' [10,11]. A high coronary calcium score, in particular when adjusted for age and gender, is predictive of coronary adverse events (Table 4.1) [12–18]. The absence of coronary calcium virtually rules out the presence of coronary atherosclerosis and is associated with a very low risk of adverse coronary events (Table 4.2).

The data on whether the predictive value of coronary calcium scoring is additional to the risk classification using traditional risk factors has been controversial [19] but several recent large studies have shown that coronary calcium quantification carries independent predictive value for adverse cardiac events and all-cause mortality [17,18,20]. This has resulted in the statements of the Third Joint Task Force of European and Other Societies on Cardiovascular Disease Protection in Clinical Practice that the 'calcium score is an important parameter to detect asymptomatic individuals at high risk for future

Table 4.1 Predictive value of electron-beam CT-determined coronary calcium score

Study	*n*	Mean age (years)	Gender (% male)	FUP	Events (death/MI)	Calcium score cut-off	Risk ratio

Table 4.2 Significance of coronary calcium

Absent	Present
Presence of atherosclerosis unlikely	Presence of atherosclerosis
Low likelihood of severe luminal narrowing	Higher amount of calcium increases the likelihood of obstructions; however, this is not site-specific
Nearly always normal coronary angiogram	Total amount of calcium correlates with total plaque burden but still severely underestimates the amount of histological plaque burden
Low risk of cardiovascular event (2–5 years)	High calcium adjusted for age and gender is associated with higher likelihood of cardiac adverse event (in the next 2–5 years)

cardiac events, independent of the traditional risk factors' [21,22]. However, coronary calcium scanning cannot be recommended as a screening method for the unselected general population although it may play a role in selected individuals at intermediate risk of coronary events [18]. Absence or a low calcium score in these individuals may downgrade them to a low-risk group without an urgent need for preventive measures while a high calcium score may promote these individuals to a high-risk group in need of a more aggressive risk-factor modification [18].

Assessment of coronary stenoses

To visualize the coronary lumen and detect coronary stenoses by MDCT, data are acquired in spiral mode and retrospectively ECG-gated image reconstruction is applied to maximize temporal and spatial resolution. A large number of studies comparing 12-slice and 16-slice MDCT with conventional coronary angiography have been published [23–30]. It has been shown that in patients with a high heart rate, the occurrence of motion artefacts is frequent and the diagnostic performance of MDCT deteriorates [23]. Most recent studies performed with 12-slice and 16-slice systems incorporated the use of oral or intravenous beta-blockers prior to the scan to reduce heart rate and avoid motion artefacts. The detector collimation of 16-slice scanners varies between 16 × 0.75 mm, and 16 × 0.625 mm, the rotation time varies between 370 ms and 500 ms, and the total scan time is generally 20 s or less.

Contrast enhancement is achieved by intravenous injection of an iodine-containing contrast medium, preferably followed by a saline bolus ('bolus chaser') (Fig. 4.12). To synchronize data acquisition and the contrast enhancement, either a 'test bolus' can be injected to determine the contrast-transit time, or the entire bolus can be injected at once and then data acquisition is automatically initiated when the arrival of contrast medium is detected (by repeated acquisition of slices at the level of the aortic root). The radiation output, in terms of tube voltage (kV) and current (mA), can be adjusted according to the patient's weight to improve image quality.

The reported diagnostic accuracy of a 12-slice to 16-slice CT scanner to detect significant coronary stenoses (> 50% luminal diameter stenosis) has been found to be high (Figs 4.13, 4.14 and 4.15). Sensitivities between 63 and 95% and specificities between 86 and 98% have been reported, and, as compared to earlier scanner generations,

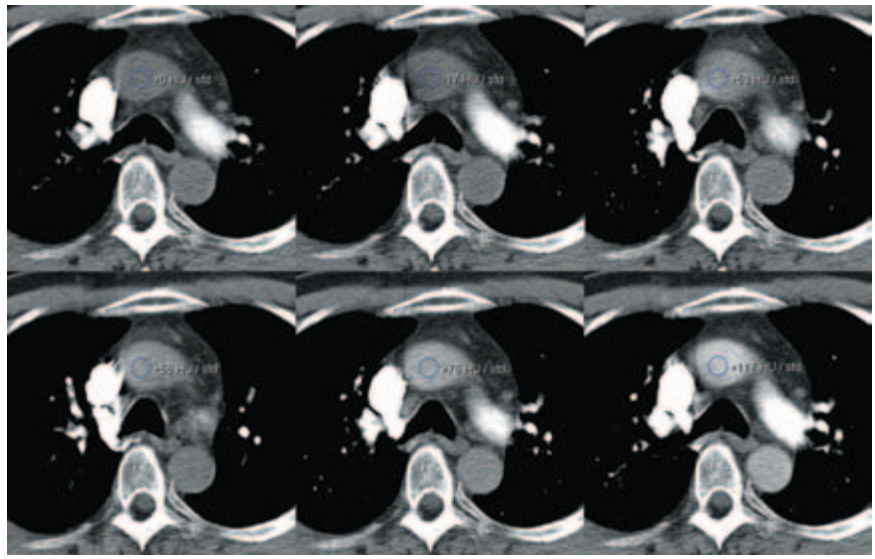

Figure 4.12 CT data acquisition technique. (A) Monitoring of the arrival of the contrast bolus in the aorta can be achieved after positioning a region of interest at the level of the ascending aorta and scanning the axial images at different time intervals (e.g. every second). (B) Hounsfield units within the region of interest are measured and the CT scan is automatically started when a predefined threshold has been reached (e.g. +100 HU).

fewer segments and vessels were excluded based on impaired image quality (Table 4.3) [23–30]. In a few studies, the average heart rate could be reduced to less than 60 beats per minute, and by limiting the evaluation to larger coronary vessels (≥ 2.0 mm diameter), a high sensitivity and specificity could be achieved without exclusion of any coronary segments because of impaired image quality (Table 4.3) [23,25,29]. Overestimation of stenosis severity, particularly in calcified vessels, resulted in a substantial number of false-positive diagnoses and a modest positive predictive value. Evaluation of smaller coronary segments and the presence of severe calcifications reduced the diagnostic accuracy of contrast-enhanced MDCT for detection of stenoses.

In particular, the high negative predictive value (97–98% in nearly all published studies) suggests that the

current technique may be clinically useful to rule out significant coronary artery stenoses.

A severe limitation for CT coronary imaging is an irregular heart rhythm (for instance atrial fibrillation), which does not permit reliable visualization of the coronary arteries. Severe coronary calcification causes artefacts as a result of partial volume effects and beam hardening, which may lead to overestimation of plaque size and lumen narrowing while the high density of calcium obscures the underlying lumen which may prohibit reliable assessment of the integrity of the coronary lumen. The effects of coronary calcium are reduced by using thin-slice collimation, and are aggravated if motion artefact is additionally present. Of great concern is the rather high radiation exposure associated with MDCT imaging of the coronary arteries.

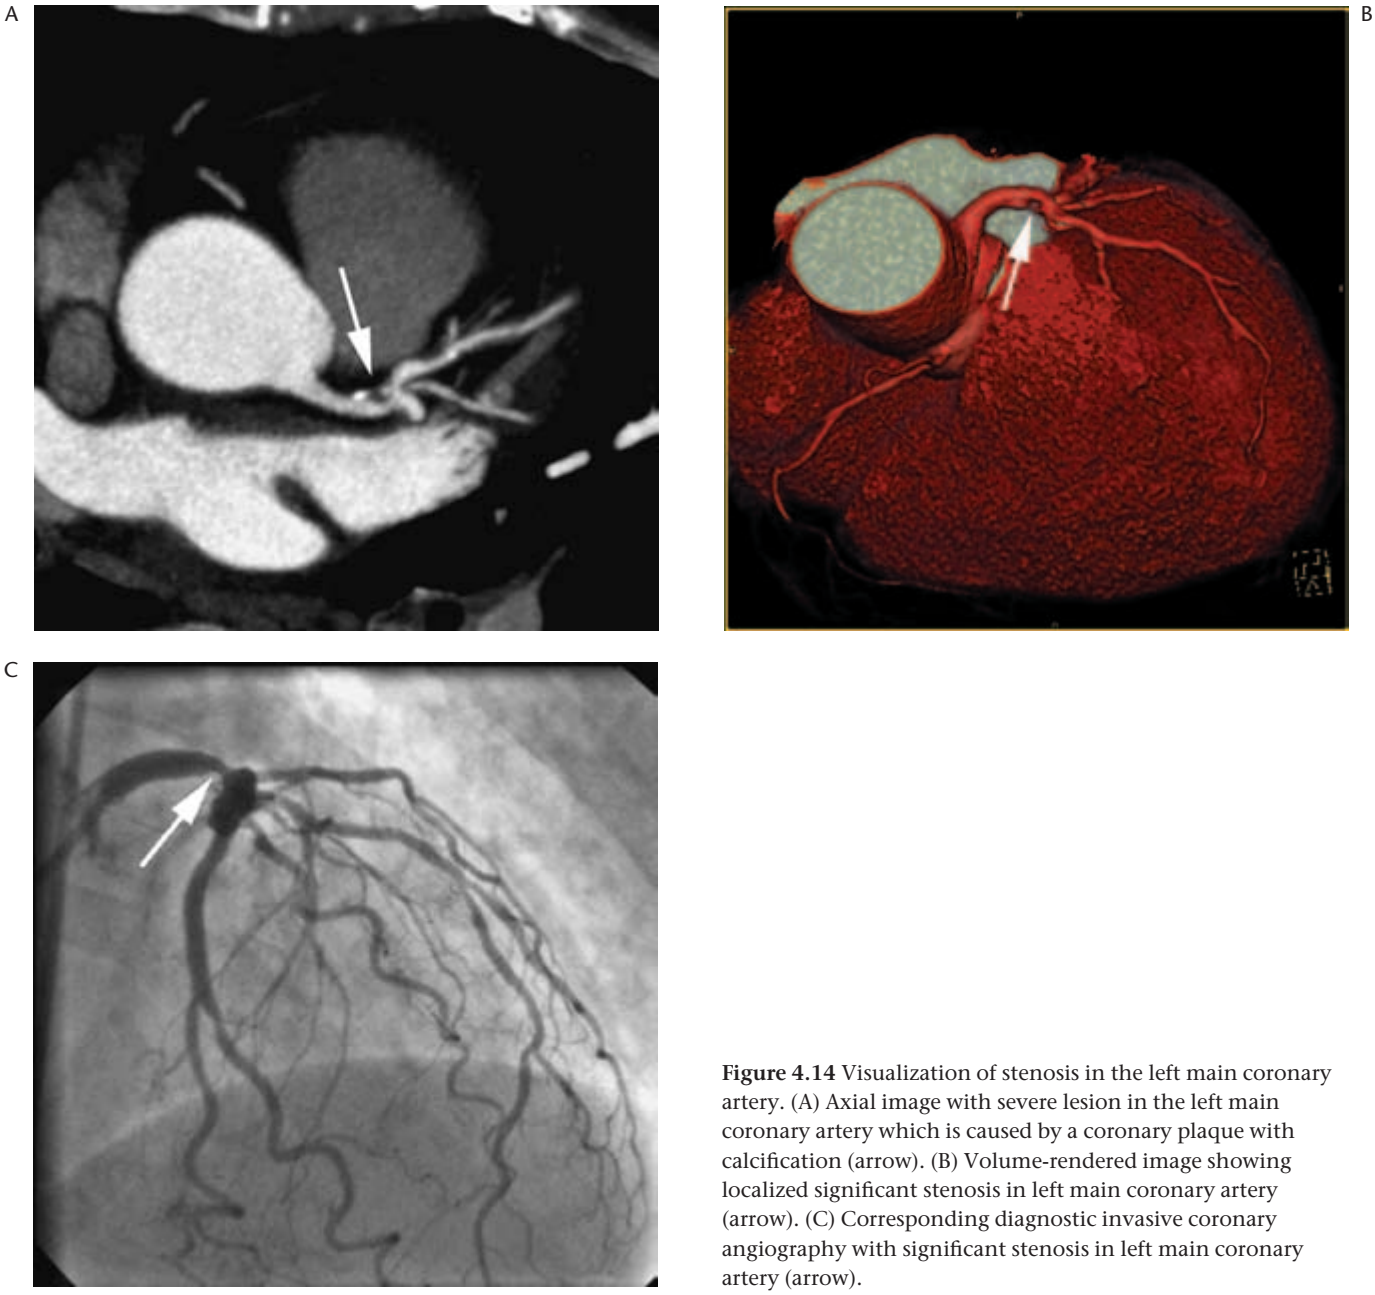

Figure 4.14 Visualization of stenosis in the left main coronary artery. (A) Axial image with severe lesion in the left main coronary artery which is caused by a coronary plaque with calcification (arrow). (B) Volume-rendered image showing localized significant stenosis in left main coronary artery (arrow). (C) Corresponding diagnostic invasive coronary angiography with significant stenosis in left main coronary artery (arrow).

Coronary anomalies

Cross-sectional MDCT imaging, especially in combination with two- and three-dimensional image reconstruction techniques, permits the accurate assessment of the aberrant origin and course of anomalous coronary arteries [31,32]. Because the origin and course of coronary anomalies can sometimes be difficult to assess with conventional coronary angiography, CT may be considered a first-choice diagnostic modality (Fig. 4.16). The course of an anomalous coronary artery running between the pulmonary outflow tract and aorta which may be the cause of sudden death can be readily assessed (Fig. 4.17).

Bypass grafts

Patency versus occlusion of venous and arterial coronary artery bypass grafts can accurately be assessed by CT [33].

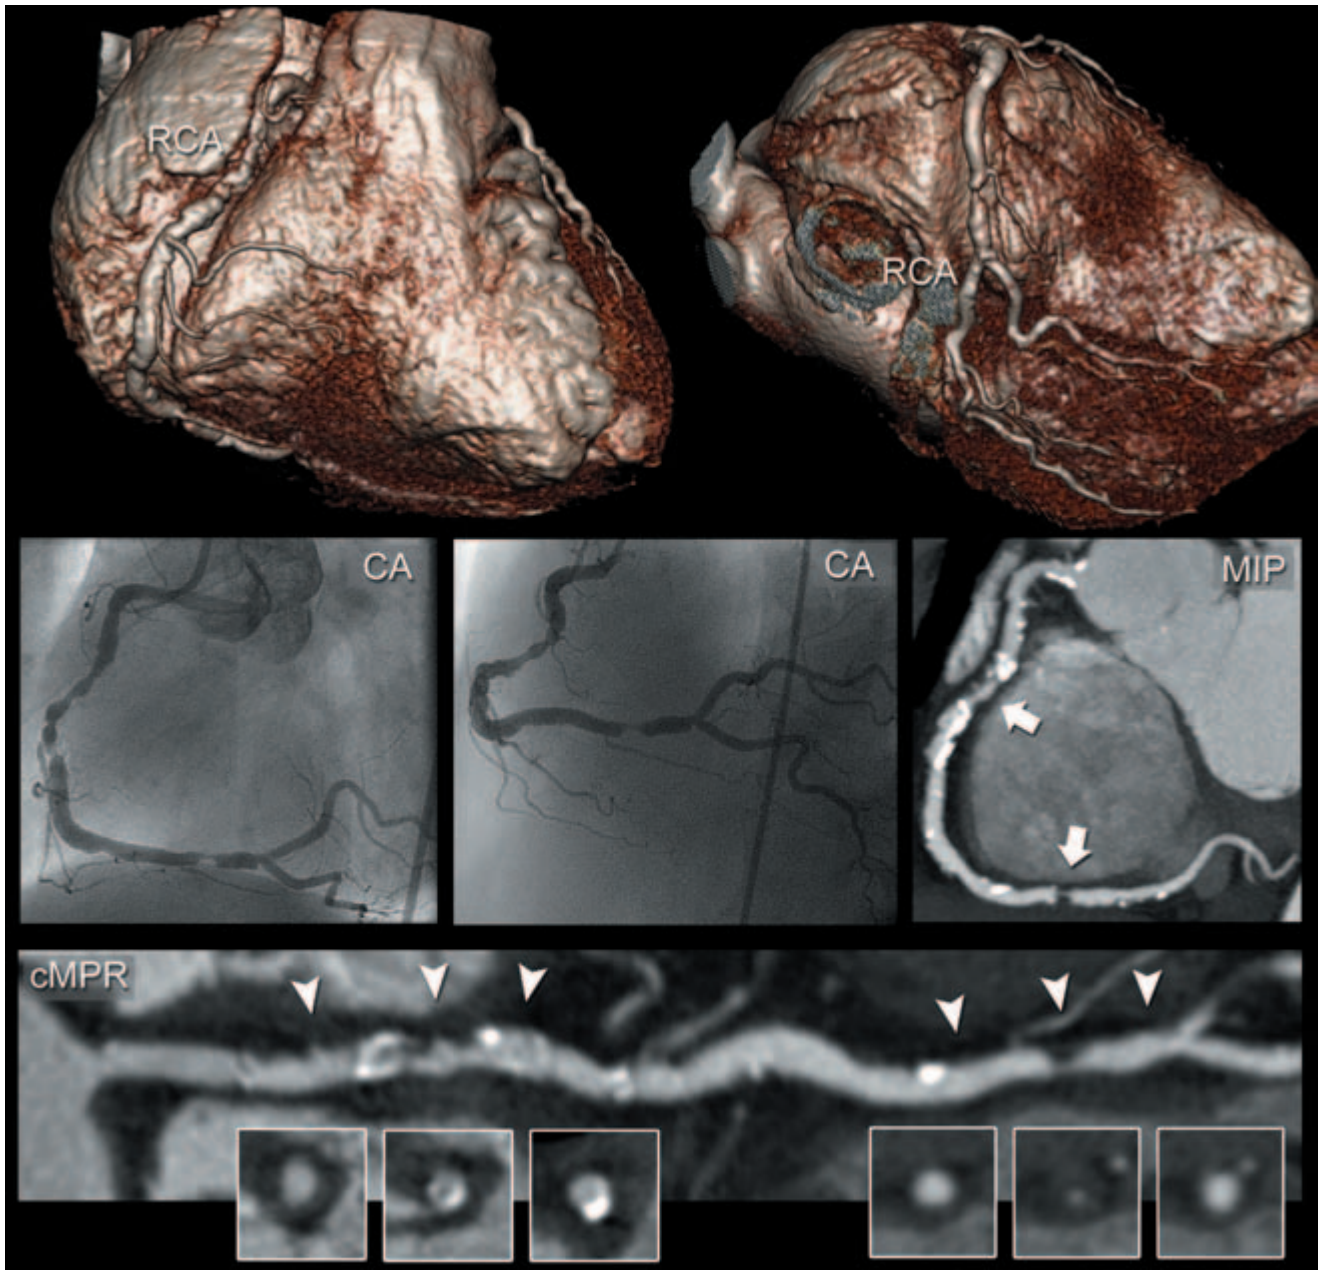

Figure 4.15 Visualization of stenoses in the right coronary artery. CT coronary angiogram and corresponding conventional angiogram (CA) of a right coronary artery (RCA). Volume-rendered CT images (coloured images) show the presence of a large, dominant RCA. Detailed maximum intensity projected and curved multiplanar reconstructed CT images reveal the presence of two significant lesions—one long significant lesion located at the mid RCA, another short significant lesion located at the distal RCA. Cross-sectional CT images (inlays) show the presence of both non-calcified and calcified plaque tissue within the proximal stenosis, whereas exclusively non-calcified plaque tissue is visualized within the more distal stenosis. The presence of two significant lesions was confirmed on the diagnostic conventional angiogram. CA, conventional angiogram; cMPR, curved multiplanar reconstructed image; MIP, maximum intensity projection; RCA, right coronary artery.

Figure 4.16 Visualization of anomalous coronary artery. The right coronary artery originates from the left coronary cusp (arrow).

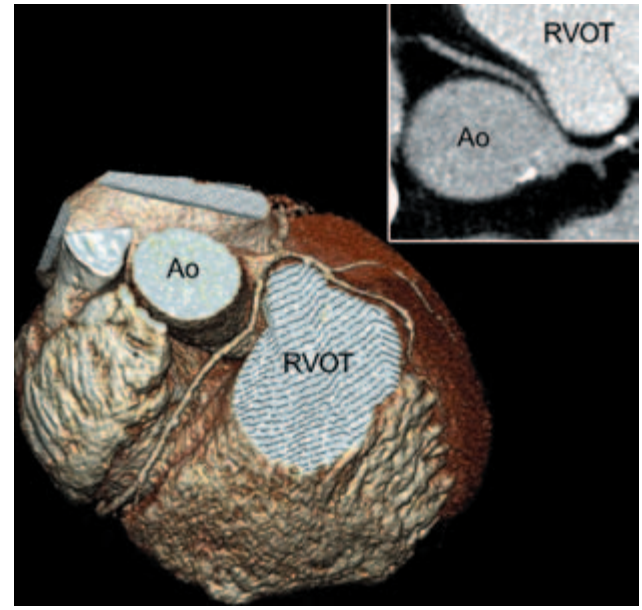

Figure 4.17 Visualization of anomalous coronary artery. Anomalous origin of the right coronary artery, which arises from the left main coronary artery. The proximal part of the right coronary artery runs between the aorta and the right ventricular outflow tract. Ao, aorta; RVOT, right ventricular outflow tract.

However, the accuracy for detection of graft stenosis, in particular at the distal anastomotic site, has so far been limited [26,34] (Fig. 4.18). Furthermore, clinical evaluation of patients after bypass surgery usually requires not only information about the status of the bypass grafts, but also about the native coronary arteries (and collaterals). As a result of both the severity and extent of disease and the usually severe calcification of native arteries in patients with bypass grafts, assessment of stenoses in the native coronary arteries in these patients is often difficult and the clinical role of comprehensive post-bypass evaluation using CT imaging in these patients is therefore limited.

Coronary stents

The occlusion or patency of a stent can be assessed by MDCT based on the presence of contrast-opacification within and distally from the stent. However, because of the significant artefacts caused by the dense stent material, accurate detection of obstructive lesions within the boundaries of small coronary stents is not reliable [35,36]. Current scanner generations permit, apart from patency assessment, also the detection of non-occlusive neo-intimal hyperplasia and in-stent restenosis (Fig. 4.19) in larger coronary stents (e.g. those > 4 mm in diameter) [37]. Clinical application of MDCT for the follow-up of patients after stent implantation cannot be recommended.

Coronary plaque imaging

MDCT delineates both extraluminal and intraluminal coronary atherosclerosis, and may thus provide information about the severity, extent and distribution of coronary disease, of plaque tissue composition and of vessel wall remodelling [38–40] (Fig. 4.20). Compared to intracoronary ultrasound as the standard of reference, the sensitivity of MDCT to detect the presence of non-stenotic coronary plaque was found to range between approximately 50–80% for non-calcified plaques and 95% for calcific plaques, with a specificity of approximately 90% [38,39]. However, MDCT significantly underestimated the plaque volume per coronary segment when compared with intracoronary ultrasound volume measurements [38].

Contrast-enhanced MDCT imaging has furthermore been shown to have the potential to differentiate calcified and non-calcified plaques in the coronary artery wall. Calcified plaques have a high tissue density and appear brighter than the contrast-enhanced coronary lumen on the CT images. Non-calcified plaques have a tissue density which is higher than the surrounding perivascular fat but lower than the contrast-enhanced lumen. Based on initial studies comparing MDCT with histology and intravascular ultrasound, it appeared that fibrous plaques

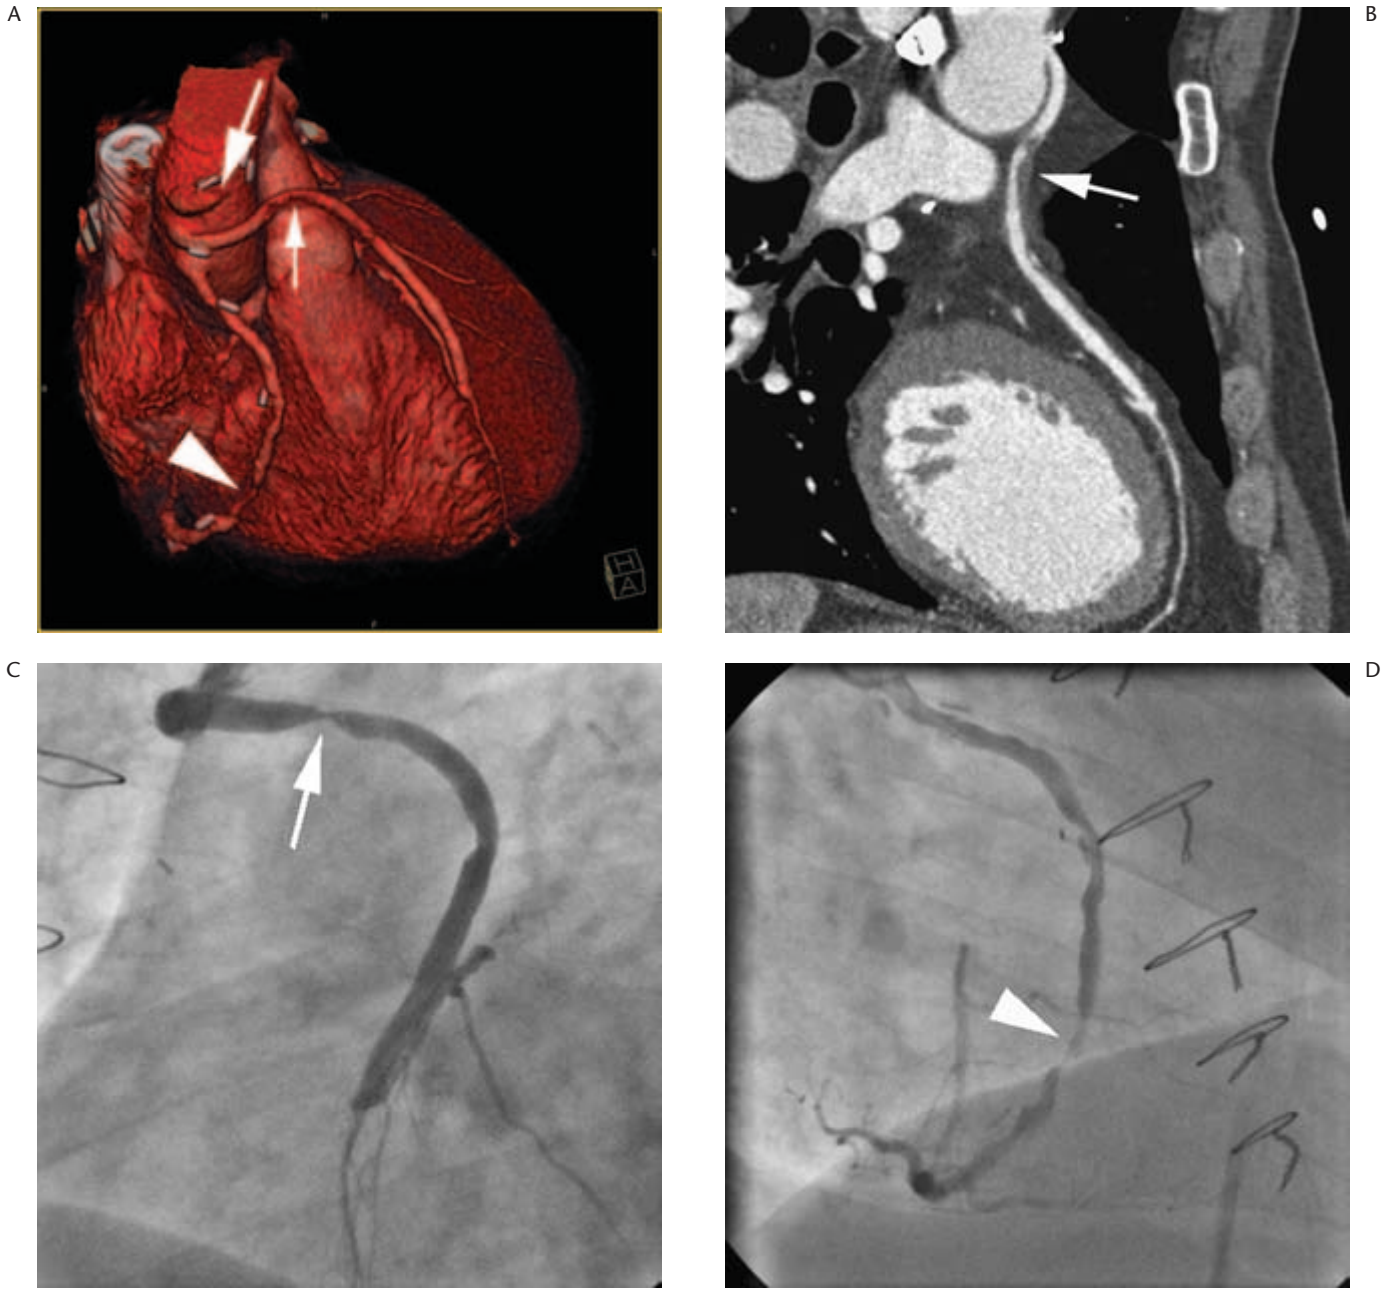

Figure 4.18 Visualization of coronary artery bypass grafts. Patient with three venous coronary bypass grafts. MDCT (16 × 0.75 mm collimation, 370 ms rotation time). (A) Three-dimensional reconstruction obtained by MDCT which shows occlusion of the graft to the left circumflex coronary artery (large arrow), stenosis of the graft to the left anterior descending coronary artery (small arrow), and stenosis of the graft to the right coronary artery (arrowhead). (B) Multiplanar reconstruction of the graft to the left anterior descending coronary artery showing the lumen reduction and the plaque material that causes the stenosis (arrow). (C) Invasive coronary angiogram of the graft to the left anterior descending coronary artery showing the stenosis (arrow). (D) Invasive coronary angiogram of the graft to the right coronary artery showing the stenosis (arrowhead).

and lipid-rich plaques may be differentiated based on their CT attenuation values. However, in clinical practice it was shown that the average density measured within lipid-rich plaques was lower than in fibrous plaques, but there was a considerable overlap in density values, making the assessment of plaque characteristics in a given lesion less reliable [39]. MDCT can also identify coronary plaques with positive (expansive) vessel wall remodelling

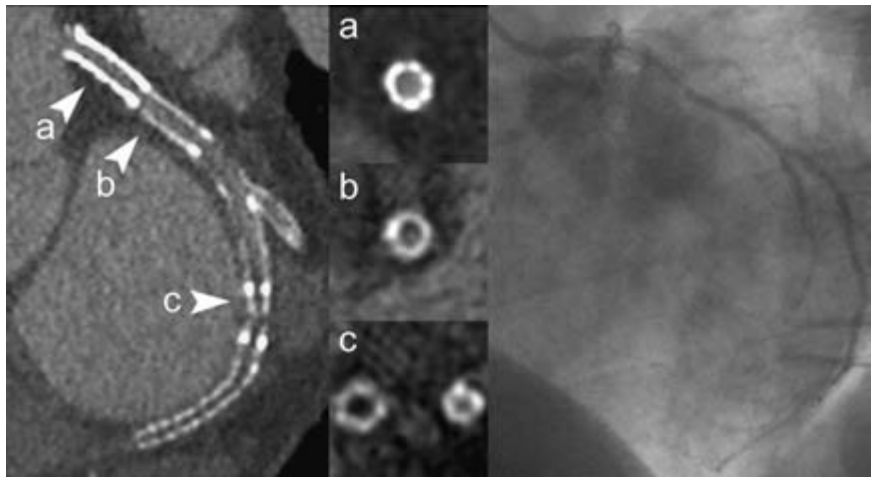

Figure 4.19 Visualization of coronary stent. Curved multiplanar reconstruction of the circumflex coronary artery (left). Cross-sectional images obtained at different levels reveal a patent left main stent (a), in-stent restenosis at the mid part of the circumflex (b), and an occluded stent more distal (c). These findings were confirmed on the conventional angiogram (right). A patent stent in a marginal branch is also displayed (c).

and negative (shrinkage) vessel wall remodelling [40]. MDCT allows the assessment of the total atherosclerotic plaque burden of the coronary tree [41].

The potential of MDCT for plaque detection and characterization, vessel remodelling and assessment of total CT plaque burden is promising but higher resolution imaging is needed before it can be embraced as a reliable diagnostic tool.

Cardiac and pericardial abnormalities

Cardiac CT, as a result of its capability for high-resolution imaging of the entire heart and high contrast between the contrast-enhanced blood pool and surrounding tissues, permits the assessment of cardiac morphology with high image quality. It can thus theoretically be applied in numerous clinical situations calling for accurate visualization of cardiac morphology. However, CT imaging is associated with radiation exposure and in most cases requires iodinated contrast agent. Therefore, the morphology of the heart and pericardium is usually assessed by echocardiography or magnetic resonance imaging. All the same, CT can serve as a second-choice technique and provide accurate information on cardiac morphology and pathology if echocardiography and magnetic resonance cannot be performed with satisfactory image quality.

Cardiac masses and thrombi

Cardiac tumours appear on CT as contrast-filling defects or deformities of the contrast-filled cardiac cavities or as thickening, often inhomogeneous, of the soft cardiac tissue (e.g. myocardium or pericardium). CT has limited capabilities for soft-tissue characterization and for exact delineation of tumours that infiltrate or are immediately adjacent to the myocardium can therefore be difficult [42]. However, the presence of calcium (e.g. in myxomas), can sometimes be diagnostically helpful and can easily be established or ruled out by CT.

Similar to tumours, intracardiac thrombi are depicted as contrast-filling defects within the opacified cardiac chambers. Thrombi may be solitary or multiple and may be sessile, pedunculated or laminar in shape. Atrial thrombi, mostly located within the left atrial appendage, are the most frequently occurring cardiac thrombi and will appear as a filling defect (Fig. 4.21). However, it has to be considered that poor atrial function, as in atrial fibrillation, may result in poor opacification of the atrial appendage after injection of contrast, even in the absence of thrombus.

Thrombi within the left ventricle are usually located adjacent to infarcted myocardium with associated wall motion abnormalities and are often seen after anterior wall myocardial infarction (Fig. 4.22). The differentiation of thrombus from myocardium and papillary muscle may be difficult. Older thrombi can be calcified.

Pericardial abnormalities

In CT images, the pericardium can usually be appreciated on the anterior face of the heart. It is delineated as a thin structure of soft-tissue density, adjacent to mediastinal fat ventrally and epicardial fat dorsally. The thickness of normal pericardium is 1–2 mm, but inferiorly, at the insertion of the pericardium to the diaphragm, it thickens to 3–4 mm [43].

Pericardial abnormalities include thickening and calcification of the pericardium, pericardial effusion and localized pericardial masses or intrapericardial tumours. Pericardial thickening may be localized or general. It may involve both parietal and visceral pericardium and

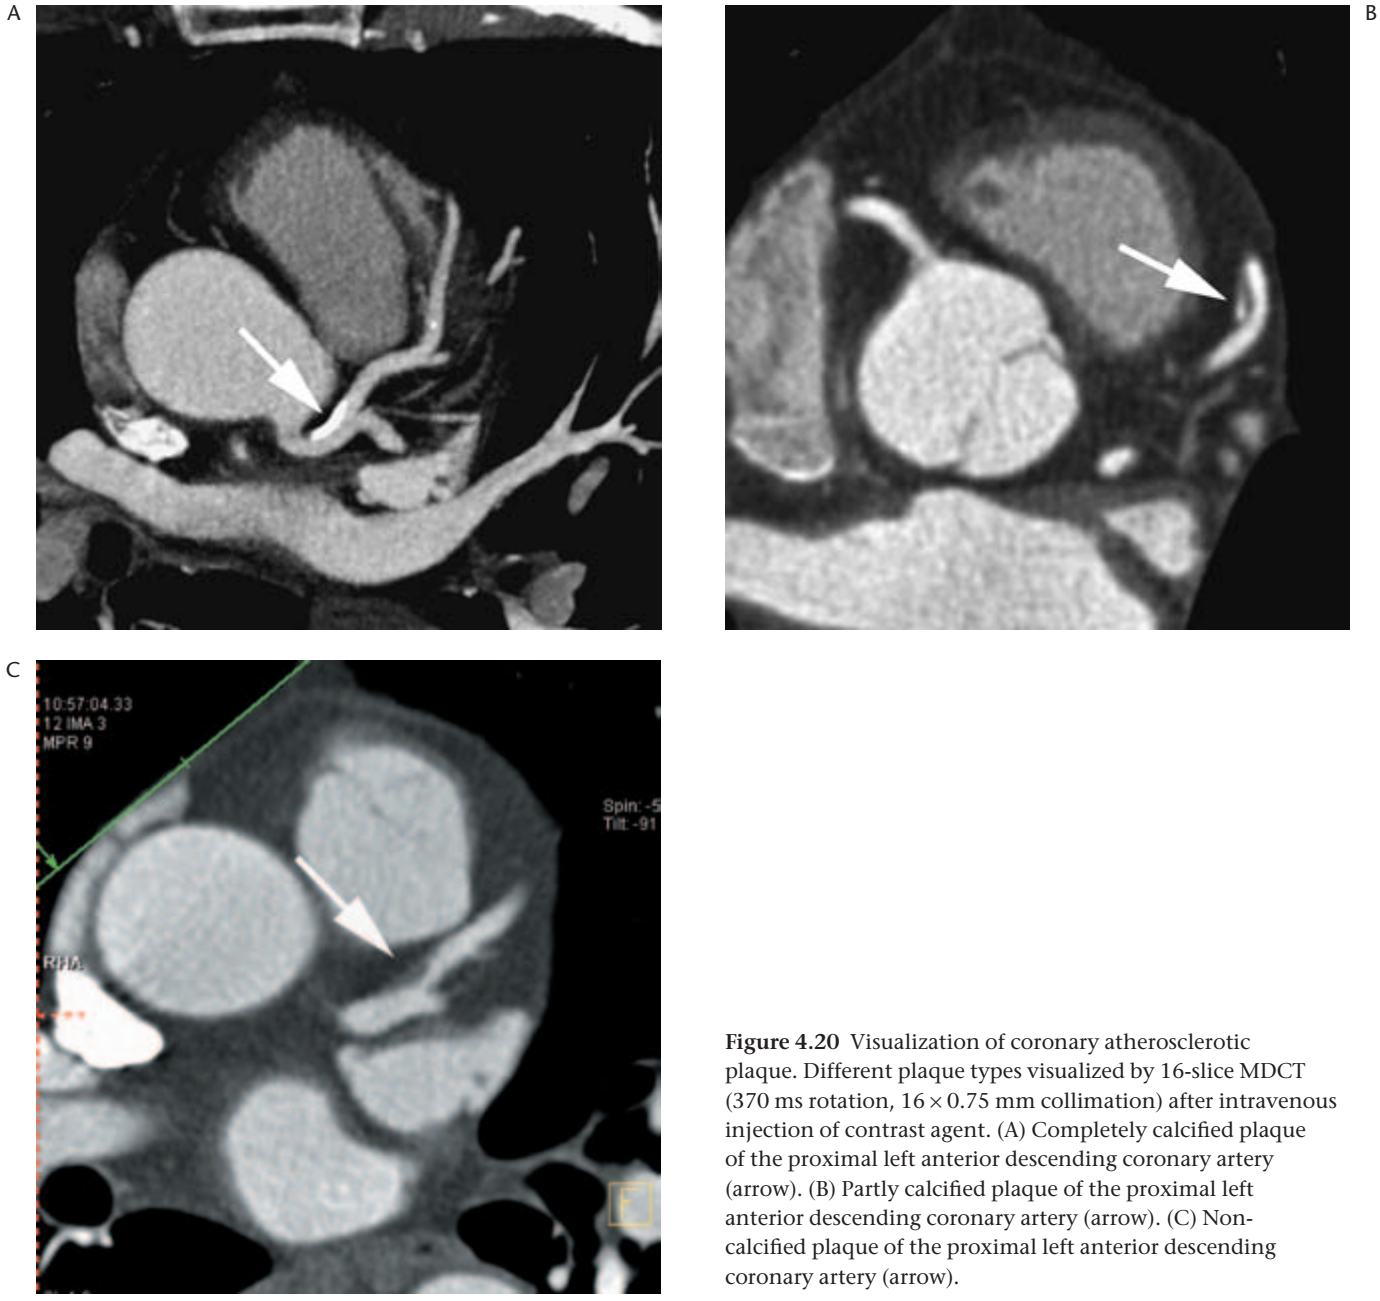

Figure 4.20 Visualization of coronary atherosclerotic plaque. Different plaque types visualized by 16-slice MDCT (370 ms rotation, 16 × 0.75 mm collimation) after intravenous injection of contrast agent. (A) Completely calcified plaque of the proximal left anterior descending coronary artery (arrow). (B) Partly calcified plaque of the proximal left anterior descending coronary artery (arrow). (C) Non-calcified plaque of the proximal left anterior descending coronary artery (arrow).

sometimes the myocardium. However, the presence of pericardial thickening by itself is no proof of haemodynamically relevant pericardial constriction. The detection of pericardial calcification can be helpful in this context (Fig. 4.23). Pericardial effusion usually accumulates in the caudal portion of the pericardium and appears as increased density dorsal to the left ventricular myocardium. As the effusion increases it will extend to the ventral surface of the right atrium and ventricle. Postoperative pericardial effusions can be localized, e.g. adjacent to the right atrium. Pericardial cysts appear as a round or oval mass usually in the right pericardiophrenic angle (Fig. 4.24). The cysts are filled with fluid that has a CT density similar to water. Breast and lung carcinoma can metastasize to the pericardium.

Great vessels

Since the great vessels are subjected to motion caused by cardiac contraction, the high imaging speed of the modern CT scanner, its high spatial resolution and high contrast between vessel lumen and surrounding tissue

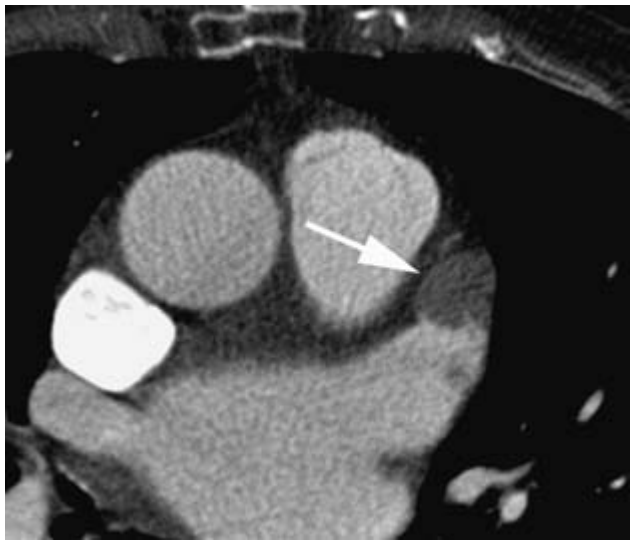

Figure 4.21 Visualization of atrial thrombus. A filling defect is shown in the left atrial appendage (arrow).

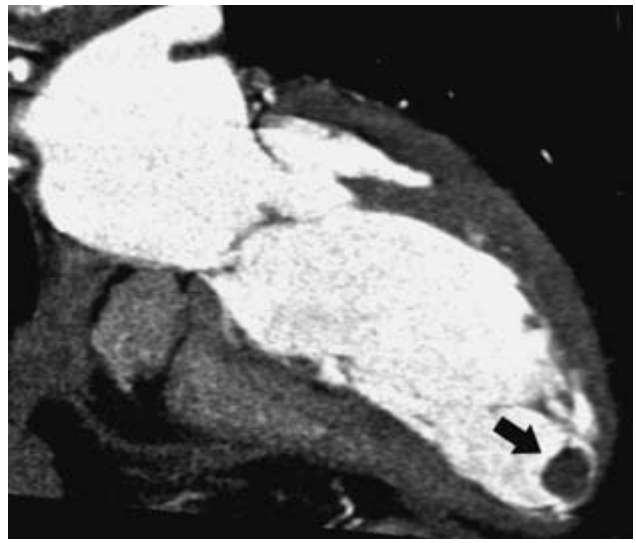

Figure 4.22 Visualization of a ventricular thrombus. The thrombus is at the apex of the left ventricle (arrow).

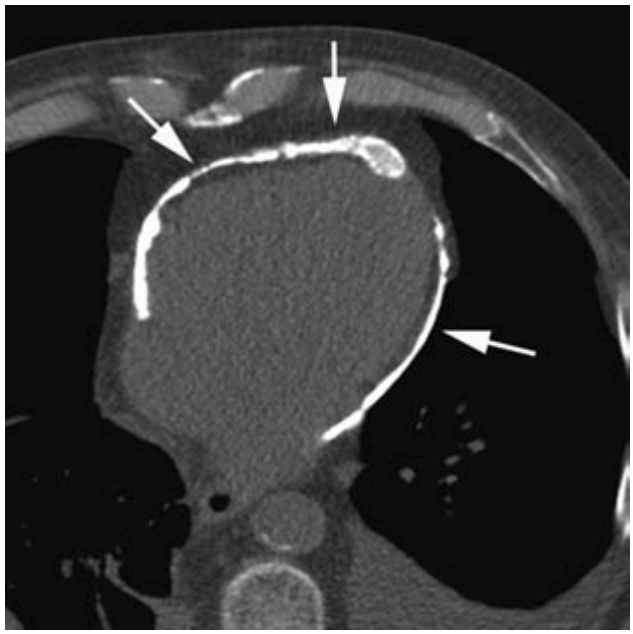

Figure 4.23 Visualization of pericardial calcification. Thickened pericardium with severe calcifications (arrows).

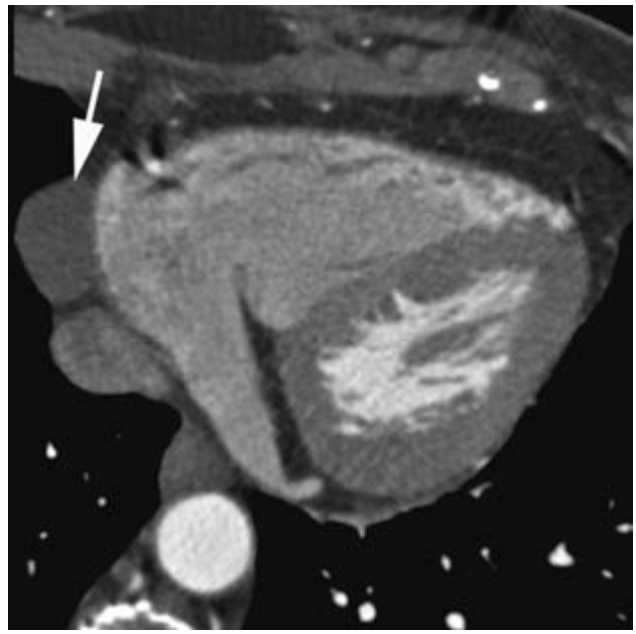

Figure 4.24 Visualization of pericardial cyst. Pericardial cyst in the right costophrenic angle (arrow).

have made MDCT scanning an important, reliable clinical diagnostic modality in evaluating the great vessels of the thorax. To visualize the great vessels by CT, the blood pool has to be enhanced by intravenous contrast agent and data acquisition has to be timed correctly to ensure peak enhancement of the vessel lumen during image acquisition. ECG-gated image acquisition is not necessary in all cases and untriggered data acquisition may lead to significant reduction in radiation dose.

Thoracic aortic aneurysm

Aneurysms of the aorta are caused by degeneration of the media. This is most frequently seen in atherosclerotic disease but is also seen as a consequence of Marfan syndrome, cystic medial necrosis, trauma, post-stenotic dilatation or infectious mycotic diseases.

Aneurysms can be divided into true aneurysms and false aneurysms. A true aneurysm involves all wall layers,

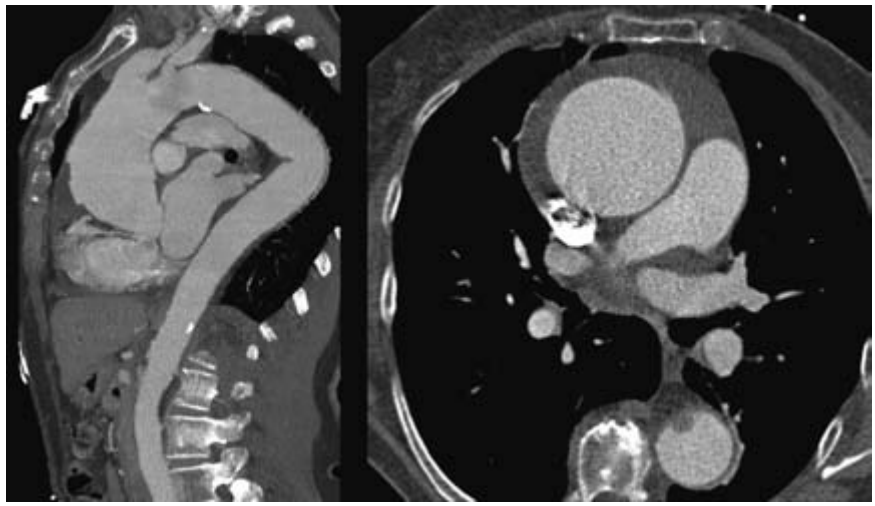

Figure 4.25 Visualization of aneurysm of the aorta. Aneurysmatic dilatation of the ascending aorta (A). An axial image at the level of the aortic arch (B) reveals a significant difference in lumen diameter between the ascending and descending aorta. A significant amount of fluid in the pericardial space is surrounding the ascending aorta.

Figure 4.26 Visualization of aneurysm of the aorta. Small saccular aneurysm at the level of the aortic arch (arrowhead, A). The small neck and the location are easily appreciated on the para-coronal plane. The cross-section of the aortic arch shows the eccentric configuration of the aneurysm (B).

is often associated with atherosclerosis and is usually fusiform in shape (Fig. 4.25). False aneurysms consist of a perforation or penetration of the intima and media of the vessel wall, and are contained by adventitia and perivascular tissue (Fig. 4.26). They are often saccular in shape, have a narrow neck and are associated with trauma or infection.

Thoracic aneurysms are often filled with mural thrombi and long-standing aneurysms may be calcified. On CT, aneurysms are seen as (localized) increases of the aortic diameter.

Aortic dissection

A dissection is caused by a tear within the intimal layer of the artery with subsequent development and antegrade propagation of a false lumen tracking along the media. There can also be retrograde extension of a dissection with involvement of the aortic valve. The false lumen is often large in diameter and may end blindly or re-enter the true lumen. The false lumen may become occluded by thrombus or may remain patent. Dissections are usually associated with hypertension or Marfan syndrome. They can be classified according to the De Bakey or Stanford classifications, which both differentiate involvement of the ascending aorta (DeBakey I and II, Stanford A), which constitutes a surgical emergency and serious prognosis, from dissections limited to the descending aorta (DeBakey III, Stanford B) which in the absence of complications are best treated medically and have a relatively good prognosis.

On CT, a dissection can be recognized by the presence of an intimal flap separating the true and false lumens

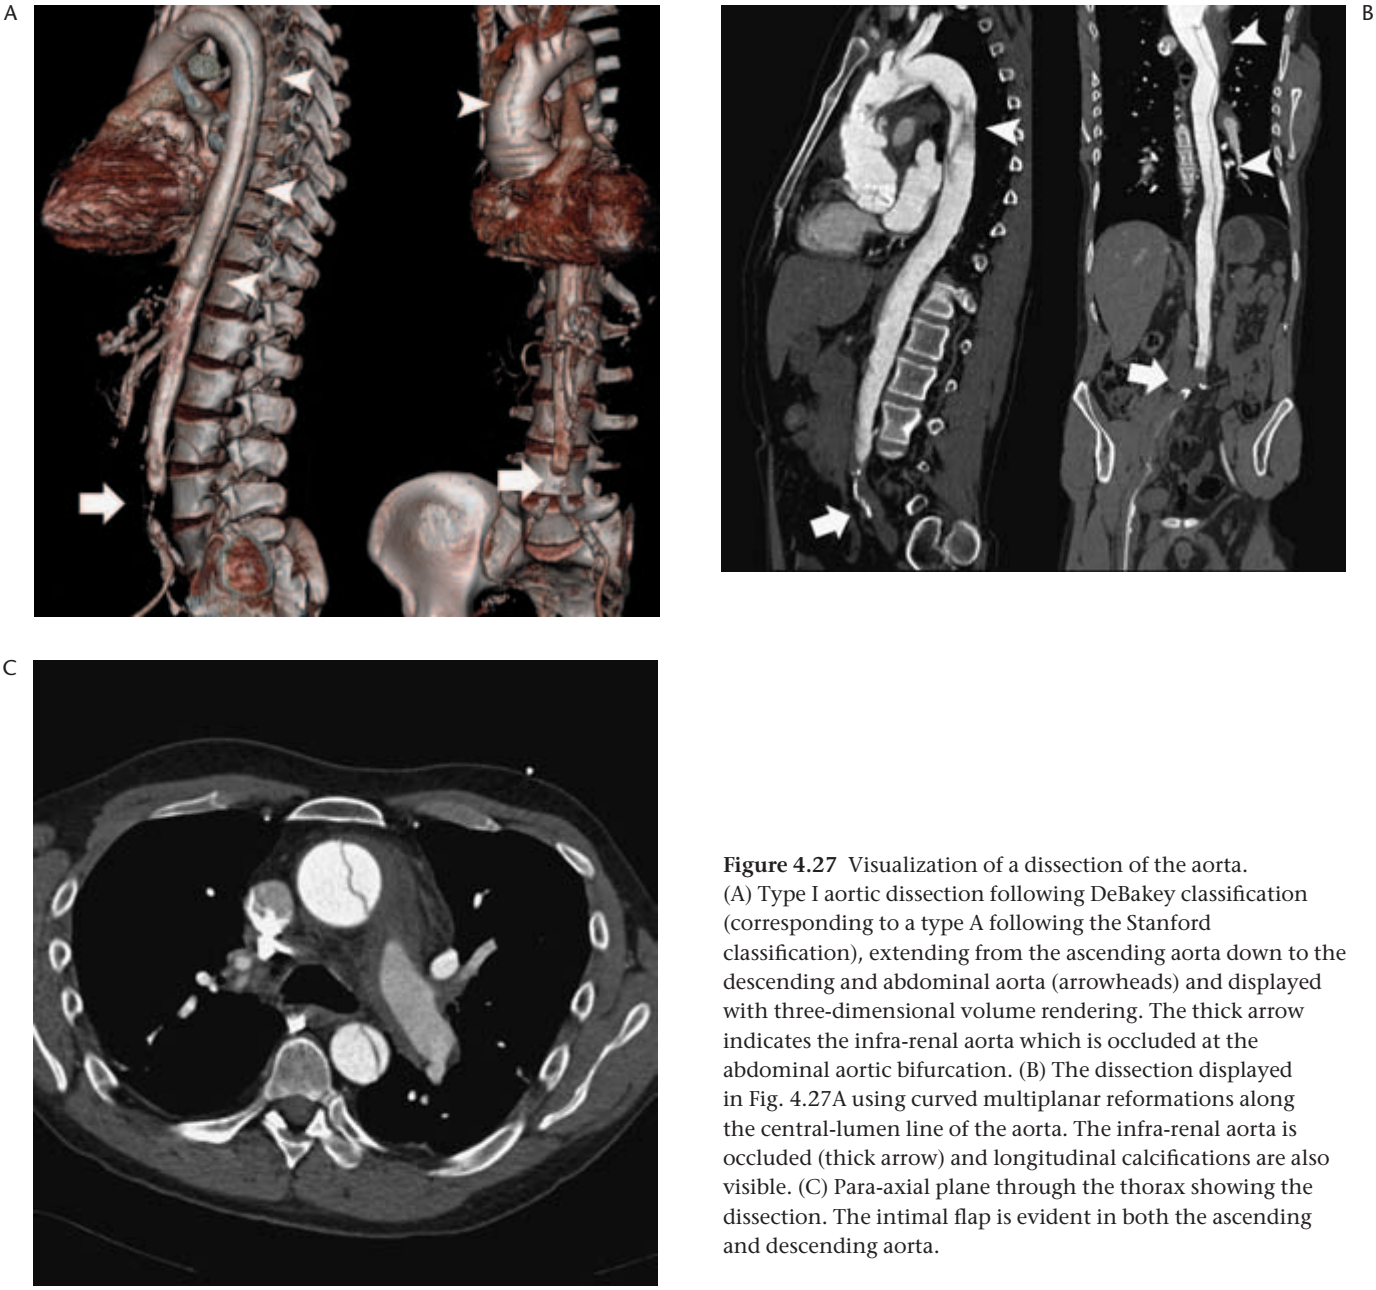

Figure 4.27 Visualization of a dissection of the aorta. (A) Type I aortic dissection following DeBakey classification (corresponding to a type A following the Stanford classification), extending from the ascending aorta down to the descending and abdominal aorta (arrowheads) and displayed with three-dimensional volume rendering. The thick arrow indicates the infra-renal aorta which is occluded at the abdominal aortic bifurcation. (B) The dissection displayed in Fig. 4.27A using curved multiplanar reformations along the central-lumen line of the aorta. The infra-renal aorta is occluded (thick arrow) and longitudinal calcifications are also visible. (C) Para-axial plane through the thorax showing the dissection. The intimal flap is evident in both the ascending and descending aorta.

(Fig. 4.27). More indirect CT signs of dissection include inward displacement of intimal calcification by the false lumen, differential contrast opacification between the true and false lumens, presence of (unenhanced) thrombus in the false lumen, thickening of the aortic wall, and, potentially, pericardial effusion.

Pulmonary emboli

CT scanning has been demonstrated to provide high diagnostic accuracy for the detection of pulmonary embolism. Pulmonary emboli on CT are shown as obstruction or filling defects of the contrast-enhanced common pulmonary artery, right or left pulmonary arteries or their side branches (Fig. 4.28). Pulmonary emboli are usually bilateral [44].

Pulmonary veins

CT imaging can accurately depict the anatomy of pulmonary venous return to the left atrium (Fig. 4.29). This can be important in the context of electrophysiological interventions, such as pulmonary vein isolation as a treatment for atrial fibrillation. In addition, the

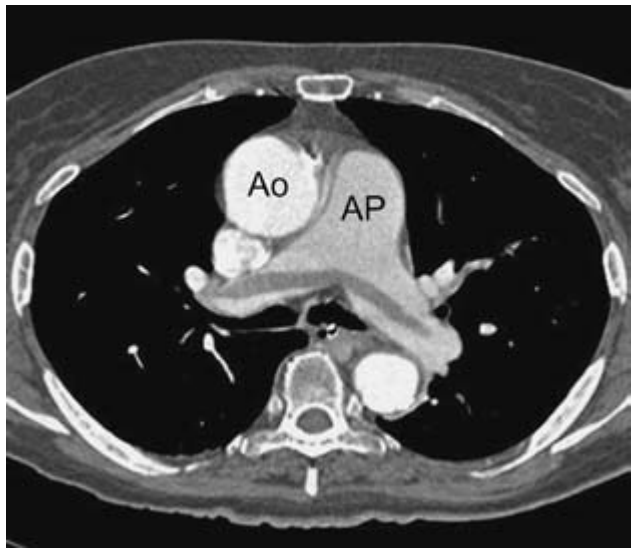

Figure 4.28 Visualization of pulmonary embolism. Large pulmonary embolism at the level of the bifurcation of the pulmonary artery. Ao, aorta; AP, arteria pulmonalis.

occurrence of pulmonary vein stenosis after ablation can be assessed by CT [45].

Functional imaging with computerized tomography

Because data are acquired throughout the complete cardiac cycle, MDCT allows reconstruction of multiple phases and assessment of global and regional cardiac function. Short-axis images at different levels (e.g. apical, mid and basal) of the ventricle and at different cardiac phases in the cardiac cycle can be reconstructed using dedicated software. Tracing of the left ventricular cavity (semi-automatic) at end-systole and end-diastole provides exact information about end-systolic and end-diastolic volumes and permits the calculation of stroke volume and ejection fraction. Additional tracing of the left ventricular epicardial contour provides quantitative information about left ventricular wall motion, wall thickness and thickening (Fig. 4.30). Regional myocardial wall thinning after myocardial infarction can be seen on the CT datasets. Several studies have shown that there is a good correlation of the various parameters of left ventricular function derived from MDCT in comparison to magnetic resonance imaging, biplane ventriculography and echocardiography [46,47].

Figure 4.29 Visualization of pulmonary veins. Volume-rendered CT images can be used to evaluate the anatomy of the pulmonary veins (posterior view).

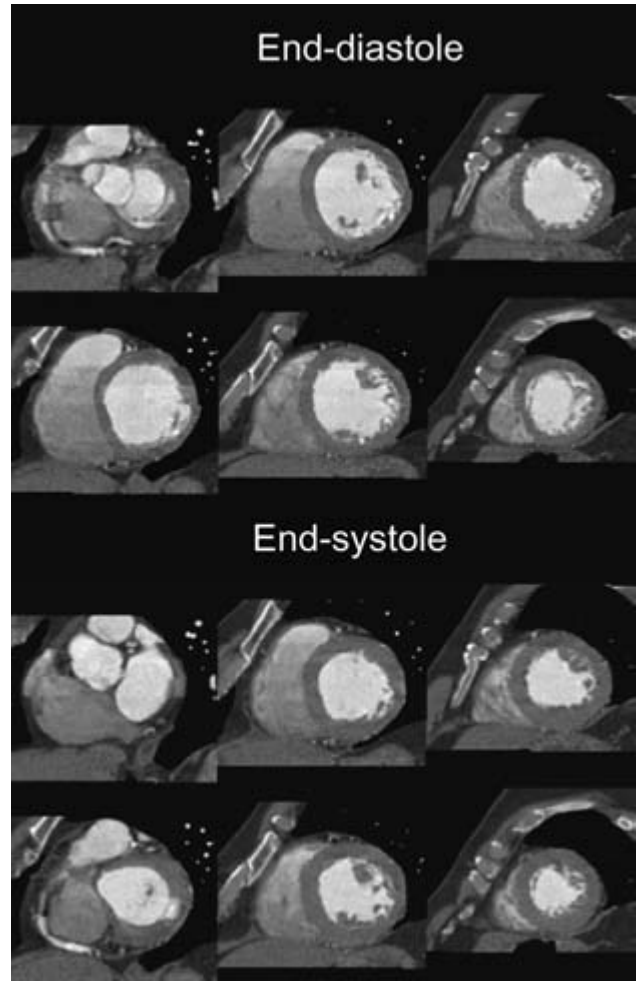

Figure 4.30 Visualization of left ventricle during systole and diastole. Reconstruction of short-axis images of the left ventricle during different time intervals of the cardiac cycle can be used to evaluate the left ventricular performance.

Personal perspective

Selective conventional coronary angiography still remains vital to planning catheter-based or surgical treatment of coronary artery stenoses and serves as a road map for catheter-based coronary diagnostic modalities such as intravascular ultrasound, optical coherence tomography, thermography. The high spatial and temporal resolution of invasive coronary angiography will not be matched by MDCT, but it is to be expected that the imaging performance of this technique will become sufficient to allow clinically reliable assessment of the coronary anatomy either to exclude the presence of any significant coronary obstruction and avoid catheterization, or to detect the presence of one or more significant coronary stenoses and avoid diagnostic angiography prior to coronary revascularization. The technical advances of CT scanners in recent years have been rapid and will continue to take place. The clinical role of CT coronary artery imaging may thus be expected to evolve further in the years ahead. Established and evolving indications in relation to coronary calcium and the coronary (bypass graft) lumen are presented in Table 4.4. The prospect that CT will allow early detection of coronary atherosclerosis in asymptomatic individuals is exciting; however, this would require a significant reduction of the radiation exposure of current CT scanners.

Table 4.4 Clinical role of cardiac CT

Established indications	Evolving indications
Coronary calcium for risk stratification	Coronary stenosis detection
Anomalous coronary arteries	Evaluation of bypass grafts
Pulmonary embolism	Evaluation of coronary stents
Cardiac masses and thrombi	Left ventricular function
Aortic aneurysms and dissection	Assessment of total coronary plaque burden
Cardiac calcification (valvular, pericardial)	Assessment of vulnerable plaque

5 Nuclear Cardiology

Philipp A. Kaufmann, Paolo G. Camici and S. Richard Underwood

Summary

Non-invasive images of the myocardium that reflect myocardial perfusion can be obtained either by using conventional nuclear medicine radiopharmaceuticals and cameras or by positron emission tomography (PET). Myocardial perfusion scintigraphy (MPS) with thallium-201- and/or technetium-^{m}99-labelled sestamibi and tetrofosmin, in combination with single photon emission computerized tomography (SPECT), is a robust and well validated technique for the identification of myocardial ischaemia and infarction with high sensitivity and specificity. In selected subsets, e.g. patients with left bundle branch block and those unable to exercise, MPS can be the technique of choice for the demonstration of myocardial ischaemia. ^{99m}Technetium-labelled myocardial perfusion agents have a high-count density which enables acquisition of electrocardiogram-gated images. Spatial and temporal changes in activity during the cardiac cycle reflect regional myocardial motion and thickening and this technique allows left ventricular volume, ejection fraction, myocardial motion and thickening to be measured in addition to the information on perfusion. Since the main feature of an acute coronary syndrome is reduced myocardial perfusion, MPS can provide important diagnostic and prognostic information in the emergency department and allows patient stratification in the postinfarction phase. PET provides absolute measurement of myocardial blood flow and metabolism and, although potentially usable as a clinical tool, so far has been mainly employed as a powerful research instrument. PET has enabled the demonstration of coronary microvascular dysfunction and has highlighted the potential contribution of the microcirculation to myocardial ischaemia in patients with angiographically normal coronary arteries. Finally, both SPECT and PET are invaluable tools for the identification of viable and hibernating myocardium in patients with coronary artery disease and congestive heart failure.

Diagnosis of coronary artery disease

Chronic chest pain

Sensitivity and specificity

A range of investigations is normally used in patients with suspected coronary artery disease (CAD), the simplest 'investigation' being the history. Typical angina is a good indicator of myocardial ischaemia and abolition of symptoms is the primary aim of treatment. Symptoms, however, can be indeterminate and they do not indicate the site or extent of underlying ischaemia. It is therefore often helpful to proceed to further investigations to aid the diagnosis and to guide future management. Myocardial perfusion scintigraphy (MPS) is a robust, non-invasive and widely available method of assessing regional myocardial perfusion, and has an obvious role in the clinical setting. Many studies have assessed the sensitivity and specificity of this technique for the detection of CAD, coronary arteriography usually being used as the standard by which the accuracy of scintigraphy is judged. The wisdom of this approach can be debated but at least the arteriogram provides a universal standard for coronary anatomy even if it is less suited to the assessment of coronary arterial function. Published figures for

sensitivity and specificity of MPS vary widely and depend upon the characteristics of the population studied (its gender, presenting symptoms, medication, previous infarction, etc.), the imaging technique used [planar or single photon computed emission tomography (SPECT), qualitative or semi-quantitative analysis], and the experience of the centre. Good accuracy can be achieved using the modern techniques with tomographic imaging; sensitivity and specificity as high as 91% and 89%, respectively, can be obtained [1]. This is significantly better than exercise electrocardiography (ECG) for which a large meta-analysis has shown sensitivity of 68% and specificity 77%.

It is reasonable to ask therefore whether MPS should not replace exercise ECG in patients with suspected CAD. Several factors militate against this. The most important is the relative availability of the two techniques, but radiation burden and cost are also relevant. Although the cost of myocardial perfusion imaging (370 euros) is higher than that of the exercise ECG (120 euros) [2], this is more than outweighed by its greater effectiveness. Studies of cost-effectiveness have shown significant advantages for strategies of investigation using MPS, with savings in total diagnostic and management costs over 2 years in the region of 20% in centres routinely using scintigraphy.

Many centres use a staged approach with the exercise ECG being the initial stress test, followed by MPS if the likelihood of disease is indeterminate after the exercise ECG, or if further information on myocardial perfusion is required to assist management decisions. MPS should be the initial investigation in patients who are unlikely to exercise adequately, in women (because of the very high number of false-positive ECGs), and if the exercise ECG will be uninterpretable because of resting abnormalities such as left bundle branch block, pre-excitation, left ventricular hypertrophy, or drug effects.

The three commercially available perfusion tracers have equal accuracy for the detection of CAD [3]. Thallium-201 (^{201}Tl) has better uptake characteristics and, in theory, provides defects with greater contrast, but technetium-^{m}99 (Tc)-labelled sestamibi and tetrofosmin images are superior in terms of resolution and susceptibility to attenuation artefacts. The net effect of these technical differences in clinical practice is negligible, but the technetium tracers are preferred in obese patients or when ECG-gating is required. In fact, ECG-gating can aid the distinction between artefact and perfusion defect (Fig. 5.1) and can increase confidence in reporting [4]. Attenuation correction is another technique that can reduce artefacts, although it is controversial whether this can be achieved without loss of sensitivity and attenuation correction is not used routinely in most centres.

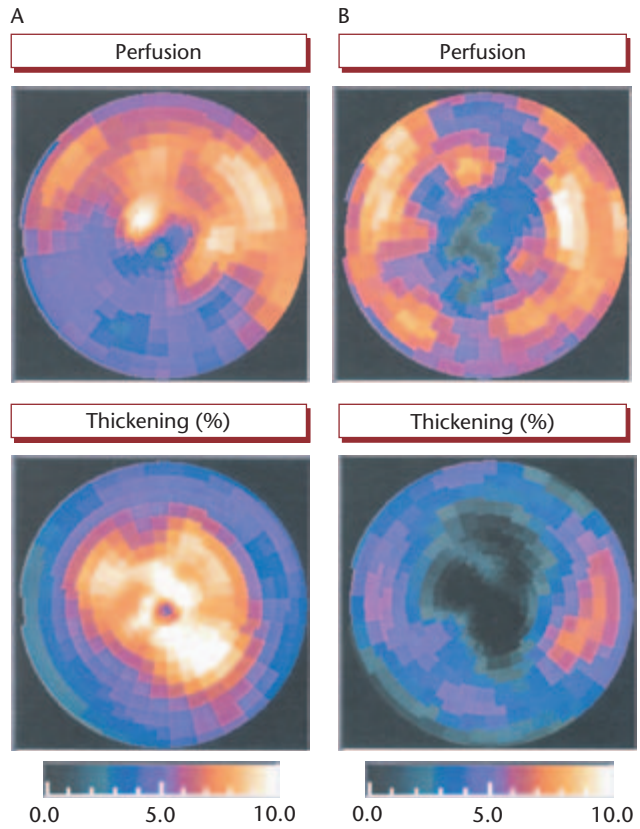

Figure 5.1 Polar map of a normalized rest perfusion scan (top) with the corresponding map representing the thickening assessed by gated SPECT (bottom). (A) Example of a patient with a fixed inferoseptal perfusion defect but normal thickening, identifying the perfusion defect as an attenuation artefact. (B) Example of a patient with a fixed apical perfusion defect with congruent decreased wall thickening, confirming that the perfusion defect is a scar.

Attenuation correction

Soft-tissue attenuation in the chest produces regional inhomogeneities in the normal pattern of tracer uptake and is one of the most frequent causes of artefact in MPS. Attenuation refers to the combined effects of photoelectric absorption and Compton scattering. The former occurs when a photon interacts with an orbital electron in the tissue and the total energy of the photon is lost. The latter indicates the interaction of a photon in the patient prior to detection, which makes the photon change direction. If patient positioning for rest and stress acquisition is kept constant, soft-tissue attenuation appears as a fixed defect. The resulting uncertainty in differentiating between a fixed defect due to an attenuation artefact and myocardial infarction can reduce the specificity of the test for detecting CAD. Several methods of non-uniform

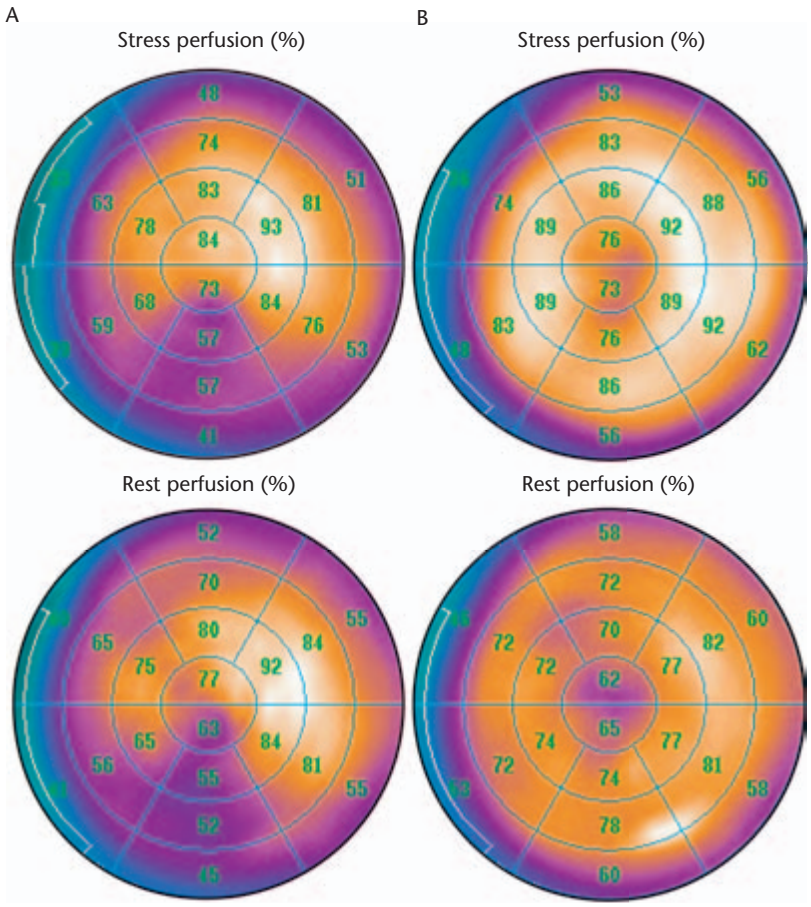

Figure 5.2 Polar map of a normalized stress (top) and corresponding rest perfusion scan (bottom) of an obese male patient with normal coronary arteries. (A) There appears to be a fixed inferior defect in the images without attenuation correction. (B) After attenuation correction with a CT (using a hybrid SPECT-CT scanner) perfusion appears normal, indicating that the inferior defect was the result of attenuation.

attenuation correction are now available commercially, albeit with variable clinical success (Fig. 5.2). Although several studies of attenuation-corrected SPECT have demonstrated improved specificity with no change in overall sensitivity, attenuation correction is not yet widely used. The relative capabilities of gated SPECT and attenuation correction to improve diagnostic specificity are still uncertain.

ECG-gated SPECT

^{99m}Tc-labelled myocardial perfusion agents are valid alternatives to ^{201}Tl for the assessment of CAD. Their high-count density has enabled the acquisition of ECG-gated SPECT studies. ECG-gating allows simultaneous assessment of resting ventricular function and either stress or rest perfusion. Spatial and temporal changes in activity during the cardiac cycle reflect regional myocardial motion and thickening respectively and automated detection of endocardial and epicardial contours allows left ventricular volume, ejection fraction, myocardial motion and thickening to be measured accurately and normally without user intervention. Assessment of motion aids the distinction between attenuation artefact and true perfusion abnormality because infarcted myocardium is unlikely to move or thicken normally and hence reporting confidence is increased and additional prognostic information is obtained [5].

Several fully automatic methods of measuring left ventricular function (Fig. 5.3) have been developed [6] and validated against a variety of techniques, such as equilibrium and first-pass radionuclide ventriculography, X-ray contrast ventriculography, magnetic resonance imaging and two-dimensional echocardiography.

Positron emission tomography

The most commonly used radiopharmaceuticals for positron emission tomographic (PET) imaging of myocardial perfusion are [^{15}O]water, [^{13}N]ammonia and rubidium-82 (^{82}Rb). For the last two tracers sensitivities between 83% and 100% have been reported for the detection of CAD with specificities between 73% and 100%. The main advantages of ^{82}Rb are its short half-life of 78 s and the

A

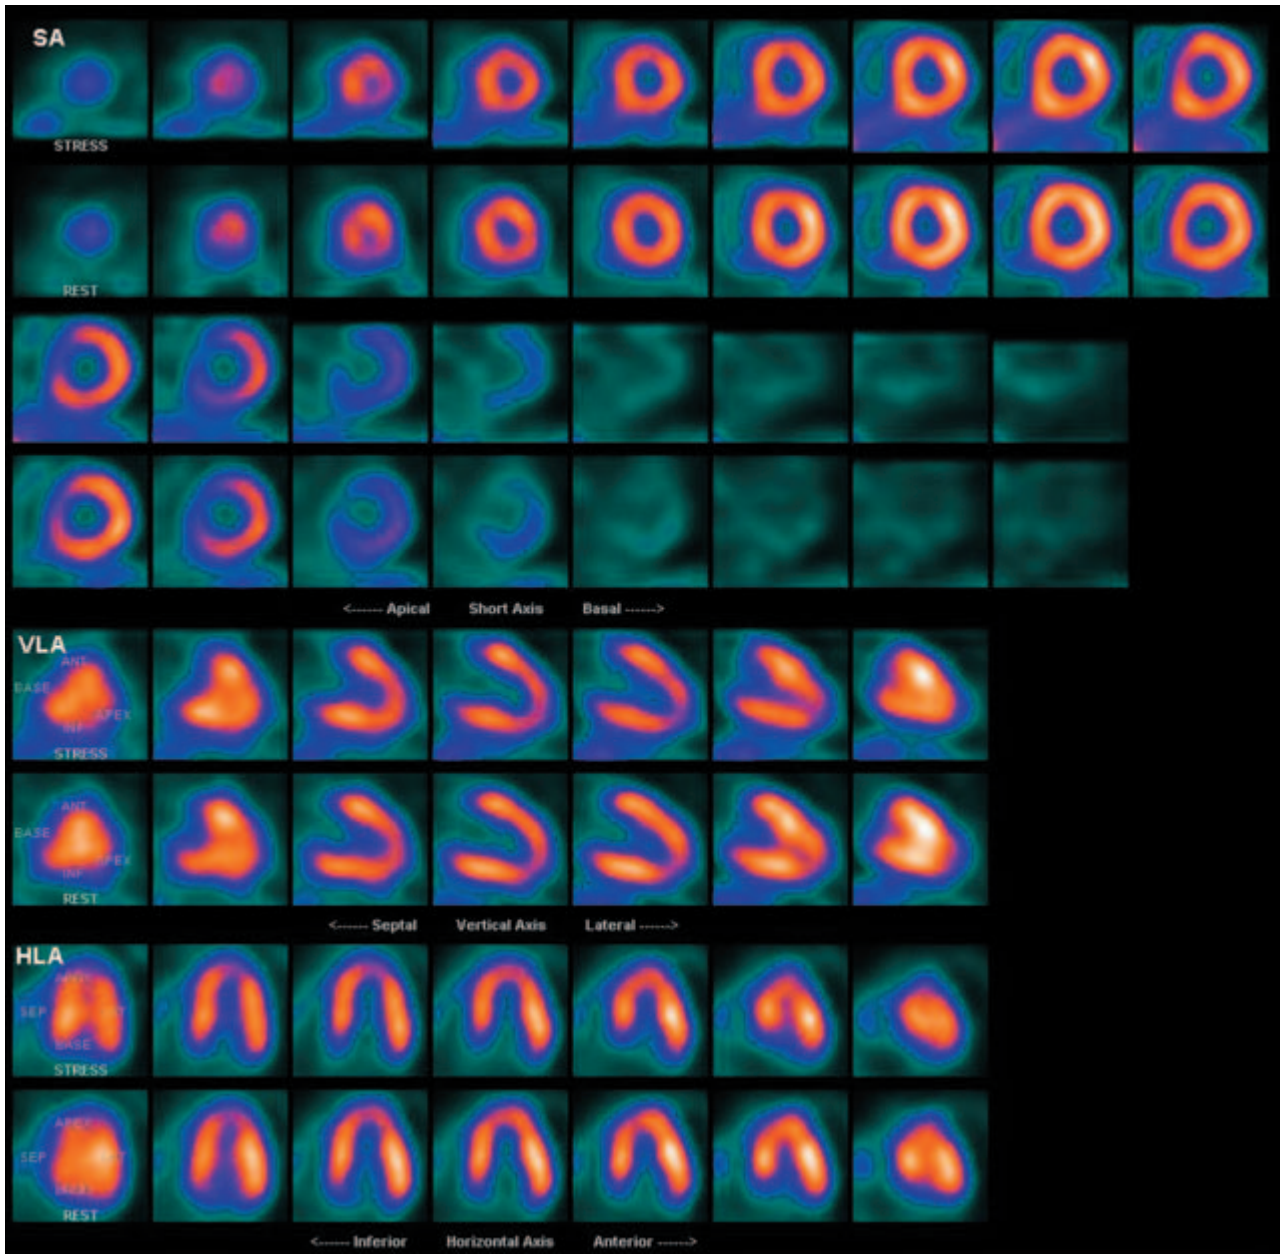

Figure 5.3 (A–C) Example from a female patient with normal coronary arteries and normal myocardial perfusion at rest and at stress assessed with ^{99m}Tc-labelled tetrofosmin. (A) The top four rows contain short-axis (SA) slices (stress and rest), the lower four rows represent the vertical (VLA) and horizontal (HLA) long-axis slices. All slices show normal perfusion without defect.

fact that it is readily produced at the point of use by an ^{82}Rb generator without the need for a cyclotron. Although several methods of quantifying regional myocardial perfusion using ^{82}Rb have been described, their accuracy is limited by the dependence of myocardial extraction of this tracer on perfusion and on the metabolic state of the myocardium. The high energy of the positron emitted (3.15 MeV) also reduces resolution of the images because of the long track of the positron before annihilation with an electron.

Both [^{13}N]ammonia and [^{15}O]water are the most commonly used PET tracers for the quantification of regional

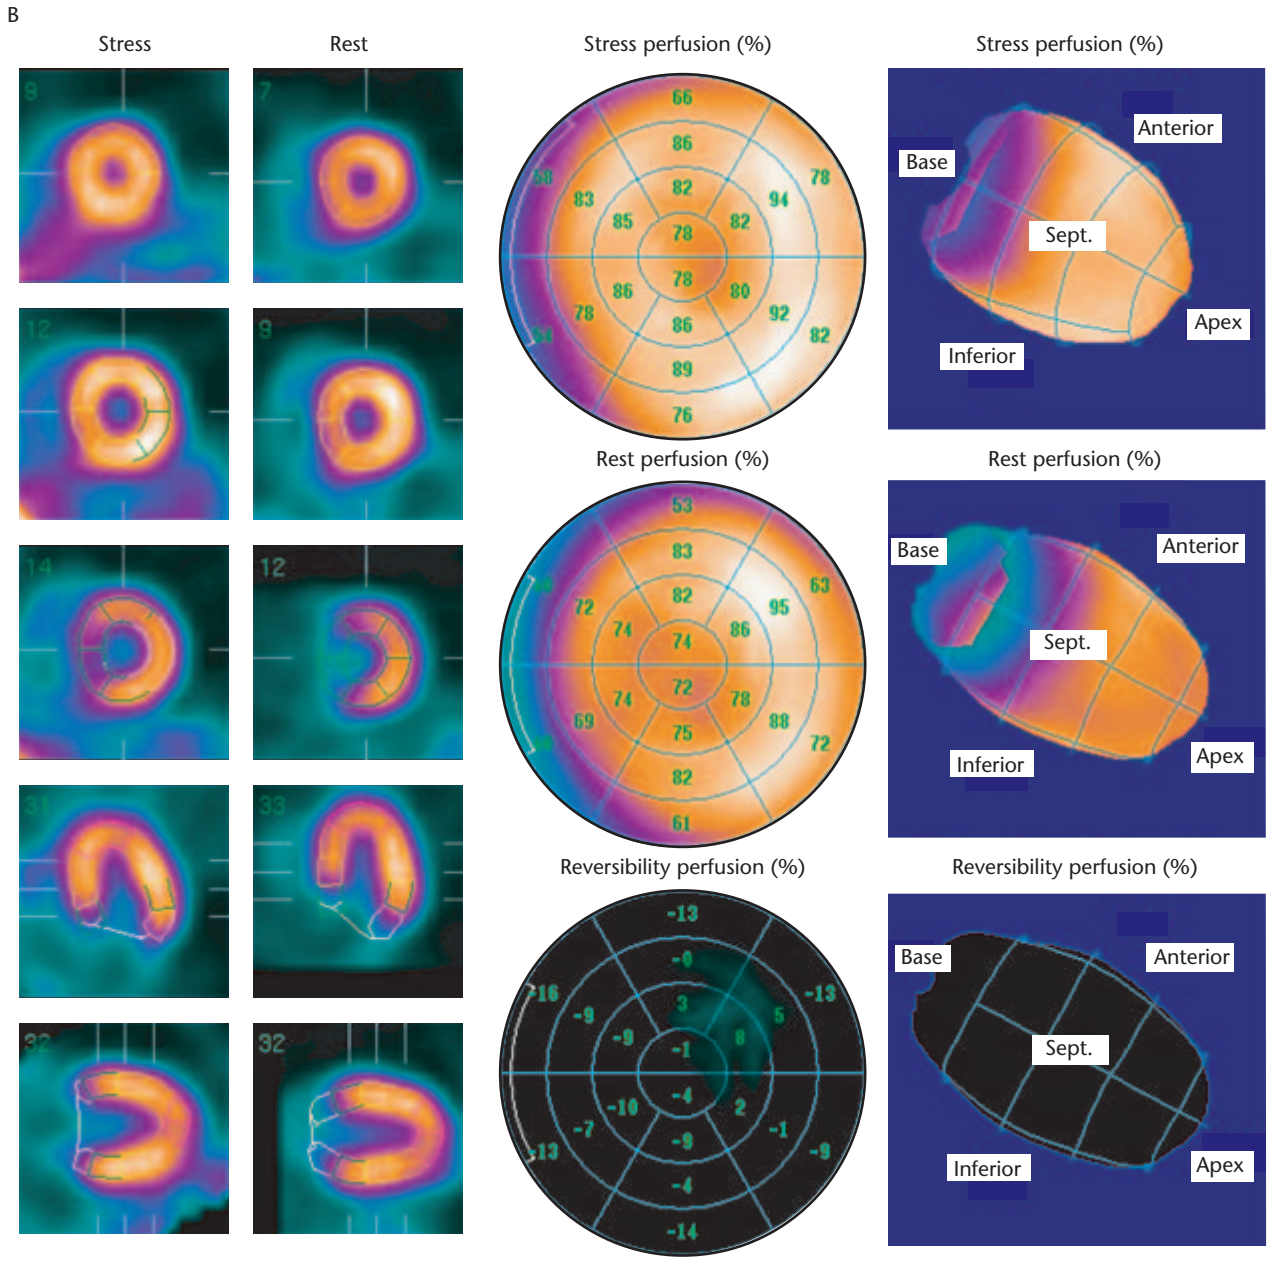

Figure 5.3 (*cont'd*) (B) Right: Polar plots and three-dimensional view of the perfusion scan indicating normal perfusion at rest and at stress. Left: The apical, mid-ventricular and basal short-axis slices illustrate the location of the radial-search boundaries. The mid-ventricular vertical and horizontal long-axis slice images illustrate the placement of the apical and basal slice selections.

myocardial perfusion. They have similar half-lives of 10 and 2 minutes respectively and so they both require an on-site cyclotron, which limits their widespread use. [^{15}O]water is superior to [^{13}N]ammonia as a perfusion tracer because it is metabolically inert and it diffuses freely across capillary and sarcolemmal membranes. It equilibrates rapidly between the vascular and extravascular spaces and its myocardial uptake varies linearly with perfusion over a wide range. However, [^{15}O]water has an important shortcoming compared with [^{13}N]ammonia: it does not accumulate in myocardial cells and it does not therefore provide images for clinical use. In contrast, [^{13}N]ammonia accumulates in myocardial cells and provides high-quality images of perfusion (Fig. 5.4). Therefore, it is the preferred tracer for clinical use provided that a cyclotron is available. The problem of attenuation

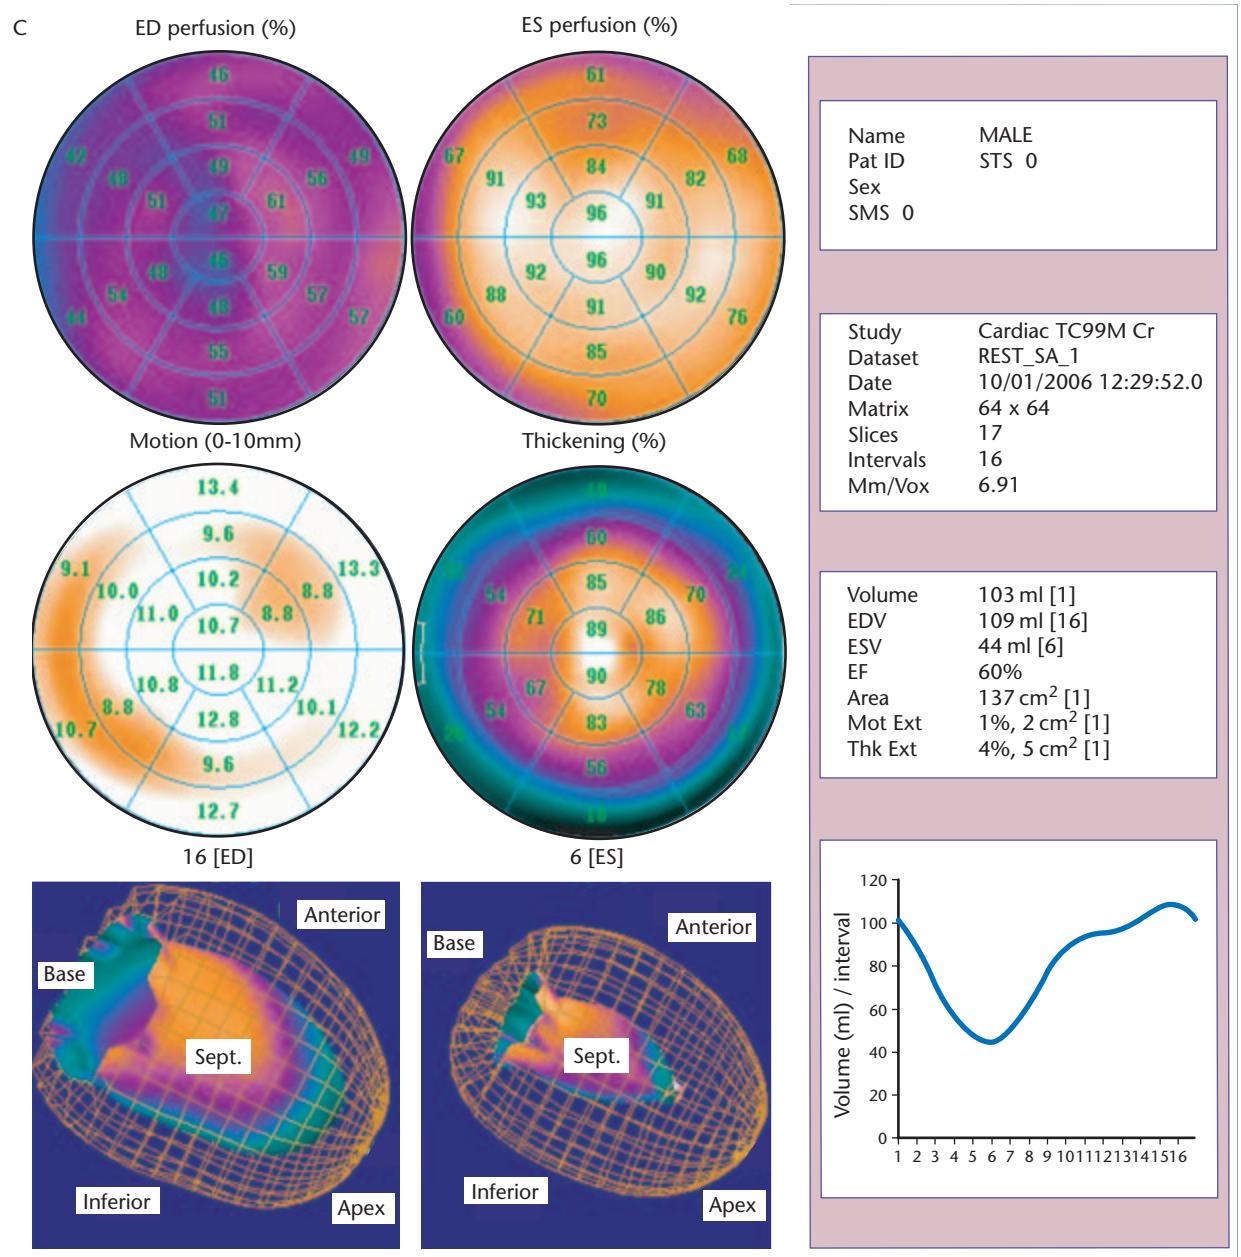

Figure 5.3 (*cont'd*) (C) Quantitative gated SPECT analysis (normal female patient). Left ventricular ejection fraction (LVEF) is 84%: in patients with end-systolic LV volume less than 15 ml EF is often overestimated. Nevertheless there is quantitative proof of normal LV wall motion and thickening, with a summed wall motion (SMS) and summed wall thickening score (STS) of 0. The LV time–volume curve shows excellent diastolic function (rapid filling as a result of rapid relaxation in the early diastolic time and second peak filling as a result of atrial contraction in the late diastolic phase).

correction has been solved for PET by using external ^{68}Ge or X-ray sources as recently established in the hybrid PET/CT scanners [7].

Because of the higher resolution of PET and its integrated attenuation correction, its accuracy for the detection of CAD is thought to be superior to that of SPECT, although only a small number of studies has directly compared the techniques [3] and it is not known if its higher cost outweighs its greater accuracy. In complex coronary disease, particularly multivessel disease where there may be no normal reference segment, PET is preferred (Fig. 5.5). Quantification may allow the demon-

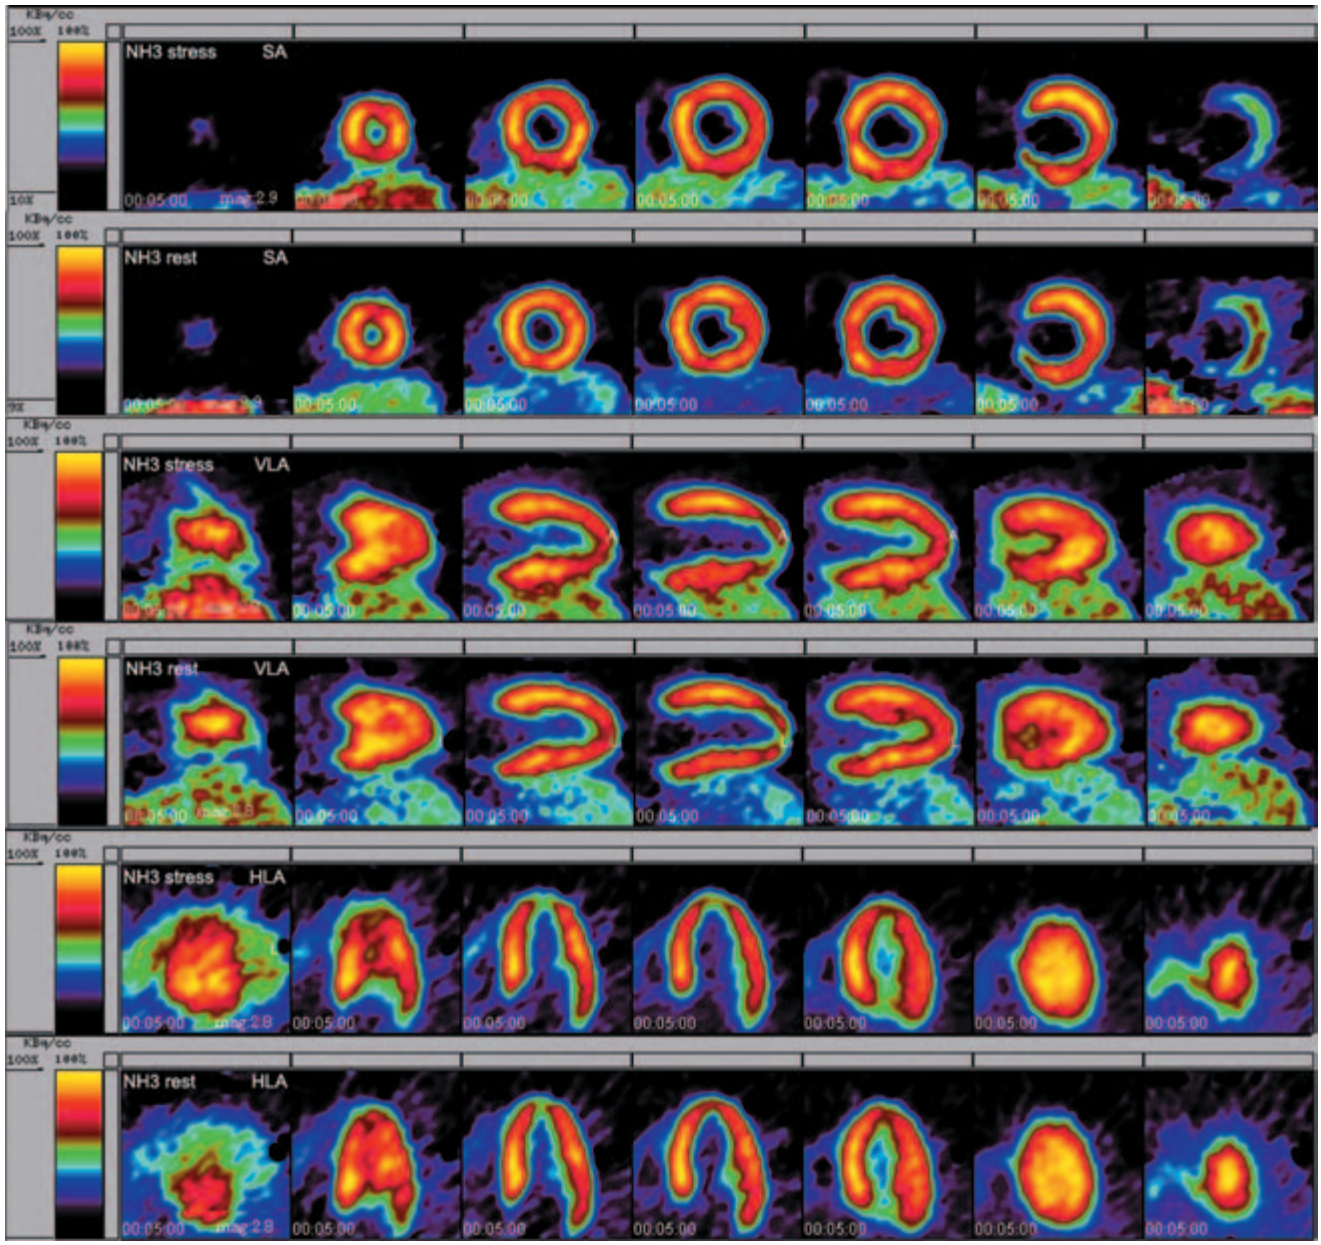

Figure 5.4 PET perfusion scan using [^{13}N]ammonia as perfusion tracer. Short axis (SA), vertical (VLA) and horizontal long axis (HLA) indicate normal perfusion during adenosine stress as well as at rest.

stration of endothelial dysfunction before an anatomical stenosis is apparent and it has had a great impact on our understanding of the pathophysiology of coronary disease [8].

Multislice X-ray computerized tomography (MSCT) is a rapidly developing technology that may facilitate the broader application of cardiac and coronary CT in the near future. The combination of non-invasive coronary angiography with the assessment of myocardial perfusion by radionuclide techniques provides a new non-invasive strategy for assessing known or suspected coronary disease with simultaneous assessment of coronary anatomy and function. Preliminary studies are promising (Fig. 5.6).

Acute coronary syndromes

Chest pain unit

The majority of patients presenting to emergency departments with chest pain are admitted because the initial

Figure 5.5 (A) Short-axis (SA, upper rows) and horizontal long-axis (HLA) cuts of PET perfusion scan with [^{13}N]ammonia from a patient with suspected coronary artery disease. The images show a defect in the left ventricular lateral wall that becomes evident during adenosine stress. Blunted hyperaemic response cannot be distinguished from a decrease in absolute flow (potentially induced by a steal phenomenon). (B) Quantification of myocardial blood flow reveals an absolute decrease in blood flow during adenosine stress, indicating that steal phenomena may be involved. Coronary angiography confirmed subtotal occlusion of the left circumflex coronary artery. Sep, septum; ant, anterior; lat, lateral; inf, inferior; CFR, coronary flow reserve; sep-i, septal inferior; sep-a, septal anterior.

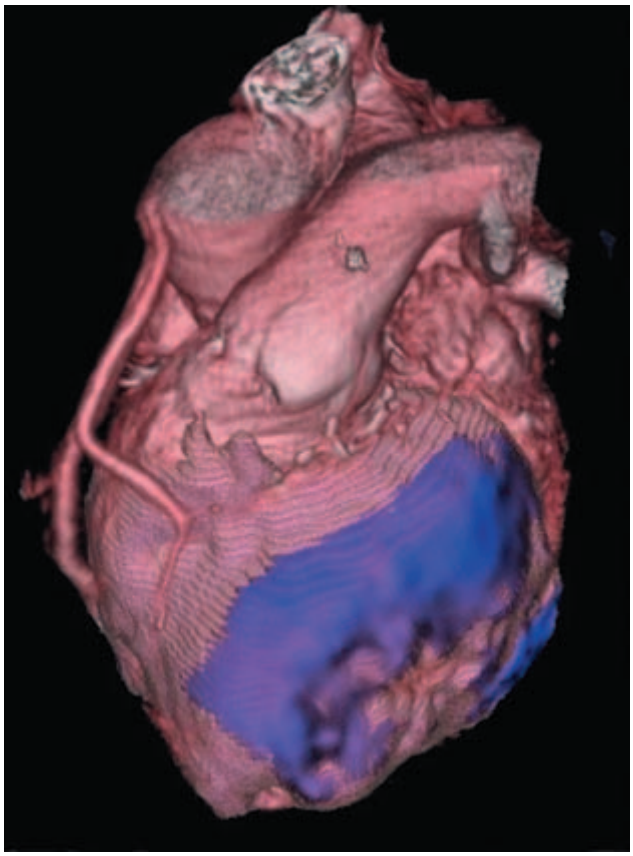

Figure 5.6 Anterior three-dimensional image of the heart obtained by CT in a patient with multivessel coronary disease and previous bypass grafting. Stress perfusion information from PET is superimposed with blue indicating an area of reduced perfusion. Bypass grafts to the left anterior descending and right coronary arteries are patent but a graft to the left circumflex artery is occluded and is therefore not visualized. The ischaemic area is in the territory of this graft.

clinical examination, ECG results and cardiac enzyme levels are insufficient to exclude an acute coronary syndrome, although most patients without obvious ECG changes do not have an acute syndrome. Conversely, a substantial minority of patients who are discharged from the emergency department have undetected acute ischaemia and an adverse outcome. Because the main feature of an acute coronary syndrome is reduced myocardial perfusion, MPS in the emergency department can provide important diagnostic and prognostic information. It has not been used widely because of the logistical problems of providing an acute radionuclide-imaging service, but several studies have now shown the effectiveness and cost-effectiveness of MPS in the acute setting, especially when the resting ECG is not diagnostic of myocardial ischaemia. A resting perfusion defect has a high positive predictive value for acute infarction in patients without history of previous myocardial infarction, particularly if it is associated with a wall motion abnormality on gated imaging, and these patients should be admitted to the coronary care unit. Conversely, a normal perfusion scan excludes acute infarction and exercise ECG or stress MPS can be the next diagnostic step. If the perfusion tracer can be injected during chest pain, a normal perfusion scan excludes a cardiac cause and allows the patient to be discharged. In patients with symptoms suggestive of an acute coronary syndrome, acute MPS reduces unnecessary hospital admission without reducing the appropriate admission of patients with a genuine acute coronary syndrome [9]. The sensitivity of acute rest MPS for the diagnosis of myocardial infarction is high very early after the onset of ischaemia, in contrast to serum enzyme markers, which require several hours to become clearly abnormal. Patients discharged with normal MPS have a very low likelihood of future cardiac events whereas patients with abnormal scans are at higher risk [10].

An intriguing option in patients with acute chest pain that has settled is to perform SPECT with free fatty acids [e.g. ^{123}I-labelled (*p*-iodophenyl)-3-(R,S)methyl-pentadecanoic acid (BMIPP)] because fatty acid metabolism is reduced for some time after acute ischaemia has resolved. This 'metabolic memory' might allow diagnosis for up to 24 hours after ischaemic chest pain and the theory is proven in principle although it has not been widely applied.

Risk assessment after myocardial infarction

Because the prognosis of ST segment elevation myocardial infarction (STEMI) is determined by left ventricular ejection fraction (LVEF), infarct size and residual viable myocardium, radionuclide techniques provide important information that aids patient management. MPS provides additional prognostic information over clinical factors and LVEF and coronary angiography may not provide prognostic information beyond this. MPS with vasodilator stress allows the risk to be assessed safely 2–5 days after infarction and is superior to early submaximal exercise testing.

Patients with small, fixed perfusion defects have a good prognosis, and are unlikely to benefit from invasive investigation and revascularization. Conversely, patients with MPS markers of high risk can be referred for coronary angiography and possible revascularization, although the superiority of revascularization over medical therapy has not been established in this setting [11]. Although primary percutaneous coronary intervention is the treatment of choice in STEMI, it is not currently available in all centres and some patients present too late for

alternative thrombolysis. When this is the case, MPS is very helpful for risk stratification and a large prospective randomized trial (INSPIRE—Adenos*IN*e *S*estamibi SPECT *P*ost *I*nfa*R*ction *E*valuation) will determine the value of early MPS in assessing risk and subsequent changes after medical therapy and revascularization [12].

In unstable angina and non-STEMI an early invasive strategy is recommended for patients with indicators of high risk and no serious comorbidities and this can be assessed by exercise ECG and by MPS [13]. MPS is particularly useful for assessing the risk of unstable angina once it has been stabilized.

Specific patient populations

The exercise ECG has moderate specificity for the detection of CAD in the absence of resting repolarization abnormalities, left ventricular hypertrophy and if patients are not treated with digoxin. Thus, when the resting ECG is normal and the likelihood of CAD from clinical assessment is low (for instance less than 25%) a stepwise strategy is appropriate with an exercise ECG as the initial diagnostic test. When the likelihood of CAD is very low (for instance less than 10%) then the best strategy will be reassurance without any provocative testing. If the resting ECG is abnormal or the likelihood of CAD is greater than 25% then MPS may be the better initial test on grounds of cost-effectiveness [2].

Women

The exercise ECG has lower specificity for the detection of CAD in women than in men and so MPS is a better diagnostic test even at lower likelihoods of disease. Pharmacological stress MPS is particularly valuable in women who are unable to exercise maximally. Although perfusion images are susceptible to breast attenuation artefacts, specificity can be maintained with awareness of the potential for artefacts, by using ^{99m}Tc perfusion tracers rather than ^{201}Tl, and employing ECG-gating and attenuation correction. The sensitivity of MPS is similar in men and women. PET perfusion imaging, when available, may be an additional way of avoiding attenuation artefacts.

Normal ECG, unable to exercise

Patients unable to exercise because of physical limitations, such as arthritis, amputations, peripheral vascular disease or pulmonary disease, should undergo MPS with pharmacological stress as the initial diagnostic test. Inability to exercise is itself an adverse prognostic indicator, presumably because of the increased incidence of CAD, and this should be borne in mind when interpreting MPS in these subjects.

Conduction abnormality

Patients with conduction abnormalities, such as left bundle branch block, bifascicular block and paced rhythms, may have inducible and fixed perfusion abnormalities on MPS even in the absence of underlying CAD, particularly when imaged during exercise or dobutamine stress (Fig. 5.7). Similar defects are much less common in patients with right bundle branch block although they can occur. These defects most commonly are confined to the septum although they can be more extensive. The causes of these defects in patients with conduction abnormalities

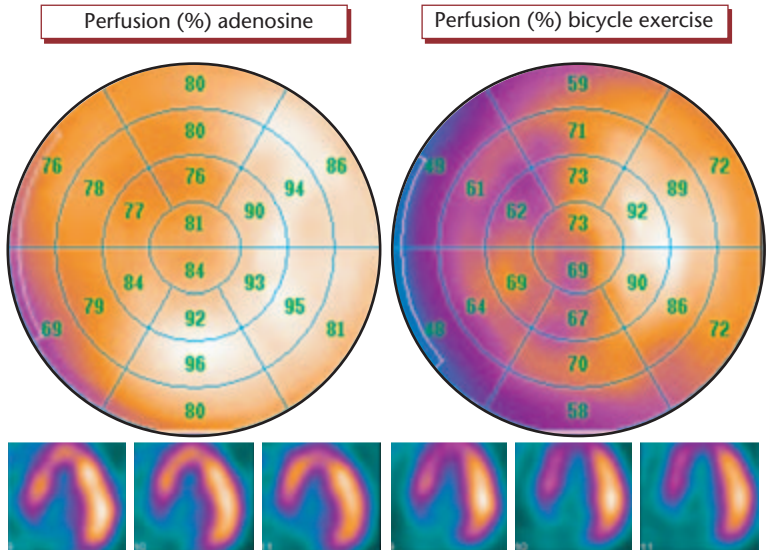

Figure 5.7 Polar maps of two perfusion scans, obtained using different stressors, in the same patient with left bundle branch block. During adenosine stress (left) perfusion is homogeneous while during bicycle exercise stress (right) there is reduced septal perfusion despite normal coronary arteries.

are still uncertain and are likely to be multifactorial, but they generally reflect true perfusion heterogeneities related to delayed septal relaxation and shorter diastolic perfusion time, or possibly to reduced regional afterload and hence reduced myocardial oxygen demand. Fixed defects may be the result of reduced myocardial thickening or they may result from an underlying myocardial abnormality such as cardiomyopathy.

The specificity of MPS for the detection of CAD is therefore reduced in these patients when dynamic exercise is used, but specificity is maintained using vasodilator stress if the heart rate does not increase significantly. In practice, when there is a diagnostic problem in a patient with left bundle branch block or paced rhythm MPS should be performed with adenosine or dipyridamole without additional exercise. A normal study excludes underlying coronary obstruction but an abnormal study may be less helpful diagnostically.

Prognosis of CAD

Beyond diagnosis, the most valuable contribution that MPS can make to the management of known or suspected CAD is to assess the likelihood of a future coronary event such as myocardial infarction or coronary death. Prognosis is strongly influenced by the extent and severity of inducible perfusion defects and this can guide the need for further invasive investigation and revascularization. MPS is a more powerful prognostic indicator than clinical assessment, the exercise ECG and coronary angiography, and provides incremental prognostic value even once the other tests have been performed [14].

The most important variables that predict the likelihood of future events are the extent and depth of the inducible perfusion abnormality. The relative value of the fixed component of a stress defect is unclear, but it is likely that left ventricular function is the best indicator of prognosis in patients with predominantly fixed defects. Thus, the patient with extensive ischaemia is at high risk of a coronary event and sudden death irrespective of the presence of infarction, and the patient without ischaemia but with a fixed defect is only at risk if the defect leads to significantly impaired function. Additional markers of risk are increased lung uptake on stress thallium images, because this indicates raised pulmonary capillary pressure either at rest or in response to stress, and ventricular dilation that is greater in stress thallium images than at rest. Transient ischaemic dilation can also be seen with ^{99m}Tc imaging and it may be the result of extensive subendocardial ischaemia giving the impression of cavity dilation.

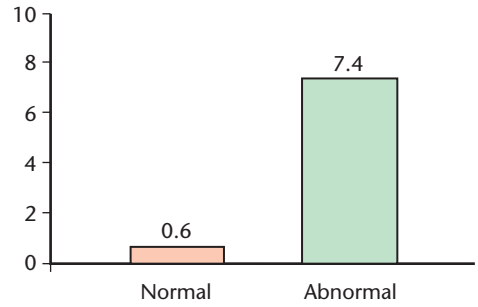

Figure 5.8 Rate of death or non-fatal myocardial infarction in patients with normal and abnormal stress MPS from 14 published reports comprising more than 12 000 patients. Reprinted with permission [15].

In patients with known or suspected CAD, a normal perfusion scan is very valuable because it indicates a likelihood of coronary events of less than 1% per year [15], a rate that is lower than that in an asymptomatic population (Fig. 5.8). Thus, whether non-obstructive CAD is present or not, further investigation can be avoided. This negative predictive value is independent of the imaging agent and technique, the method of stress, the population studied and the clinical setting. Exercise radionuclide ventriculography has also been used to assess prognosis because abnormal regional contraction is an early manifestation of inducible ischaemia [16]. Stress LVEF provides more information than resting LVEF because it reflects the extent of both infarction and transient ischaemia. However, the comparative prognostic value of perfusion imaging and exercise ventriculography has not been fully assessed, although it has been suggested that knowledge of rest and stress LVEF from resting gated MPS and stress first-pass ventriculography provides additional prognostic information compared with the perfusion information alone.

Preoperative risk assessment

A common clinical problem is that of assessing cardiac risk in patients who require non-cardiac surgery. In this, as in other clinical settings, MPS provides useful information although these patients are generally at low cardiac risk and the predictive value of a normal perfusion study is greater than that of an abnormal study. Whether investigation beyond simple clinical assessment is required should be based upon the urgency of the surgery and its own cardiac risk, the risk factors of the individual, and the individual's exercise tolerance. Patients with only minor clinical predictors (age > 70 years, abnormal resting ECG,

history of stroke or hypertension) who require low-risk (endoscopic or superficial procedures, cataract surgery and breast surgery) to moderate-risk surgery (carotid endarterectomy, head and neck surgery, intraperitoneal and intrathoracic surgery, orthopaedic surgery and prostate surgery) are not at high risk and do not require further investigation. Patients with intermediate clinical predictors (stable angina, prior infarction, treated heart failure, or diabetes) or with minor predictors and impaired exercise tolerance need further assessment if they are to undergo moderate-risk or high-risk surgery. Patients at high clinical risk (recent infarction or unstable angina, decompensated heart failure, or significant arrhythmias) require investigation even for low-risk surgery.

For patients who are able to exercise, further investigation normally means exercise ECG, but if the resting ECG is abnormal or in patients who are unable to exercise, MPS should be used instead. If further testing suggests a low risk, then surgery can proceed as planned. If it suggests a high risk then the need for coronary angiography and revascularization is determined by the clinical setting. In general terms, revascularization should not be performed if it would not have been performed in the absence of surgery because the risk of revascularization may still exceed the risk of non-cardiac surgery. In patients at intermediate risk after further testing, the best strategy is uncertain but aggressive medical management at the time of surgery rather than revascularization is preferred. This medical management involves rigorous control of pain, fluid balance and coagulation state after surgery, as well as preoperative beta-blockade and possibly perioperative nitrate infusion.

Management of myocardial revascularization

MPS can be valuable both before and after myocardial revascularization, either by angioplasty or bypass surgery. Neither procedure should be undertaken without objective evidence of ischaemia and perfusion imaging is often the most reliable way of obtaining this information and of ensuring that angioplasty is targeted at the culprit lesion [17]. It has an excellent negative predictive value for predicting restenosis and clinical events after angioplasty, and this can be particularly helpful in patients with recurrent but atypical symptoms. Routine MPS after angioplasty in the absence of symptoms is not common, although it can sometimes be useful as a new baseline in case symptoms recur. It can, however, be justified routinely in patients with impaired left ventricular function, proximal disease of the left anterior descending coronary artery and multivessel disease, suboptimal results of angioplasty, diabetes, and in those with occupations requiring low coronary risk. If MPS is performed after angioplasty then it should ideally be performed at least 6 weeks after the procedure because perfusion abnormalities can persist for some time even with a good anatomical result. Possible exceptions to this are patients with high-risk anatomy who can benefit from earlier imaging.

As with angioplasty, patients who are asymptomatic after bypass surgery do not routinely undergo perfusion imaging, although it can be helpful as a baseline for future management because revascularization is not infrequently incomplete. More commonly it is used for follow-up and it can be used roughly 5 years after surgery to guard against silent progression of prognostically important disease. Patients with symptoms after surgery may certainly benefit from MPS and the algorithms to be used are very similar to those in the diagnostic setting.

Myocardial infarction

Infarct detection

The diagnosis of acute myocardial infarction is normally made from the clinical history, the ECG, and from cardiac enzymes. In most cases these provide a conclusive answer but the diagnosis can be unclear in those seen late after the onset of chest pain, those with a conduction abnormality or pacemaker, those with perioperative infarction, and those in whom right ventricular infarction is a possibility. Nuclear techniques may then be helpful.

A number of radiopharmaceuticals have an affinity for acutely necrotic myocardium. Imaging of ^{99m}Tc-pyrophosphate has a sensitivity of at least 85% for the detection of acute infarction when performed 1–3 days after the event. Specificity is lower because uptake may occur in areas of old infarction or aneurysm, and also in areas of subclinical myocardial damage after unstable angina. Persistent blood pool activity or activity in bone and skeletal muscles can also cause difficulties, although these may be overcome by tomographic acquisition. In clinical practice, the technique is not used commonly, but it can be helpful in cases of doubt.

Imaging with anti-myosin antibodies labelled with indium has also been used and it has both high sensitivity and specificity. A multicentre trial of 492 patients showed sensitivities of 94% in Q-wave infarction and 84% in non-Q-wave infarction. Specificity was 93% in patients with chest pain but no infarction and there was focal uptake in 48% of patients with unstable angina suggesting subclinical infarction [18]. Despite this, the long time that is required after injection to obtain images limits its use for the early detection of infarction. This is also a drawback when using this compound for the detection of myocarditis and transplant rejection.

Myocardial salvage

Because ^{99m}Tc-labelled perfusion agents (MIBI and tetrofosmin) do not redistribute, they can be used in acute infarction to demonstrate the territory at risk before thrombolysis or acute angioplasty, and to assess the amount of myocardial salvage. The tracer is injected immediately before intervention and imaging can be performed several hours later once the intervention is complete and the clinical situation is stable. The defect will then correspond to the territory at risk and repeat injection and imaging several days later will show the actual extent of infarction. This is not a technique that can guide the need for intervention but it has been used in a number of clinical trials to assess the effect of acute intervention and to compare different regimes of thrombolysis on infarct size.

Management after infarction

An important aspect of clinical management after infarction is to identify patients at high risk of further events such as re-infarction or death, and hopefully to intervene to prevent these events. Clinical indicators of high risk in the acute phase include hypotension, left ventricular failure and malignant arrhythmias and these patients are candidates for early coronary angiography. After the acute phase however, prognosis is related to the degree of left ventricular dysfunction and the extent and severity of residual ischaemia; radionuclide imaging can assess both of these objectively. LVEF at the time of discharge or 10–14 days after infarction is a strong predictor of mortality, and patients with impaired function in particular can benefit from MPS to assess whether viable but jeopardized myocardium remains in the infarct zone and whether remote territories may also be jeopardized by ischaemia.

Heart failure: myocardial viability and hibernation

The term 'viable' is an umbrella term that includes several different subtypes of myocardium. One of these is hibernating myocardium, which is chronically dysfunctional but still viable myocardium that recovers function after coronary revascularization. For many years the functional sequelae of chronic CAD were considered to be irreversible and amenable only to palliative therapy. For example akinesis on the left ventriculogram implied infarcted myocardium or scar. We now know that chronic left ventricular dysfunction in patients with CAD is not necessarily irreversible and areas of akinetic myocardium have frequently been observed to improve in function after revascularization.

In 1978 Diamond *et al*. [19] suggested the possibility that 'ischaemic non-infarcted myocardium can exist in a state of function hibernation'. Several years later Rahimtoola [20] popularized the concept of hibernating myocardium and noted 'there is a prolonged subacute or chronic stage of myocardial ischaemia that is frequently not accompanied by pain and in which myocardial contractility and metabolism and ventricular function are reduced to match the reduced blood supply'. It is now known that perfusion is not always significantly reduced at rest in myocardial hibernation, but the debate on whether resting myocardial blood flow to hibernating myocardium is reduced or not has attracted a lot of interest and, undoubtedly, has contributed significantly to stimulate new research on heart failure patients with coronary artery disease. Although the debate is not over yet, some of the initial paradigms have been shown to be incorrect while new pathophysiological concepts have emerged. Clinically, the concept of hibernation has made a significant contribution to our understanding and management of patients with advanced ischaemic left ventricular dysfunction. Failure to identify and rescue hibernating myocardium may lead to loss of viable myocytes, progressive deterioration of heart failure and death. A number of imaging techniques have been used to detect viable myocardium and to characterize it as hibernating.

PET

Initial studies indicated that myocardial hibernation and infarction could be distinguished by a combination of PET perfusion imaging using [^{13}N]ammonia and metabolic imaging using the glucose analogue [^{18}F]fluorodeoxyglucose (FDG) after an oral glucose load. Regions with a concordant reduction in both [^{13}N]ammonia and FDG uptake ('perfusion–metabolism match', Fig. 5.9) were predominantly infarcted, whereas regions with reduced [^{13}N]ammonia uptake but preserved or increased FDG uptake ('perfusion–metabolism mismatch', Fig. 5.9) were hibernating [21]. Myocardial FDG uptake, however, depends on many factors such as dietary state, cardiac workload, insulin sensitivity, sympathetic drive and the presence and severity of ischaemia. These factors lead to variable FDG uptake in the fasted or glucose-loaded state and complicate image interpretation.

Semi-quantitative and quantitative analyses of FDG uptake improve the detection of viable myocardium but require standardization of imaging conditions particularly with regard to myocardial glucose uptake. Many

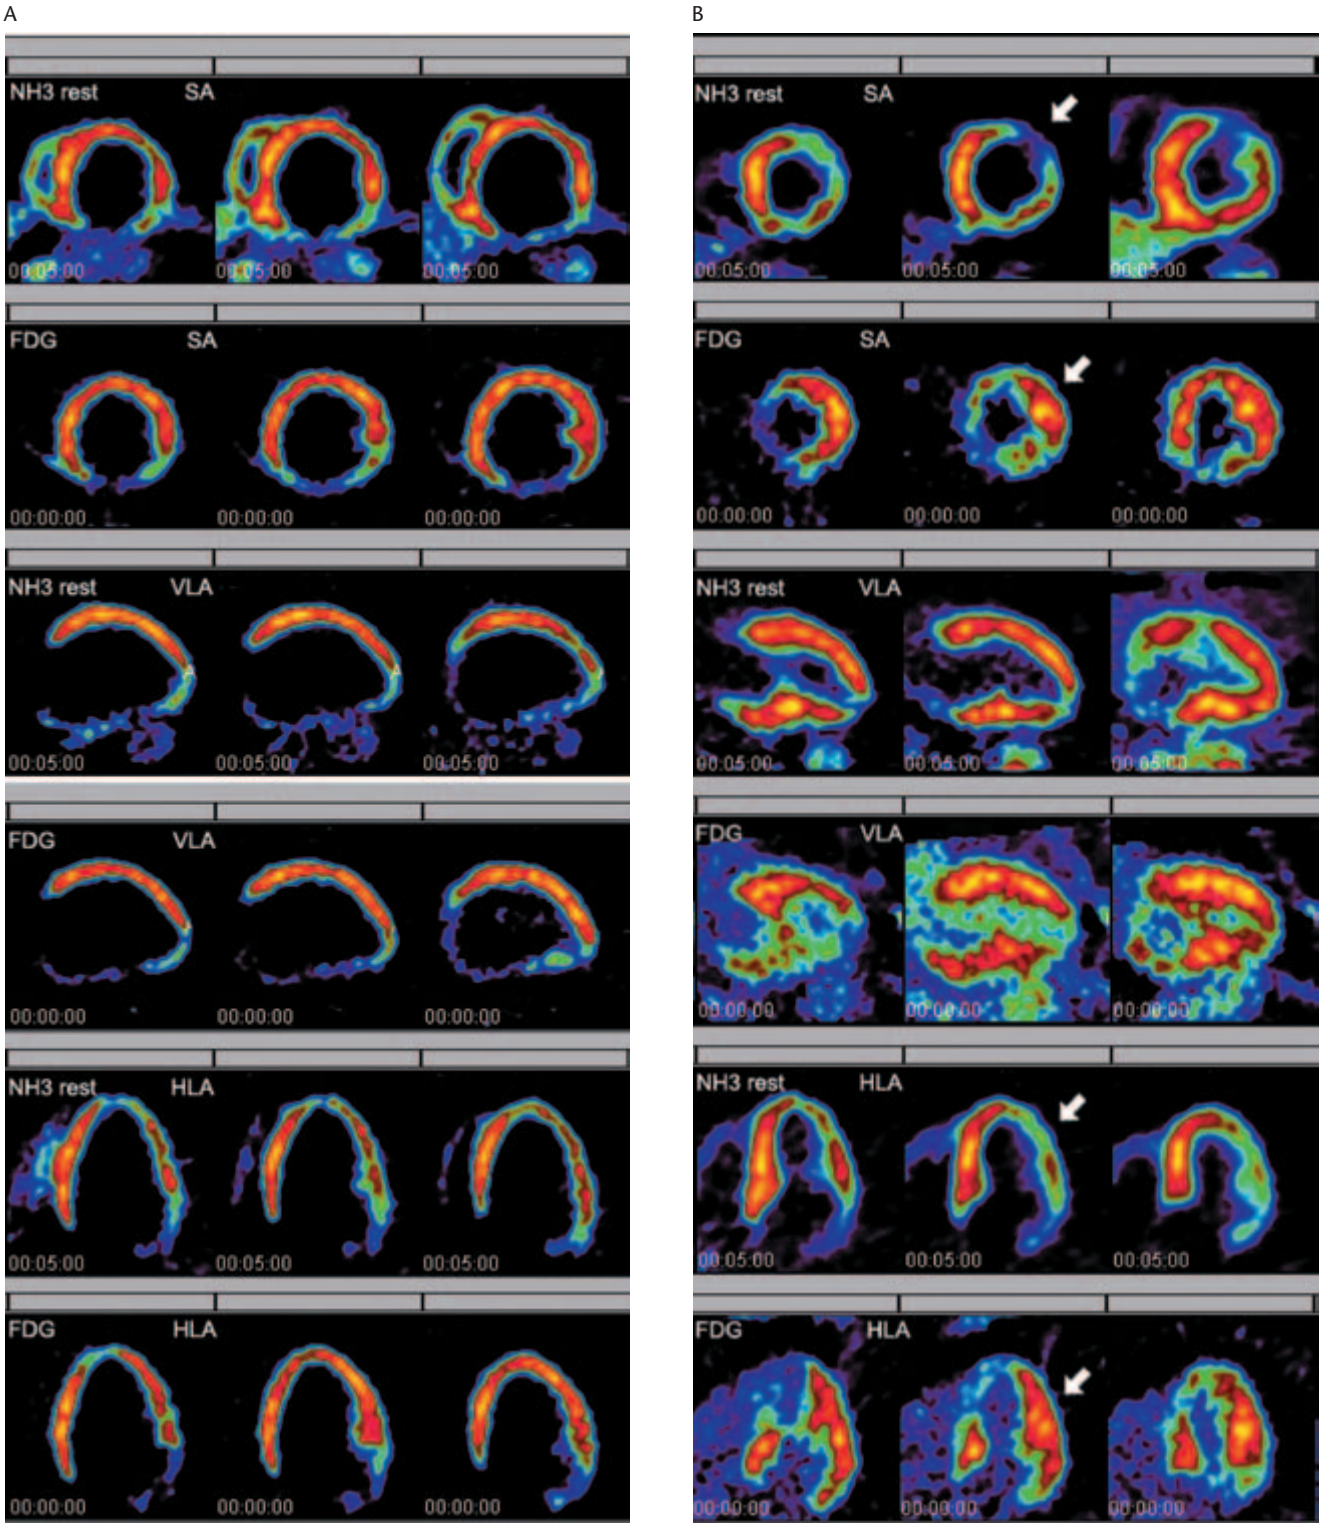

Figure 5.9 Short-axis (SA), vertical long-axis (VLA) and horizontal long-axis (HLA) tomograms of [^{13}N]ammonia (NH_3) perfusion at rest and [^{18}F]fluorodeoxy-glucose (FDG) metabolism. (A) Matched inferior defect of perfusion and metabolism indicating infarction without viable myocardium. (B) Anterolateral defect of perfusion with preserved FDG uptake indicating viable tissue. The mismatch of perfusion and metabolism indicates hibernating myocardium (white arrow).

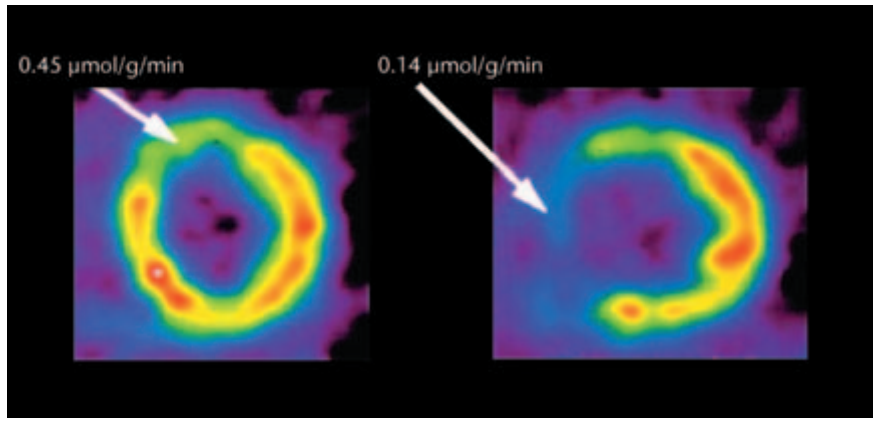

Figure 5.10 Quantitative images of myocardial [^{18}F]fluorodeoxy-glucose (FDG) uptake. Left, the anterior wall is viable with FDG uptake above the threshold of 0.25 µmol/g/min. Right, the septum does not contain clinically significant viable myocardium.

patients with CAD are insulin resistant and have poor FDG image quality after an oral glucose load. Myocardial glucose metabolism can therefore be standardized using the hyperinsulinaemic–euglycaemic clamp, essentially the simultaneous infusion of insulin and glucose acting on the tissue as a metabolic challenge and stimulating maximal FDG uptake [22]. This allows absolute values of glucose metabolism to be measured (µmol/g/min) and aids comparisons between different subjects and centres (Fig. 5.10). To determine the threshold value above which the best prediction of improvement in functional class of at least one grade could be obtained, in a prospective study in 24 patients undergoing coronary revascularization, a receiver–operator characteristic curve (ROC) was constructed. According to this analysis the optimal operating point on the curve (point of best compromise between sensitivity and specificity) was at the absolute threshold of FDG uptake of 0.25 µmol/g/min (where the gold standard was the evidence of functional recovery at follow-up) [23]. By comparing FDG images obtained under these conditions with regional wall motion from another imaging technique, the need for a simultaneous perfusion tracer is avoided.

In summary, clinically there is now wide consensus on the importance of identifying and treating hibernating myocardium in patients with coronary artery disease and heart failure. Although randomized studies are needed before a definitive influence on clinical practice is achieved, the contribution of the existing experimental studies is compelling.

Single photon tracers

The disadvantage of PET is that it is not widely available. Thallium provides information on both myocardial perfusion and viability and has been widely used for identifying myocardial hibernation. Because redistribution can be slow or incomplete in regions of reduced perfusion, the usual stress/redistribution protocol can underestimate myocardial viability and additional steps to ensure complete assessment of viability are required. These include late redistribution imaging at 8–72 hours after stress injection, re-injection of tracer at rest after redistribution imaging, and a resting injection on a separate day with both early and delayed imaging.

In any of these viability images, the amount of viable myocardium is proportional to the amount of tracer uptake relative to a normal area. A common threshold for defining clinically significant viability is 50% of maximal uptake although the best threshold may be higher. In addition to detecting viable myocardium in an area of akinesis it is important to demonstrate inducible ischaemia before diagnosing hibernation because hibernation is an ischaemic syndrome.

MIBI and tetrofosmin have also been used for the detection of viable and hibernating myocardium. In theory these tracers may underestimate viability in areas with reduced resting perfusion because they are combined tracers of viability and perfusion without the property of redistribution that allows viability to be assessed independently. Some studies have therefore found thallium to be better for the assessment of viability but others have found them to provide comparable information. It does appear though that if the tracers are given under the cover of intravenous or sublingual nitrates, then resting perfusion is improved and the technetium tracers are good markers of viability.

ECG-gated SPECT

An important problem in studies of hibernation is that viability and function are often assessed from different techniques, and it can be difficult to be sure that the same myocardial segments are being compared. Thus, the ideal technique should combine information on viability, perfusion and function in a single image, and ECG-gated

technetium MPS is very helpful. In regions of previous infarction with reduced tracer uptake, the assessment is more difficult, but this is not a major limitation because these areas contain little viable myocardium and may not benefit from revascularization.

Microvascular disease

Until recently, ischaemic heart disease was primarily thought be caused by disease of large vessels, particularly the conduit coronary arteries. However, it is now clear that abnormalities of the coronary microcirculation may contribute to the generation of ischaemia even in the absence of demonstrable disease of the large epicardial arteries. Microvascular disease often precedes epicardial coronary disease and its extent may have independent prognostic value.

Myocardial perfusion reserve is the ratio of myocardial perfusion during maximal coronary vasodilation and at baseline. It is an integrated measure of flow through the epicardial coronary arteries and perfusion through the microcirculation and it can be used to assess the function of the coronary circulation as a whole. An abnormal perfusion reserve can be the result of narrowing of the epicardial coronary arteries or, in the absence of angiographically demonstrable atherosclerotic disease, may reflect dysfunction of the coronary microcirculation. The latter can be caused by structural (e.g. vascular remodelling with reduced lumen to wall ratio) or functional (e.g. vasoconstriction) changes, which may involve neurohumoral factors and/or endothelial dysfunction. Furthermore, an abnormal perfusion reserve may also reflect changes in coronary and/or systemic haemodynamics as well as changes in extravascular coronary resistance (e.g. increased intramyocardial pressure).

The coronary microcirculation cannot be imaged directly in man *in vivo*. The resistance vessels in the coronary circulation are not generally visible on angiography and are too small to be catheterized selectively. Instead, indirect parameters such as myocardial perfusion and perfusion reserve can be used because, in the absence of coronary stenoses, they provide an index of microvascular function.

PET can be used to measure both absolute myocardial perfusion and perfusion reserve and microvascular dysfunction has been demonstrated in patients with hypercholesterolaemia, hypertension and diabetes and in those who smoke. The measurements can also be used as surrogate end-points to assess the effectiveness of therapeutic interventions such as α- and β-adrenoreceptor blockade [24], lipid-lowering, antioxidants [25], cardiovascular conditioning and coronary angioplasty. They also provide prognostic information [26,27] and microvascular dysfunction assessed by PET is an independent predictor of long-term outcome and cardiovascular death in patients with hypertrophic and dilated cardiomyopathies (Fig. 5.11).

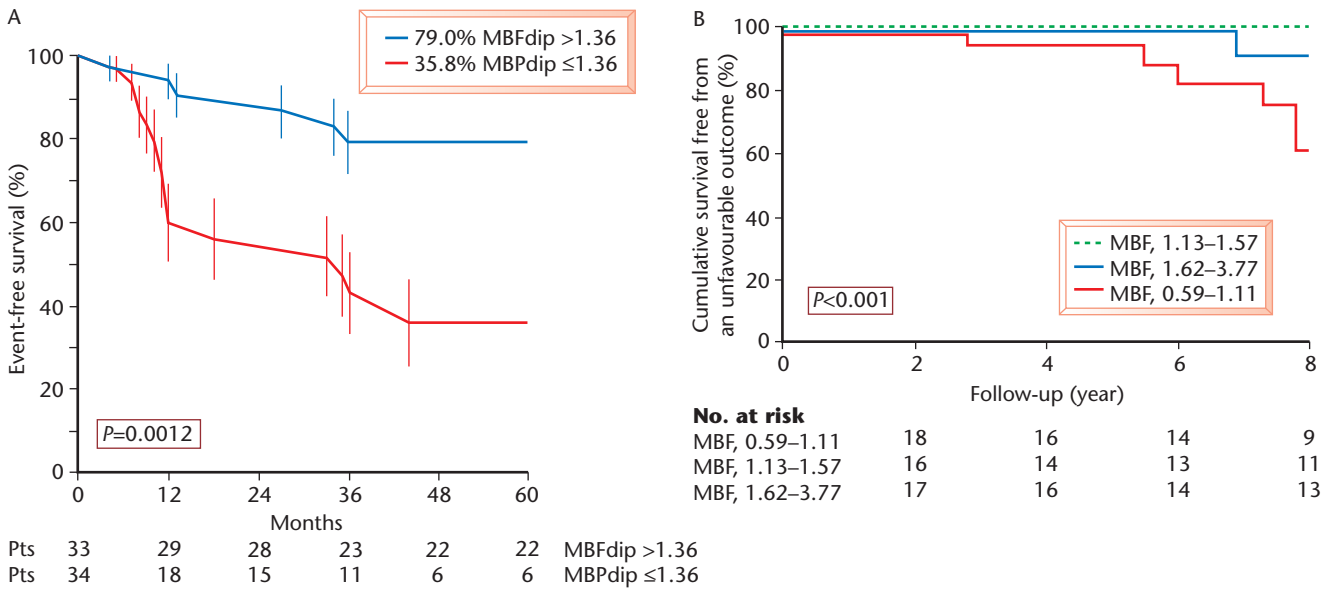

Figure 5.11 Kaplan–Meier event-free survival curves over 5 years in patients with dilated (A) and hypertrophic cardiomyopathy (B). Event-free survival is lowest in those patients with a severely blunted blood flow response to dipyridamole. Reprinted with permission [26,27].

Personal perspective

The first nuclear cardiology examinations were performed as early as 1927, when Blumgart and Weiss measured circulation times by intravenously injected radon gas. The next milestone followed in 1965 when Anger and colleagues first demonstrated the ability to define cardiac transit with a single-crystal scintillation camera. Although the 1970s and the early 1980s witnessed the onset of quantification of planar and tomographic imaging with SPECT and later with PET, it was only two decades ago that the prognostic applications of stress radionuclide imaging modalities were defined and pharmacologic stress imaging protocols were validated. In the 1990s, the role of nuclear imaging in the assessment of myocardial viability was established. Since then, nuclear cardiology has become an important cornerstone of cardiovascular evaluation in daily clinical routine. Myocardial perfusion study is a well-established, non-invasive technique with a large body of evidence to support its effectiveness in the diagnosis and management of angina and myocardial infarction. Nuclear cardiology procedures are an integral part of many clinical guidelines for the investigation and management of angina and myocardial infarction.

Despite its well-defined role with a broad-based set of clinical applications, the main strength of nuclear cardiology appears to lie in its enormous potential for innovation and progress. The combination of new biologically derived radiopharmaceuticals and advances in imaging technologies such as the integration of CT into PET and SPECT will undoubtedly continue to stimulate much scientific activity and provide new clinical applications for diagnosis, functional characterization and prognosis as well as evaluation of therapeutic strategies.

6 Invasive Imaging and Haemodynamics

Christian Seiler and Carlo Di Mario

Summary

Right- and left-sided cardiac pressure, oxygen and ventricular volume measurements together with coronary angiography are the basis for the functional and structural characterization of the majority of heart diseases.

Cardiac output is calculated as: oxygen consumption ÷ arteriovenous oxygen difference.

Detection and localization of intracardiac shunts can be performed using blood oxygen saturation as the indicator.

Vascular resistance is determined on the basis of Ohm's law (= pressure gradient ÷ flow).

The calculation of valve orifice area is based on its direct relationship to cardiac output, and on its inverse association to the square root of the pressure drop across the valve.

The coronary artery tree structure is intimately linked to its functional obligation of myocardial oxygen supply.

Varying oxygen demands by the myocardium are satisfied by altering coronary flow rates.

The main cause of a mismatch between myocardial oxygen demand and supply is coronary artery disease with its atherosclerotic narrowings.

In the event of an acute coronary occlusion, myocardial infarct size is determined by the following factors: time of occlusion, the size of myocardial area at risk, and the inverse of collateral supply to the occluded vascular territory.

Coronary pressure-derived fractional flow reserve is a useful way to describe the functional severity of coronary artery stenoses.

Introduction

Therapeutic decisions in cardiology are crucially determined by invasive circulatory imaging and haemodynamics, which are essential for understanding the pathophysiological and diagnostic aspects of cardiovascular disease. This is related to the fact that the cardiovascular system can be elegantly conceptualized using mechanical laws and the basic dimensions of mass (M), length (L), time (t) and temperature. Invasive examination allows the most direct determination of parameters derived from these dimensions, such as volume (L^3), force ($F = M \times$ acceleration), pressure (F/L^2) and flow (L^3/t), i.e. variables that permit the exact description of the forces generated by the different cardiac chambers. Thus, assessment of the haemodynamics of the circulation enables one to grasp the system's function, whereas invasive imaging depicts its structure in terms of lumen size, arterial branch lengths, branching patterns, etc. Accordingly, the goal of this chapter is to provide practical suggestions on how to become familiar with invasive techniques, how haemodynamic variables are obtained invasively and how the structure of the coronary artery tree is visualized. Finally, the epidemiologically important issue of coronary artery haemodynamics, including the relevance of coronary atherosclerotic lesions, is also discussed.

Percutaneous techniques of cardiac catheterization

Right side of the heart

Following local anaesthesia, the femoral vein is punctured before the common femoral artery is catheterized, and the sheath introduced by the Seldinger technique [1]. Using a 6F Swan–Ganz catheter allows a mostly easy passage to the pulmonary artery with low risk of injury to the right-heart chambers. To advance the catheter from the femoral vein to the pulmonary artery, the tip of the catheter is advanced from the lower right atrium by clockwise rotation over the tricuspid orifice, and then advanced into the right ventricle. To reach the pulmonary artery, the catheter must be slightly withdrawn so that its tip lies horizontally and just to the left of the spine. Clockwise rotation then causes the tip of the catheter to point upwards towards the right ventricular outflow tract. The catheter should only be advanced when it is in this position in order to minimize the risk of arrhythmia and injury to the right ventricular wall. If these manoeuvres fail to gain access to the pulmonary artery due to enlarged right-heart chambers, the catheter may be withdrawn to the right atrium and formed into a large 'reverse loop' by catching the tip in a hepatic vein and advancing the catheter quickly into the right atrium. This allows the tip of the catheter to advance through the tricuspid valve in an upward position. The catheter should then cross the pulmonic valve and advance to a pulmonary wedge position without difficulty. If the pulmonic valve cannot be passed, a 0.53-mm (0.021-inch) guidewire can be employed to facilitate positioning in the pulmonary artery. Once in the pulmonary wedge position, measurements of pressure and blood oxygen saturation are started. Following measurement of the wedge pressure, the catheter is withdrawn into the proximal pulmonary artery, into the right ventricle and then into the right atrium, with corresponding recordings of pressure and oxygen saturation. Unsuspected anatomical abnormalities encountered during right-heart catheterization include passage across a patent foramen ovale into the left atrium (Fig. 6.1), a persistent left superior vena cava, a patent ductus arteriosus or an anomalous pulmonary vein (Fig. 6.2).

Left side of the heart

The common femoral artery is punctured as follows: the three middle fingers of the left hand palpate the pulse and the skin is pierced with the needle three finger-breadths below the inguinal ligament [2]. After puncture of the artery, a 0.89-mm (0.035-inch) J-guidewire should be advanced carefully into the needle. It should move freely up the aorta and be placed at the level of the diaphragm. When it is difficult to advance the guidewire close to the tip of the needle, the wire should be withdrawn to ascertain that forceful arterial flow is still pre-

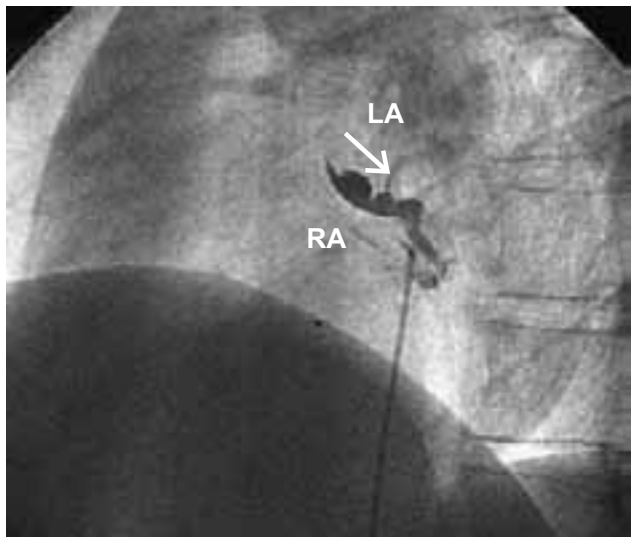

Figure 6.1 Patent foramen ovale. Imaging (lateral view) using radiographic contrast medium of the interatrial septum ('tunnel' between septum primum and septum secundum) with a small jet (arrow) between the right atrium (RA) and left atrium (LA).

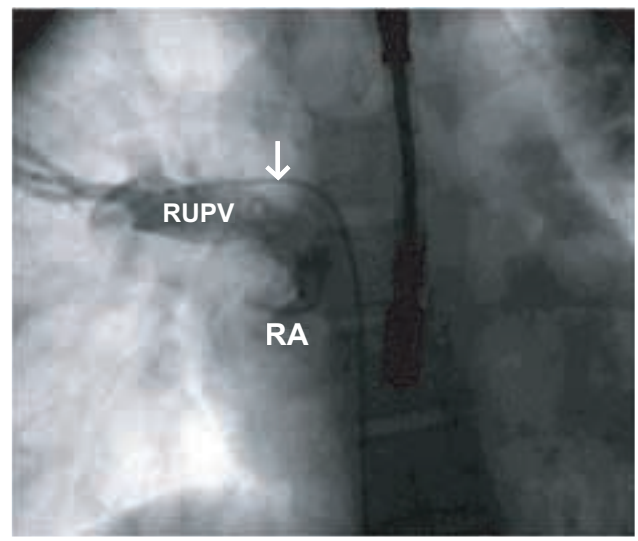

Figure 6.2 Anomalous right upper pulmonary venous return. Injection of contrast material via a multipurpose catheter (arrow) inserted in the right upper pulmonary vein (RUPV). The catheter is introduced in the right femoral vein. The contrast is filling the right atrium (RA).

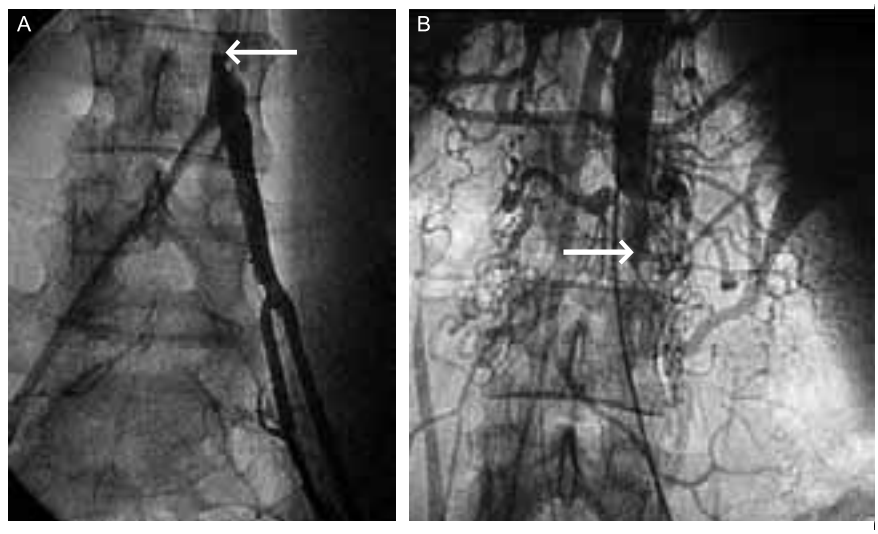

Figure 6.3 Chronic occlusion of the abdominal aorta immediately proximal to the iliac artery bifurcation (arrows). (A) Contrast injection from the left superficial femoral artey. (B) Contrast injection from the thoracic aorta descendens: imaging of multiple corkscrew-like collateral arteries bypassing the occlusion.

sent; if not, the needle should be removed and the groin compressed for 5 min. Problems that can be encountered in advancing the guidewire include severe arterial tortuosity, stenosis, occlusion (Fig. 6.3) or dissection. Left heart catheterization via the femoral approach is performed using an appropriately sized vascular sheath (we use 4–5F for diagnostic coronary angiography, 5–6F for percutaneous coronary interventions). The sheath is introduced via the guidewire and flushed with heparinized saline. In our institution, intravenous anticoagulation using heparin 5000 units is established in all cases except those undergoing diagnostic coronary angiography only. All left-heart catheters are exchanged via the guidewire, which is positioned with its tip at the level of the diaphragm. The pigtail catheter for left ventricular pressure measurements and angiography can be easily advanced across the aortic valve in the absence of aortic stenosis. If the latter is present, a 0.89-mm (0.035-inch) straight guidewire is employed to cross the valve, with its soft tip leading and pointing towards the stenotic valve and with the pigtail catheter pulled back into the ascending aorta by about 4–5 cm. In this position, the wire tip usually quivers in the systolic jet. The pigtail catheter remains fixed and the guidewire is moved towards the valve in attempts to cross it. If this is not possible, the process can be repeated using a Judkins right coronary catheter or a left Amplatz catheter, both of which allow better targeting of the valve opening than the pigtail catheter. When the guidewire has crossed the valve, it should be placed in the left ventricle, with a loop to minimize the risk of injury to the left ventricle. Relative contraindications for left heart catheterization via the femoral artery include occlusive peripheral vascular disease (Fig. 6.3), extreme iliac tortuosity, aortic abdominal aneurysm, femoral graft surgery and gross obesity.

Haemodynamic measurements during cardiac catheterization

Pressure measurements

An important goal of cardiac catheterization is precise assessment of pressure waves generated by the different cardiac chambers. Pressure is equal to force per unit area (in dynes/cm^2), force being transmitted through fluid as a wave. Considered as a complex periodic waveform, the pressure wave can be subdivided into a series of sine waves of variable amplitude and cycle frequency, whereby the sine wave frequency is expressed as harmonics or multiples of the fundamental frequency of the composite wave. This is important practically because an ideal pressure recording system must respond with identical amplitude for a given input throughout the range of frequencies contained within the pressure wave. The sensitivity of such an instrument can be defined as the amplitude ratio of the recorded (output) to the input signal. Its frequency response is the ratio between output and input amplitude over a range of frequencies of the input signal. A stiff as opposed to a flabby pressure-sensing membrane renders the recording instrument less sensitive but more frequency responsive. The useful frequency response of commonly used pressure measurement systems is less than 20 cycles/s (1 cycle/s corresponds to a heart rate of 60 b.p.m.). For example, the dicrotic notch of the aortic pressure curve contains frequencies above 10 cycles/s. The natural frequency of a sensing membrane and how it determines the degree of damping (by friction) is another important feature of the instrument, because its dynamic response is largely

determined by them. The amplitude of an output signal tends to be augmented as the frequency of the input signal approaches the natural frequency of the membrane. In this situation, the sensing membrane begins to vibrate with increasing energy, i.e. it resonates. Damping dissipates the energy of the oscillating membrane, and optimal damping dissipates the energy gradually such that there is a constant output/input amplitude ratio. Optimally, the system must be set up to have the highest possible natural frequency and optimal damping: the former is directly proportional to the size of the catheter system, and inversely related to the length of the catheter plus tubing and to the square root of the catheter and tubing compliance and the fluid density filling the system. Damping is introduced into the system by filling the tubing with a viscous medium.

Blood oxygen measurement and flow and shunt calculations

According to the Fick principle [3], the total uptake or consumption of a substance by an organ is the product of the blood flow to that organ and the arteriovenous concentration difference of the substance. Since measurements of flow, particularly cardiac output, is of central importance in invasive cardiology, the determination of blood oxygen is similarly pivotal, since cardiac output is most often calculated on the basis of the Fick oxygen method:

$$\text{Cardiac output} = \frac{\text{oxygen consumption}}{\text{arteriovenous oxygen difference}}$$

Oxygen consumption is measured directly by a polarographic method or the Douglas bag method. Alternatively, oxygen consumption can be predicted on the basis of the patient's body surface area corrected for age and gender. Thus it is assumed that resting oxygen consumption is 125 ml/m^2, or 110 ml/m^2 for older patients. Assumed versus directly obtained values for oxygen consumption are likely to introduce errors of > 10% [4].

The arteriovenous oxygen difference is determined on the basis of blood sampling from appropriately positioned catheters in the left ventricle and the pulmonary artery. The oxygen content of the arterial and venous blood samples is the product of the measured oxygen saturation (percent) and the oxygen-carrying capacity (in millilitres of oxygen per litre of blood). The former can be determined by reflectance oximetry of heparinized blood, which measures the percentage of haemoglobin present as oxyhaemoglobin. Oxygen-carrying capacity is approximated by multiplying the patient's haemoglobin (in grams per litre) by 1.36 (i.e. millilitres of oxygen per gram of haemoglobin).

Detection and localization of an intracardiac shunt can be easily performed using blood oxygen saturation as the indicator, which is obtained at many different sites within and close to the heart (i.e. 'oximetry run'; Figs 6.4 and 6.5) [5]. Quantification of the shunt is based on

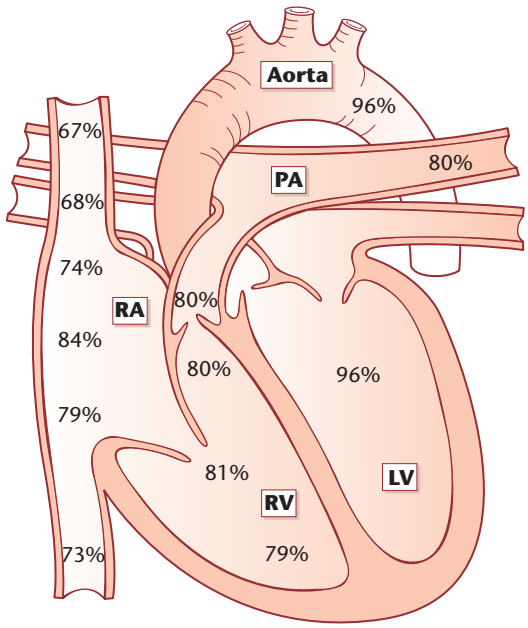

Figure 6.4 'Oximetry run' with multiple intracardiac oxygen saturation values in a patient with atrial septal defect. The 'step-up' detected in the right atrium (RA) identifies a left-to-right shunt at this location. LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

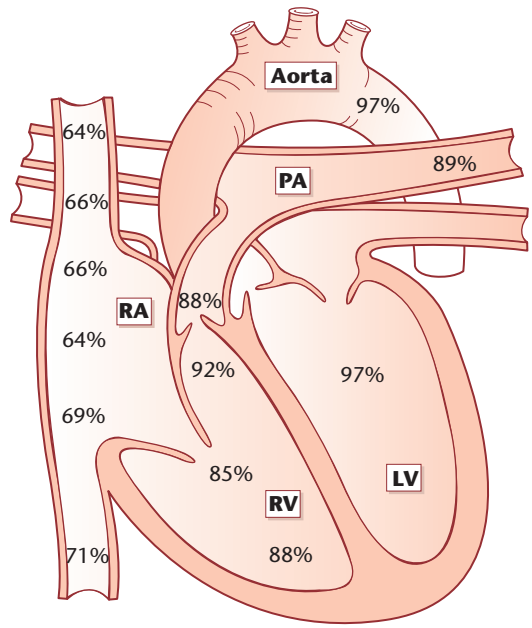

Figure 6.5 'Oximetry run' with multiple intracardiac oxygen saturation values in a patient with ventricular septal defect. The 'step-up' detected in the right ventricle (RV) identifies a left-to-right shunt at this location. LV, left ventricle; PA, pulmonary artery; RA, right atrium.

measurements of pulmonary (Q_p, l/min) and systemic (Q_s) cardiac output as outlined above. Specifically

Q_p = Oxygen consumption/(pulmonary venous oxygen content – pulmonary arterial oxygen content)

Q_s = Oxygen consumption/(systemic arterial oxygen content – mixed venous oxygen content)

The key to measuring Q_s in the presence of an intracardiac shunt is that the mixed venous oxygen content must be obtained in the chamber immediately proximal to the shunt.

Ventricular volume

Quantitative information on ventricular dimension, area and wall thickness derived from left ventricular cineangiography allows assessment of ventricular volume, ejection fraction, mass and wall stress (together with pressure measurement). Ventriculograms are usually recorded on cine film at 30–60 frames/s, and radiographic contrast agent is injected at rates of 7–15 ml/s for a total volume of 30–50 ml. For the calculation of left ventricular volume, the outermost margin of visible radiographic contrast is traced. Volume (V) is computed using long-axis (L) and short-axis (S) measurements ($V = {}^1/_6\pi LS^2$) or area–length measurements ($V = 8A^2/3\pi L$) using an ellipsoid approximation for ventricular shape. Alternatively, techniques based on Simpson's rule, which is independent of assumptions regarding ventricular shape, may be used. Correction has to be made for magnification of the ventricular image onto the image intensifier.

Vascular resistance

Calculations of vascular resistance are usually applied to the pulmonary circulation (normal value 67 ± 30 dynes/s/cm^{-5}) and systemic circulation (normal value 1170 ± 270 dynes/s/cm^{-5}). Vascular resistance (R) is determined on the basis of Ohm's law ($R = \Delta P/Q$), where Q is the cardiac output and ΔP is the pressure gradient across the pulmonary circulation (mean pulmonary artery pressure – mean left atrial pressure) or across the systemic circulation (mean aortic pressure – mean central venous pressure). The mentioned equations yield arbitrary resistance units (also called hybrid resistance units or Wood units in mmHg/l/min), and for conversion to metric units expressed in dynes/s/cm^{-5} a factor of 80 has to be used.

Valve area calculations

As valvular stenosis develops, the valve orifice poses progressively greater resistance to flow across the opening, resulting in a pressure drop across the valve. Greater flow across the valve yields greater pressure gradient. These qualitative relationships, Torricelli's law describing flow across a round orifice ($A = Q/VC_C$) and the relation between flow velocity and pressure drop ($V = C_v(2g\Delta P)^{1/2}$), form the basis of the calculation of valvular orifice area (A) using cardiac pressure (ΔP; Figs 6.6 and 6.7) and flow (Q) measurements [6]:

$$A = Q/C_vC_C(2g\Delta P)^{1/2}$$

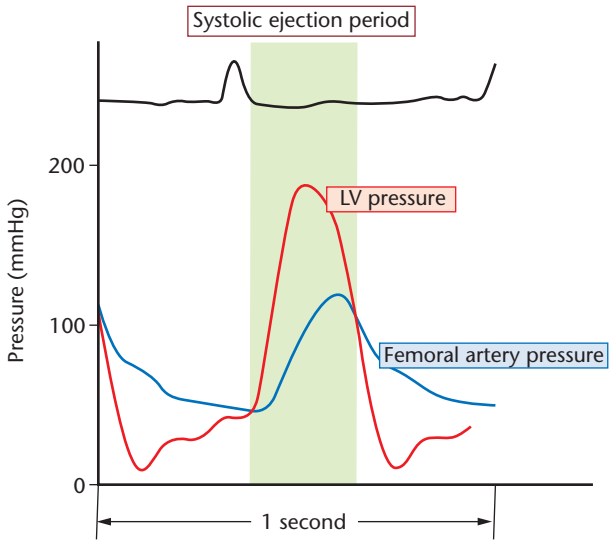

Figure 6.6 Simultaneous ECG, left ventricular (LV) and femoral artery pressure recordings in a patient with aortic stenosis and insufficiency. During the systolic ejection period, there is a marked pressure gradient. At end-diastole, aortic regurgitation leads to pressure equilibration of systemic arterial and left ventricular pressure.

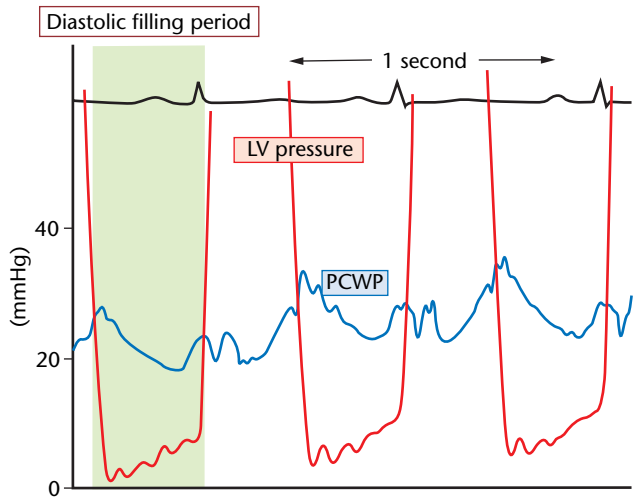

Figure 6.7 Simultaneous ECG, left ventricular (LV) and pulmonary capillary wedge pressure (PCWP) recordings in a patient with mitral stenosis indicated by the severe pressure gradient during the diastolic filling period.

where C_C and C_v are a coefficient of orifice contraction and a coefficient of velocity correcting for energy loss as pressure energy is converted to kinetic energy, respectively; and g is acceleration due to gravity (980 cm/s^2). In the case of aortic valve area (AVA) and mitral valve area (MVA), the following specific formulae can be used:

$$\text{AVA} = (\text{cardiac output/systolic ejection period} \times \text{heart rate})/44.3\Delta P^{1/2}$$

$$\text{MVA} = (\text{cardiac output/diastolic filling period} \times \text{heart rate})/37.7\Delta P^{1/2}$$

Invasive imaging techniques and coronary morphology

Coronary angiography

Consent for the procedure, risks and benefits of angiography

Although the techniques of angiography and angioplasty should only be performed by qualified and dedicated operators, every cardiologist treating adult patients must be aware of the indications, risks and potential benefits of this procedure. Table 6.1 indicates the complications in a general population but the data are too old to reflect practices such as the radial approach or the use of new contrast agents [7]. These figures are a good indication for average patients but they must be individualized for morbid obesity, diabetes, peripheral vascular disease and poor left ventricular function. The most frequent complications of angiography occur at the catheter entry site. The 2–5% incidence currently quoted is based on series using a femoral approach before the use of 4F and 5F catheters. Closure devices have reduced the time to ambulation, increased patient comfort and shortened the hospital stay but do not appear to have modified the bleeding risk and have added some rare specific new complications (infection, embolization or arterial stenoses due to components of the closure device or procoagulant factors injected into the bloodstream). Large haematomas requiring drainage, blood transfusions and prolonged bed rest, severe obesity and hospitalization are rare and often consequent to inability to comply with bed rest or clinical need for prolonged anticoagulation. Other more serious vascular complications include pseudo-aneurysm, fortunately often closed with ultrasound-guided compression and/or selective thrombin injection, arteriovenous fistulae, arterial thrombosis and distal embolization. The most dreadful but fortunately rare vascular complication is retroperitoneal bleeding, mostly managed conservatively, while iliac or aortic dissections tend to seal spontaneously if antegrade flow is preserved. For radial procedures a negative Allen test is sufficient to exclude critical hand ischaemia even in cases of total radial occlusion (1–4% of patients), and large haematomas are rare. The possibly serious complications of the brachial approach, percutaneous or surgical, can be prevented by not using this route, which can almost always be substituted by radial puncture. The frequency of serious complications, such as death, myocardial infarction or cerebrovascular accident with permanent damage, is very low (0.1–0.2%). Myocardial infarction is often due to catheter-induced ostial damage due to pre-existing severe pathology or the presence of unstable plaques at risk of embolization and can potentially be treated with angioplasty and stenting. Stroke is the consequence of thromboembolism due to thrombi in the access sheath or the catheter, dislodgement of plaques from the iliac vessels or aorta, calcium from the aortic valve or thrombi in the left ventricle. Meticulous attention to catheter flushing and atraumatic wire-lead insertion can reduce but not eliminate the risk, whilst there is no evidence that systemic heparinization is required for diagnostic catheterization. Death can be the direct consequence of infarction, stroke or cardiac and vascular perforation but

Table 6.1 Complications of diagnostic angiography

	Incidence (‰)	
Death	1.0–1.5	
Myocardial infarction	1.0–2.0	
Neurological events		Cumulative incidence 1.5–2.5‰
Permanent	1.0–2.0	
Transient deficit	3.0–5.0	
Ventricular fibrillation/tachycardia requiring defibrillation	1.0–2.0	
Vascular/bleeding complications		
Requiring surgery or late US-guided compression or thrombin injection	10–20	
Managed conservatively	10–50	

US, ultrasound.

can also be induced by late complications of prolonged hospitalizations triggered by relatively minor complications such as bleeding events and renal dysfunction. A clear explanation of other more frequent albeit minor and promptly controlled adverse effects helps the patient to accept them without unnecessary stress. Reactions to the contrast medium (nausea, vomiting, rash) are very rare and the amount of contrast used for a diagnostic angiogram cannot induce permanent renal damage unless a severe previous dysfunction was present. Bradycardia and hypotension develop because of periprocedural vasovagal reactions, prevented by generous sedation, liberal local anaesthesia, reassurance and appropriate filling with intravenous fluids. Other major arrhythmias (ventricular fibrillation and tachycardias, supraventricular arrhythmias) can be induced by catheter dumping, excessively prolonged injection or mechanical stimulation.

Catheter selection and manipulation

Improvements in catheter technology have allowed the flow rate obtained with old 8F (1F = 0.33 mm) diagnostic catheters to be achieved with 6F thin-walled catheters and satisfactory coronary opacification with 4F and 5F diagnostic catheters. Newly developed automatic injectors with adjustable increases in injection pressure have the potential to allow more consistent homogeneous opacification of large left coronary arteries through 4–5F catheters. Pre-shaped catheters (e.g. Judkins, Amplatz) can be used for injection of both coronary vessels, not only via the femoral and left radial or brachial approach but also the right radial/brachial approach. A reduction in pressure with ventricularization (low diastolic values) of the pressure waveform indicates that the catheter is obstructing flow. This may be caused by the presence of a true ostial stenosis, by the small size of the coronary ostium or by deep engagement of the catheter beyond the left main or first curve of the right coronary artery, often causing ostial spasm. Injection of intracoronary nitrates and gentle test injections with careful withdrawal of the catheter can identify and solve these various problems. It is very important not to start the injection before the angiographic acquisition in order to identify calcifications or late staining of contrast. Contrast injection should be sufficiently rapid and large to fully replace the epicardial vascular volume and avoid the phenomenon of streaming or incomplete visualization. When the proximal coronary segments are fully opacified, the prolongation of injection offers no diagnostic advantage, increases the contrast volume used and carries potential risks in vessels with a large epicardial volume and slow flow. On the other hand, angiographic acquisition should be prolonged to allow visualization of the distal vessels, identification of TIMI flow and characterization of type of dissection (with/without persistence of contrast at the end of the injection). An important determinant of injection duration is the need to visualize collaterals for occluded vessels, which also means adjustment of the view to include the recipient vessel in the image.

Left coronary artery

CANNULATION

In the majority of cases a standard 4.0 Judkins catheter can be used. Occasionally, in small females a 3.5-mm or even 3.0-mm left Judkins catheter can be used as first choice; if it is known by previous invasive or non-invasive examination that there is an enlarged ascending aorta, a 4.5 or 5.0 left Judkins catheter can be preferred. The optimal view for engaging both the right and left coronary arteries is the left anterior oblique view where the ostium is not covered by the aorta (Fig. 6.8). The left coronary artery requires only minimal catheter manipulation; the J-tipped 0.89-mm (0.035-inch) wire is

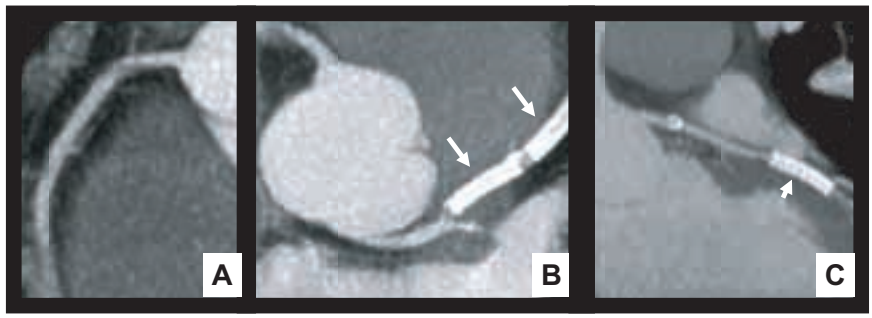

Figure 6.8 Multislice computerized tomography (B) shows the origin of both coronary ostia in an axial view simulating an angiographic spider view (note the two stents in the proximal left anterior descending artery, arrows). The two multiplanar reconstructions on the right and left delineate the ostium of the right coronary artery (A) and left coronary artery (C) with a stent easily visible in the left circumflex artery (arrow). If cannulation of the arteries is performed using an anteroposterior view, a common mistake repeatedly performed, injections in the aortic root will never catch the position and level of the coronary ostia. It is also intuitive that the left catheter will often directly cannulate the left coronary ostium while anterior rotation is required to engage the right coronary ostium.

atraumatically advanced to the level of the aortic valve and the tip of the previously flushed Judkins catheter is opened as low as possible pointing to the left coronary ostium. When retrograde bleeding ensures the catheter has been purged of air, a pressure line is connected and a test injection performed, often showing that the catheter is already engaged or is located immediately below or in front of the ostium. In the latter case, gentle withdrawal of the catheter tip (helped by asking the patient to take a deep breath) will allow engagement of the catheter tip in most cases. If the tip of the catheter immediately closes in the ascending aorta, prolonged attempts with the same catheter should be avoided and rapid switching to a larger catheter is probably advantageous in terms of time lost and contrast used. When it is known that the coronary ostia are of an unusual size or position (aortic valve disease, Marfan's syndrome, congenital heart disease), it is probably worthwhile performing an aortic angiogram in the left anterior oblique view in order to guide catheter selection, since this may require unusual shapes (e.g. left Judkins 6.0 or left Amplatz 2.0 and 3.0).

OPTIMAL VIEWS (Fig. 6.9)

The main advantage of the so-called spider view (left 40–55°, caudal 25–40°) is to delineate the branching of the left main coronary artery from the aorta and its bifurcation into the left anterior descending (LAD) and left circumflex (LCX) arteries (or trifurcation if an intermediate artery is present). For this reason it is better to acquire this view first in order to exclude this most fearsome lesion location, at risk of plaque disruption during catheter injection and which may require an urgent surgical approach. The LAD artery is greatly foreshortened in the mid and distal segments in this view but stenosis of the proximal segment or of the ostium of the first diagonal branch is often optimally shown. The LCX artery, on the other hand, is optimally opened in its proximal and mid segments. The classical 30–40° right view is limited by the frequent superimposition of the proximal LAD and LCX and should be replaced by shallow right caudal views, which also offer less movement during respiration for angioplasty and which minimize irradiation. A smaller angulation to the right (10–20°) avoids superimposition of the catheter and the spine and, combined with relatively skewed caudal angulations (30–40°), opens the angle between LAD and LCX (and intermediate branch, if present) sufficiently to obtain optimal images of the proximal and mid segment of the LCX and bifurcation of its marginal branches. The image is of more limited interest for the proximal and mid LAD because of the frequent superimposition of diagonal and septal branches but remains the most important view for the distal LAD. Skewed cranial views (40° or more), with 5–10° angulation to the right to avoid superimposition of the catheter and the vertebral spine, elongate the proximal and mid LAD and open the bifurcation of the proximal diagonal branches which run to the right, clearly distinguished from the septal branches which run to the left of the screen. The segments that are foreshortened in this view are the distal LAD and the proximal LCX but this view is also ideal for visualizing the distal posterolateral branches of the LCX and, in the 15–20% of cases with left dominance or codominance, the left posterior descending artery (PDA). In the left cranial view (30–45° left, 25–40° cranial) the LAD is further elongated by asking the patient to take a deep breath and maintain breath-holding during injection. The cranial view also offers optimal views of the mid and distal segments of the LCX, and is especially useful in the presence of a dominant LCX. The lateral view is far from standard in modern coronary angiography because the additional value of this view is quite limited, only providing excellent visualization of the mid/distal LAD around the apex, information which is at most complementary to right caudal views. Occasionally, however, eccentric short lesions of the proximal and mid segment of the LAD might be covered by septal or diagonal branches in all the conventional previously reported views and can be better visualized in the lateral projection, sometimes using variable cranial or caudal angulations to ensure no superimposition from the diagnostic catheter and side branches.

Right coronary artery

CANNULATION

For visualizing the right coronary artery (RCA) the standard strategy uses a 4.0 right Judkins diagnostic catheter in the left anterior oblique view. In this view, the catheter must be rotated to point to the left of the screen and this is better achieved when the rotation is performed during a slow pull-back motion of the catheter from the right coronary sinus. Breath-holding after a deep inspiration may facilitate this manoeuvre. In 10–15% of cases a high origin of the RCA complicates the search for the right coronary ostium. Even in the presence of a hypoplastic non-dominant RCA, selective injection is still required because small proximal branches can be an important source of collaterals for occluded vessels. It is often possible to obtain a semi-selective injection with the Judkins catheter that will further guide catheter selection. A multipurpose catheter should be used for downward-looking RCAs, and Amplatz right 2 or Amplatz left 1 or 2 are required in patients with high take-off and/or with dilatation of the coronary sinus and ascending aorta. Careful review of the images should be performed before finishing the examination in order to avoid missing a

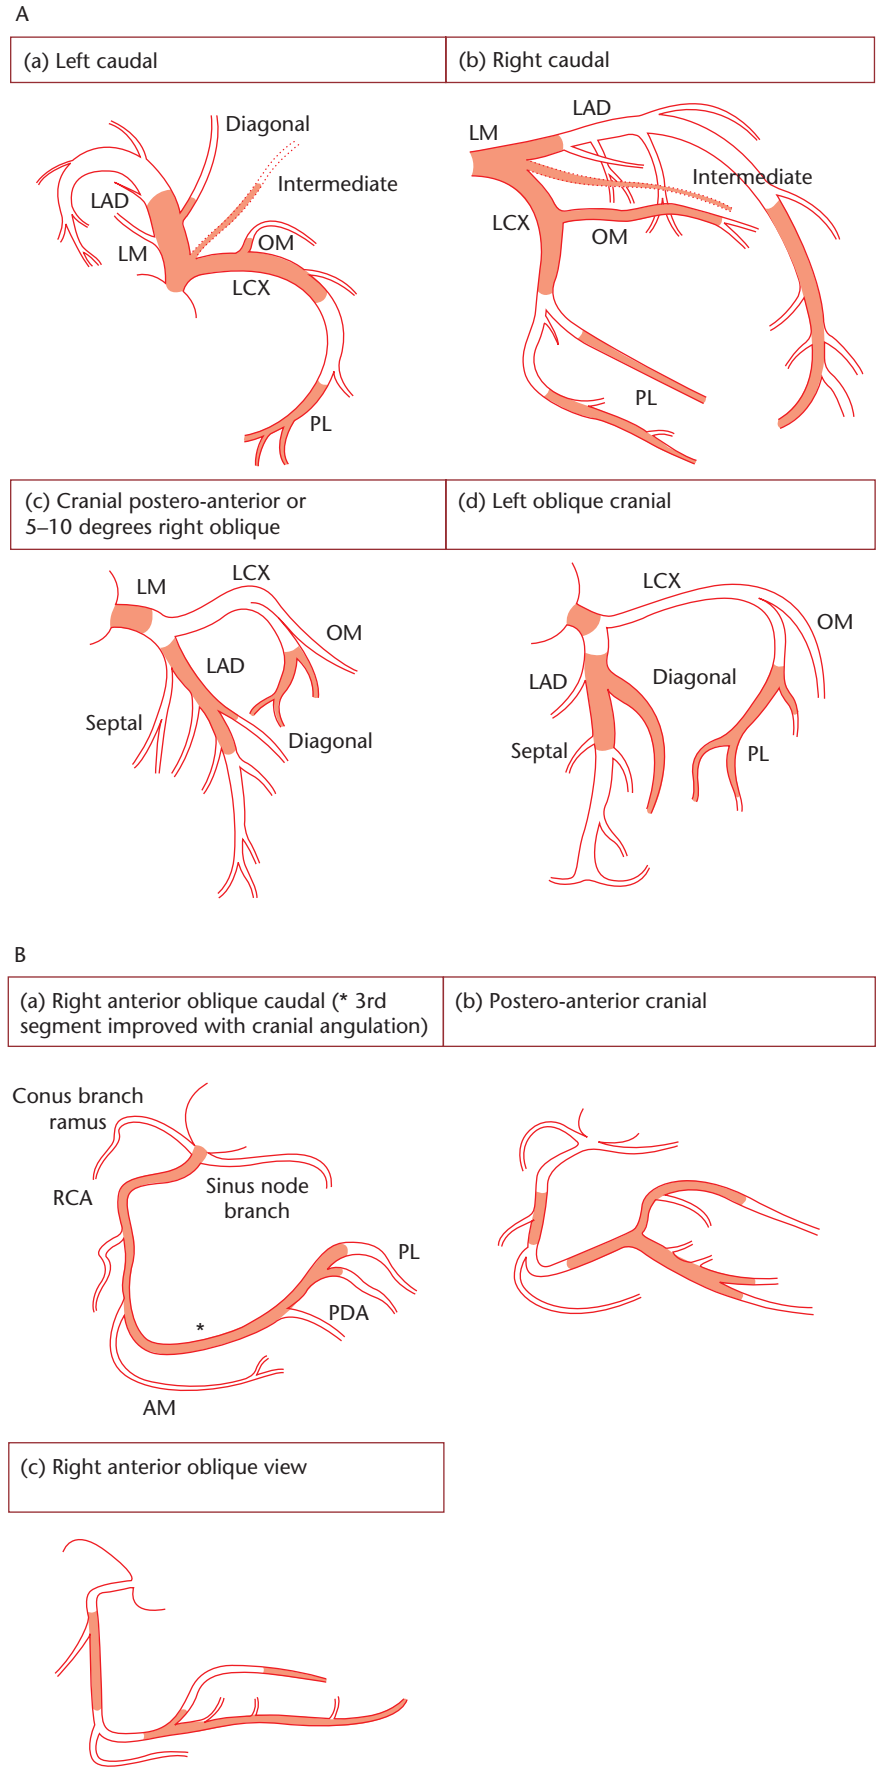

Figure 6.9 The most frequent angiographic projections: their relative merits in the visualization of different coronary segments are indicated.

separate origin from the aorta or an abnormal origin from the proximal RCA of the LCX, the most frequent coronary anomaly, or the separate origin of a conus branch that provides important collaterals to occluded arteries.

OPTIMAL VIEWS

The RCA has few branches in the first, second and third segments (from the ostium to the crux cordis) and often two views (left anterior and right anterior oblique views) are sufficient to identify all stenoses, including eccentric stenoses. The lateral view might be ideal for assessment of the mid segment of the artery and may occasionally be used as a working projection for occlusions in this segment or stent positioning. The problems with these standard views lie in the difficulties of interpretation in the presence of stenoses at the crux cordis or at the ostia of the PDA and posterolateral branches. Cranial angulation (30°) of the left anterior view is often sufficient to solve diagnostic questions but many operators prefer to use as a routine view a cranial (30°) postero-anterior view of the RCA, which clearly delineates the region of the crux cordis and possible lesions of the PDA or posterolateral branches.

Venous bypass grafts and left internal mammary artery

Aortic anastomoses of radial arteries or venous grafts are rarely indicated by radio-opaque markers positioned at the time of operation (a neglected practice in cardiac surgery), but can often be visualized in the left anterior oblique view a few centimetres above the ostium of the RCA by dragging the right Judkins catheter along the right profile of the ascending aorta. Although the position and direction of aortic anastomoses is influenced by the surgical technique, in general the anastomosis for the RCA tends to be the lowest and to have a more vertical origin from the aorta, so that selective cannulation may require the use of a multipurpose catheter. Grafts for the marginal or diagonal branches often require catheter rotation and occasionally catheters with a longer tip (right or left Amplatz 1 and 2, left coronary bypass catheters) are required. Instead of wasting a large amount of contrast in locating the ostium, it can be cost-effective to perform an aortogram with the pigtail catheter slightly above the usual supravalvular position, immediately above the level of the RCA, in order to ascertain at least the number of open grafts. A limitation is obviously the inability to detect grafts with extremely slow flow; however, these are often identified because of the presence of contrast staining in cases of recent occlusion.

For the left mammary artery, the origin of the subclavian arteries can be more easily engaged in a left anterior oblique view (40–60°). Complete visualization of the internal mammary is of paramount importance because it is crucial not only to know whether the left internal mammary artery is patent but also to exclude the presence of distal stenoses (anastomotic or in the distal native vessels) and to visualize collaterals for other occluded vessels. The selective visualization of the mammary artery is more easily achieved with a specially designed catheter, which has a longer tip than the classical right Judkins catheter. In case of failure, other types of modified left internal mammary catheter with a hook-like shape can be tested. Selective engagement is often made difficult by the presence of severe tortuosity of the proximal subclavian artery, which makes manipulation of the left internal mammary catheter very difficult. The problems are greater for the right internal mammary artery because of the more tortuous track from the ascending aorta. A power injection through 6F large-lumen diagnostic or guide catheters can occasionally avoid the troubles and risks of a true superselective injection of the internal mammary arteries in very tortuous and frail subclavian vessels, reducing brachial flow with a pressure cuff inflated around the arm. Alternatively, a radial approach (more often left as the left mammary is most frequently used) can be the safest solution if multiple attempts from the groin remain unsuccessful. The distal anastomosis of the mammary artery is often optimally opened in the lateral view, which is also ideal for excluding adhesion of the left internal mammary to the sternum, a condition that may increase the risk of surgical reintervention with median sternotomy.

Angiographic report

Coronary angiography requires a report indicating the vascular access site, type and size of catheters used, type and total amount of contrast, allergic reactions or other procedural complications, closure devices, aortic pressure and heart rate and rhythm before and after the procedure. After having described the type of dominance and possible anomalies of origin and location, each individual coronary segment (from the left main to three segments for the LAD and RCA, two for the LCX plus the main diagonal, intermediate, marginal and posterolateral branches) and the presence of a lesion must be indicated, with description of the characteristics as indicated in Table 6.2. While the terms 'irregular' and 'mild' can be used to describe stenoses of < 30% and 30–50%, stenoses of 50% or greater require attempts at visual estimation of severity based on comparison with the closest normal-looking reference segment. The presence of thrombus and irregularities of stenosis contour are often more subjective, although the presence of multiple unfavourable characteristics (graded ABC in the ACC/AHA Task Force definitions [8]) is still predictive of immediate success and complications.

Besides the pressure measurements, in the angiographic report the operator must indicate the semi-

Table 6.2 Qualitative definitions of angiographic lesions

Eccentric: luminal edge in outer one-quarter of the normal lumen
Irregular: ulceration, aneurysm or saw-tooth pattern
Discrete: estimated lesion length < 10 mm
Tubular: estimated lesion length 10–20 mm
Diffuse: estimated lesion length ≥ 20 mm
Ostial: within 3 mm from origin
Angulated: ≥ 45° angle between centre-line of proximal and distal segments
Bifurcational: branch ≥ 1.5 mm involving the lesion
Calcified: readily apparent densities within the vessel wall at the site of the lesion
Functionally occluded (99% diameter stenosis): antegrade flow TIMI 1
Totally occluded (100% diameter stenosis): antegrade flow TIMI 0 with/without opacification from collaterals
Thrombotic: intraluminal filling defect separated from the vessel wall in two views (with or without contrast staining)

Type A (ACC/AHA): discrete, concentric, non-angulated, readily accessible, regular, non-calcified or minimally calcified, non-occlusive, non-ostial, non-bifurcational, non-thrombotic lesion
Type B: tubular, eccentric, with two ≥ 75% bends proximal to the stenosis, angulated (but less than 90°), irregular, calcific, occluded (functional or > 3 months), ostial, bifurcational (side branch accessible for wire protection), thrombotic lesion
Type C: diffuse, three ≥ 75° bends in the proximal segment, angulated (≥ 90°), occluded > 3 months old or unknown duration), bifurcational (side branch non-accessible), degenerated vein graft

quantitative estimate of left ventricular cavity size and the presence and type of wall motion abnormality (from normal to hypokinetic, akinetic or dyskinetic). Five regions should be reported for the right anterior oblique view and two for the left anterior oblique view (Fig. 6.10). The presence of thrombi or other filling defects and abnormalities in shape must also be reported.

Mitral insufficiency is graded 1–4 according to the presence and amount of regurgitant flow (Table 6.3) and, for the most severe levels, also allows delineation of the contours of the left atrial cavity. Obviously, the size of the left ventricular and, especially, left atrial cavity, the acuteness of the process, the position of the catheter and rate and volume injected may modify this semi-quantitative assessment, which remains subjective, although the distinction between non-surgical (grade 1 and 2) and possible surgical (grade 3 and 4) severity is established in most patients. Whilst angiography is not the easiest technique for defining absolute volumes, relative changes such as left ventricular ejection fraction must be regularly measured using the quantitative packages all digital systems offer.

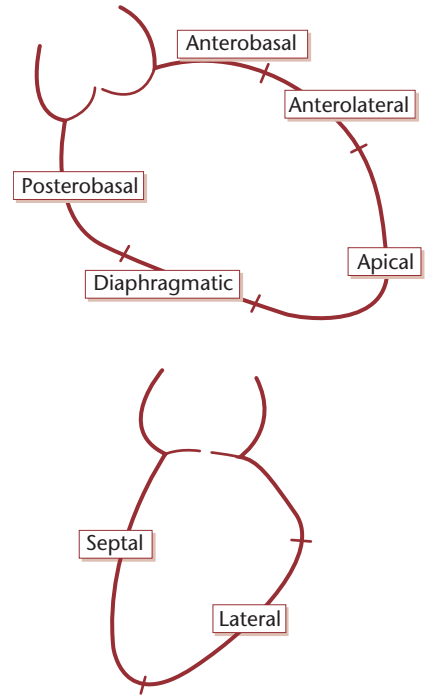

Figure 6.10 Regional wall motion during left ventriculography as assessed in the right and left oblique views.

Table 6.3 Semi-quantitative classification of mitral regurgitation

Trivial (grade 1 or 1+/4+): contrast material enters the left atrium during systole without filling the entire atrial cavity and is cleared in the subsequent beat
Mild (grade 2 or 2+/4+): contrast opacification of the left atrium is less dense than the opacification of the left ventricle but contrast is not cleared with each beat
Moderate/severe (grade 3 or 3+/4+): opacification of the left atrium is as dense as the opacification of the left venticle
Severe (grade 4 or 4+/4+): opacification of the left atrium greater than that of the left ventricle and/or complete atrial filling in one systole and/or contrast opacifies the pulmonary veins

Angiography in heart valve diseases and cardiomyopathies

The progress of echocardiography has made angiography redundant for the evaluation of many valvular disorders and cardiomyopathies. When the severity of valve disease requires surgical replacement or repair, coronary angiography is required in all candidates above 40 years of age (or younger if multiple risk factors or anginal symptoms are present). While no other acquisitions or injections in heart cavities are strictly necessary, in the absence of severe haemodynamic compromise or renal impairment, left ventriculography is recommended for all

patients with mitral valve disease and aortic insufficiency. Besides confirming the presence and severity of mitral regurgitation or indirect signs of mitral stenosis, the examination will define the presence and pattern of left ventricular dysfunction. For aortic stenosis, crossing the valve when the need for valve replacement is already unequivocally confirmed by symptoms and non-invasive tests is not recommended. If, however, there is any doubt concerning the accuracy and reproducibility of the Doppler flow velocity measurement, the additional minimal risk of embolization and perforation while crossing a stenotic and calcific aortic valve becomes clinically acceptable. Pre-shaped catheters (right or left Judkins or Amplatz) are more likely to obtain good orientation of the straight floppy end of a conventional or hydrophilic wire. Once the gradient is measured, for left ventriculography it is recommended that a pigtail catheter for injection is advanced over a 0.89-mm (0.035-inch) J-tipped 260-cm wire. Occasionally, when pressure measurements in the right heart are required to better define the severity of mitral valve stenosis and pulmonary hypertension, injection of the right ventricle can offer additional data to confirm presence and severity of right ventricular dilatation and tricuspid regurgitation. In the laevophase, after having delineated the size of the arterial and venous pulmonary tree and circulation time, the dilatation of the left atrium and abnormal movement of the mitral cusps can be observed. In patients with aortic valve disease, the presence and severity of calcifications of the aortic cusps and ascending aorta, number of cusps and deformity of cusp opening, and presence of a pre-shaped aortic jet can be judged from both left ventriculography and aortography. The semi-quantitative assessment of the degree of aortic dilatation, the severity of aortic insufficiency (Table 6.4) and the description of irregularities and calcifications of the aortic wall are other key features to describe in a patient with aortic valve disease, hypertension or Marfan's syndrome.

Table 6.4 Semi-quantitative classification of aortic regurgitation

Trivial (grade 1 or 1+/4+): contrast visible in the left ventricle, without reaching the apex, clears during each heart beat
Mild (grade 2 or 2+/4+): contrast opacification less dense than that of the ascending which does not clear during a single heart beat
Moderate/severe (grade 3 or 3+/4+): opacification of the left ventricle as intense as that of the ascending aorta
Severe (grade 4 or 4+/4+): opacification of the left ventricle more intense than that of the ascending aorta and/or full left ventricular cavity opacified in one beat

Intracoronary ultrasound imaging

When intravascular ultrasound (IVUS) was introduced 15 years ago, the pioneers of this technique believed it could replace angiography in the same way that endoscopic techniques have replaced conventional radiological assessment in gastroenterology. There are a number of reasons why this has not happened.

1. Unlike endoscopy, the technique does not stand alone, since it requires fluoroscopy and contrast injection to advance the IVUS probe.
2. Complete IVUS examination of all the major coronary vessels and their branches including the distal segments is impossible.
3. Despite the fact that the fundamental insights derived from IVUS have dramatically improved our techniques of percutaneous revascularization and our approach to atherosclerosis, no studies have shown clinical benefit over angiographic guidance alone.

Image acquisition

Miniaturized flexible intracoronary ultrasound probes of 2.8F (Atlantis Boston-Scientific) and 2.9F (Eagle-Eye, Volcano Endosonics), compatible with conventional 6F guiding catheters, generate high-resolution cross-sectional images by spinning a single piezoelectric crystal at 360° or by activating in sequence multiple (64) transducer elements. Larger probes with lower frequencies to improve penetration (10–15 MHz) are used for intracardiac or intravascular examination of peripheral arteries but their use is illustrated with the specific technique of application. To add a third dimension (length) to the tomographic representation of the vessel wall, the catheter (in multi-element array systems) or the inner driving cable of the ultrasound crystal (in mechanical probes) is connected to a precise pull-back system. Some investigators prefer the greater resolution and dynamic range that a mechanical system with a single large crystal (centre frequency 40 MHz) can offer and consider favourably the unusual modality of imaging through a steady distal sheath that remains in position during the IVUS examination, with accurate pull-back allowed by the absence of friction against the vessel wall (Table 6.5).

The safety of the technique was investigated in the early days [9], when stiffer and larger probes were available, although these studies showed that the main complication was spasm with dissection and thrombosis limited to before and after angioplasty. More interestingly, no difference was observed in the mean diameter of arteries of heart transplant recipients repeatedly instrumented or non-instrumented with ultrasound probes [10].

Table 6.5 Protocol of intravascular ultrasound image acquisition

Before imaging
Connection of the ultrasound catheter with the imaging console
Patient demographics and vessel examined entered
For mechanical transducer, accurate flushing with a small syringe
Connect the catheter/handle to the motorized pull-back system set to 5 mm/s
Activate and test that an image is generated before insertion
Inject 0.1–0.3 mg nitroglycerine or 1–3 mg isosorbide dinitrate according to pressure and risk of spasm

During imaging
For electronic catheters, before intracoronary insertion withdraw the guiding catheter, obtain an image immediately outside the coronary ostium and and subtract the ring down artefact
Advance the catheter distal to the segments of interest
Optimize the ultrasound setting (depth and gain), start tape recording and/or digital archiving and activate mechanical pull-back
Check ECG and pressure during pull-back to exclude prolonged ischaemia, especially during pre-dilatation imaging
Complete the pull-back, in general waiting until the catheter reaches the coronary ostium or is withdrawn inside the guiding catheter
Avoid stopping mechanical pull-back at all cross-sections of interest, which should be recalled from the tape or digital archive
Re-insert the catheter for acquisition of images in a segment of interest only if there are doubts about image interpretation, for example if there is a need to use saline flushing in a specific segment to confirm the presence of ulcerated plaques, dissections, lumen/intima border in the presence of slow flow or if there is a need to use contrast injection to identify the location of a given cross-section along the vessel

After imaging
Flush the ultrasound catheter (particularly mechanical probes) and clean it
Reposition the catheter ready for a new pull-back
Identify and perform measurements (diameter and areas) of the most important cross-sections (usually reference segment, proximal and/or distal or both, minimal cross-sectional area within the lesion or minimal cross-sectional stent area or other segments of interest)
Allow longitudinal display of the image after longitudinal reconstruction (long view) and measure the length of the segment of interest (e.g. length of segment to be stented)
Store the images in a DICOM digital format ideally with the same CD or in a server with the same identification of the DICOM angiographic images
Prepare a report including measurements and qualitative image interpretation

Image interpretation

MEASUREMENTS

A truly normal intima is beyond the axial resolution of IVUS which, even at 40 MHz, is greater than 70 μm *in vivo*. However, in most patients treated for coronary artery disease, almost all the sites explored in the coronaries will exhibit much intimal thickening, due to ageing as well as to early atherosclerotic changes, and which is separate from the underlying adventitia. The acoustic interface between the echo-poor muscular media and the intensely bright collagen and elastic fibres of the adventitia induces an appearance often described as 'threelayered' or 'target-like'.

Table 6.6 indicates the main measurements available with ultrasound. Both the European Society of Cardiology [11] and the American College of Cardiology [12] provide guidelines regarding common nomenclature and methods of qualitative and quantitative analysis of IVUS images. The most obvious measurement available with a technique that provides a circumferential image of the vessel is area, with the external contour drawn at the leading edge of the surrounding structures (Fig. 6.11). The area of the lumen and the area within the external elastic membrane (EEM), also called total vessel area, are the two most important dimensions and their difference provides the area of the intima–media complex. After treatment, stent area can also be measured but this is equivalent to the lumen area immediately after deployment unless a strut is not apposed to the vessel wall or there is plaque prolapse narrowing the lumen. In the era before the advent of drug-eluting stents (DES), weeks and months after stent deployment a rim of tissue of variable thickness constantly covered the stent struts, allowing easy definition of the neointimal area, calculated as the difference between stent area and lumen area at follow-up. The antiproliferative effect of DES often reduces intimal coverage to a thickness beyond the resolution capabilities of ultrasound.

Linear measurements are also possible with ultrasound and are required when IVUS is used to size devices

Table 6.6 Intracoronary ultrasound measurements in common use

Measurement	Units	Definition	Comments
Lumen area	mm^2	Area inside the intimal leading edge	If separation between intima and lumen is unclear because of lumen irregularities (ulcus within plaques of dissections) or because of slow flow, injection of saline may facilitate contour detection. Ideally do not perform measurement during saline infusion (increased lumen because of higher pressure, and different speed of ultrasound in saline than in blood)
EEM area (total vessel area)	mm^2	Area inside the leading edge of the adventitia	Do not trace if > 90° of vessel circumference not visible because of shadowing or attentuation
Stent area	mm^2	Area inside the stent struts	Stented area corresponds to lumen area unless a strut is not apposed to the vessel wall (under-expansion or localized aneurysm) or there is plaque prolapse
Plaque plus media area	mm^2	Difference between EEM area and lumen area in a corresponding cross-section	Not detectable if obscured by the presence of superficial calcium or stent struts
In-stent neointimal area	mm^2	Difference between stent area and lumen area images in images acquired late after stent deployment	Can be missed because of very poor echogenicity of the intimal areas, difficult to distinguish from the lumen, especially in cases of subocclusive restenosis or because (drug-eluting) stent is reduced to a micrometric rim of thickening below the threshold of measurement with ultrasound
Percentage plaque area	%	Percentage of EEM area occupied by plaque and calculated as: (EEM area – lumen area)/EEM area × 100	
Percentage neointimal area	%	(Stent area – lumen area)/stent area × 100	
Plaque eccentricity index		Measurement of plaque eccentricity calculated as the ratio between minimal and maximal plaque plus media thickness	1 indicates concentric plaque, < 1 indicates increasing plaque eccentricity. **NB** American authors tend to use the reverse index, with larger numbers indicating progressively greater eccentricity
In-stent lumen volume	mm^3	Lumen volume inside the stent segment calculated with multiple equispaced area measurements and Simpson's rule or with automatic contour detection of multiple cross-sectional and longitudinal contours	Immediately after stent deployment, area should be equal to stent volume
Stent volume	mm^3	Volume inside the stent	Easily calculated because of the bright stent landmarks
Neointimal stent volume	mm^3	Difference between stent volume and lumen volume inside the stent	More difficult to assess with drug-eluting stents because of the extremely thin rim of intimal hyperplasia
Percentage intimal volume in-stent	%	(Stent area – lumen area)/stent area × 100	Ideal biological indicator of intimal proliferation inside a stent

EEM, external elastic membrane.

for vessel dilatation, such as balloons and stents. Unfortunately, the vessel lumen and, especially, the area inside the EEM are rarely truly circular because plaques mostly grow eccentrically or because the probe is not perfectly aligned with the long axis of the vessel, generating an oblique cut of the vessel. Two linear measurements are normally required for each cross-sectional image: minimal and maximal diameter. Minimal and maximal plaque thickness are also used to provide an index of plaque eccentricity (Fig. 6.11). In clinical practice, area and linear measurements are rarely taken in more than two or three locations, corresponding to the minimal lumen or stent area and to a reference site outside the stenotic segment or the stent. This last site is more subjective, although a cross-section with the largest area and/or the smallest plaque burden within 5–10 mm of the margins of the

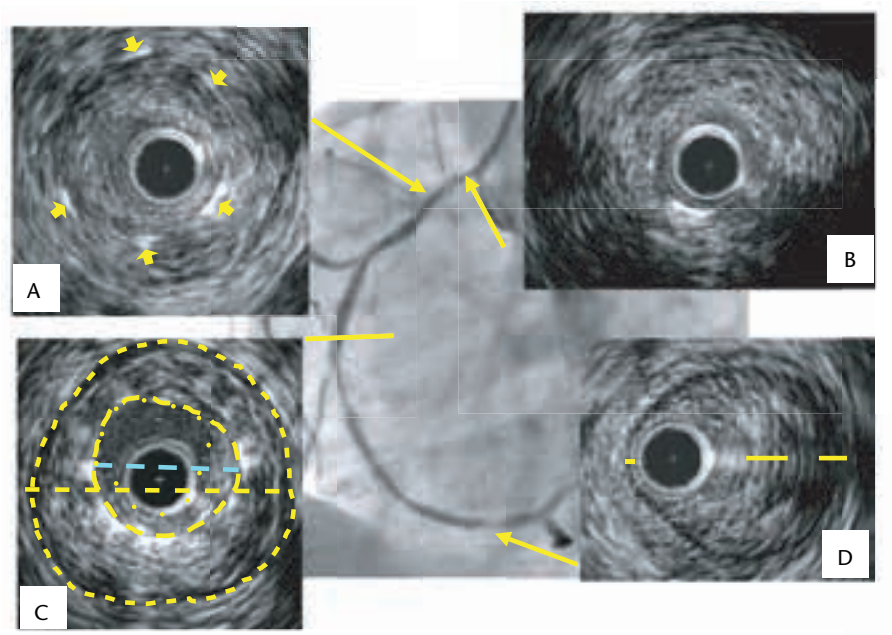

Figure 6.11 Four intravascular ultrasound cross-sectional images corresponding to the positions indicated in the left anterior oblique angiographic image of a right coronary artery in a patient with diffuse restenosis 3 months after multiple stents were implanted from the ostium to the mid segment. (A) Gross under-expansion and diffuse hyperplasia within the stent indicated by the bright dots/strips (arrowheads). (B) In this cross-section at the level of the vessel ostium the absence of stents is obvious, with restenosis probably due to recoil of the large concentric lesion not covered during the initial procedure. (C) Lumen (inner dotted line), stent (dashed lines around circumference and across maximal diameter) and vessel (external elastic membrane, EEM) area (outer dotted line around circumference and across maximal diameter). Using the 1-mm divisions of the calibration grid, it is apparent that the stent diameter is 2.3 mm compared with an EEM diameter of 4.5 mm. (D) Distal stenosis: the extreme eccentricity (0.2 mm minimal plaque thickness, 1.9 mm maximal plaque thickness) cannot be understood with ultrasound.

stenotic segment or stent edge is often used. If there is obvious vessel tapering, a proximal and distal reference should always be measured. The comparison between vessel area in the stenosis and at a reference site allows calculation of the remodelling index. This is able to confirm the main mechanism of plaque accommodation *in vitro* (described by Glagov in pathology studies) and verifies the presence of total vessel enlargement and positive remodelling; also, but more rarely, it allows determination of the presence of negative remodelling, both as a spontaneous process or as a consequence of shrinkage promoted by angioplasty (Fig. 6.12). In research applications, especially assessment of plaque changes over time, IVUS must overcome its limitations in order to provide precise identification of the same site in serial examinations and to obtain a more reliable assessment of biological processes involving multiple vessel segments (restenosis or progression of atherosclerosis), accomplished by averaging the lumen, stent and/or vessel measurements over a certain length, with longitudinal measurements determined by steady pull-back at known speed during examination. This allows either estimation of volumes by measurement of multiple equidistant cross-sections (Simpson's rule) or precise measurement by interpolating longitudinal and cross-sectional contours [13]. Unfortunately, the lack of sharp contours between lumen and intima and, especially, between intima–media and adventitia rarely allows measurements so perfect as not to require tedious manual corrections of the automated contour detection methods now incorporated in all modern IVUS equipment.

QUALITATIVE ASSESSMENT

The echo-intensity of the different plaque components in the image varies according to the system settings and requires a standard intensity for comparison. The adventitia, relatively spared by the disease process, offers a natural site for comparison of the different components of the atherosclerotic plaque, which are rarely homogeneous and often contain various components of different echo-reflectivity (Fig. 6.13). The presence of acoustic shadowing and reverberations are specific landmarks of the presence of calcifications, which can be detected with greater sensitivity than with angiography, and can be measured as their circumferential extension (in degrees or quadrants), length and location within the plaque (from superficial subendothelial calcium speckles to deep deposits at the base of the plaque). Plaques with low

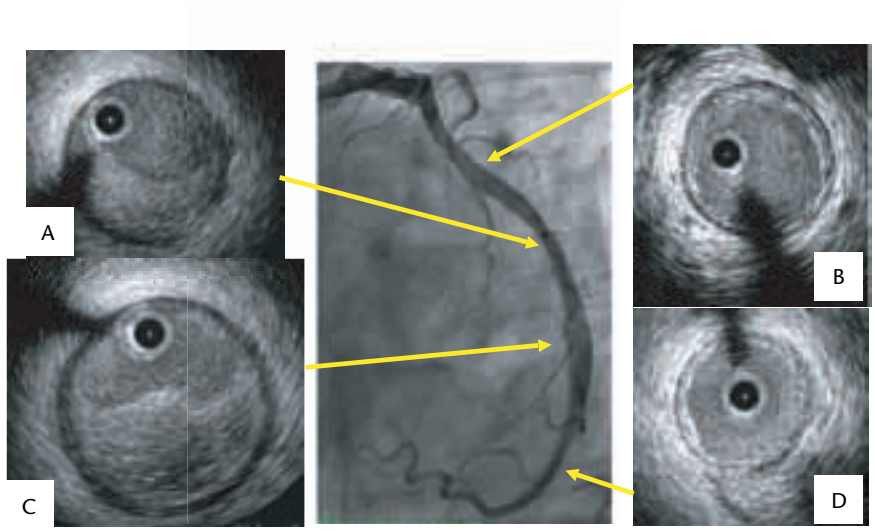

Figure 6.12 Four intravascular ultrasound cross-sectional images corresponding to the positions indicated in the left anterior oblique angiographic image of a left circumflex artery in a patient with recent ST-elevation lateral myocardial infarction 3 days after thrombolysis. The absence of severe residual stenosis is confirmed by ultrasound, which shows extreme positive remodelling when the cross-sections at the level of the culprit lesion (A and C) are compared with the proximal (B) and distal (D) reference cross-sections, where only a concentric rim of fibrous plaque is observed. Note that the eccentric plaque in (A) has a much lower echogenicity than the surrounding adventitia and that the inhomogeneous texture of the plaque in (C) is due to plaque rupture with channels communicating with the lumen inside the plaque. The absence of regular concavity of the intimal edge suggests recent thrombosis.

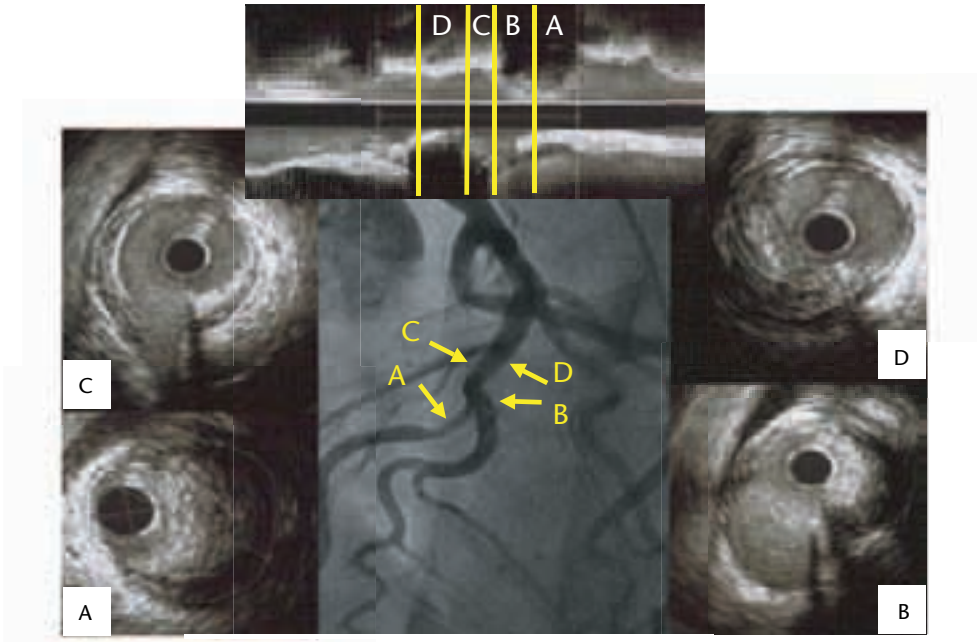

Figure 6.13 Four intravascular ultrasound cross-sectional images corresponding to the positions indicated in the cranial left anterior oblique angiographic image of a left anterior descending coronary artery in a patient with a lesion immediately distal to the bifurcation of a large diagonal branch. The heterogeneous plaque composition and involvement of the main vessel proximal to the bifurcation are clearly displayed in the longitudinal reconstruction of the multiple images acquired during pull-back. (A) Main subocclusive eccentric fibrotic lesion with no lumen around the ultrasound catheter. (B) Cross-section at the origin of the diagonal branch (below) shows normal intima in the branch but a large eccentric plaque opposite the bifurcation. More proximally (C) a fibrous concentric plaque is observed, with a large inhomogeneous eccentric plaque in (D) at a level which appears angiographically normal.

echo-reflectivity are often described as 'soft', a very unfortunate term since most of these plaques are far from mechanically pliable and include histological components as dyshomogeneous as fibrofatty tissue, thrombus, and neointima inside stents.

Other qualitative characteristics include the presence of plaque disruption, both before treatment (niches, ulcus, spontaneous dissections with thrombi, with positive pathological remodelling and frequently multifocal, are the pathognomonic changes expected in unstable syndromes) (Fig. 6.12) [14] and after angioplasty (rupture, dissection, mural haematoma). In the stent era other qualitative characteristics are important, such as strut malapposition with blood speckles visible between stent and wall. These changes are rather frequent immediately after stent deployment unless a consistent attempt is made to use IVUS to size the balloons for final stent expansion. At follow-up, only IVUS examination immediately after deployment can distinguish between persistent malapposition, present from the time of deployment, and acquired malapposition, possibly a more worrisome phenomenon related to wall remodelling, lysis of thrombus or toxic vascular effects of the antiproliferative drug.

Prestenotic atherosclerosis

Patients with angina or silent myocardial ischaemia dismissed as 'false positive' or 'possible vasospastic angina' [15] or 'cryptogenic' myocardial infarction because of the presence of a normal or near-normal coronary angiogram show atherosclerotic changes on IVUS in the majority of cases, suggesting more aggressive treatment of the risk factors in order to tackle both disease progression and impaired coronary vasomotion. The new challenge for treatment of coronary artery disease is the detection of plaques not yet impairing flow but at risk of rapid progression and destabilization. 'Vulnerable' plaques, characterized by a thin fibrous cap and a large superficial lipid pool, can be detected with increasing frequency and greater reliability using high-frequency IVUS probes [16]. Still, not all episodes of unstable angina and infarction are caused by 'vulnerable' plaques (erosion, protruding calcium, ischaemia secondary to increased demand), and the resolution and qualitative interpretation of IVUS is insufficient to precisely measure the fibrous cap and fully ascertain the presence of areas of lipid infiltration. IVUS can be a very reliable tool for validating other accurate non-invasive imaging modalities, such as cardiac magnetic resonance imaging and high-resolution 64-slice electron beam computed tomography. The other important application is the serial study of atherosclerotic segments before and after aggressive treatment of plaque progression. Three-dimensional reconstruction of IVUS cross-sections generates a volume of plaque in a given segment, identified by reliable anatomical markers (side branches, aortic anastomosis) and has become the technique of choice for the assessment of progression/regression of coronary atherosclerosis and comparison of the effects of different drug regimens. Allograft vasculopathy is another field now of limited application because of the decreasing number of transplants performed and the shortness of donors. In donor-related coronary athero-sclerosis, IVUS often shows spectacular regression after heart transplantation. Both the early development of atherosclerotic changes (> 0.5 mm thickness in the first year post transplant) and its progression in serial studies carry a negative prognostic value. IVUS can also be used to monitor the effect of drugs to prevent or delay coronary vasculopathy.

Lesions of intermediate severity

The superiority of IVUS over angiography for detecting coronary stenoses that are difficult to assess in multiple views allows its use in the study of lesions of questionable severity. The threshold of absolute cross-sectional area that determines whether intervention must be carried out is 4.0 mm^2 in a native coronary artery [17]. The threshold for the left main coronary artery is more controversial, but an absolute area > 5.9 mm^2 (or 2.8 mm diameter) has recently been shown to be associated with a normal fractional flow reserve and a good 3-year prognosis, even if left untreated [18]. The diameter of the lumen and size and characteristics of the plaque, the relationship of the lesion with other branches, especially for ostial and bifurcational lesions, and the type of remodelling are important factors that guide the angioplasty procedure; IVUS can also be used after the procedure to confirm the effectiveness of treatment.

Guidance of coronary interventions

The wealth of data accumulated in the attempt to demonstrate the usefulness of IVUS for guiding balloon angioplasty and atherectomy is now obsolete because of the universal use of coronary stenting. Nevertheless, it is obvious from trials such as PICTURE [19] and CLOUT [20] that IVUS is the most sensitive technique for detecting dissection after balloon dilatation and for determining the most appropriate balloon size to safely achieve a large lumen gain. Other trials showing the equivalence of IVUS-guided coronary angioplasty and stenting are only of historical interest. Stenting was the main promoter of the use of ultrasound in the interventional community [21]. The detection of incomplete stent deployment and apposition as causes of subacute stent

thrombosis and the consequent development of the technique of high-pressure stent implantation made IVUS almost routine during stenting procedures. The use of IVUS has progressively decreased since this technique was first developed as multiple randomized trials have shown the efficacy of adequate double antiplatelet treatment without ultrasound guidance in reducing subacute stent thrombosis to 1–1.5% in discrete lesions suitable for stenting. Registry data and meta-analysis on the ability of IVUS to reduce restenosis after stenting have given conflicting results, with the most important published randomized trial being completely negative [22].

The use of antiproliferative stent coatings to reduce intimal hyperplasia has revolutionized modern interventional cardiology and profoundly modified the technique of stent implantation. Serial IVUS examinations in large multicentre randomized trials have confirmed a consistent reduction of in-stent hyperplasia in comparison with conventional stents and have excluded the development of acquired stent malapposition and late aneurysms, thus contributing to the rapid success of DES [23].

With in-stent restenosis dramatically reduced to single figures in most lesion subsets, edge restenosis has become a more frequent cause of treatment failure. Ultrasound can be used to optimize the selection of stent length and for precise placement of the stent, and also to avoid leaving segments of severe plaque accumulation or dissection uncovered. Meticulous attempts to over-expand DES in order to reduce the risk of restenosis ('the bigger the better') has become a technique of the past. However, in most restenoses within DES, gross under-expansion has been observed [24]. A threshold of absolute minimal lumen cross-sectional area within the stent of 5.0 mm^2 has been advocated based on IVUS analysis of the SIRIUS trial [25]. For long lesions or calcified vessels or in segments of difficult angiographic assessment (ostia or bifurcations), ultrasound is the only way to properly control expansion.

Complete apposition of equispaced stent struts is not only important for reducing thrombogenicity but also allows the stent to work as a reservoir, delivering the antiproliferative drugs where needed [26]. Incomplete apposition cannot be assessed with angiography, and in large vessels and long lesions in tapering vessels is a frequent phenomenon, possibly explaining some of the failures of DES. Full lesion coverage is very difficult to confirm with angiography in ostial stenoses or bifurcational lesions (Fig. 6.13), no matter which technique is used for stent implantation. In bifurcational lesions, even modern ultrasound probes cannot easily cross in the direction of the side branch, especially if T-stenting or crush techniques are used, but IVUS might be the only way to understand how often treatment failure is due to incomplete stent expansion and lesion coverage or to excessive deformation of the stent struts with these techniques. Even with optimal IVUS guidance to select the irradiating dose, brachytherapy has too narrow a therapeutic window, with stimulatory effects at the edges and persistent late stent thrombosis. With both conventional bare metal stents and DES, retreatment is currently performed with the use of DES, although knowledge of the initial mechanism of restenosis (under-expansion, hyperplasia, incomplete lesion coverage) (Fig. 6.11) is important for selecting the proper length and diameter of stent to be deployed and for guiding its expansion.

Functional assessment of the coronary circulation

Basic structure–function relation of the coronary circulation

In the normal heart, there is a match between myocardial oxygen requirements and coronary supply, the reason for which lies in the unique structural design but also functional adaptability of the coronary artery circulation and the interrelation between the two [27]. Myocardial oxygen demand is mostly determined by ventricular wall stress, heart rate and myocardial contractility. Oxygen supply meets the respective demand by the capacity of the blood to carry oxygen and by the rate of coronary blood flow (in ml/min). Since oxygen-carrying capacity remains quite constant, varying oxygen demands by the myocardium are predominantly satisfied by altering coronary flow rates (Q). According to Ohm's law, $Q = \Delta P/R_m$, where ΔP is the coronary perfusion pressure drop between the aorta and the coronary sinus, and R_m is coronary microcirculatory resistance (Fig. 6.14). Oxygen supply under physiological conditions is not adjusted by coronary perfusion pressure but rather by the vascular resistance R_m, a composite of serial resistances and the result of the following factors: basic architecture of the coronary arterial tree, external compression exerted on the coronary vessels during the cardiac cycle, and intrinsic control of coronary tone. Epicardial coronary artery atherosclerotic narrowings are serial resistance elements further contributing to R_m by their static presence but also by their functional sequelae.

The basic anatomical structure of the human coronary artery tree represents an integral determinant of R_m and can be described in terms of lumen cross-sectional areas, arterial branch lengths and branching patterns. The relation among these variables and the blood flow

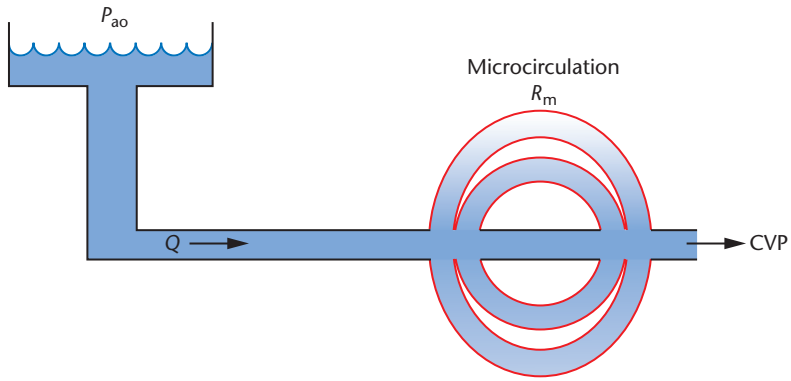

Figure 6.14 Schematic model of the coronary circulation with the parameters essential for the description of coronary flow rate (Q) according to Ohm's law: pressure drop between aortic pressure (P_{ao}) and central venous pressure (CVP) across the coronary circulation is the product of Q and microcirculatory resistance (R_m).

rate (Q) supplied to the downstream myocardial mass (M) has been theoretically derived on the basis of physical principles [27]. One of these principles assumes that the pressure drop (ΔP) along the streamline of the coronary circulation results solely from viscous friction of the blood. Thus, ΔP or the viscous energy loss can be described by the Hagen–Poiseuille equation, $\Delta P = Q \times 8\eta L/\pi r^4$, where ΔP is mean aortic minus mean central venous pressure, Q is coronary blood flow rate, η is the viscosity of blood, L is the vessel segment length and r is vessel radius. The principle of minimum viscous energy loss for the transport of blood in the coronary circulation defines the smallest possible energy balance between viscous energy loss and the energy content of blood plus vasculature (potential energy) (Fig. 6.15). For any given value of Q or M (assuming a constant normal absolute myocardial perfusion at rest of ~1 ml/min/g myocardium), the

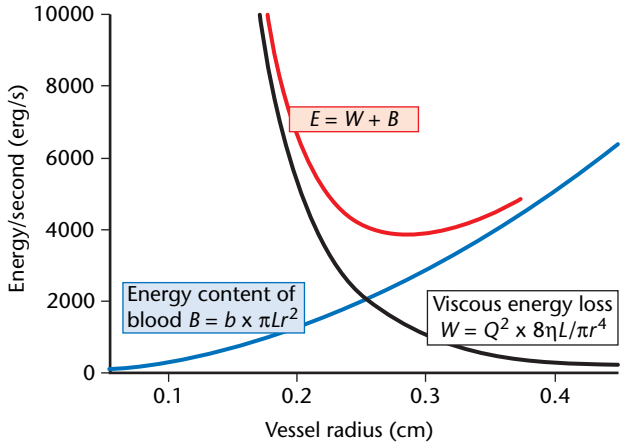

Figure 6.15 Principle of minimum viscous energy loss for the transport of blood governing the design of the coronary artery tree. Ideally, the vessel radius at a site within the tree where flow is 200 ml/min is such that the balance between the energy required to overcome viscous friction of blood flow (W) and the energy cost for the maintenance of the vasculature and blood (B) is minimal: $d(W + B)/dr = 0$ (nadir of the red curve).

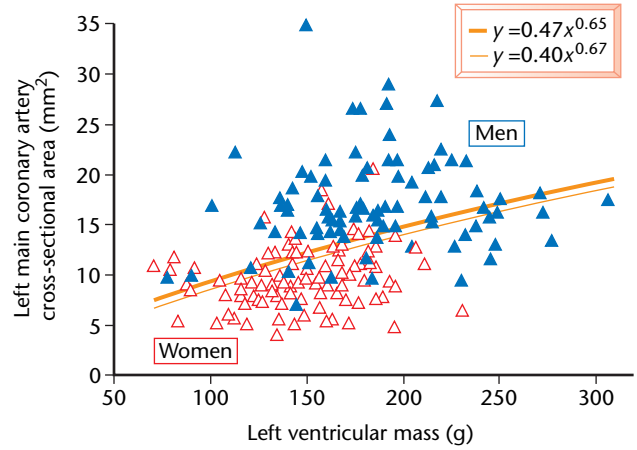

Figure 6.16 Association between left main coronary artery cross-sectional area (vertical axis) and left ventricular mass (horizontal axis) in men (closed symbols) and women (open symbols) without cardiovascular disease. The thin regression curve indicates the theoretically expected relation according to the law of minimum viscous energy loss for the transport of blood.

cross-sectional area A (in mm^2) at any corresponding site within the coronary artery tree can be given as $A = 0.4M^{2/3}$ [27].

The correctness of this equation in describing the basic structure–function relation of the coronary arterial tree has been confirmed empirically in humans using coronary angiographic and echocardiographic data (Fig. 6.16) [27,28]. Total left ventricular mass (M_{tot}) can be determined by echocardiography, whereas regional myocardial mass M at any point in the coronary artery tree has been documented to be tightly related to the product of M_{tot} and the ratio between regional and total summed coronary artery branch lengths (Fig. 6.17) [29]. Regional myocardial mass M represents the prognostically important variable 'area at risk for myocardial infarction' [30].

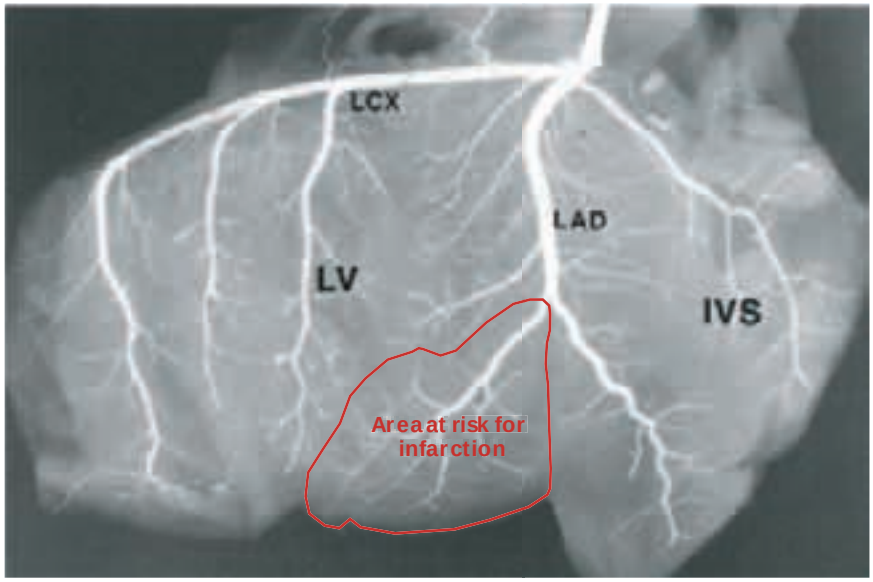

Figure 6.17 Post-mortem preparation of canine left coronary artery tree filled with barium gelatine. The red perimeter encircles the area at risk for left ventricular (LV) myocardial infarction in the case of a hypothetical distal left anterior descending coronary artery (LAD) occlusion. IVS, interventricular septum; LCX, left circumflex coronary artery.

Measurement of flow and Doppler flow velocity measurements

Absolute perfusion (ml/min/g) is the gold standard for assessing myocardial blood supply. Hence, its measurement in humans using positron emission tomography [31] or, very recently, myocardial contrast echocardiography [32] under resting and hyperaemic conditions provides the principal variable for judging whether there is a mismatch between myocardial supply and demand. Invasively, absolute myocardial perfusion cannot be directly obtained. However, it can be calculated on the basis of flow rate (Q) and regional myocardial mass (M) measurements as described above (perfusion = Q/M). Based on the continuity equation, Q is the product of coronary artery cross-sectional area (A) and spatial mean velocity (v_{mean}, cm/s). Invasively, these parameters or estimates of it (in the case of v_{mean}) can be obtained by quantitative coronary angiography and by intravascular Doppler measurements using sensor-tipped angioplasty guidewires. Currently available 0.36-mm (0.014-inch) Doppler guidewires determine temporarily averaged

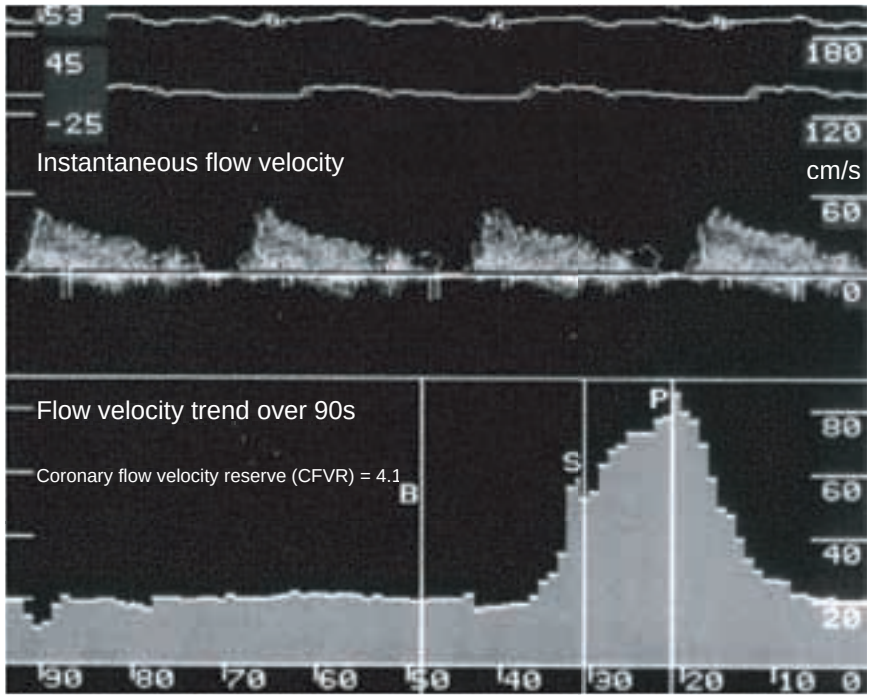

Figure 6.18 Intracoronary Doppler flow velocity recordings. The upper panel shows instantaneous flow velocity obtained during resting conditions; horizontal axis shows time in seconds. The lower panel depicts the flow velocity trend at rest (B, baseline) and during hyperaemia (P, peak velocity).

coronary peak flow velocities. Average peak flow velocity roughly corresponds to $^1/_2 v_{mean}$ [33]. Figure 6.18 depicts a coronary Doppler flow velocity profile obtained in a normal coronary artery with an average peak flow velocity of 21 cm/s. Given that the epicardial coronary artery calibre is maintained constant at maximal vasodilation by nitroglycerine, the vascular capacity to increase flow in response to a hyperaemic stimulus can be estimated invasively by assessing flow velocity during hyperaemia and at rest. The ratio between the two mentioned parameters is called coronary flow velocity reserve. Since a Doppler flow velocity guidewire can be employed as a regular angioplasty guidewire, it may be placed distal to an inflated angioplasty balloon located in an atherosclerotic stenotic lesion undergoing percutaneous coronary intervention (Fig. 6.19). In this particular setting, coronary occlusive flow velocity is obtained, which is directly indicative of (but not equal to) the flow via collateral arteries to the vascular area of interest (Fig. 6.20). A coronary occlusive flow velocity relative to the flow velocity during vessel patency under resting conditions ≥ 25% (i.e. collateral flow index, CFI; Fig. 6.20) has been shown to be sufficiently high to prevent electrocardiographic signs of myocardial ischaemia during a 1-min coronary balloon occlusion [34].

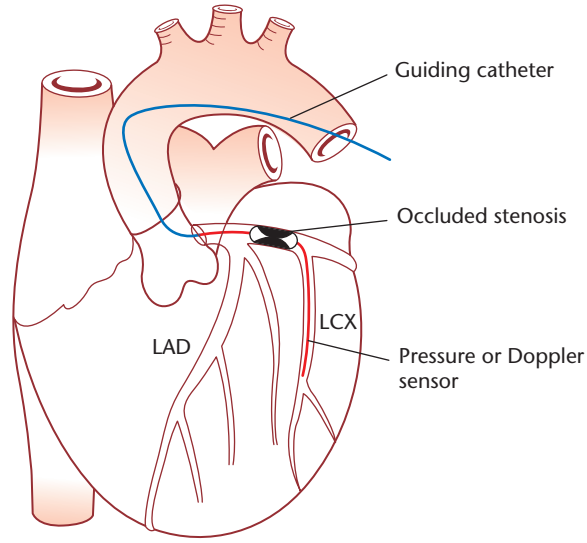

Figure 6.19 Schematic drawing of the heart and great vessels with the invasive set-up used for sensor-tipped angioplasty guidewire measurements of distal coronary occlusive pressure or velocity values. LAD, left anterior descending coronary artery; LCX, left circumflex coronary artery.

Coronary collateral circulation

In the event of acute coronary occlusion, the prognostically crucial variable of myocardial infarct size is determined by the following factors: time of occlusion, size of the above-mentioned area at risk (see Fig. 6.17), whether the myocardium has been preconditioned before complete occlusion by repetitive bouts of ischaemia, and the inverse of collateral supply to the occluded vascular territory [30]. In fact, the area at risk for infarction can be entirely replaced by a sufficiently developed collateral

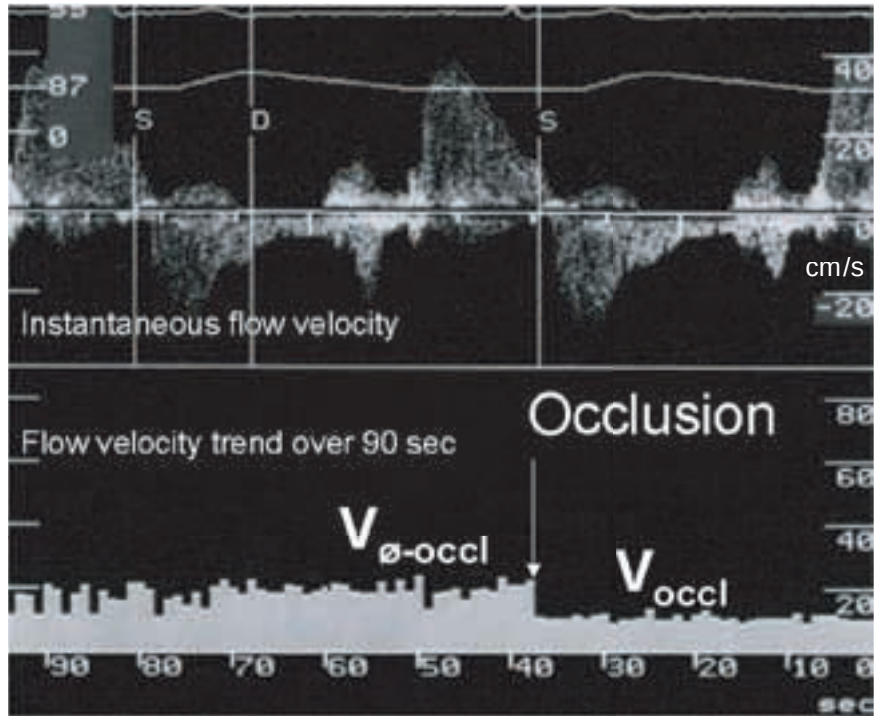

Figure 6.20 Upper panel: instantaneous bidirectional occlusive coronary flow velocity signal (V_{occl}). Lower panel: coronary flow velocity trend obtained during occlusion (right side) and during vessel patency ($V_{ø\text{-}occl}$; left side). The ratio between V_{occl} and $V_{ø\text{-}occl}$ is an index for coronary collateral relative to normal flow (collateral flow index, CFI).

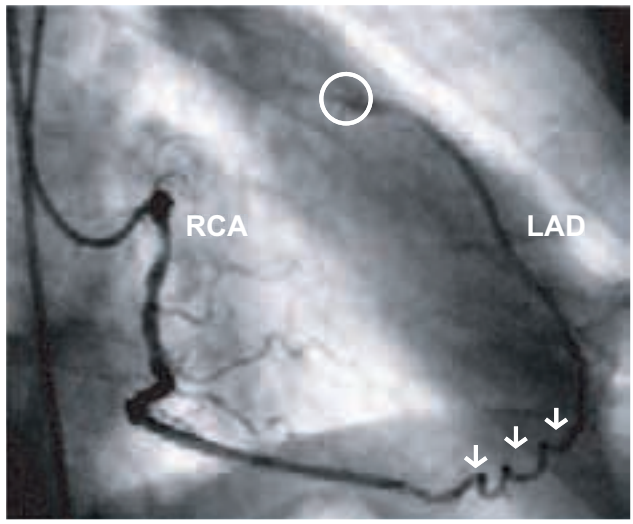

Figure 6.21 Right coronary artery (RCA) angiogram with entire retrograde filling of the occluded (circle) left anterior descending coronary artery (LAD) via a single large collateral artery (arrows).

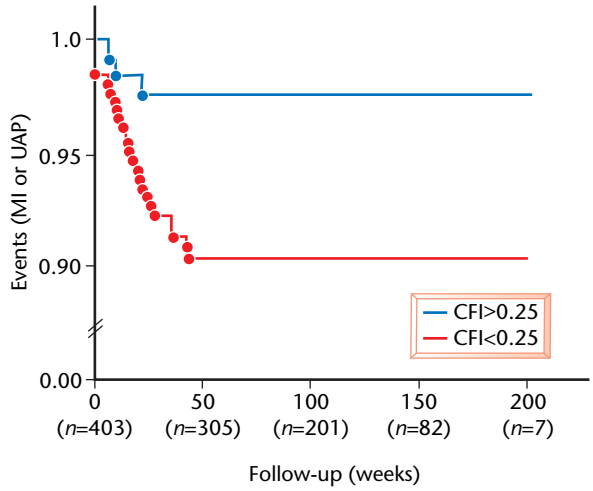

Figure 6.22 Cumulative 4-year event rate (vertical axis) of myocardial infarction (MI) or unstable angina pectoris (UAP) in patients with stable coronary artery disease and an invasively obtained collateral flow index (CFI) of < 0.25 or ≥ 0.25 ($P = 0.01$). CFI < 0.25 indicates collateral flow insufficient to prevent myocardial ischaemia during a 1-min coronary occlusion.

circulation, thus 'shrinking' it to zero and, accordingly, reducing infarct size to zero irrespective of coronary occlusion time (Fig. 6.21). Numerous earlier investigations have shown a protective role of well versus poorly grown collateral arteries, with smaller infarcts, less ventricular aneurysm formation, improved ventricular function, fewer future cardiovascular events (Fig. 6.22) [35] and improved survival [36]. However, the functional relevance of coronary collateral vessels in humans was also a matter of debate for many years [37]. Much of this controversy was likely due to inadequate means for gauging human coronary collaterals and the investigation of populations too small to be representative of all patients with coronary artery disease. The latter is well illustrated by the fact that among patients with haemodynamically significant atherosclerotic lesions, only about one-third have functionally sufficient coronary collaterals able to prevent signs of myocardial ischaemia during brief vascular occlusions (Fig. 6.23) [38]. In the absence of stenoses, it has been traditionally assumed that coronary arteries are functional end-arteries. Using direct and quantitative intracoronary collateral measurements, however, it has been documented very recently that the notion of the human coronary circulation being built without preformed functioning anastomoses between vascular territories is a myth rather than reality; in the

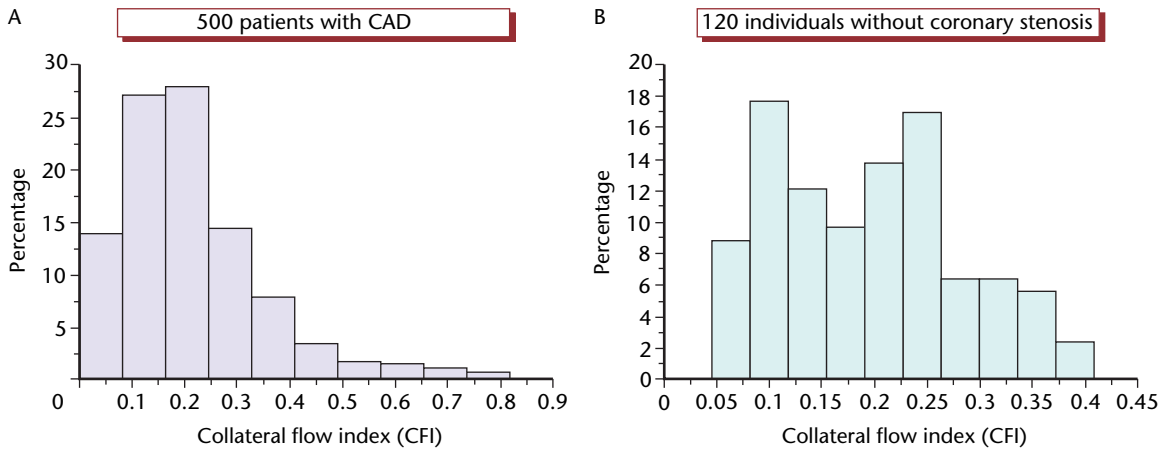

Figure 6.23 Percentage distribution of collateral flow index (CFI; horizontal axis) among (A) 500 patients with coronary artery disease (CAD; two-thirds with CFI < 0.25) and (B) among 120 individuals without coronary artery stenoses (three-quarters with CFI < 0.25).

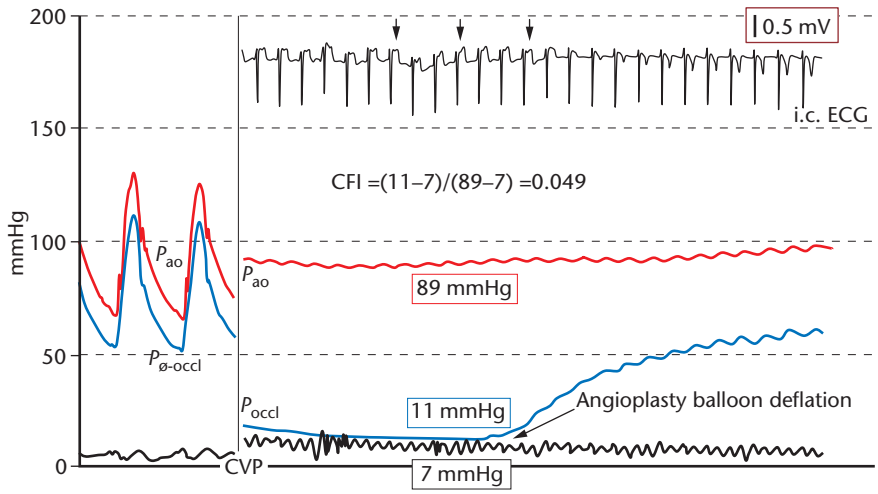

Figure 6.24 Determination of pressure-derived collateral flow index (CFI). Left side: non-occlusive phasic aortic pressure (P_{ao}), distal coronary pressure ($P_{ø\text{-}occl}$) and central venous pressure (CVP). During coronary balloon occlusion, mean coronary occlusive pressure (P_{occl}, blue curve) is 11 mmHg, while mean aortic pressure (red curve) is 89 mmHg. Coronary collateral flow is not sufficient to prevent ECG signs of myocardial ischaemia (arrows).

absence of obstructive coronary artery disease or even in entirely normal hearts, there is collateral flow to a briefly occluded coronary artery sufficient to prevent ECG signs of myocardial ischaemia in one-fifth to one-fourth of the population studied (Fig. 6.23) [39].

Coronary collateral flow can be precisely determined only during vascular occlusion of the collateral-receiving artery (see Fig. 6.19). Presently, the gold standard for quantitative clinical coronary collateral assessment is measurement of intracoronary occlusive flow velocity- or pressure-derived CFI, which expresses collateral flow as a fraction of flow during vessel patency. Pressure-derived CFI is determined by simultaneous measurement of mean aortic pressure (P_{ao}), mean distal coronary occlusive pressure (P_{occl}) and central venous pressure (CVP) (Figs 6.24 and 6.25) [34].

$$CFI = (P_{occl} - CVP)/(P_{ao} - CVP)$$

The coronary angiographic method for collateral qualification most widely used is similar but not identical to the one first described by Rentrop *et al.* [40]. The latter provides a score from 0 to 3 for recruitable collateral vessels upon occlusion of the ipsilateral artery, the former an identical score for spontaneously visible collaterals without artificial vascular occlusion.

A variety of physiological molecules have been identified that appear to promote angiogenesis (formation of capillary-like vessels) and arteriogenesis (formation of collateral arteries). Most act by stimulating migration and proliferation of endothelial cells and/or smooth muscle cells, like the family of fibroblast growth factors (FGF) and vascular endothelial growth factors (VEGF). Other growth factor candidates include placental growth factor, angiopoietin 1, transforming growth factor β, platelet-derived growth factor, and about half a dozen other cytokines, proteases and proteins [41]. Arteriogenesis has

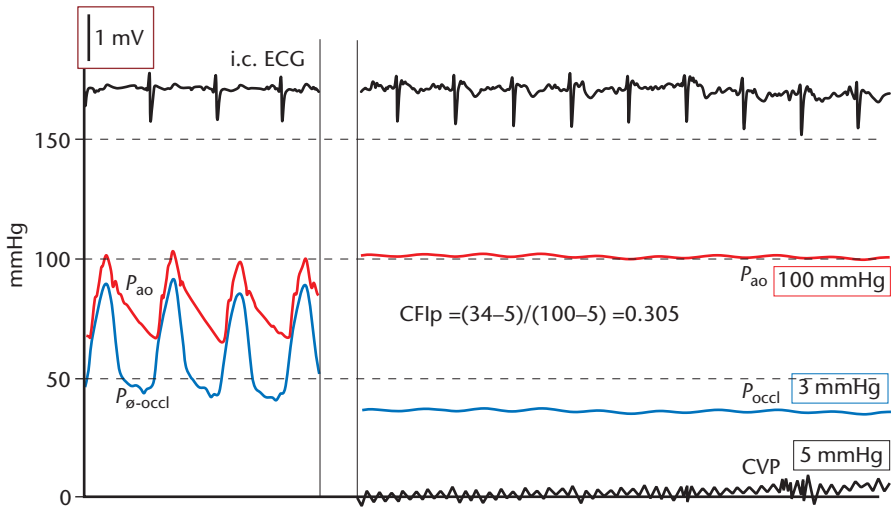

Figure 6.25 Determination of pressure-derived collateral flow index (CFI) in a patient with sufficient coronary collateral flow (see also Fig. 6.18). See Fig. 6.24 for explanation of abbreviations.

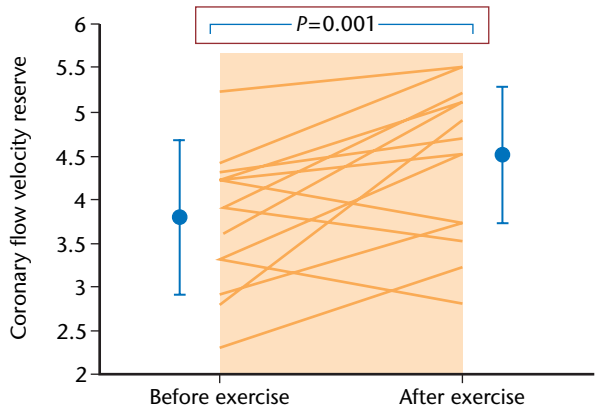

Figure 6.26 Intracoronary Doppler-derived coronary flow velocity reserve (vertical axis) before and after a long-term physical endurance exercise programme in eight healthy volunteers.

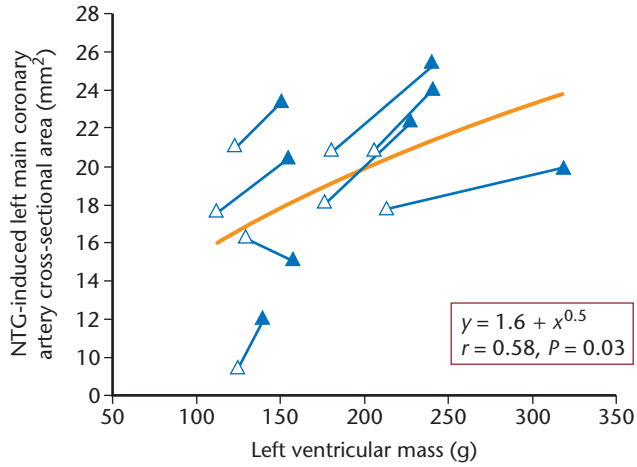

Figure 6.27 Left main coronary artery size (vertical axis) in relation to left ventricular mass in eight healthy volunteers before (open symbols) and after (closed symbols) a long-term physical endurance exercise programme.

been shown to be induced by activated macrophages, lipopolysaccharide, monocyte chemotactic protein 1, tumour necrosis factor α, FGF, and also via granulocyte–macrophage colony-stimulating factor (recombinant human GM-CSF; Molgramostim) [42]. In the first randomized placebo-controlled clinical trial, GM-CSF has been shown to be effective with regard to sequentially and invasively obtained collateral flow among 21 patients with coronary artery disease [43]. Arteriogenesis is related to enhanced shear forces at the vessel wall in response to increased flow through pre-existing collateral connections [44].

Regulation of myocardial blood flow

Likely induced by a similar mechanism of flow-induced vascular functional adaptation and structural remodelling, chronic endurance exercise in healthy individuals leads to enhanced coronary hyperaemic flow capacity (Fig. 6.26) as well as to more sizeable coronary arteries (Fig. 6.27) [45]. Such a chronic response to enhanced myocardial blood flow demand is based on its acute adaptability, which is pivotal since the heart cannot increase oxygen extraction on demand. Thus, any additional oxygen requirement must be met by an increase in coronary flow, and regulation including autoregulation of coronary vascular resistance (R_m) is the most important mediator of this process. Autoregulation refers to the intrinsic mechanisms that maintain blood flow constant at aortic perfusion pressures between 60 and 130 mmHg [46]. Acute regulation of myocardial blood flow is mediated by extrinsic factors, but mainly by the following intrinsic factors: accumulation of local metabolites, neural innervation and endothelium-derived substances.

1 *Local metabolites*. Adenosine, a product of adenosine diphosphate and monophosphate metabolized during states of hypoxaemia, is thought to be the prime metabolic mediator of vascular tone resulting in vasodilation. By binding to receptors on vascular smooth muscle cells, adenosine decreases calcium entry into cells, which leads to relaxation, vasodilatation and decreased vascular resistance. Other mediators include lactate, acetate, hydrogen ions and carbon dioxide.
2 *Neural innervation*. The neural control of vascular resistance has both sympathetic and parasympathetic components. Under normal conditions, the contribution of the parasympathetic system seems to be minor, but sympathetic receptors play an important role. Coronary vessels contain both α and β adrenergic receptors. Stimulation of α-adrenergic receptors results in vasoconstriction, while β_2-receptor stimulation promotes vasodilatation. Stimulation of β_1 receptors, by causing enhanced metabolic demand through augmented myocardial contractility, increases heart rate and conduction and secondarily results in increased myocardial blood flow.
3 *Endothelial factors*. Endothelial cells of the arterial wall produce a number of vasoactive substances that contribute to the regulation of vascular tone. Endothelial vasodilators include nitric oxide, prostacyclin and endothelium-derived hyperpolarizing factor. A very powerful endothelial-derived vasoconstrictor is endothelin 1. Nitric oxide regulates vascular tone by diffusing into and relaxing adjacent arterial smooth muscle via a cyclic

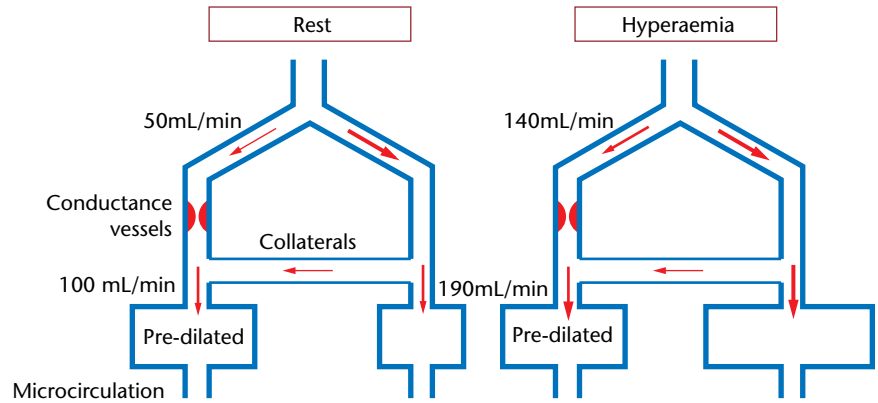

Figure 6.28 Schematic drawing of the concept of coronary flow reserve. At rest (left side), the microcirculatory vascular resistance downstream of a coronary stenosis is reduced in order to maintain myocardial perfusion. During hyperaemia (right side), the capacity for further dilatation of the pre-dilated microcirculation in the stenotic vascular region is reduced, resulting in only a limited increase in coronary flow (coronary flow reserve = 190/100 ml/min, normal value > 2–2.5).

guanosine monophosphate-dependent mechanism. Under normal basal conditions, nitric oxide is constantly released and is additionally stimulated by factors such as low oxygen tension, thrombin, platelet products, acetylcholine and increased wall shear stress (e.g. during exercise). A blunted response to these stimuli may occur in different diseases (e.g. hypertension, diabetes, hypercholesterolaemia) even in the absence of a flow-limiting coronary artery stenosis.

Coronary atherosclerotic stenotic lesions on their own also influence the regulation of myocardial blood flow by inducing microvascular dilatation, which is directly dependent on the degree of pressure drop across the lesion (Fig. 6.28). This adaptive mechanism is a specific facet of coronary autoregulation aimed at maintaining constant coronary flow. Under resting conditions, flow distal to a stenotic lesion remains normal until a tight obstruction of 80–85% in diameter is reached (Fig. 6.29). However, coronary flow achieved during hyperaemia begins to decline when the diameter of the stenosis is already < 50% (Fig. 6.29). This is related to the fact that the vasodilatory capacity of the microcirculation downstream of a stenosis is partly or entirely expended under resting conditions. The extent to which microvascular resistance can be lowered or to which coronary or myocardial flow can increase is generally referred to as absolute coronary or myocardial flow reserve (CFR). Specifically, CFR is defined as coronary flow during hyperaemia divided by flow obtained at rest [47]. A four- to five-fold increase after a maximum vasodilatory stimulus identifies a normal CFR. Apart from a stenotic lesion, CFR is influenced by several other factors, such as heart rate, blood pressure, left ventricular hypertrophy and microvascular disease. Relative flow reserve, i.e. the maximum blood flow in a stenotic artery divided by maximum flow in an adjacent normal artery [48], is less dependent on some of the mentioned cofactors of CFR because it does not account for baseline flow. Fractional flow reserve (FFR) is defined as the ratio of hyperaemic coronary flow in the stenotic region to hyperaemic flow in the same area if no lesion were present [49].

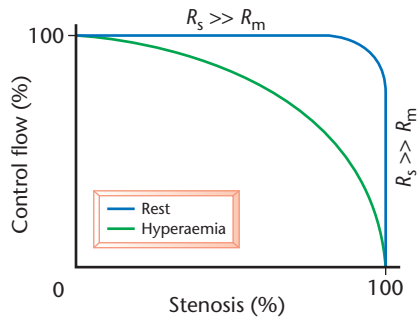

Figure 6.29 At rest, microcirculatory vascular resistance (R_m) downstream of a coronary stenosis dominates the resistance of the stenotic lesion (R_s), which explains why only a very severe stenosis (horizontal axis) leads to a reduction in coronary flow. During hyperaemia, the presence of only mild stenosis leads to the situation where R_s is predominant, and coronary flow is thus reduced.

Hyperaemic stimuli

In the absence of sufficient coronary collateral flow, a brief coronary occlusion of 1 min in a normal coronary artery typically induces a four to five times increase in coronary blood flow above resting level immediately after release of the occlusion. Initially, it was thought that short-lasting myocardial ischaemia is the most potent stimulus for achieving maximum flow or minimal myocardial resistance. However, in animals it appears that even during low-flow ischaemia the resistance vessels retain some degree of vasomotor tone [50]. Similarly, some residual flow reserve has been described in humans even in the presence of ischaemia [51]. Conversely, it has been found in patients after successful angioplasty that intracoronary flow velocity increased similarly in response to vascular occlusion as after administration of

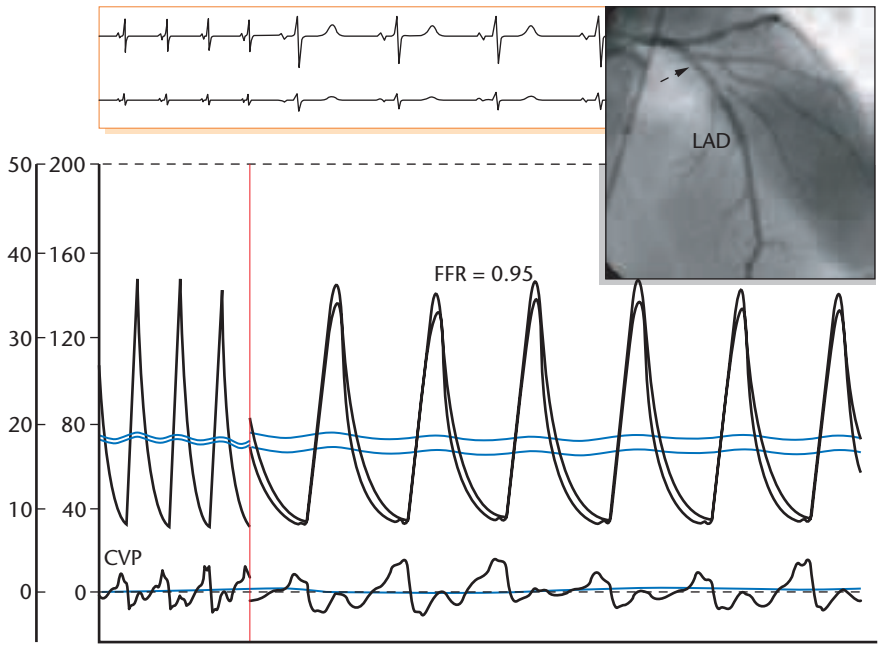

Figure 6.30 Recording of phasic and mean aortic pressure (P_{ao}), distal coronary artery pressure (P_d) and central venous pressure (CVP) at rest (left side) and during hyperaemia in a patient with mild narrowing (arrow) of the left anterior descending coronary artery (LAD; right panel). Fractional flow reserve (FFR) is 0.95 and thus the LAD stenosis is not haemodynamically relevant.

papaverine [52]. Such controversies on the maximally achievable hyperaemic response may be related to different degrees of ischaemia induced by coronary occlusion, i.e. the lack of accounting for collateral supply to the blocked vascular area. The most physiological stress that induces hyperaemia is physical exercise. Cardiac pacing increases coronary flow only modestly by a factor of 2–2.5. Among the pharmacological agents to induce hyperaemia, acetylcholine is the only direct endothelium-dependent vasodilator: in the presence of an injured endothelial cell layer, an inappropriate coronary constriction likely occurs, which can be relieved using nitroglycerine. Adenosine is a very safe coronary vasodilator due to its short half-life of only a few seconds; it acts via reduction of microcirculatory resistance, leading to coronary flow enhancement [53]. Intracoronary papaverine causes relatively brief (15–30 s) maximal hyperaemia, but the total dose that can be given is limited by its slow systemic excretion (half-life 3–6 h). Intracoronary papaverine prolongs the QT interval and can cause polymorphous ventricular tachycardia. Intravenous dipyridamole also elicits maximal hyperaemia, but its duration of action is too long (> 30 min) to allow repeated measurements during the same study.

Fractional flow reserve

As indicated above, there are several non-invasive and invasive methods for gaining information on the physiological relevance of epicardial coronary stenoses and also on microvascular coronary disease. The recent development of sensor-tipped angioplasty guidewires as well as the inclusion of hyperaemia into the routine test protocol has revived interest in the invasive functional assessment of coronary artery disease. Measurements of CFR and of hyperaemic flow versus pressure slope index have been documented to be critically influenced by altering heart rate, blood pressure, etc., whereas pressure-derived FFR appears to be less dependent on haemodynamic changes [54]. Pijls *et al*. [49] have provided the theoretical coronary haemodynamic background relevant when using simultaneous aortic and distal coronary *pressure* measurements during hyperaemia as the basis for calculation of a coronary *flow* index. Aside from the practical ease of obtaining measurements with sensor-tipped pressure wire as opposed to Doppler wire (problem of wall artefacts and position dependency within the coronary tree), there is a clear threshold of < 75% coronary hyperaemic flow across a stenotic lesion relative to normal flow in the absence of lesions (myocardial FFR < 0.75) (Figs 6.30 and 6.31) that reliably detects myocardial ischaemia as found by nuclear myocardial perfusion imaging or stress echocardiography [55]. However, distal pressure (P_d, the numerator in the calculation of FFR) depends on flow across the stenotic lesion, which is determined not only by stenotic resistance but also by microvascular resistance. A change in the latter affects distal pressure and flow inversely. Accordingly, a recent investigation has found that categorized cut-off values for simultaneously obtained FFR and CFR of 0.75 and 2.0 respectively have agreed in only 73% [56]. In the group with normal FFR but pathological CFR, the microvascular resistance index was higher than in the group with pathological FFR but normal CFR.

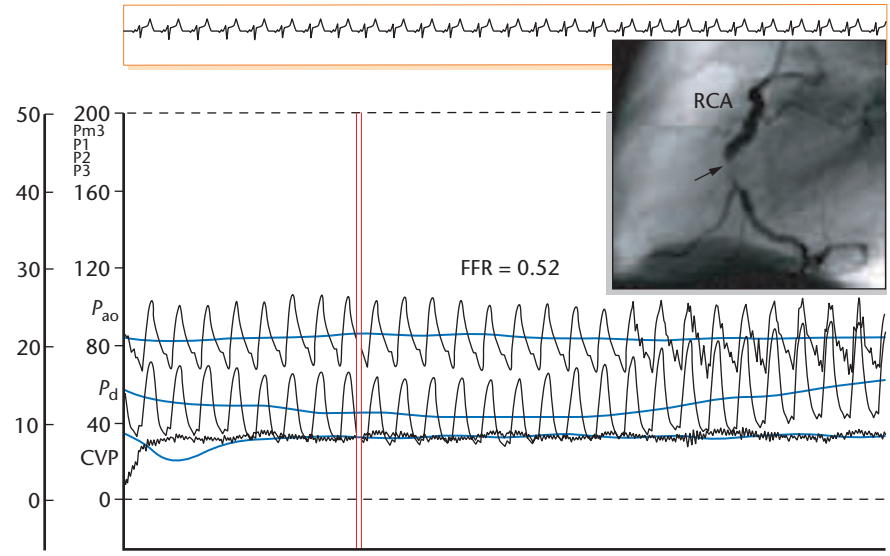

Figure 6.31 Recording of phasic and mean aortic pressure (P_{ao}), distal coronary artery pressure (P_d) and central venous pressure (CVP) during hyperaemia in a patient with severe narrowing (arrow) of the right coronary artery (RCA; right panel). Fractional flow reserve (FFR) is 0.52 and thus the RCA stenosis is haemodynamically highly relevant.

Personal perspective

Therapeutic decisions in cardiology are crucially determined by invasive circulatory imaging and haemodynamics, both of which are essential for understanding pathophysiological and diagnostic aspects of cardiovascular disease. The latter has been and will continue to be indispensable for the thorough choice of treatment plans for cardiovascular diseases. Since *invasive* examination is the only tool providing directly all the *basic* physical dimensions for the comprehensive description of the circulatory system, and since it also allows impromptu therapeutic action for treating cardiovascular disease, it is and will continue to be conceptually advantageous over several other non-invasive haemodynamic and imaging techniques. Presently, the most important entity for invasive imaging and treatment in the Western world is atherosclerotic coronary artery disease (CAD). Percutaneous coronary artery intervention (PCI) has become much more important than bypass surgery as treatment pillar for CAD during the past 25 years. The introduction of coronary stenting and drug-eluting stents for preventing arterial restenosis has decisively contributed to the success of PCI. In patients with no option for the traditional forms of coronary revascularization (about one-third of individuals with CAD), the therapeutic promotion of natural coronary bypasses, i.e. collateral growth or coronary arteriogenesis, has emerged as a promising treatment option which will steadily gain momentum.

7 Genetics of Cardiovascular Diseases

Silvia G. Priori, Carlo Napolitano, Stephen Humphries, Maria Cristina Digilio, Paul Kotwinski and Bruno Marino

Summary

Molecular genetics is progressively entering clinical practice and it is affecting patients' management. Most of our current knowledge derives from the application to molecular diagnosis of the findings of the pivotal studies that have unveiled the genes that cause the so-called monogenic diseases. Thanks to these studies we have learnt that disorders such as hypertrophic cardiomyopathy, dilated cardiomyopathy or long QT syndrome arise from a large spectrum of genetic defects and that the type of DNA abnormality is not only a molecular curiosity but also bears prognostic and therapeutic implications. Furthermore, thanks to the genetic studies on monogenic diseases, our knowledge of basic mechanisms leading to structural and electrical derangements of the myocardium has grown remarkably. The next challenge for molecular geneticists involved in cardiovascular disease is to investigate the role of DNA variants or single nucleotide polymorphisms in determining the predisposition to develop more complex phenotypes such as ischaemic heart disease, hypertension and heart failure.

This chapter will review the current understanding of genetic determinants of cardiovascular diseases with a focus on the practical role of genetic testing for risk stratification and management.

Inheritance of human diseases: monogenic versus polygenic diseases

Inherited diseases can be divided into monogenic and polygenic forms. Monogenic diseases are inherited as Mendelian traits while polygenic disease encompasses a large group of human diseases in which the evidence of 'familial clustering' suggests a role for genetic factors but the phenotype is not the consequence of mutations in a single gene (e.g. hypertension, coronary artery disease). In the last decade, the distinction between monogenic and polygenic diseases has become less obvious [1,2]. Phenomena such as incomplete penetrance, repeatedly reported in monogenic diseases, strongly suggest that even those diseases inherited as Mendelian traits are not simply the consequence of a single genetic defect. Accordingly, even in monogenic diseases the presence of additional genetic modifiers may concur to determining the severity of clinical manifestations.

Monogenic diseases

Monogenic diseases are inherited as dominant or recessive traits with five major inheritance patterns.

- *Autosomal dominant* (autosomes are all human chromosomes with the exception of the sex-related X and Y chromosomes). The chance of transmission to the offspring is 50%; both males and females can be affected. Only one mutated allele is sufficient to cause the phenotype.
- *Autosomal recessive*. Only the homozygote is clinically affected (two mutated alleles must be present) while the heterozygote is defined as a 'healthy carrier' or shows very mild signs of the disease. The chance of receiving two defective alleles/genes (one from the mother and one from the father) is 25%. Fifty per cent of the offspring will receive only one defective allele (heterozygotes) and 25% will receive two normal alleles (homozygotes).

Table 7.1 Clinical applicability of genetic testing in monogenic cardiac diseases*

	Success rate	Identification of silent carriers/diagnosis	Reproductive risk assessment	Prognosis	Therapy
HCM	60–65%	+	+	+/–	–
DCM	na	+	+	–	–
ARVC	< 10%	+	+	–	–
MFS	80–90%	+	+	–	–
LQTS	60–65%	+	+	+	+
BrS	20%	+	+	–	–
CPVT	50%	+	+	+	–
NS	40%	+	+	–	–

*Only conditions in which consistent epidemiological data are available have been listed. HCM, hypertrophic cardiomyopathy; DCM, dilated cardiomyopathy; ARVC, arrhythmogenic right ventricular cardiomyopathy; MFS, Marfan syndrome; LQTS, long QT syndrome; BrS, Brugada syndrome; CPVT, catecholaminergic polymorphic ventricular tachycardia; NS, Noonan syndrome; na, not applicable.

- *X-linked dominant*. Both males and females can be affected but no male-to-male transmission is possible and an affected male has a 100% chance of transmitting the disease to daughters. For female-to-female transmission of the defective allele there is a chance of 50%.
- *X-linked recessive*. Heterozygous females are healthy carriers and 50% of their sons are clinically affected. No female-to-female transmission of the disease is possible but 50% of daughters are silent carriers. Affected males will generate unaffected males and heterozygous unaffected females (healthy carriers). [The Y chromosome is usually involved in gross chromosomal anomalies (translocation, deletions) but very rare cases of monogenic disorders have been reported.]
- *Matrilineal transmission*. This refers to diseases caused by mitochondrial DNA. Since mitochondria are only present in oocytes and not in sperm, only females may transmit the disease to the offspring.

In clinical practice, it is often arduous to identify the patterns of inheritance based on the analysis of the phenotype because low penetrance and variable expressivity may obscure the picture. Time-dependent penetrance is a frequent phenomenon in genetics. The clinical manifestations become progressively worse during a lifetime because the organ damage induced by the defective gene accumulates. This is the case in hypertrophic cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy and dilated cardiomyopathy where disease penetrance may reach 100% when patients live long enough to manifest the symptoms.

The practical value of genetic analysis in monogenic diseases ranges from moderate to very high. In all diseases the principal role of identifying a mutation in the proband of a family is that of allowing an accurate diagnosis among family members including the silent carriers (i.e. presymptomatic diagnosis). In selected diseases, the identification of a mutation is of major importance for risk stratification and treatment of the patients. Table 7.1 summarizes the clinical value of genetic testing in different monogenic diseases.

Polygenic diseases

Many of the most prevalent cardiovascular disorders, such as coronary artery disease, hypertension and heart failure, are clearly not inherited as Mendelian traits but they 'cluster in families' whose members appear to be particularly susceptible to developing a specific phenotype. It is suggested that common DNA variations or single nucleotide polymorphisms (SNPs) account for this 'predisposition' to become affected by these acquired conditions. The human genome sequence is now published and much research involves identifying and cataloguing the extent of human genetic diversity, leading to the development of the SNPs 'Map' (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=Snp). By definition, a SNP is a nucleotide sequence variation within organisms of the same species. SNPs are most frequently silent (silent polymorphisms) but there are functionally active variants. These latter result in altered biological function by affecting differential gene expression or protein function and they are usually located either in regulatory or in coding regions of the genes. Functional SNPs may have neutral, beneficial or detrimental consequences as determined by interaction with environmental stressors.

Inherited (monogenic) diseases with myocardial involvement

Hypertrophic cardiomyopathy

Clinical presentation

Hypertrophic cardiomyopathy (HCM) is diagnosed when left ventricular hypertrophy (typically asymmetric in distribution) is present in the absence of cardiac or systemic conditions (e.g. hypertension or aortic stenosis), that could potentially induce a hypertrophy of the magnitude observed in a given patient. At histology the disease is characterized by myocyte disarray and hypertrophy, interstitial fibrosis and thickening of the media of the intramural coronary arteries [3]. The severity of the phenotype is largely heterogeneous and hypertrophy preferentially involves the interventricular septum. Most patients have remarkable regional variations in the extent of hypertrophy.

The guidelines for diagnosis and management of HCM were recently outlined in a joint consensus document of the American College of Cardiology and European Society of Cardiology [3].

Genetic bases

Most cases of HCM are transmitted as an autosomal dominant trait while other uncommon variants are inherited as autosomal recessive, X-linked or 'mitochondrial' disorders. A positive family history is noticeable in only two-thirds of cases but this may be an underestimate because of the incomplete penetrance. The prevalence of HCM is estimated to be 1 per 500, making HCM one of the most prevalent genetic diseases. The list of genes implicated in HCM has grown impressively over the last 10 years and, to date, 19 genes and two loci have been identified. Recent data suggest that mutations in the HCM genes also cause some of the milder forms of ventricular hypertrophy in the elderly, which are usually considered as acquired conditions [4].

An altered function of proteins of the cardiac sarcomere is the most frequent cause of HCM (Fig. 7.1). In such instances, myocardial hypertrophy is the only phenotype ('pure' HCM). Non-sarcomeric proteins have also been associated with HCM in a minority of cases. These variants usually show additional phenotypes such as abnormal conduction pathways (Wolff–Parkinson–White), sensorineural deafness, neurological and neurogenic muscular atrophy, trunk hypotonia and encephalopathy.

Although HCM is primarily an autosomal dominant trait, rare instances of sarcomeric protein mutations are inherited as a recessive trait (homozygous or compound heterozygous). In these cases the phenotype is usually severe since patients are carriers of two abnormal alleles.

Pathophysiology

The general scheme for HCM pathophysiology is that of a primary disorder of contractile function (Fig. 7.1). In this context, hypertrophy represents an adaptation to the inability to generate sufficient contractile strength to maintain adequate cardiac output. Fibroblast proliferation (fibrosis) and tissue disarray are the result of such adaptive modifications.

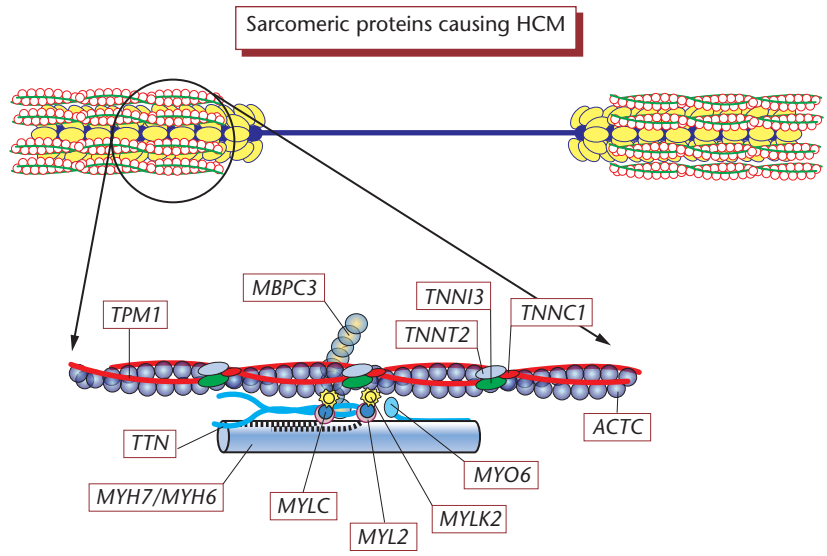

Figure 7.1 Schematic representation of a cardiac muscle sarcomere. The circled section represents the area in which myosin–actin interaction take place. Most of the key proteins involved in the hypertrophic cardiomyopathy pathogenesis take part in this macromolecular complex.

Functional expression studies of mutant sarcomeric proteins show a variety of abnormalities, spanning defects in myofibril formation, altered ATPase activity, Ca^{2+} sensitivity and impaired actin–myosin interaction.

In vitro studies have shown that mutant sarcomeres are usually incorporated in the myofibril, but assembly abnormalities (reduced incorporation efficiency and accelerated disruption/catabolism) may occur. Whether the myocardial disarray observed at a clinical level may be a direct consequence of mutant protein mis-incorporation and/or mis-folding has not yet been definitely established.

The globular (head) domain of β-myosin heavy chain is the site of actin binding and the region of ATP utilization (hydrolysis). *MYH7* mutations may alter the actin-dependent ATPase activity by disrupting the actin–myosin interaction. Several experimental studies also suggest that at least some HCM mutations increase the calcium sensitivity of the contractile apparatus. Additionally, functional studies from muscle biopsies in humans and in mouse models of HCM demonstrate a depressed shortening velocity and power, and increased Ca^{2+} mobilization. These phenomena may represent the initial signal for myocardial compensatory hypertrophy. For a review see ref. [5].

Genotype–phenotype correlation

HCM is characterized by a wide spectrum of clinical phenotypes. Therefore, the attempt to derive prognostic information based on the specific defect is an attractive perspective. However, limitation to this approach still exists. Most HCM patients carry mutations that are unique to their family, so genotype–phenotype correlations may only apply to a small subset of patients. Furthermore, the spectrum of clinical presentation is so wide that one single genetic factor is probably not enough to account for it, and environmental modifiers may play a significant role.

MYH7

The β-myosin heavy-chain gene is mutated in approximately 35–50% of the genotyped families [6]. A single mutation R403Q appears to have higher prevalence and together with other mutations (R719W, R453C) it has been associated with an adverse prognosis [7]. Near normal life expectancy was reported for other allelic variants such as Vl606M, L908V and G256Q, P513C [7,8].

TNNT2

TNNT2 defects are often associated with milder cardiac hypertrophy than other genetic variants of the disease, yet may manifest with a high proportion of arrhythmic events and sudden cardiac death. Incomplete penetrance has also been reported [9]. The relative prevalence of the *TNNT2* mutation is between 6.5 and 15% [9].

MYBPC3

Recent data suggested that the *MYBPC3* gene is probably the most prevalent variant [6]. *MYBPC3*-HCM is characterized by late onset and severe prognosis related to a high incidence of sudden arrhythmic death [4]. Epidemiological data collected in patients with *MYBPC3* mutations emphasize the need to continue tight monitoring of individuals belonging to families affected by HCM because delayed onset may unexpectedly pose a risk of sudden death in adults and middle-aged individuals who were considered unaffected at an early age.

TPM1

Mutations of the α-tropomyosin gene are a relatively infrequent cause of HCM, representing approximately 3–5% of the genotyped individuals [7]. The phenotype is of intermediate severity with heterogeneous cardiac hypertrophy. However, in the individual patient the possibility of developing severe hypertrophy and clinical manifestations cannot be ruled out. Variable levels of cardiac hypertrophy and also of cardiac dilatation with heart failure have been reported among carriers of α-tropomyosin mutations [10].

Too few families and too little information are available to attempt genotype–phenotype correlations in the remaining genetic variants of HCM. In these patients genetic testing is useful for diagnostic purposes and reproductive risk assessment but not for clinical management.

PRKAG2 (HCM and pre-excitation syndrome)

A short PR interval, prolonged QRS, with a slurred upstroke of the R wave ('delta' wave) and a predisposition to paroxysmal supraventricular tachycardia in the context of an otherwise normal heart are the characterizing features of the Wolff–Parkinson–White (WPW) syndrome. In rare instances, this WPW pattern is observed with a familial distribution.

More recently two independent groups [11,12] reported familial cases in which HCM and WPW phenotypes cosegregated with a mutation in the *PRKAG2* gene. This gene encodes for the gamma2 regulatory subunit of the AMP-activated protein kinase and it is directly implicated in the synthesis of cardiac energy substrates. The mutations in this gene induce a compensatory hypertrophy as a result of the reduced energy supply to the contractile elements. From a clinical standpoint it must be pointed out that the association of HCM and WPW is more frequent than the known prevalence of *PRKAG2* mutation. Thus, this phenotype is likely often to be an aspecific finding [13].

Table 7.2 Modifier genes in hypertrophic cardiomyopathy

Gene/variant	Gene product	Clinical variable	Result	Number of patients	Ref
ACE-D allele	Angiotensin converting enzyme	Cardiac hypertrophy SCD	Allelic frequency 0.69 HCM vs. 0.57 not affected Allelic frequency 0.74 (high SCD incidence) Allelic frequency 0.55 (low SCD incidence)	100	[14]
AGT	Angotensinogen	LVMI	Not significant	108	[15]
AT1a	Angiotensin II Receptor 1a	LVMI	Not significant		
END1–AA and *–AG* alleles	Endothelin 1	LVMI	Accounts for 7.3% of the variability of the LVMI		
TNF-α—*G308A* allele	Tumour necrosis factor	LVMI	Accounts for 6.0% of variability	142	[16]
IL-6—*G174C* allele	Interleukin-6	LVMI	Not significant		
IGF-2—*G829A* allele	Insulin-like growth factor-2	LVMI	Not significant		
TGF-β1—*C509T*	Transforming growth factor β-1	LVMI	Not significant		
CTP11B2—*T344C*	Aldosterone synthase	LVMI	Not significant		

LVMI, left ventricular mass index; SCD, sudden cardiac death.

Genetic modifiers in HCM

The identification of 'modifier genes' is an attractive possibility for the improvement of genotype-based risk stratification. Hints for the existence and clinical relevance of genetic modifiers in HCM have been brought to light [14–16] (Table 7.2). Despite their early stage, these studies suggest that the clinical course of HCM may be influenced by additional genetic factors. In the future this approach may allow individualized risk profiling by elucidation of a series of genetic variables. However, it is still too early to implement these observations in clinical practice.

Clinical applicability of genetic testing in HCM

The molecular epidemiology of HCM has been systematically addressed [6] by screening the entire open reading frame of nine HCM genes in 197 probands (*MYH7*, *MYBPC3*, *TNNI3*, *TNNT2*, *MYL2*, *MYL3*, *TPM1*, *ACTC* and *TNNC1*). Approximately 63% of these patients have been successfully genotyped (Table 7.1). Interestingly two genes, *MYH7* and *MYBPC3*, made up 82% of genotyped patients, while troponin T and troponin I were present in 6.5% of probands. Therefore, a genetic screening limited to the four major genes leads to the identification of the genetic defect in more than 60% of patients with clinically confirmed HCM. Two additional findings are worth mentioning: (1) nearly all genotyped families have a different mutation, thus indicating that the screening for known mutations is not useful; and (2) approximately 5% of patients present with more than one genetic defect (on the same or on two different genes), therefore genetic testing of all genes has to be completed in all patients even if a first genetic defect has been found.

Dilated cardiomyopathy

Clinical presentation

Ventricular dilatation can have different causes ranging from myocarditis as a result of viral infections to coronary artery disease and systemic diseases. The most frequent forms of dilated cardiomyopathy (DCM) are those secondary to ischaemic and valvular heart disease. In some instances, no aetiological factor can be identified and the disease is defined as 'idiopathic'. Idiopathic DCM may occur in sporadic as well in familial forms. The familial form of DCM frequently presents with associated cardiac phenotypes (e.g. conduction delays, bradycardia, atrioventricular and intraventricular conduction delay) or extracardiac phenotypes (e.g. skeletal muscle dystrophy, myopathy, deafness, mental retardation, endocrine system abnormalities, granulocytopenia).

In the absence of a familial distribution of the phenotype and of extracardiac manifestations pointing to specific syndromes no clear-cut differences of clinical

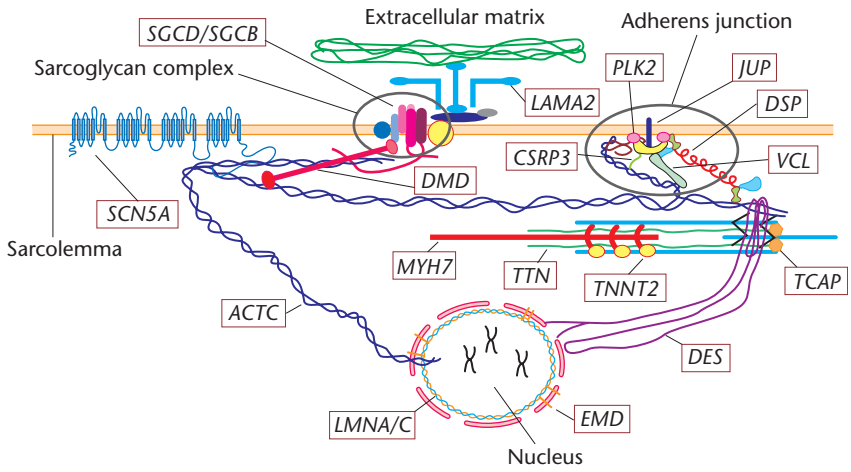

Figure 7.2 Structural proteins associated with inherited dilated cardiomyopathy. Four groups of proteins are identified: cytoskeletal proteins, sarcoglycan complex proteins, nuclear envelope proteins and adherens junction proteins.

manifestations exist between familial and non-familial cases. Therefore, the diagnosis of idiopathic DCM (which may have a genetic origin) is often made by excluding all clinically detectable causes.

Genetic bases and pathophysiology

The list of DCM genes is still expanding. Some additional genetic loci (a chromosomal region where the affected gene is likely to be located) have been identified by linkage analysis but no genes or mutations have been so far identified.

The most frequent pattern of inheritance is autosomal dominant, but autosomal recessive, matrilineal and X-linked transmissions have also been reported.

No studies have systematically assessed the relative prevalence of the various DCM subtypes. The genetic screening of single genes in a relatively large series of patients with idiopathic DCM yielded few genotyped probands [5]. Therefore, either several genes account for a few patients each, or a major DCM-related gene is yet to be identified.

An important consequence of this blurred picture is the limited clinical applicability of genetic testing (Table 7.1). The only exception is probably the *LMNA* gene, which appears to account for a relatively large number of patients and is associated with a specific phenotype that facilitates the selection of patients who are likely to benefit from the genetic analysis (see below).

The genetic heterogeneity of DCM is impressive and five major groups of molecules are involved:

- cytoskeletal proteins;
- adherens junction proteins;
- nuclear envelope and nuclear lamina proteins;
- sarcomeric proteins;
- mitochondrial DNA.

CYTOSKELETAL PROTEINS

The cytoskeletal-protein-encoding genes known to cause DCM are: desmin (*DES*), δ- and β-sarcoglycan (*SGCD, SGCB*), dystrophin (*DMD*) and cardiac actin (also considered a sarcomeric protein by some authors) (Fig. 7.2).

Desmin belongs to the intermediate filaments protein family and is thought to take part in force transmission. The *DES* gene may cause both DCM associated with skeletal myopathy, and pure DCM. Desmin-related disease is a familial disorder characterized by skeletal muscle weakness, cardiac conduction blocks, arrhythmias, restrictive heart failure, and by intracytoplasmic accumulation of desmin-reactive deposits in cardiac and skeletal muscle cells.

δ-Sarcoglycan is a transmembrane protein that heterotetramerizes with the other sarcoglycan isoforms (α, β and γ) to form a protein aggregate defined as 'dystrophin-associated transmembrane complex' (Fig. 7.2). This structure plays an important role in maintaining the correct assembly of the cytoskeleton and in allowing efficient force transmission in contractile cells. Mutational analysis has demonstrated that the *SGCD* gene may also cause a pure DCM phenotype in the absence of any sign of skeletal muscle involvement [17]. An additional sarcoglycan complex protein involved in a few DCM cases [18] is the β-sarcoglycan (*SGCB*) that primarily causes a severe autosomal recessive variant of limb-girdle muscular dystrophy.

The first hint for the involvement of dystrophin in a gene of X-linked DCM came from the observation of low levels of cardiac dystrophin but normal skeletal muscle dystrophin in some patients, and by linkage data mapping the X-linked DCM locus to the short arm of chromosome X. These data have subsequently been confirmed by other authors who identified DCM mutations in the *DMD* gene [19].

ADHERENS JUNCTION PROTEINS

Inherited DCM may also develop as a result of mutations of the genes encoding for adherens junction proteins (Fig. 7.2), a macromolecular complex connecting the cytoskeleton to the adjacent cells. Metavinculin results from a cardiac-specific splice variant of the vinculin gene (*VCL*). It interacts with α-actinin to anchor the cytoskeleton with the sarcolemma at the adherens junction level, thus participating in the cell-to-cell adhesion process. Altered interactions between metavinculin and actin have been reported in patients with *VCL* mutations [20]. There are anecdotal reports of additional genes (*DSP* and *CSRP3*) but their epidemiological relevance is not known at the present time.

NUCLEAR ENVELOPE AND NUCLEAR LAMINA PROTEINS

Two proteins of the nuclear structure have been associated with DCM: emerin, which causes the X-linked Emery–Dreifuss muscular dystrophy and lamin, which causes the more frequent autosomal dominant variant (Fig. 7.2).

Dilatation and conduction defects are the typical cardiac features of Emery–Dreifuss muscular dystrophy that may present with or without skeletal muscle abnormalities. In heart, the specific localization of emerin to desmosomes and adherens fascia could account for the characteristic conduction defects described in patients with Emery–Dreifuss muscular dystrophy. Since emerin is a ubiquitous protein the existence of alterations limited to skeletal and cardiac muscle remains difficult to explain.

There is another autosomal dominant muscular dystrophy with cardiac involvement that closely resembles Emery–Dreifuss muscular dystrophy but with normal emerin distribution. The locus for this autosomal dominant variant was mapped in 1999 [21] to chromosome 1 (1q11-q23) and mutations were reported in the *LMNA* gene, encoding two proteins of the nuclear lamina: lamins A and C. Lamins form dimers through their rod domain and interact with chromatin and with other key proteins of the inner nuclear membrane. When mutated, *LMNA* causes not only autosomal dominant Emery–Dreifuss muscular dystrophy but also autosomal dominant DCM with conduction defects with no muscular involvement. More than 60 known *LMNA/C* mutations may not only cause DCM and Emery–Dreifuss muscular dystrophy but also other allelic phenotypes: partial lipodystrophy, Charcot–Marie–Tooth disease, limb-girdle muscular dystrophy, partial lipodystrophy, mandibulosacral dysplasia and increased plasma leptin levels. The association of DCM with conduction defects is a typical feature of the *LMNA* mutation and it represents an indication for genetic testing in all patients with this phenotype.

SARCOMERIC PROTEINS

Actin has been traditionally considered a sarcomeric protein but its functional role is not only related to force generation but also to force transmission to the cytoskeleton. Although cardiac actin was known to be a cause of inherited HCM, its physiological role indicates that the *ACTC* gene is also a potential candidate for DCM. Olson *et al*. [22] were able to identify a single amino acid substitution in two families with DCM. Both mutations affected conserved amino acids in domains of actin that attached to Z bands and intercalated discs. Other studies have attempted to define the prevalence of actin defects in DCM families but have failed to find other relatives with actin-related disease [5].

While the 'double function' of the cardiac actin gene made it rational to suggest this protein as a potential candidate gene for both DCM and HCM, the identification of mutations of force-generating (sarcomeric) proteins in DCM patients has introduced a novel concept in the interpretation of DCM pathophysiology. Two of the major determinants of HCM, *MYH7* (cardiac myosin heavy chain) and *TNNT2* (cardiac troponin T) genes, may cause DCM [23] (Figs 7.1 and 7.2). Thus, DCM and HCM are allelic disorders in many instances and may have a similar pathogenesis. The thin border between HCM and DCM is well depicted by genotyped HCM patients who progress to DCM. Some cases of DCM may represent a final stage of HCM.

An additional sarcomeric protein causing DCM but not HCM is telethonin (*TCAP* gene) which is probably a very rare cause of cardiac dilatation and heart failure [24]. Telethonin is a sarcomeric protein that localizes to the Z discs of skeletal and cardiac muscle where it acts as a molecular 'ruler' for the assembly of the sarcomere by providing spatially defined binding sites for other sarcomeric proteins.

MITOCHONDRIAL DNA

Evidence of a mitochondrial form of DCM initially came from two cases of early-onset fatal DCM associated with the presence of large deletions of mitochondrial DNA [25]. Other reports followed and mutations in mitochondrial DNA encoding for histidine tRNA [26] and isoleucine tRNA [27] were identified. Interestingly, both mitochondrial DNA genes have also been implicated in HCM. Mitochondrial DNA defects cause very complex phenotypes with multiorgan involvement including deafness, focal glomerulosclerosis and epilepsy. The pathophysiological mechanisms leading from these mutations

to the clinical phenotype are largely unknown but are likely to involve energetic substrate production.

OTHER VARIANTS

A mutation in the *G4.5* gene in a family with malignant form of DCM co-segregating with an X-linked pattern has been reported [28]. This finding indicates that Barth syndrome and this DCM variant are allelic diseases. *G4.5* is expressed at high levels in cardiac and skeletal muscle and encodes for an alternatively spliced protein called tafazzin, which has no known similarities to other proteins and of which the function is unknown. Another *G4.5* allelic disease is left ventricular non-compaction (see below).

Additional genes that may cause rare instances of DCM have been reported. These genetic variants not only involve structures devoted to force transmission control (*DSP*) and chaperone-like proteins (*CRYAB*), but also transmembrane ion channel subunits (*ABCC9*). This latter finding has been very recently confirmed in two independent studies in which cardiac sodium channel (*SCN5A*) mutations have been identified in six families with DCM, heart failure and atrial fibrillation (the *SCN5A* gene is discussed in more detail below).

In summary, genetically determined abnormalities of several proteins have been associated with DCM. Most of the DCM genes have an important physiological role in maintaining cell shape, mechanical resistance and morphological integrity. The cytoskeleton contributes substantially to cell stability by anchoring subcellular structures and it is also linked with desmosomes, thus participating in cell-to-cell adhesion. Sarcomeric proteins, and possibly mitochondrial DNA, may cause DCM by an impairment of the force generation capabilities. Given the important physiological role of DCM-related genes, it is not surprising that mutations cause often severe phenotypes with multiorgan involvement.

Left ventricular non-compaction

Left ventricular non-compaction is the result of an arrest of myocardial morphogenesis. The disorder is characterized by a hypertrophic left ventricle with deep trabeculations and poor systolic function, with or without associated left ventricular dilatation. In some cases, the right ventricle is also affected. Left ventricular non-compaction may be an isolated disorder or it may be associated with congenital heart anomalies such as ventricular septal defects, pulmonary valve stenosis, and atrial septal defects. It becomes clinically overt at any time from infancy through adolescence and the clinical course of the disease is often severe with a progressive worsening of contractile function. Three genes causing left ventricular non-compaction are known:

- Alpha-dystrobrevin (*DTNA*), a protein participating in the dystrophin-associated complex [29].
- Cypher/*ZASP*, a gene encoding for a component of the Z-line in both skeletal and cardiac muscle, participating in assembly and targeting of cytoskeletal proteins [30] .
- *G4.5*, a gene with unknown function also causing X-linked DCM [29].

This evidence shows that the pathophysiology of left ventricular non-compaction is similar to that of DCM associated with cytoskeletal protein mutations.

Arrhythmogenic right ventricular cardiomyopathy

Clinical presentation and management

Arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC) is a predominantly autosomal dominant disease characterized by myocardial degeneration and fibro-fatty infiltration of the right ventricular free wall, the subtricuspid region and the outflow tract. A rare autosomal recessive variant (Naxos disease) characterized by the typical myocardial involvement, palmar keratosis and woolly hair has been also described.

Syncope and sudden death as a result of ventricular arrhythmias, often precipitated by intense physical activity, are the typical manifestations of ARVC. Conversely, the cases progressing to heart failure are rare. Diagnosis is based on the identification of right ventricular dilatation, adipose tissue infiltration and kinetic abnormalities. Electrocardiographic (ECG) abnormalities are also important diagnostic criteria (T-wave inversion in leads V1–V3 and late potentials on the signal-averaged ECG. Major and minor diagnostic criteria have been defined by a task force of the European Society of Cardiology) [31].

Genetic bases and pathophysiology

The estimated prevalence of ARVC ranges from 6 per 10 000 in the general population to 4.4 per 1000 in some areas with higher prevalence. However, it is unclear whether such regional clustering of the disease is related to real differences in the distribution of disease alleles in certain areas or to referral bias occurring in some specialized centres. Nine genetic loci are known. For three of them, the autosomal dominant *ARVD2* [32], *ARVD8* [33] and *ARVD9* [34], and for the autosomal recessive *NAXOS1* [35] the corresponding gene has been identified.

Based on the published data the *ARVD9* (plakophilin gene, *PLK2*) appears to be the most prevalent variant. Desmoplakin (*DSP*), identified in few *ARVD8* families, and plakoglobin (*JUP*), causing *NAXOS1*, are major constituents of the desmosomes and the intermediate junc-

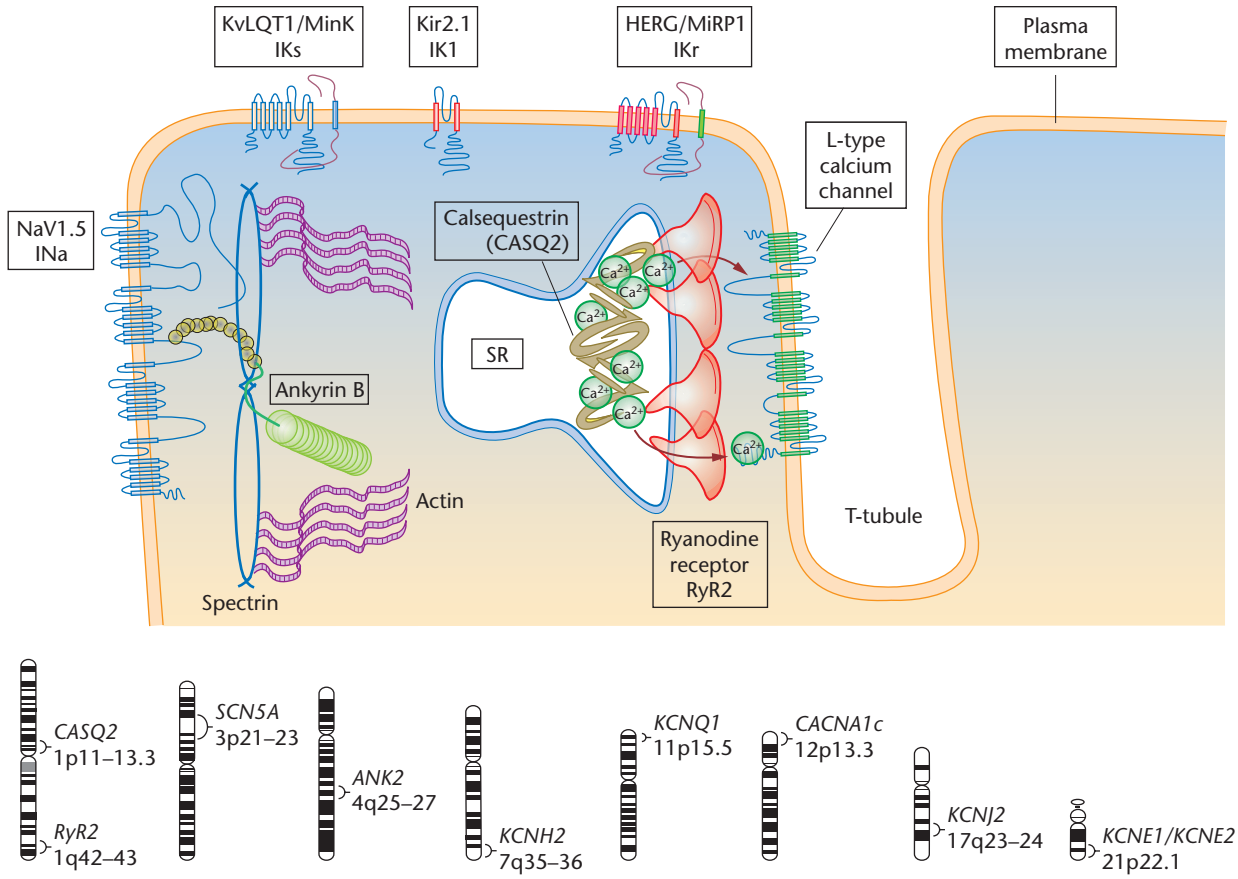

Figure 7.3 Diagram showing the proteins involved in the pathogenesis of monogenic diseases causing arrhythmias and sudden death in the structurally normal heart. The relevant proteins are highlighted with boxes. The inset at the bottom shows the chromosomal localization of the corresponding genes (see text for details).

tions (Fig. 7.2). They link the cytoskeleton, by binding the intermediate filaments, to the plasmalemma and adjacent cells. Mutations in genes encoding for desmoplakin and plakoglobin suggest that altered integrity at cardiac myocyte cell–cell junctions may promote myocyte degeneration and death. Interestingly the pathogenetic mechanisms of right ventricle dilatation likely to be involved in these variants appear similar to those of dilated cardiomyopathy as a result of abnormalities in cytoskeletal proteins.

The fourth ARVC gene (locus: *ARVD2*) is the cardiac ryanodine receptor, RyR2 (see section on catecholaminergic polymorphic ventricular tachycardia for details) (Fig. 7.3). *ARVD2* constitutes a rare and clinically atypical or 'concealed' form of arrhythmogenic right ventricular dysplasia and presents with exercise-induced bidirectional ventricular tachycardia very similar to those of catecholaminergic polymorphic ventricular tachycardia. It is still a matter of debate whether such patients fulfil the diagnostic criteria for ARVC.

Few patients with ARVC have been successfully genotyped so far, and the genes mentioned above account for a minority of the clinically affected patients. If we consider that apoptosis [36] and inflammation [37] may also play a role in ARVC pathogenesis, it is rational to hypothesize that only a fraction of ARVC cases could be determined by a single gene mutation. Some cases might be the result of environmental factors (e.g. viral myocarditis) acting on a vulnerable substrate that in turn may be determined by several genetic factors (SNPs), thus setting the picture of a polygenic disease.

Marfan syndrome

Clinical presentation and diagnosis

Marfan syndrome (MFS) affects mainly the skeletal apparatus, the eyes and the cardiovascular system. Skeletal abnormalities include: increased height, disproportionately

long limbs and digits, anterior chest deformity, mild to moderate joint laxity and vertebral column deformity (scoliosis and thoracic lordosis) [38]. Myopia, increased axial orbital length, corneal flatness and subluxation of the lenses (ectopia lentis) are ocular findings. At the cardiovascular level, mitral valve prolapse, mitral regurgitation, dilatation of the aortic root and aortic regurgitation have been reported [38]. The major life-threatening cardiovascular complication is aneurysm of the aorta and aortic dissection, which represent the major cause of mortality and morbidity [38].

The mean age of death for overt MFS is 45 years, but the survival is modulated by gender, with males having a worse prognosis. Usually, sporadic MFS cases present with more severe phenotypes compared with the familial ones. In these latter instances, diagnosis during infancy may be difficult. Diagnostic criteria for MFS have been published pointing to the need for the application of strict rules, especially for relatives, to avoid over-diagnosis [39]. MFS is usually treated with beta-blockers and surgery, when indicated, to correct aortic dilatation.

Genetic bases and pathophysiology

MFS presents with highly variable expression, but complete non-penetrance (silent gene carriers) has not been definitively documented. In the pregenetic era, a number of abnormalities of connective tissue proteins were reported and the pathophysiology of the disease was attributed to abnormalities of collagen primary structure and cross-linking and to abnormal hyaluronic acid synthesis. A consistent deficiency of elastin-associated microfibrillar fibres was also shown, and directed attention toward fibrillin, a glycoprotein of the microfibrillar component of the elastic fibre system.

When MFS was mapped to chromosome 15, the fibrillin gene (*FBN1*) was immediately identified as a strong candidate. In 1991 [40] the first *FBN1* mutation in a patient with MFS was reported. This finding was subsequently confirmed by several groups and it is now evident that *FBN1* accounts for the vast majority of MFS with more than 300 mutations published in the last decade. A second locus on 3p25–p24.2 was mapped in 1994 but the corresponding gene has not yet been identified [41].

Interestingly, *FBN1* mutations have been found not only in MFS but also in a range of connective tissue disorders, collectively termed 'fibrillinopathies', ranging from mild phenotypes, such as isolated ectopia lentis, to severe disorders including neonatal MFS, which generally leads to death within the first 2 years of life.

The pathophysiology of fibrillin-linked MFS is characterized by an abnormal metabolism of this protein. Mutated fibrillin subunits appear to exert a dominant-negative effect on the wild-type subunits, thus inhibiting the correct polymerization of collagen fibres. Other *in vitro* assays have suggested that, while synthesis and secretion of the polypeptides is unaffected, mutated polypeptides were significantly more susceptible to proteolytic degradation as compared with their wild-type counterparts.

Genetic screening of *FBN1* leads to the identification of a pathogenetic mutation in the majority of cases (Table 7.1).

Inherited (monogenic) disorders in the structurally normal heart

This group of diseases typically occurs in the absence of morpholoigical abnormalities of the heart. They are also called 'primary electrical disorders' or 'inherited arrhythmogenic diseases' because their primary manifestation is a cardiac arrhythmia (Fig. 7.3). A peculiar electrocardiographic phenotype, marker of electrical instability, is often recognized. Common symptoms are syncope and sudden death as a result of ventricular fibrillation. The common denominator is the abnormality of proteins controlling the excitability of myocardial cells. In recent years, mounting evidence has highlighted the concept that allelic variants (i.e. two or more phenotypes caused by mutations in the same gene) are the rule rather than the exception in these conditions [42]. The *KCNQ1* gene causes the type 1 variant of long QT syndrome, and the type 2 variant of short QT syndrome and familial atrial fibrillation. Likewise, *KCNH2* causes both long QT syndrome type 2 and short QT syndrome type 1, and the cardiac sodium channel gene (*SCN5A*) causes long QT syndrome, Brugada syndrome, progressive cardiac conduction defect and sick sinus syndrome (Fig. 7.4). Finally *KCNJ2* (the inward rectifier gene) causes Andersen syndrome and short QT syndrome [42,43].

Long QT syndrome

Clinical presentation

The long QT syndrome (LQTS) is an inherited arrhythmogenic disease occurring in the structurally normal heart that may cause sudden death. The mean age of onset of symptoms (syncope or sudden death) is 12 years and earlier onset is usually associated with a more severe form of the disease. The estimated prevalence of this disorder is between 1 per 10 000 and 1 per 5000. Two major

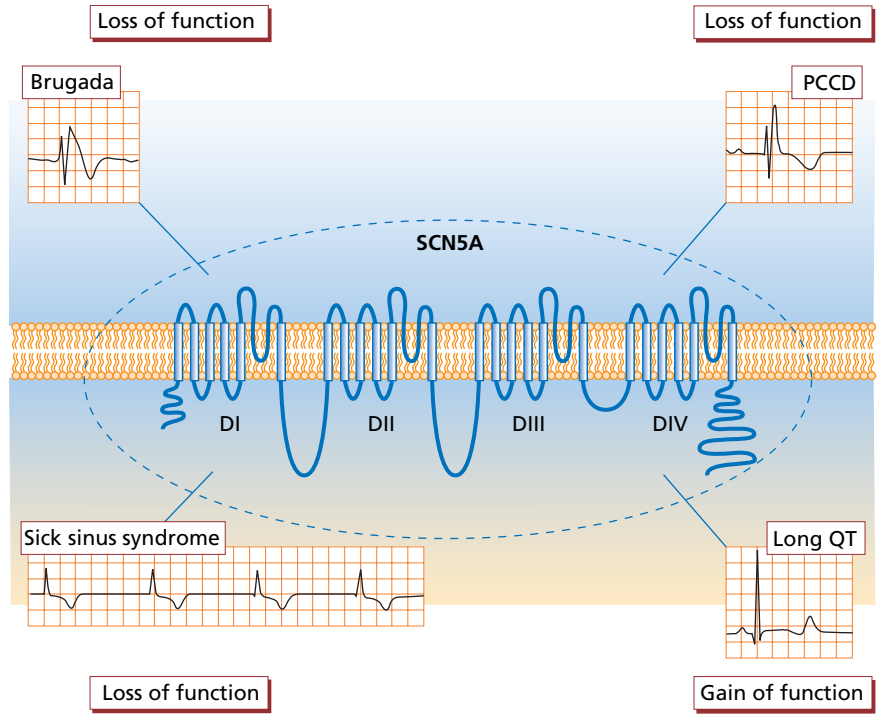

Figure 7.4 Schematic representation of the Nav1.5 protein and ECG phenotypes caused by cardiac sodium channel (*SCN5A*) mutations. The net effects of the genetic defects demonstrated in the *in vitro* studies are also reported.

phenotypic variants were originally described in the early 1960s: one autosomal dominant (Romano–Ward syndrome) and one rare autosomal recessive (Jervell and Lange-Nielsen syndrome, JLN) also presenting with sensorineural deafness. Another rare LQTS variant presenting with syndactyly and congenital heart defects has recently been linked to a cardiac calcium channel mutation.

Affected patients have abnormally prolonged repolarization (QT interval on the surface electrocardiogram), abnormal T-wave morphology and life-threatening cardiac arrhythmias [44]. Cardiac events are often precipitated by physical or emotional stress but in a small subset cardiac events occur at rest [44]. This observation constitutes the basis for the effectiveness of beta-blockers, which are the cornerstone of therapy in LQTS. For patients unresponsive to this approach, an implantable cardioverter-defibrillator and/or cardiac sympathetic denervation have been proposed. As discussed in the 'genotype–phenotype' section LQTS is the inherited cardiac disease in which genetic data have proved to be most helpful for patient management. Accordingly, locus-specific risk stratification for therapeutic management has been proposed.

Genetic bases and pathophysiology

There are currently eight identified LQTS genes. The typical LQTS phenotype with or without deafness may be the result of mutations in five different genes while three variants display QT interval prolongation in the context of a multiorgan disease (Andersen syndrome and Timothy syndrome) or with additional electrocardiographic features (LQT4—see below). The discovery of the genetic basis of LQTS started in the early 1990s with the mapping of four LQTS loci on chromosomes 11, 3, 7 and 4 [42]. The genes for these loci have been subsequently identified as *KCNQ1* (LQT1), *KCNH2* (LQT2) and *SCN5A* (LQT3) [42]. More recently, mutations in two additional genes on chromosome 21, *KCNE1* (LQT5) and *KCNE2* (LQT6), were reported. All the LQT1–3 and LQT5–8 genes encode for cardiac ion channel subunits (Figs 7.3 and 7.5). The exception is LQT4 which is caused by mutations in the *ANK2* gene: an intracellular protein called ankyrin B that is involved in ion channel anchoring and proper localization to the plasmalemma [45] (Fig. 7.3).

Sporadic LQTS patients have been described clinically and molecular genetics has allowed the distinction between patients who have *de novo* mutations and those that are the only clinically affected subject in a family with low penetrance [46] or, probably in rare instances, they may originate from parental mosaicism [47].

Defective I_{Ks} (LQT1, LQT5, JLN1 and JLN2)

KCNQ1 (causing LQT1 and JLN1) and *KCNE1* (causing LQT5 and JLN2) encode respectively for the alpha-subunit (*KvLQT1*) and the beta-subunit (*MinK*) of the potassium

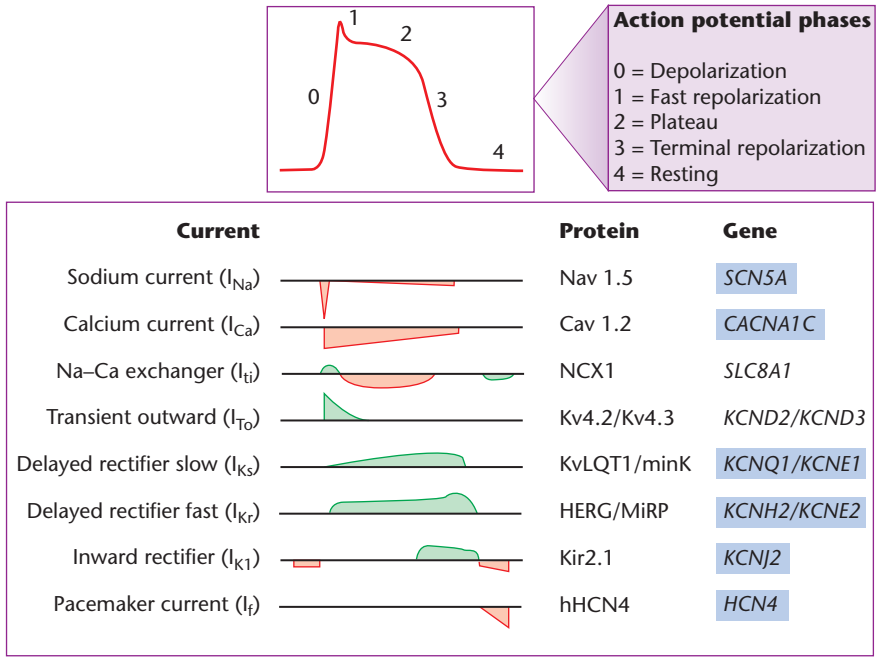

Figure 7.5 Ionic currents underlying the cardiac action potential. A ventricular action potential is represented with its four distinct phases, which are defined in the inset. The bottom panel from left to right shows the ionic current names with the abbreviated standard definition in brackets, a schematic representation of their time course during the action potential phases (red colour indicates an inward—going into the cell—current while outward currents are depicted in green). Some channels may conduct in inward or outward direction according to the membrane voltage at any given time point of the electrical cycle. The standard names of the protein and their respective genes are reported on the left. Blue-boxed gene symbols are those causing one or more clinical entities.

channel conducting the I_{Ks} current, the slow component of the delayed rectifier current (I_K), the major repolarizing current during phase 3 of the cardiac action potential (Fig. 7.5). To form a functional channel, KvLQT1 proteins form homotetramers and co-assemble with MinK subunits (Fig. 7.3).

LQT1 is the most prevalent genetic form of LQTS accounting for approximately 50% of genotyped patients. Hundreds of different mutations have been reported and *in vitro* expression of mutated proteins suggests multiple biophysical consequences but all of them ultimately causing a loss of function [48]. Homozygous or compound heterozygous mutations of *KCNQ1* also cause a Jervell and Lange-Nielsen form of LQTS (JLN1).

KCNE1 (LQT5) mutations are rather infrequent, accounting for approximately 2–3% of genotyped LQTS patients and they may cause both Romano–Ward (LQT5) and, if homozygous, Jervell and Lange-Nielsen (JLN2) syndromes.

From a clinical standpoint LQT1 patients present with a more straightforward adrenergic trigger for cardiac events [49]. LQT1 is also characterized by a lower penetrance and more benign prognosis compared with LQT2 and LQT3 [50].

Defective I_{Kr} (LQT2 and LQT6)

The *KCNH2* (LQT2) and *KCNE2* (LQT6) genes encode for the alpha-subunit (HERG) and the beta-subunit (MiRP) of the potassium channel conducting the I_{Kr} current, the rapid component of the cardiac delayed rectifier (Figs 7.3 and 7.5). The *KCNH2*-encoded protein, HERG, is a transmembrane protein that forms homotetramers in the plasmalemma to make up functional channels. LQT2 is the second most common variant of LQTS accounting for 35–40% of mutations. Functional expression studies have demonstrated that *KCNH2* mutations cause a reduction of the I_{Kr} current, but, similarly to LQT1 mutations, this effect is realized through different biophysical mechanisms [42] and also through intracellular processing abnormalities (trafficking defect) of the mutant proteins. LQT2 is characterized by higher penetrance and severity than LQT1, especially for females [50]. Mutations in the *KCNE2* gene (MiRP protein) cause the LQT6 variant of LQTS, which has a very low relative prevalence (< 1%) and the associated phenotypes are characterized by incomplete penetrance and very mild manifestations.

Defective I_{Na} (LQT3)

SCN5A encodes for the cardiac sodium channel conducting inward current (I_{Na}) (Fig. 7.5). At variance with the KvLQT1 and HERG proteins (which form homotetramers), a single *SCN5A* transcript forms a fully functional channel protein (called Nav1.5) (Fig. 7.3). The first reported *SCN5A* mutations in LQT3 patients were clustered in regions controlling channel inactivation, i.e. the linker between the third (DIII) and fourth (DIV) transmembrane domain (Fig. 7.4). Subsequently several allelic variants have been reported and functional expression studies have shown that, at variance with LQT1- and LQT2-associated mutations, LQT3 defects cause a gain of func-

tion (Fig. 7.4) with an increased I_{Na} [42]. The prevalence of LQT3 among LQTS patient is estimated to be 10–15%.

Defective ankyrin B (LQT4)

The phenotype of the LQT4 patients differs from typical LQTS. Most of the affected individuals, besides having QT interval prolongation, also present with severe sinus bradycardia, paroxysmal atrial fibrillation (detected in > 50% of the patients) and with polyphasic T waves. Recently, a missense mutation in the *ANK2* gene was identified in one family [45]. *ANK2* encodes for an intracellular protein (ankyrin B) that regulates the proper intracellular localization of plasmalemmal ion channels (calcium channel, sodium channel, sodium/calcium exchanger) and sarcoplasmic reticulum channels (ryanodine receptor, inositol triphosphate receptor). The low number of LQT4 patients genotyped so far prevents the definition of prevalence (which appears low) and phenotypic features of this variant of LQTS.

Defective I_{Ca} (LQT8—Timothy syndrome)

LQT8, also called Timothy syndrome, is a complex disorder in which severe QT interval prolongation is invariably associated with cutaneous syndactyly (hands and feet) and a number of additional abnormal phenotypes occurring with variable incidence among affected subjects. The markedly prolonged ventricular repolarization (the QT interval duration often exceeds 600 ms) frequently causes the appearance of 2 : 1 functional atrioventricular block. This severe cardiac phenotype is the major cause of the high mortality of this variant. A high proportion of LQT8 patients have congenital heart defects, mild mental retardation, autism and metabolic disturbances (severe hypoglycaemia, recurrent infections).

The therapeutic approach to LQT8 is unavoidably empiric because of the limited clinical experience. No indication of the effectiveness of beta-blockers or other drugs is available and, because of the high risk of severe arrhythmias, primary prevention with implantable cardioverter-defibrillator therapy may be considered.

A missense mutation (*G408R*) in the *CACNA1c* gene encoding for the cardiac voltage-gated calcium channel (CaV1.2) is the cause of all LQT8 cases so far reported [51]. The functional characterization *in vitro* showed a net increase of calcium inward current and a prolongation of action potential duration [51].

Genotype–phenotype correlation

In the last few years several studies have outlined the distinguishing features of the three most common genetic variants of LQTS (LQT1, LQT2, LQT3), which account for approximately 97% of all genotyped patients.

Locus-specific repolarization morphology (Fig. 7.6) and locus-specific triggers for cardiac events have been described [52]. LQT1 patients usually develop symptoms during physical activity, conversely LQT3 patients have events while at rest. Auditory stimuli and arousal are relatively specific triggers for LQT2 patients while swimming is a predisposing setting for cardiac events in LQT1 patients [52].

Locus-specific differences of the natural history of LQTS have also been demonstrated and allow genotype-based risk stratification [52] (Fig. 7.7). A QTc interval > 500 ms, and an LQT2 or LQT3 genotype determines the worst prognosis. Gender differentially modulates the outcome according to the underlying genetic defect: the LQT3 males and LQT2 females are the highest risk subgroups.

Finally, a recent study has demonstrated that the response to beta-blocker therapy is significantly modulated by the genotype and, specifically, the protection afforded by this therapy is only partial for LQT2 and LQT3 patients [53].

Brugada syndrome

Clinical presentation

Brugada syndrome is clinically characterized by ST segment elevation in the right precordial leads (V1 to V3), right bundle branch block and susceptibility to ventricular tachyarrhythmia (Fig. 7.6). The age of onset of clinical manifestations (syncope or cardiac arrest) is the third to fourth decade of life, although malignant forms with earlier or neonatal onset have been reported. Cardiac events typically occur during sleep or at rest [54]. The disease is inherited as an autosomal dominant trait but there is a striking male to female ratio of 8 : 1 of clinical manifestations. Since no effective pharmacological treatment has so far proved effective for Brugada syndrome patients, the implant of an automatic defibrillator (implantable cardioverter-defibrillator) is currently the only available option for high-risk patients. Therefore, risk stratification is a primary issue for Brugada syndrome management. Available evidence attributes the highest risk to patients with a spontaneously abnormal ECG and a history of syncope (Fig. 7.7). The usefulness of programmed electrical stimulation in the identification of high-risk patients is less certain. Implantable cardioverter-defibrillator therapy is also indicated in all cases for secondary prevention of ventricular fibrillation.

Genetic basis and pathophysiology

The initial report of *SCN5A* mutations in Brugada syndrome was published in 1998 and, as of today, tens of

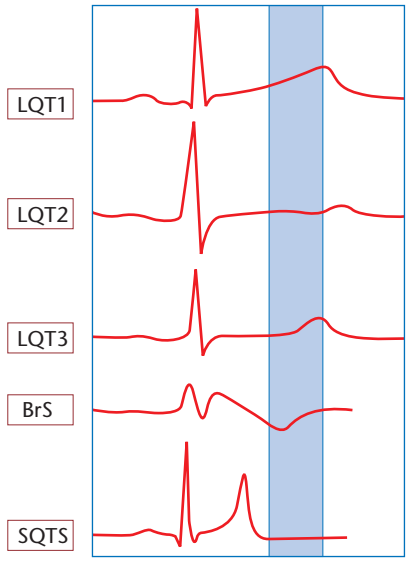

Figure 7.6 Examples of repolarization patterns caused by transmembrane cardiac ion channel mutations. The highlighted area depicts the range of a normal QT interval. LQT1, broad-based smooth T wave; LQT2, low amplitude and notched T wave; LQT3, straight ST segment with small, relatively rapid T wave; BrS, ST segment elevation and right bundle branch block. SQTS, short QT interval (< 320 ms), peaked and very fast T wave (resembling hyperkalaemia). LQT1/2/3, long QT syndromes type 1, type 2 and type 3; BrS, Brugada syndrome; SQTS, short QT syndrome.

different mutations have been reported (Fig. 7.8). Unfortunately, *SCN5A* accounts for no more than 20% of cases [55]. Therefore, genetic testing is not conclusive in 80% of Brugada syndrome patients. Another Brugada syndrome locus was mapped on the short arm of chromosome 3 (3p22-25) but so far the gene responsible for Brugada syndrome at this locus remains unknown. Given such limited knowledge the management and the risk stratification must be done on a clinical ground (Fig. 7.7). Nonetheless, genetic testing, when successful, allows confirmation of the diagnosis in borderline cases, identification of silent carriers and assessment of the reproductive risk (Table 7.1).

Several electrophysiological abnormalities have been identified by *in vitro* expression or Brugada syndrome mutation but the overall effect is that of a loss of sodium current [42] (Fig. 7.4). Very recently a novel mechanism was described for a *SCN5A* mutation that does not directly impair sodium current but causes a loss of binding of Nav1.5 with its intracellular targeting chaperone ankyrin G [56]. Consequently, mutated Nav1.5 is not properly localized at the level of intercalated discs.

Progressive cardiac conduction defect

Clinical presentation

Progressive cardiac conduction defect (PCCD) is a common disorder especially in the older population. It is characterized by progressive slowing of cardiac conduction through the His–Purkinje system with right or left bundle branch block and widening of the QRS complexes. In many cases the conduction block generates long pauses and severe bradycardia that may cause dizziness and syncope. PCCD is a major cause of pacemaker implantation in the world. In the majority of cases, it develops as a sporadic trait and is a degenerative disease that occurs with aging. However, in other instances familial cases have been reported, thus suggesting a genetic predisposition.

Genetic defects and pathophysiology

The first identified PCCD, also defined as progressive familial heart block (or PFHB), locus maps to 19q13.3 with an autosomal dominant inheritance. The linkage with this region was subsequently confirmed by other authors but the corresponding gene is yet to be identified. Conversely, by candidate gene screening, after the exclusion of the 19q linkage, another group [57] described two families with conduction defects and identified in both a mutation in the *SCN5A* gene (Fig. 7.8). *In vitro* assays suggest a loss of function effect [42] (Figs 7.4 and 7.8).

Sick sinus syndrome

Clinical presentation

Sick sinus syndrome (SSS) is a disorder phenotypically associated with PCCD that manifests with bradycardia, syncope, dizziness and fatigue. In some cases sinus node dysfunction and cardiac conduction defects may co-exist. As for PCCD, the majority of cases of SSS occur among older subjects and are thought to represent a manifestation of aging of myocardial specialized tissues controlling rhythm generation and conduction. Familial recurrence of SSS has been anecdotally reported and an autosomal dominant inheritance has been suggested but it is considered an 'exceptional finding'.

Genetic defects and pathophysiology

In 2003, Benson *et al*. [58] described five affected children from three kindreds with congenital SSS, and identified compound heterozygosity for six distinct mutations in the *SCN5A* gene. Two of these mutations had previously

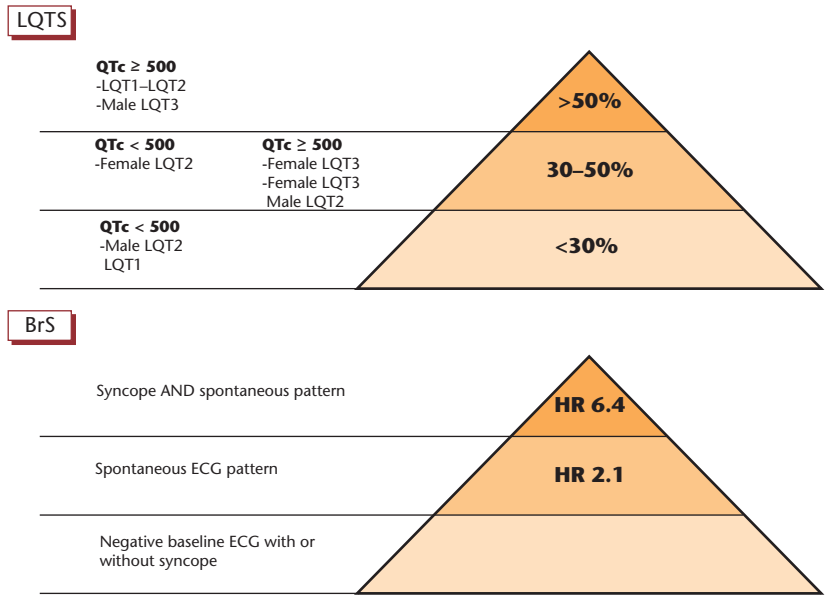

Figure 7.7 Upper panel: risk stratification according to clinical presentation and genotype in the long QT syndrome (LQTS). Three risk groups are identified for both diseases (low risk—pale orange, intermediate risk—light orange, and high risk—orange) according to the probability of experiencing a first cardiac event (syncope or cardiac arrest) in the absence of therapy from birth up to age 40 years. QTc, genotype and gender participate in the subgroup's definition among LQTS patients. Lower panel: risk stratification in Brugada syndrome (BrS) patients according to clinical presentation. The three risk groups (low risk—pale orange, intermediate risk—light orange, and high risk—orange) represent the variable risk of cardiac arrest or sudden death. The highest risk group comprises patients with a history of syncope and a spontaneously abnormal ECG (see text). These subjects have a more than six-fold risk increase (HR, hazard ratio 6.4) compared with reference category (negative baseline ECG, i.e. diagnostic only after administration of sodium-channel blockers—without syncope).

been associated with Brugada syndrome. Heterozygous carriers were asymptomatic, but showed subclinical cardiac conduction disease, particularly first-degree heart block suggesting a close relationship between PCCD and SSS. These data support an autosomal recessive pattern. As for PCCD, *in vitro* expression of the SSS mutation is consistent with a loss of function (Figs 7.4 and 7.8).

Familial atrial fibrillation

Clinical presentation

Atrial fibrillation is the most common sustained arrhythmia encountered in clinical practice. It is the most frequent cause of embolic stroke, accounting for

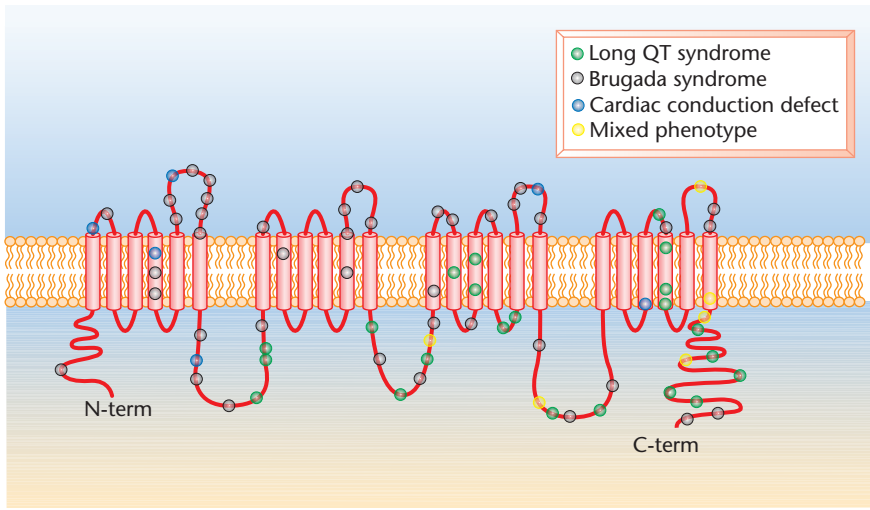

Figure 7.8 Schematic representation of a cardiac sodium-channel protein localizing across the lipid bilayer (as for the other ion channels of the plasmalemma, both amino- and carboxy-terminal extremities are in the intracellular compartment). Each reported mutation (as of January 2004) is represented by a circle with the number indicating the mutated codon with colour coding for the identified phenotypes. From http://pc4.fsm.it:81/cardmoc, with permission.

approximately 75 000 strokes per year in the USA and leading to more hospital admissions than any other arrhythmia. In the majority of cases atrial fibrillation is an acquired disorder but in 3–31% of cases no underlying cardiovascular disease can be detected and in some of them a familial inheritance is evident [59].

Genetic bases and pathophysiology

The first hint for a genetic predisposition to familial atrial fibrillation was published in 1997 [60]. In this report an autosomal dominant inheritance was demonstrated and linkage analysis mapped the familial atrial fibrillation locus to the long arm of chromosome 10 (10q22-q24) in three families. The gene located in this region has not been discovered yet. More recently, an additional locus has been mapped to the short arm of chromosome 11 (11p15.5) [61] and a missense mutation of *KCNQ1* has been reported. This genetic defect causes a gain-of-function effect on the KvLQT1/minK channel (see LQT1). The authors speculated that the *KCNQ1* familial atrial fibrillation mutation is likely to initiate and maintain the arrhythmia by reducing action potential duration and the effective refractory period in atrial myocytes.

Very recently, another familial atrial fibrillation mutation has been reported in the *KCNE2* gene (R27C) [62]. Functional studies revealed also in this case a gain-of-function of I_{Ks} (it should be recalled here that some authors suggest that KvLQT1 coassembles not only with minK but also with MirP protein).

Despite such important developments, it is important to emphasize the fact that the genetic determinants of the majority of familial atrial fibrillation cases remain poorly characterized. Therefore, the clinical applicability of genetic testing for familial atrial fibrillation is now limited to research activity.

Short QT syndrome

Clinical presentation

The first anecdotal report of a clinical condition characterized by abnormally short repolarization and ventricular arrhythmias was published in the year 2000 [63]. A persistently short QT interval (260–275 ms) has been reported with narrow and peaked T wave (absence of ST segment). Short QT syndrome (SQTS) is also characterized by the absence of structural heart defects, a quite remarkable familial history of sudden cardiac death and a typical, hyperkalaemic-like T-wave pattern at the resting ECG (Fig. 7.6).

Genetic bases and pathophysiology

Two different *KCNH2* missense mutations resulting in the same amino acid substitution were identified in two SQTS families [64]. By means of *in vitro* expression the authors observed a gain of function effect that explains the abbreviation of the action potential, which manifests as QT interval shortening on the surface ECG. Mutations in *KCNH2* are therefore the substrate for type 1 short QT syndrome (SQT1).

Genetic heterogeneity in SQTS was recently demonstrated by two groups of scientists who reported gain of function mutations in *KCNQ1* (SQT2 is therefore allelic to familial atrial fibrillation) [65] and in *KCNJ2* (SQT3 is therefore allelic to LQT7) [43].

The recent findings on the genetic defects underlying the SQTS phenotype, together with the data on LQT3 and BrS, demonstrate that at least five genes involved in the inherited arrhythmogenic diseases (*KCNQ1*, *KCNH2*, *SCN5A*, *KCNE2* and *KCNJ2*) may harbour both gain and loss of function mutations and that according to these primary biophysical consequences they give rise to different phenotypes. While the electrocardiographic manifestations diverge, the common denominator of these different clinical entities is the electrically unstable substrate that leads to cardiac arrhythmias and sudden death.

Catecholaminergic polymorphic ventricular tachycardia

Clinical presentation

Catecholaminergic polymorphic ventricular tachycardia (CPVT) [66] is characterized by exercise-induced or acute emotion-induced polymorphic ventricular arrhythmias, often causing syncope, a normal resting electrocardiogram and the absence of structural cardiac abnormalities. Symptoms usually develop during childhood or adolescence although there are anecdotal reports of first symptoms during adulthood. In approximately 13% of cases a cardiac arrest is the first manifestation of the disease and familial history of one or multiple sudden deaths is present in 30% of cases [67].

The resting electrocardiogram is unremarkable with the exception of sinus bradycardia and prominent 'U' waves reported in some patients [67]. Therefore, the diagnosis of CPVT at resting ECG is not feasible. Conversely ventricular arrhythmia is reproducibly induced during graded exercise (Fig. 7.9) with an alternating 180° QRS axis on a beat-to-beat basis (the so-called bidirectional VT), in some patients, and irregular polymorphic VT without a 'stable' QRS vector alternans in others. Stress-induced

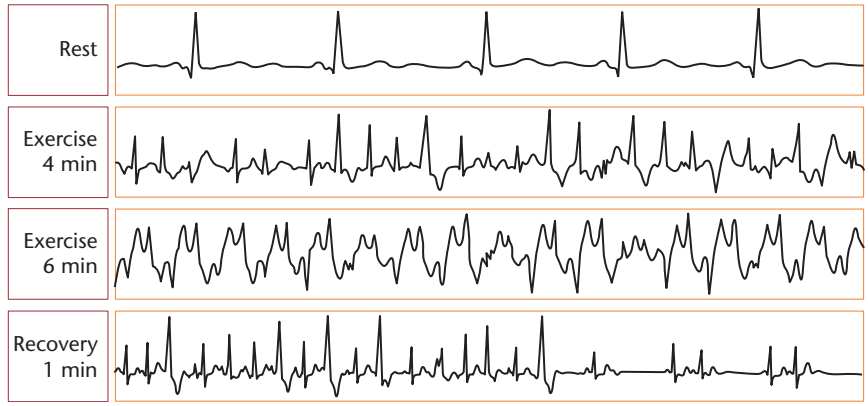

Figure 7.9 Electrocardiographic manifestations of catecholaminergic polymorphic ventricular tachycardia. The unremarkable ECG at rest is depicted in the top panel. During exercise ventricular tachyarrhythmia develops and progressively worsens while rapid relapse is evident during the recovery phase. Supraventricular arrhythmias are also evident in this patient.

supraventricular arrhythmias are also present in some patients [67].

Genetic bases and pathophysiology

CPVT1—AUTOSOMAL DOMINANT

Based on previous linkage analysis studies [68], the first CPVT gene was identified at the end of the year 2000 [69] as being the cardiac ryanodine receptor (*RyR2*). The role of RyR2 in the pathogenesis of CPVT was subsequently confirmed by other authors [70].

The ryanodine receptor is a large protein that tetramerizes across the membrane of the sarcoplasmic reticulum and forms the major sarcoplasmic reticulum Ca^{2+}-releasing channel in heart muscle. It plays a major role in the regulation of the intracellular calcium fluxes and excitation–contraction coupling. The identification of *RyR2* mutations in CPVT pointed attention for the first time to sarcoplasmic reticulum channels and to the pivotal role of intracellular Ca^{2+} handling in arrhythmogenesis and sudden death pathogenesis.

RyR2 mutant proteins have been expressed in different *in vitro* models (lipid bilayer, HEK293 cells, HL1-cardiomyocytes) and the results consistently showed that *RYR2* defects cause a Ca^{2+} 'leakage' from the sarcoplasmic reticulum during sympathetic (catecholamine) activation [71,72] while the basal channel activity appears normal.

CPVT2—AUTOSOMAL RECESSIVE

An autosomal recessive variant of CPVT has been described and linked to the short arm of chromosome one (1p23-21) [73]. Subsequently the same authors identified *CASQ2* as the gene for this locus [74]. *CASQ2* encodes the cardiac isoform of calsequestrin, a highly expressed transcript in the heart. It serves as a major Ca^{2+}-binding/buffering protein localized in the terminal cisternae of the sarcoplasmic reticulum. Calsequestrin is bound physically and functionally to the ryanodine receptor and cooperates in the control of the excitation–contraction coupling. The *CASQ2* defects so far identified cause the CPVT phenotype only in individuals carrying two abnormal alleles (homozygous or compound heterozygous) [67].

One experimental study [75] has shown that *CASQ2*-D307H mutation impairs the sarcoplasmic reticulum Ca^{2+}-storing and Ca^{2+}-release functions and destabilizes the Ca^{2+}-induced Ca^{2+}-release mechanism via reduced Ca^{2+} buffering inside the sarcoplasmic reticulum and/or altered responsiveness of the Ca^{2+}-release channel complex to luminal Ca^{2+}.

Taken together the experimental data demonstrated that both genes involved in CPVT pathogenesis affect the amount of Ca^{2+} released from the sarcoplasmic reticulum during adrenergic stimulation. Such an effect may create an electrically unstable substrate probably through triggered activity-mediated arrhythmogenesis.

Congenital heart defects

General aspects

Congenital heart defects (CHDs) are the most common form of birth defect, affecting about 8 in 1000 newborns. The classification of CHDs introduced by Clark in 1986 [76] groups cardiac malformations according to morphopathogenetic criteria instead of clinical or anatomical criteria to aid the identification of links among causes, mechanisms and defects. Epidemiological studies, particularly the Baltimore–Washington Infant Study, have shown that one-third of all CHDs are associated with

genetic syndromes or extracardiac anomalies [77]. The study of chromosomal disorders and autosomal dominant syndromes associated with specific anomalies of heart development is an essential step in identifying the genes involved in the pathogenesis of CHD. Furthermore, the accurate analysis of cardiac anatomy in patients with syndromic and non-syndromic CHDs has revealed that peculiar morphological subtypes of CHDs are related to specific genetic conditions.

Syndromic congenital heart defects

Down syndrome

Down syndrome, affecting 1 in 700 live births, is one of the most common genetic syndromes. It is related to trisomy 21, and clinical features include mental retardation, CHD, gastrointestinal malformations and characteristic facial dysmorphisms.

The prevalence of CHD in patients with Down syndrome ranges from 40 to 50%. Atrioventricular canal defect and ventricular septal defect are the CHDs more frequently found in Down syndrome (Table 7.3). The anatomical abnormalities in Down syndrome are quite specific: atrioventricular canal defect is usually complete, and is associated with left-sided obstructions, and ventricular septal defect is usually perimembranous. In some cases patients with Down syndrome may present with tetralogy of Fallot and atrial septal defect. Conversely, muscular and subarterial ventricular septal defects are rare.

Interestingly, 'mosaic' trisomy 21 is associated with a lower prevalence of CHD (30%) and less severe CHD. A Down syndrome 'critical region' on chromosome 21 has been identified following phenotypic, cytogenetic and molecular characterization of patients with partial trisomy 21. These studies showed that the 21q22.2-22.3 locus is crucially involved in Down syndrome-related CHDs [78]. This region contains about 60 genes, which are still poorly characterized.

Deletion 22 syndrome

Microdeletion of chromosome 22q11.2 is detectable in the majority of patients with DiGeorge, velocardiofacial and conotruncal anomaly syndrome. Clinical features include conotruncal CHD, palatal anomalies, neonatal

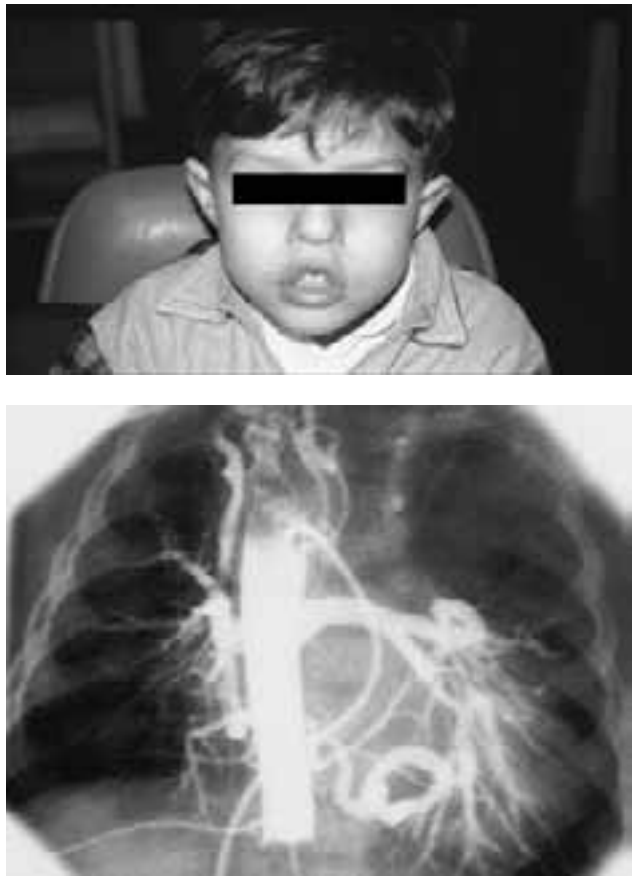

Figure 7.10 (A) Facial appearance of a patient with deletion 22 syndrome, and (B) aortography injection showing pulmonary atresia with ventricular septal defect and major aorto-pulmonary collateral arteries in deletion 22.

hypocalcaemia, thymic hypoplasia and immunological deficiency, characteristic facial dysmorphisms (Fig. 7.10A), speech and learning disabilities. There is wide variability in the clinical spectrum, ranging from death in the neonatal period to presentation with mild facial features and hypernasal speech.

Patients with deletion 22 syndrome often have abnormalities in four areas of the cardiovascular system: the aortic arch, the pulmonary arteries, the infundibular septum and the semilunar valves. In particular, the aortic arch can be right-sided, cervical, double, and the subclavian artery can be aberrant [79] (Fig. 7.10B; Table 7.3). The most frequently diagnosed abnormalities are tetralogy of Fallot (20–45%), pulmonary atresia with ventricular septal defect (15–30%), interrupted aortic arch (5–20%) and truncus arteriosus (5–10%) [79–81]. Interrupted aortic arch, truncus arteriosus and pulmonary atresia with ventricular septal defect demonstrate a specific association with deletion 22. In fact, deletion 22 is diagnosed in 45–50% of patients with interrupted aortic arch (particularly the 60–80% of those with interrupted aortic arch type B), in 45% of patients with pulmonary atresia and ventricular septal defect, and in 30–35% of patients with truncus arteriosus [79,82].

Deletion 22 is exceptionally rare among children with non-syndromic conotruncal defects, and patients with CHD and deletion 22 always present one or more extracardiac anomalies. Therefore, testing for deletion 22 is only indicated for patients in whom the heart defects are associated with the phenotypic spectrum of DiGeorge/velocardiofacial syndrome, and in those presenting with distinct anatomic conotruncal defect subtypes.

The majority of patients carry a common 3-Mb deletion, and at least 30 genes have been mapped in the deleted region. Although *TBX1* mutations have been detected recently in some patients with clinical features of DiGeorge/velocardiofacial syndrome without a detectable deletion 22 [83], it remains unclear whether several genes must be haplo-insufficient to cause a clinical phenotype or whether a single locus predominates.

Noonan syndrome and LEOPARD syndrome

Noonan syndrome is a genetic disorder characterized by CHD, facial dysmorphisms, short stature, webbed neck, chest deformities, undescended testes and cardiac malformations (50% of the cases), and hypertrophic cardiomyopathy. Pulmonary stenosis, atrioventricular canal defect, left-sided obstructive lesions, atrial septal defect and tetralogy of Fallot have been described [84]. The atrioventricular canal defect of patients with Noonan syndrome is generally 'partial', and is frequently associated with subaortic stenosis. Left-sided anatomic obstruction in Noonan syndrome can also occur (left mitral abnormalities or coarctation of the aorta).

Approximately 40% of patients with Noonan syndrome have missense mutations in the *PTPN11* gene, which encodes for the protein tyrosine phosphatase SHP2 [85].

LEOPARD syndrome is an autosomal dominant condition characterized by lentigines and 'café-au-lait' spots, CHD or arrhythmia, facial anomalies, short stature, retarded growth and sensorineural deafness. This syndrome shares several clinical features with Noonan syndrome. Specific *PTPN11* mutations have been found in almost all analysed patients with LEOPARD syndrome, proving that LEOPARD and Noonan syndromes are allelic conditions [86].

A genotype–phenotype correlation analysis shows that the distribution of CHDs is different among the two syndromes: pulmonary valve stenosis is most common in Noonan syndrome patients (mutation in exon 8), while

hypertrophic cardiomyopathy is predominant in patients with LEOPARD syndrome, associated with mutations in exons 7 and 12 [86,87]. Atrial septal defect is related to exon 3 mutations, while atrioventricular canal defect and mitral valve anomalies are related to different exon mutations [86,87].

Williams syndrome

Williams syndrome is a congenital disorder characterized by typical facial appearance, CHD, renal anomalies, growth delay, and mental retardation with a specific psychocognitive profile. The syndrome arises from a hemizygous deletion in chromosome band 7q11.23, including the gene for elastin (*ELN*) and approximately 20 surrounding genes [88]. The cardiovascular effect of the *ELN* deletion is a generalized elastin arteriopathy. The most commonly detected cardiovascular abnormality is supravalvular aortic stenosis, with a prevalence of 75% in most reported series. Histologically, there are hypertrophy and focal necrosis of the intima, and disorganization of the media of the aortic wall.

Supravalvular aortic stenosis may be isolated or, more frequently, associated with peripheral pulmonary arterial stenosis. This figure represents a rather typical phenotype, which is almost exclusive to patients with Williams syndrome. Other phenotypes include peripheral pulmonary stenosis (particularly in infants) (50%), aortic insufficiency (20%) and mitral valve prolapse (15%), and hypertension (50%).

Ellis–van Creveld syndrome

Ellis–van Creveld syndrome is an autosomal recessive disorder characterized by osteochondrodysplasia with narrow thoracic cage and short-limb dwarfism, distinct CHD, postaxial polydactyly of hands (Fig. 7.11A) and feet, and ectodermal anomalies. Cardiac involvement occurs in 60% of the patients. Partial atrioventricular canal defect with common atrium and persistent left superior vena cava is the prevalent CHD in this syndrome. Linkage analyses have mapped Ellis–van Creveld syndrome to locus 4p16.1, and a mutation in *EVC*, a gene located inside this 'critical region', has been detected [89].

Holt–Oram syndrome

The Holt–Oram syndrome is a developmental disorder characterized by malformations of the radial ray of the forelimb and CHD (Fig. 7.11B). The syndrome is transmitted as an autosomal dominant trait that is highly penetrant, although the clinical manifestations vary in differently affected subjects. Cardiac abnormalities include atrial septal defect, muscular ventricular septal defect, atrioventricular canal defect and conduction defects (Table 7.3).

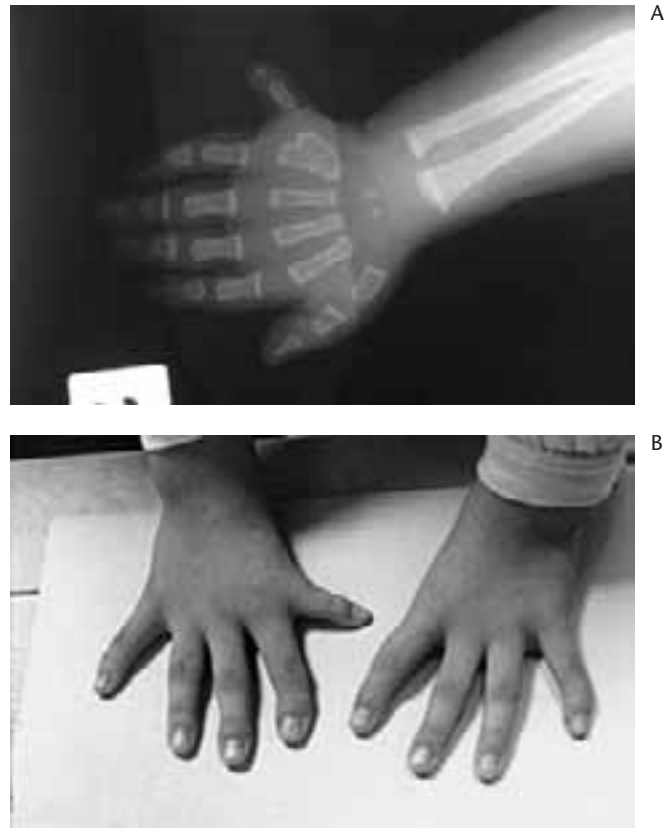

Figure 7.11 Hand X-ray examination of a patient with Ellis–van Creveld syndrome (A), showing postaxial polydactyly, and hands of a patient with Holt–Oram syndrome (B), showing radial aplasia and hypoplasia.

Mutations in *TBX5*, a member of the Brachyury(T) gene family, have been reported in Holt–Oram syndrome [90,91]. Animal models show that *TBX5* is particularly expressed at the atrial level and in the left-sided endocardium of the ventricular septum. This observation may explain the presence of atrial septal defect and muscular ventricular septal defect in this syndrome. Interestingly *TBX5* also causes a non-syndromic variant of CHD (see below).

Heterotaxia

Heterotaxia is a very complex condition including various forms of lateralization defects such as polysplenia syndrome, also known as left isomerism, and asplenia syndrome, also known as right isomerism. Left- or central-sided liver and intestinal heterotaxia can be detected as additional lateralization defects in these patients.

Table 7.4 Chromosomal loci and genes implicated in heterotaxia

Locus	Locus name	Gene symbol	Definition/gene function	OMIM ID
Xq26.2	HTX1	*ZIC3**	Zinc finger protein of cerebellum	306955 http://www.genetests.org/query?mim=306955

18p	—	Unknown	Deletion 18p syndrome	607500

*Also implicated in non-syndromic CHD.

The cardiac defect in heterotaxia consists of anomalies of the systemic and pulmonary veins, anomalies of the atrial septation and ventricular loop, and anomalies of the conotruncal region. Patients with the asplenia phenotype have right pulmonary isomerism and more severe cardiac defects, including total anomalous pulmonary venous drainage, transposition of the great arteries, complete atrioventricular canal defect and pulmonary atresia [92]. In contrast, patients with the polysplenia phenotype have left pulmonary isomerism and, usually, less severe cardiac defects, including interruption of the vena cava, partial atrioventricular canal defect and systemic outflow tract obstructions [92,93].

Several genes and chromosomal loci are implicated in heterotaxia (Table 7.4), and the available evidence suggests that an apparently single genetic defect can result in multiple phenotypes.

In addition, deletions of *LEFTYA* and *LEFTYB* in humans are found in association with left pulmonary isomerism, complete atrioventricular canal and left ventricular hypoplasia [94]. Among chromosomal anomalies, deletion 18p syndrome is specifically associated with laterality defects and heterotaxia, suggesting that this could be a 'critical region' [95].

Non-syndromic congenital heart defects

Familial recurrence risk

A 'multifactorial' model has been proposed for non-syndromic CHDs, suggesting an interplay between several genetic loci and between these loci with environmental factors [96]. Notwithstanding this general concept, co-segregation analysis suggests monogenic or oligogenic inheritance in some specific cases. The risk of recurrence for CHD in sibs of patients with non-syndromic CHD is estimated to be around 3% [96]. The risk of recurrence for non-syndromic patients with atrioventricular canal defect, tetralogy of Fallot and transposition of the great arteries is between 1 and 4%. However, if two first-degree relatives are affected, the recurrence risk for the next child is two- to three-fold greater. The evaluation of risk figures in large series of patients has practical implications in genetic counselling. The evaluation of the anatomic features of CHD segregating in single families can be an important aid in the analysis of pathogenetic links between CHDs.

Monogenic congenital defects

The relevance of the polygenic model is challenged by the increasing number of cardiac defects found to be related to a monogenic or oligogenic inheritance:

- *CFC1* is one of the four members of the EGF-CFC gene family. *CFC1* mutations have been identified in humans with CHDs in heterotaxia syndrome and in patients with non-syndromic CHD.
- *CRELD1* is a cell adhesion molecule which is developmentally expressed in the heart. Mutations in this gene have been identified in 6% of a population including patients with non-Down syndrome atrioventricular canal defect.
- *FOG2* is a co-regulator of the transcription factor GATA4, which is expressed during early heart development. Gene mutations in mice can cause tricuspid atresia and tetralogy of Fallot. *FOG2* mutations have been recently identified in humans with tetralogy of Fallot.
- *GATA4* is a transcription factor essential for heart formation. Missense *GATA4* mutations have been found in two families segregating cardiac septal defects.

- *NKX2-5* gene is a transcription factor important in early cardiac development that plays a central role in the determination of myocardial cell fate. Mutations in the *NKX2-5* gene have been identified in individuals with CHD, prevalently atrial septal defect and tetralogy of Fallot, with and without atrioventricular conduction block.
- Mutations in *Prosit240*, a gene with high expression within the heart (aorta) and brain during development, were recently identified in three patients with transposition of the great arteries.
- *TBX5*, a gene belonging to the family of transcription factors T-box, is important for cardiac septation. Mutations in the human *TBX5* gene cause CHD in the setting of Holt–Oram syndrome. Recently, somatic mutation of *TBX5* in the cardiac tissue cells of nine patients with CHD without Holt–Oram syndrome, including atrial septal defect and atrioventricular canal defect, have been detected.
- *ZIC3* is a zinc finger transcription factor causing X-linked heterotaxia. Nevertheless, mutations in *ZIC3* have also been identified in patients with non-syndromic CHDs, including transposition of the great arteries.

Incomplete penetrance is very common among inherited non-syndromic CHD (the identification of a mutation in the normal parent of an affected child), suggesting the presence of strong genetic and/or epigenetic (environmental) modifiers. Furthermore the available data suggest a high degree of genetic heterogeneity in non-syndromic CHD. Therefore the polygenic/oligogenic and the monogenic hypotheses are not mutually exclusive.

Genetic predisposition to coronary artery disease

Polygenic coronary artery disease—principles

The vast majority of common coronary artery disease (CAD) occurs on the background of polygenic susceptibility. Whilst single gene disorders, such as familial hypercholesterolaemia, can cause CAD they represent only a small minority of cases. It is the nature of polygenic disease that any single genetic variant will only provide a small or modest contribution to risk. Atherosclerosis is a time-dependent, multistep process involving the interaction of many different key biochemical pathways, lipoprotein metabolism, coagulation and inflammation. Gene variants in any of these metabolic pathways may lead to altered function of key proteins and upset the delicate balance of homeostasis. Intermediate phenotypes such as hypertension, diabetes and obesity, themselves all polygenic traits, will interact to modulate risk.

Environmental risks such as smoking, sedentary lifestyle and high-calorie diets are not simply additive with genetic risk. Gene–environment interactions are critically important, and are believed to determine which genes are recruited to determine disease susceptibility—so-called 'context dependency' (Fig. 7.12). Thus, a polymorphism may have a modest or a negligible effect on CAD risk in different individuals according to their particular environment. This is discussed further below in relation to specific variants. Gene–gene interactions are also likely to

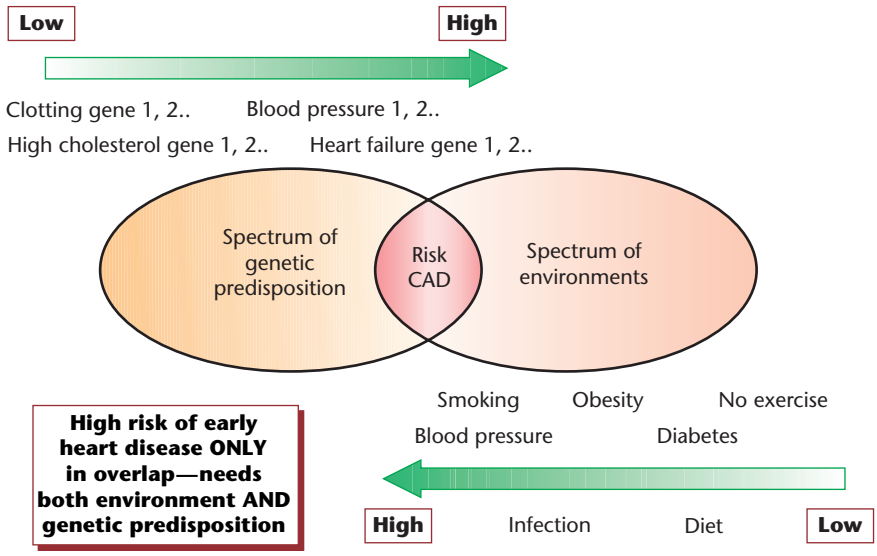

Figure 7.12 Model for gene–environment interaction (see text for details).

be important, although relatively little is understood about these in the context of CAD. Hundreds of genes may play a role in determining susceptibility to CAD [97]. Furthermore, different genes are likely to be important in different populations because of both genetic and environmental heterogeneity.

Two extreme models of allelic structure exist to explain the genetic basis of common polygenic diseases. It is likely that CAD will prove to be a mixture of the two but which model predominates will be highly significant. The common disease—common variant hypothesis predicts that common alleles at a restricted number of loci interact to cause disease [98]. The second model is that many rare alleles at a large number of loci cause disease, either single-handedly or in concert (multilocus–multiallele hypothesis) [98]. If the majority of CAD in the population is caused by common variants, considerably less time and effort will be required to determine the polygenic basis of CAD. Genetic testing would be more complicated and could be prohibitively expensive in the latter case. Thus far, most of the variations identified consist of a small number of common alleles (Table 7.5). Although too few loci have been identified for firm conclusions to be reached, this is consistent with theoretic calculations that predict that rare diseases result largely from recent mutations (thousands of years old or less), whereas common diseases result from old alleles present in ancestral populations [98].

The persistence of these alleles in the gene pool despite their propensity to cause fatal disease requires explanation. The first and most plausible reason is that most victims of CAD are past their reproductive years and therefore these genes are ignored by natural selection. The second is that alleles for cardiovascular disease are, for the most part, only lethal in the novel environment of modern humans, for example with cigarettes, abundant food and little exercise. The relative youth of modern society on an evolutionary time-scale means that these variants have not been subjected to natural selection. Finally, there may be some CAD-promoting alleles that are under positive selective pressure for unknown reasons.

Monogenic causes of CAD

Familial hypercholesterolaemia

Familial hypercholesterolaemia (FH) is an autosomal dominant inherited disorder. It has an estimated prevalence of 1 per 500, but is much more common in some populations which have recently increased in size (e.g. French-Canadians, Afrikaners and Lebanese) as a consequence of the 'founder' effect [99]. It is characterized by hypercholesterolaemia as a result of elevated plasma low-density lipoprotein (LDL) levels, cutaneous and tendon xanthomas, and premature CAD; there is usually a family history of one or more of these. Clinical coronary disease typically manifests in heterozygous FH men between the ages of 30 and 50 years, and in heterozygous FH women between 50 and 70 years [100]. FH is present in 5–10% of individuals who develop CAD under the

Table 7.5 Gene variants with published meta-analysis on coronary artery disease risk and > 2000 cases

Gene/polymorphism(s)	Risk genotype	No. of studies (No. of cases)	Size of effect (95% CI)
Cholesteryl ester transfer protein (*CETP*) TaqIB	B2B2	7 (7681)	0.78 (0.66–0.93)
Apolipoprotein B (*APOB*)			
Signal peptide Ins/Del	DD	22 (6007)	1.19 (1.05–1.35)
Gln4154Lys (Q4154L)	LL	14 (1796)	1.73 (1.19–2.50)
Lipoprotein lipase (*LPL*) Ser/Ter (S447X)	X+	4 (2252)	0.80 (0.7–1.0)
Apolipoprotein E (*APOE*) ε2, ε3, ε4	E3	10 (2152)	0.98 (0.85–1.14)
	E4		1.26 (1.13–1.41)
Paraoxonase-1 Q192R	Per R192	44 (10 106)	1.12 (1.07–1.16)*
Factor V-Leiden R506Q	Q+	6 (2390)	1.26 (0.94–1.67)‡
Plasminogen activator inhibitor-1 (PAI1) 5G/4G	4G4G	7 (2813)	1.20 (1.04–1.39)
Prothrombin G20210A	A+	19 (4944)	1.21 (0.99–1.59)†
GPIIb-IIIa P1(A2)	A2+	34 (6173)	1.13 (1.02–1.26)
Methylenetetrahydrofolate reductase (*MTHFR*) C677T	TT	40 (11 162)	1.14 (1.01–1.28)
Endothelial nitric oxide synthase (*eNOS*) Glu298Asp (E298D)	DD	14 (6036)	1.31 (1.1–1.51)
Angiotensin-converting enzyme (*ACE*) I/D	DD	51 (15 680)	1.22 (1.11–1.35)
Angiotensinogen Met235Thr (*M235T*)	TT	21 (4001)	1.19 (1.10–1.30)

*Risk fell to 1.05 (0.98–1.13) in five largest studies; †Odds ratio was 1.71 (1.16–3.42) in the 1359 subjects < 45 years; ‡Odds ratio 1.29 (1.03–1.61) upon inclusion of subjects < 55 years.

age of 55 years. Early identification of these high-risk individuals and implementation of primary prevention strategies will not only lead to longer healthier lives for those with FH but also to a decrease in the burden of coronary disease on a population basis [101]. Cost–benefit modelling based on data in the UK has demonstrated the effectiveness of cascade testing based on lipid measures in the relatives of FH patients [100], and an active programme in Holland based on molecular diagnosis has been particularly successful in identifying FH relatives [102]. Individuals with two FH-causing mutations (homozygotes and compound heterozygotes) are rare (less than 1 per million of the population in most countries); they have very severe hypercholesterolaemia and develop clinically significant CAD in the first or second decade of life.

FH is caused by a mutation in the low-density lipoprotein receptor gene (*LDLR*). To date over 700 different mutations have been identified world-wide (see http://www.ucl.ac.uk/fh) although the spectrum within a single country is much smaller. Another gene for FH is the apolipoprotein B-100 gene (*APOB*), a ligand for the LDL-receptor in which mutations have been identified in approximately 3% of FH patients in the UK, North Europe and the USA. This disorder has been designated familial defective apolipoprotein B-100 (FDB) [103]. FDB is somewhat milder in its expression but hypercholesterolaemia occurs in childhood, and early CAD is frequent. Additionally, a third locus has been identified on chromosome 1, with mutations in the gene encoding a secreted proteinase PCSK9 [104]. Finally, a recessive form of hypercholesterolaemia has been reported, caused by defects in a chaperone protein [105].

Genetic testing demonstrates a mutation in the LDLR or APOB gene for many of these patients, but this type of test is usually only available in a research setting. The usefulness of identifying the precise molecular cause of FH in a patient is primarily for the unambiguous identification of relatives, because cholesterol measures alone do not allow a clear-cut diagnosis in 10–15% of subjects.

Familial combined hyperlipidaemia

Familial combined hyperlipidaemia (FCH) is the most common of the severe hyperlipidaemias, with a prevalence of perhaps 1 per 100. The genetic inheritance pattern is complex and is likely to be polygenic/multifactorial, but the identification of the gene(s) involved is clinically relevant in identifying at-risk relatives. Recently a major gene (*USF1*) determining this phenotype has been identified in families from Finland [106]. It is a member of the basic helix–loop–helix leucine zipper (bHLH-zip) family of transcription factors. USFs are ubiquitously expressed and control the expression of genes involved in glucose and lipid metabolism. In the liver *USF1* regulates the expression of fatty acid synthase, a key enzyme in lipogenesis, in response to glucose, and is also active in adipose tissue and the pancreas. Currently no specific mutation in the *USF1* gene has been identified in patients, but a common haplotype defined by several SNPs is associated with risk of developing FCHL [106]. Whether any of these SNPs are truly functional, or whether the haplotypes are markers of an as yet undetermined functional variant, is unclear.

Coagulation disorders

Mutations in the genes for clotting factor V (factor V Leiden) and for prothrombin have been identified, each with a carrier frequency of 2–3%, but these mutations primarily increase the risk of venous thrombosis and have little effect on arterial thrombosis and risk of CAD.

The 'polygenic approach' to coronary artery disease

Phenotypes

For many measurable traits (phenotypes) there is good evidence for a relatively strongly genetic contribution to the determination of levels, which is usually estimated by 'heritability' (Fig. 7.13). For apoproteins and lipid traits, heritability varies between 40 and 60% [107], meaning that genetic factors are determining around half of the variability. For CRP and for fibrinogen, heritability is rather lower [108], reflecting the fact that they are acute-phase proteins and levels are greatly influenced by factors such as infection, malignancy or autoimmune disease. The consequence of this is that DNA-based tests do not add significantly to diagnostic utility or patient management, over-and-above the use of measures of established CAD risk factors.

Plasma lipoprotein a [Lp(a)] is a factor where levels are remarkably stable within an individual over time, and heritability is reported to be > 90% [109]. Variability at the locus coding for the apo(a) gene itself accounts for almost all of the variance of plasma Lp(a) in normal populations. The relevance of this is that a recent meta-analysis reported that levels of Lp(a) in the top tertile was associated with a 1.6-fold greater risk of CAD [110], an effect which is of similar magnitude as smoking, and

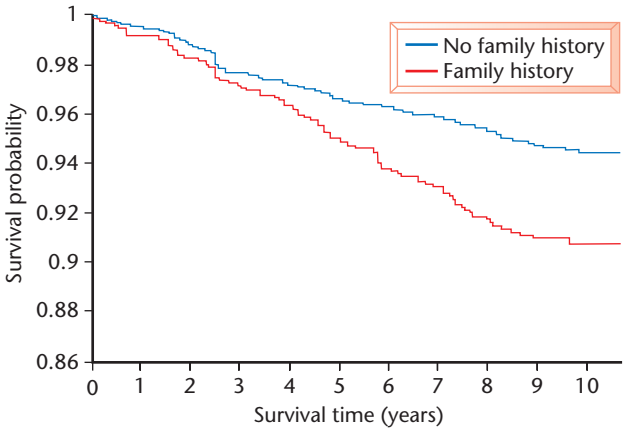

Figure 7.13 Kaplan–Meier plot for coronary artery disease (CAD) events in NPHSII, split by those with and without a family history of CAD. The NPHSII study enrolled healthy European middle-aged men. Of these 2827 answered unequivocally either yes or no to the question 'Has any person in your family ever had a heart attack?'. CAD events were defined as fatal and non-fatal myocardial infarction, plus coronary artery surgery and evidence of silent myocardial infarction on the follow-up ECG. The frequency of coronary events in men with a family history was 9.0% in comparison to 5.3% for those without. A positive family history was associated with a hazard ratio for CAD of 1.73 (95% CI 1.30, 2.31), which was 1.86 (1.37, 2.52) after adjustment for baseline age, body mass index, smoking, alcohol, cholesterol, triglyceride, fibrinogen and Lp(a).

thus the *APO*(*A*) gene would appear to be a major genetic factor for CAD.

Candidate genes for polygenic CAD

A large number of 'candidate' genes have already been investigated and a comprehensive list is beyond the scope of this report. One of the best studied genes codes for a plasma apolipoprotein called ApoE. The common *APOE* allele is called ε3, and there are two variants, ε4 and ε2 (the allele frequencies in Europeans are roughly 0.15 and 0.07 respectively). The sequence changes in the gene affect plasma clearance of the protein and the cholesterol-rich lipoproteins carrying them. The consequence of this is that there is a strong and consistent impact on plasma lipid levels (ε2 lowering and ε4 raising), which translates into an ε4 higher impact on CAD risk such that this genotype may explain 5–8% of the attributable risk of CAD in the population [111].

As shown in Table 7.5, several variants, including those in ApoE, appear to be associated with statistically robust although with rather modest effects on risk. Although these data seem encouraging, based as they are on the combined results from many studies, they need to be interpreted with some caution. Several analyses have suggested the presence of a publication bias: small statistically significant studies have been published, while those where the result was not significant have not appeared in the literature. Therefore, the meta-analysis estimates in Table 7.5 may actually be inflated, with the true value being smaller if data were available from all studies.

Although the meta-analysis risk estimates for each gene variant are modest they may still have some clinical value if they can be combined in developing a genetic risk profile. Thus, to develop useful genetic tests will require the simultaneous study of many genes and to understand how their effects add up and interact. Such understanding is still several years away.

Exemplars of environmental modification of genotype effects

The angiotensin-converting enzyme (ACE) polymorphism has probably been the most extensively studied polymorphism so far. One important feature of this polymorphism is that it appears to be a response modulator to a wide range of inducing factors. For example, it has been reported to modify the hypertrophic response of the heart to physical training, the restenotic process after stent angioplasty, the evolution of cardiac function after myocardial infarction and the survival of patients with congestive heart failure. Interestingly, other candidate gene polymorphisms may also have the characteristic of being response modifiers to a number of stimuli. A fibrinogen promoter polymorphism may affect the plasma fibrinogen response to cigarette smoking, physical training, or acute-phase reactions [112–114].

Cholesterol ester transfer protein and alcohol dehydrogenase genotypes modify the relationship between alcohol consumption and plasma high-density lipoprotein cholesterol [115,116], an amino acid variant that causes enzyme instability in the methylenetetrahydrofolate reductase protein affects the relationship between folate intake and plasma homocysteine [117] and the α-adducin polymorphism between that of salt intake and blood pressure and risk of myocardial infarction [118]. These interactions also need to be more widely replicated in larger studies but if confirmed they offer potential prospects for CAD prevention through the identification of responders to deleterious factors or beneficial ones.

Gene–environment interaction and risk prediction

Since it is now well-accepted that atherosclerosis and cardiovascular disease develop as a result of the interplay between the environment adopted by an individual and their genetic predisposition, any genetic test to predict

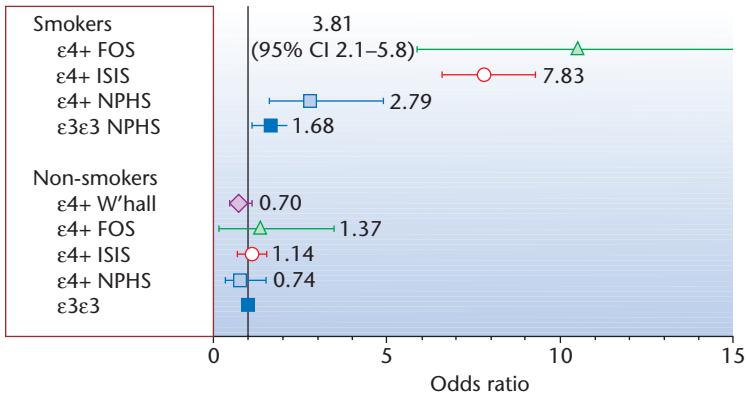

Figure 7.14 Risk of development of coronary artery disease and myocardial infarction according to *APOE* genotype and smoking habit. For each study the non-smokers with the genotype ε3–ε3 are set as the referent group. From references 119, 120 and 121.

cardiovascular disease must include such interactions in the algorithm. This interaction has also been termed the 'context dependency' to define the concept that, at the molecular level, the effect or by-product of the environmental insult modifies the molecular function of the product of the gene under observation. Genetic predisposition will also be confounded by gene–gene interactions, gender, ethnicity and pre-existing conditions such as obesity, diabetes and hypertension, as well as by factors such as medication, diet, alcohol consumption, exercise and stress. Taking into account such genotypic modifications of environmental factors for cardiovascular disease risk represents the second hurdle to successfully devising and implementing any genetic test.

Smoking is one of the major environmental risk factors influencing cardiovascular disease and there are several examples where the risk associated with smoking is modified by an individual's genotype. Several studies have reported that subjects carrying the *APOE-4* allele who were smokers had a particularly high cardiovascular disease risk compared to *APOE-4*-positive never-smokers, while risk was also low in *APOE-4*-positive ex-smokers, supporting the benefit of smoking cessation (Fig. 7.14). A re-analysis [119] of a recent large case–control study showed that compared with '*APOEε2,ε3* never-smokers', '*APOEε4* smokers' had significantly higher risk of CAD, with a greater than additive interaction on risk between genotype and smoking (relative excess risk of interaction of 1.62; 95%CI 0.4, 2.97). These data suggest that carrying the *APOEε4* allele does not significantly increase risk of cardiovascular disease unless the subject is a smoker. Clearly, any *APOE* genetic test result estimating risk in the absence of information about smoking will be misleading.

Personal perspective

In the last decade, we have learnt a lot about the genetic basis of cardiovascular diseases. Most of the knowledge gathered relates to the gene abnormalities causing monogenic diseases. This information, besides allowing the discovery of the causes of specific clinical entities, has allowed a deeper understanding of cardiovascular pathophysiology. It has now clearly shown that even in 'acquired' conditions (such as coronary artery disease) genetic factors are primary players for disease development and progression. The genotype information already has a clinical role for risk stratification and management for some specific disease, while in other instances there are still knowledge gaps to fill before this step may be achieved. Another limiting factor is the lack of availability of large-scale genotyping to assess the prevalence of inherited disorders in the population and to allow epidemiological studies to better quantify the role of SNPs in polygenic diseases.

In the future, genetics will become an important tool for defining patient-specific risk profiles in many diseases and it is likely to provide novel therapeutic strategies for patients that will eventually encompass gene therapy.

8 Clinical Pharmacology of Cardiovascular Drugs

Aroon Hingorani, Patrick Vallance and Raymond MacAllister

Summary

Rational use of drugs to treat cardiovascular disease requires an appreciation of the key principles of clinical pharmacology and specific knowledge about individual therapies. Amongst the medical disciplines, cardiovascular medicine has been in the vanguard of the development of an expanding evidence base upon which to base therapeutic decisions. Critical appraisal of this evidence has extended the remit of traditional clinical pharmacology. Therefore it is essential for those training in cardiology and cardiovascular medicine to be able to assess evidence from cardiovascular trials so that appropriate weighting can be given to trial data to inform therapeutic choice. This chapter summarizes the principles of clinical pharmacology that are relevant to cardiovascular drug therapy and provides a summary of the drugs commonly used to treat cardiovascular disease. In addition, it introduces fundamental concepts in the critical appraisal of trial data.

Introduction

Atherosclerosis and thrombosis underlie the occurrence of most clinical cardiovascular events such as stroke, angina, acute coronary syndromes, heart failure and dysrhythmias. The most widely used cardiovascular therapies modify these processes in the primary prevention, acute treatment and secondary prevention of these disorders (Fig. 8.1). Given the high incidence and prevalence of cardiovascular disease, its management represents a substantial cost for health-care providers. Moreover, in individual patients, several clinical syndromes may coexist, and be complicated by the presence of diabetes or renal impairment. As a result, many patients receive multiple drugs, often for many years. For these reasons, the therapeutic choice must be based on evidence detailing the efficacy, safety and cost of available therapies in a comparative manner. Special considerations may also apply in the elderly, in young women with childbearing potential or during pregnancy. The principles of rational prescribing, taking into account these factors, form the basis of clinical pharmacology, so that the right drug is administered to the right patient at the right time and for the right cost.

In the first section, basic concepts in clinical pharmacology are reviewed. The second section will cover relevant aspects of drug development and licensing while the third section discusses clinical trials, their design and interpretation. In each section, key principles will be highlighted using examples from cardiovascular therapeutics, with an emphasis on how to use the information contained in each section to make a rational choice of therapy. Specific details of commonly prescribed cardiovascular drug classes are covered in Tables 8.1 to 8.5. It is hoped that the principles outlined in this chapter will allow the rational prescriber to make informed and unbiased assessments of the efficacy and safety of new treatments as they arise.

Basic concepts in clinical pharmacology

Pharmacodynamics and dose–response relationships

The majority of cardiovascular drugs act on specific sites

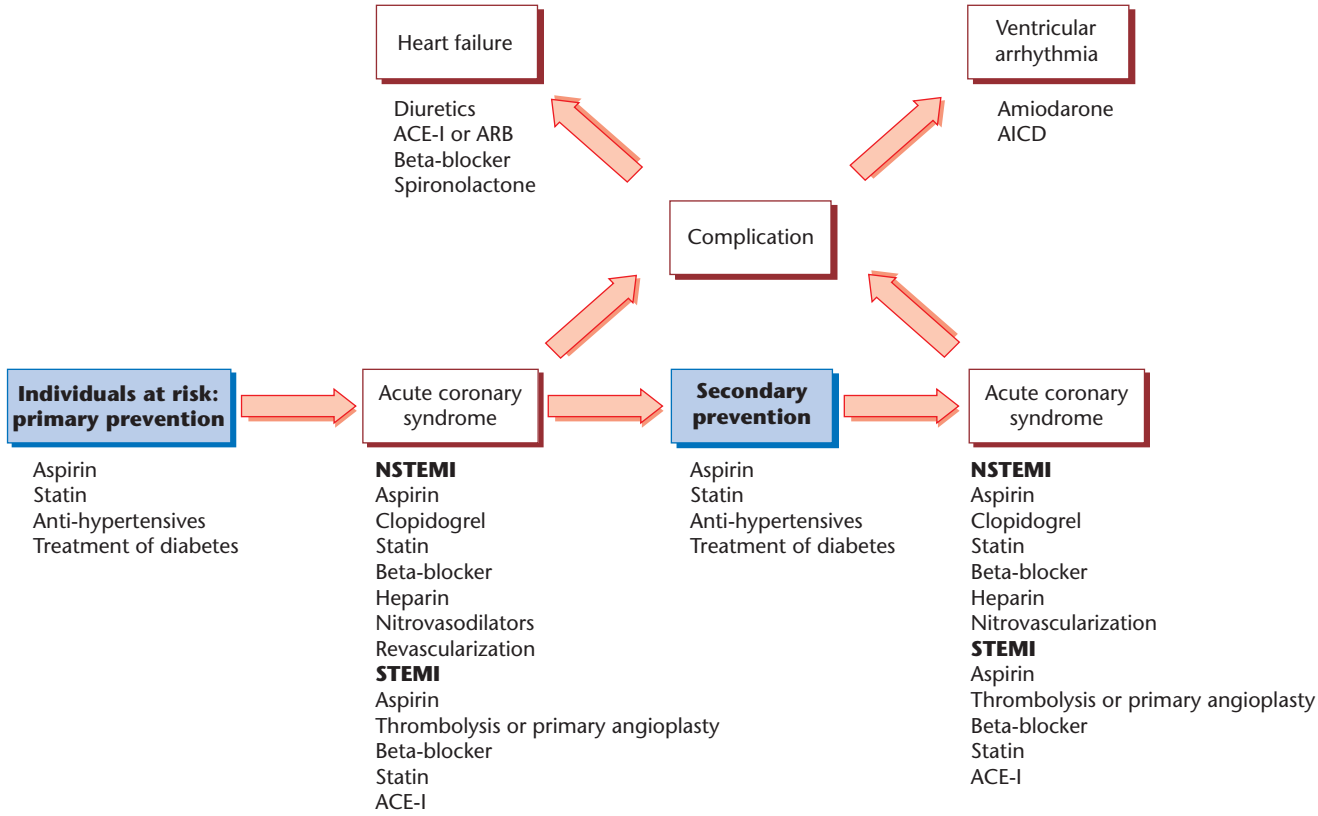

Figure 8.1 Place of drug therapies in treatment as defined by the natural history of atherothrombotic cardiovascular disease. ACE-1, angiotensin-converting enzyme inhibitor; AICD, automatic implantable cardioverter defibrillator.

on proteins, either inhibiting or stimulating enzymes, blocking or activating receptors or ion channels (an exception is cholestyramine, a cholesterol-binding agent that acts independently of a biological receptor). For certain older drugs the mechanism of action remains unclear (e.g. the vasodilator effects of hydralazine or the thiazide diuretics).

Classical molecular pharmacology deals with the interaction of a drug with its receptor. At a molecular level, the relationship between drug concentration (on a log scale) and response is typically sigmoidal. A similar relationship can be seen in patients between the dose administered and the physiological response (Fig. 8.2), although the dose–response relationship *in vivo* will also depend on pharmacokinetic parameters that determine the concentration of a drug that actually reaches its receptor. When a drug is introduced into clinical practice, the licensed dose-range ought to fall on the steep part of the dose–response curve, to facilitate dose-titration (Fig. 8.2). Occasionally, therapies are introduced into practice at a dose close to that producing a maximal response; e.g. captopril was first introduced at starting doses that were close to the plateau of the dose–response curve, resulting in significant first-dose hypotension [1]. Similarly,

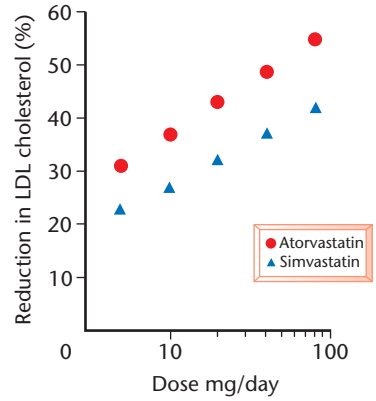

Figure 8.2 Dose–response curve of the effect of statins on low-density lipoprotein (LDL) cholesterol.

thiazide diuretics were used at supramaximal hypotensive doses for many years before it was realized that five-fold to 10-fold lower doses produced similar reductions in blood pressure but minimized adverse effects [2].

Potency and efficacy of drugs

Potency refers to the concentration (or dose) of a drug

Table 8.1 Antiplatelet agents

Drugs	Indications	Mechanism	Pharmacokinetics	Adverse effects
Aspirin	**Acute intervention** Acute coronary syndrome: STEMI, non-STEMI, unstable angina Transient ischaemic attack Acute stroke **Primary and secondary prevention of vascular events (see text)** **Coronary stent implantation** Combination with clopidogrel for 4–6 weeks. Aspirin alone continued thereafter	Irreversible inhibition of platelet COX-1 (acetylation of serine 529) resulting in inhibition of platelet thromboxane synthesis	Oral Once daily Antiplatelet dose: 75–160 mg Initial dose for acute presentations is 300 mg Plasma half-life 20 minutes Biological effect is longer lasting as a consequence of irreversible platelet COX inhibition Platelet function normalizes ~7 days after withdrawal (new platelet turnover to recover platelet COX activity)	Major gastrointestinal bleeding rate 0.1–0.2% per annum at a dose of 75 mg daily. No additional benefits of enteric coated preparations Higher doses associated with increased bleeding risks with no evidence for greater efficacy Allergic reactions Exacerbation of asthma
Clopidogrel	**Acute intervention** In addition to aspirin in patients with NSTEMI ACS at high risk **Secondary prevention of vascular events** Patients intolerant of aspirin	Inhibition of ADP-induced platelet activation by modification of the platelet $P2Y_{12}$ ADP receptor	Oral Once daily Maintenance dose is 75 mg daily Initial dose for in-patients with NSTEMI ACS 300 mg	Rash (0.26%) Major gastrointestinal bleeding (0.5%)*
Platelet IIB/IIIa receptor blockers (abciximab, eptifibatide, tirofiban)	Patients with ACS undergoing intervention Elective high-risk PCI	Inhibit the bridging of activated platelets by blocking the interaction of the IIb/IIIa receptor with fibrinogen	Intravenous weight adjusted bolus followed by an infusion	Bleeding Thrombocytopenia

*Data from the CAPRIE trial in which the equivalent rate for aspirin over a median follow-up of 18 months was 0.7%.
ACS, acute coronary syndrome; ADP, adenosine diphosphate; COX, cyclo-oxygenase; NSTEMI, non-ST segment elevation myocardial infarction; PCI, percutaneous coronary intervention; STEMI, ST segment elevation myocardial infarction.

required to achieve a given effect. Figure 8.3(A) shows the relative potencies of two drugs that inhibit the same hypothetical enzyme. Drug A is more potent than drug B, and its dose–response curve is placed leftward on the *x*-axis. Note however that both drugs achieve the same maximal effect, so they are of equivalent maximal efficacies. It should also be evident that coadministration of A and B at their maximal doses will not produce a

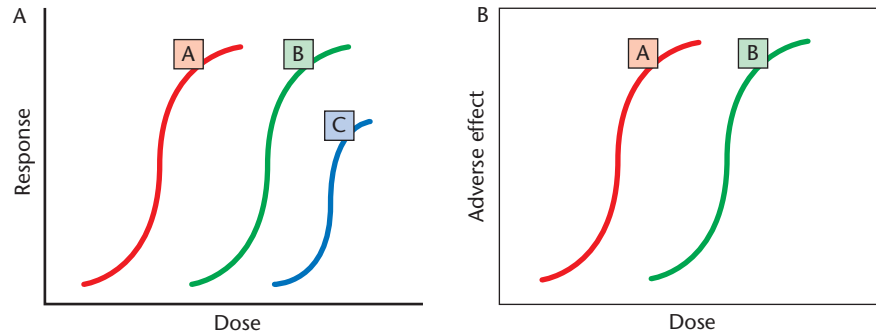

Figure 8.3 (A) Dose–response curves for drugs A, B and C that target the same receptor. A is more potent than B, but there are no differences in efficacy. C is less potent and less efficacious than A or B. (B) The increased potency of A over B is associated with increased chance of dose-dependent adverse effects; the smaller dose of A required to produce an effect will not necessarily be associated with fewer adverse effects.

Table 8.2 Anticoagulants and fibrinolytics

Drugs	Indications	Mechanism	Pharmacokinetics	Adverse effects
Heparins Unfractionated heparins (UFH) Low-molecular-weight heparins (LMWH)	**Venous thromboembolism** Prophylaxis and treatment of DVT and PE **Coronary artery disease** NSTEMI as adjunct to aspirin (and clopidogrel) STEMI only following treatment with tPA **Valvular heart disease** Anticoagulation in patients with mechanical valves undergoing surgery or other interventions	LMWH and UFH Indirect inhibition of thrombin (factor IIa) and factor Xa mediated through binding and activation of antithrombin III. UFH Additional direct binding and inhibition of IIa Ratio of Xa : IIa inhibition UFH 1:1 LMWH: 2:1 to 4:1	UFH Variable absorption by subcutaneous route. Therefore intravenous infusion adjusted to activated partial thromboplastin time LMWH Single or twice daily weight-adjusted subcutaneous injection Monitoring (by factor Xa assay) usually unnecessary	Bleeding Heparin-induced thrombocytopenia Osteoporosis LMWH preferred to UFH for most indications Exception is bridging anticoagulation around the time of surgery where intravenous UFH is preferred because of the rapid offset of action when the infusion is stopped
Warfarin	Treatment of venous thromboembolic disease Anticoagulation for a few weeks before and after cardioversion for atrial fibrillation Prevention of thromboembolic events in patients with mechanical valves	Inhibits vitamin K-dependent carboxylation and activation of factors II, VII, IX and X	Oral loading dose at initiation, with subsequent adjustment of single daily oral dose according to the international normalized ratio (INR)* Hepatic metabolism via CYP2C9 Potential for drug interactions is high	Narrow therapeutic window Bleeding risk substantially increased when INR > 4 Thromboembolic risk increased with INR < 1.7
Streptokinase (SK) **Alteplase (tPA)**	AMI in patients presenting with regional ST segment elevation or new LBBB	Promote conversion of plasminogen to plasmin either directly (tPA) or by forming a complex with plasminogen (SK)	SK: intravenous infusion over 30–60 minutes SK has up to 24-hour duration of action tPA: Intravenous bolus followed by a weight-adjusted infused dose over 90 minutes tPA infusion is followed by adjunctive intravenous heparin for 24–48 hours Action of tPA largely complete after 1 hour	Net excess of approximately two haemorrhagic strokes per 1000 patients treated more than offset by approximately 50 deaths prevented per 1000 patients treated if given within 12 hours of STEMI Major non-cerebral bleeding (4–13%) Hypotension (SK) Allergic reactions (SK) Absolute contraindications: haemorrhagic stroke at any time, ischaemic stroke within 6 months, major trauma or surgery within 3 weeks

*Target INR for treatment of venous thromboembolic disease and prevention of stroke in atrial fibrillation is 2.5. Target INR in patients with mechanical heart valves is 3.75.
DVT, deep vein thrombosis; LBBB, left bundle branch block; INR, international normalized ratio; NSTEMI, non-ST segment elevation myocardial infarction; PE, pulmonary embolism; STEMI, ST segment elevation myocardial infarction.

larger effect than administration of either A or B alone. For this reason, drugs with different mechanisms of action and different molecular targets tend to be used in combination therapy for cardiovascular disease, rather than combining drugs with the same mechanism. Drug C is both less potent and less efficacious than A or B.

Modest differences in potency between drugs with the same mechanism of action are rarely of clinical

Table 8.3 Vasodilators

Selected examples	Indications	Mechanism	Adverse effects
α-Adrenoceptor blockers Prazosin Doxazosin Phenoxybenzamine	Hypertension Heart failure Phaeochromocytoma (phenoxybenzamine)	Block α-adrenoreceptors on vascular smooth muscle Arteriolar and venodilatation	Headache, flushing, syncope, oedema
Angiotensin-converting enzyme inhibitors (ACEI) Captopril Enalapril Lisinopril	Hypertension Heart failure Secondary prevention following myocardial infarction	Inhibition of ACE leading to reduced formation of angiotensin II and impaired breakdown of bradykinin Blood pressure reduction Arterial and venous dilatation Promotion of sodium and water excretion	Hypotension Cough (5–10%) Hyperkalaemia Renal impairment (especially in presence of bilateral renal artery stenosis) Angioedema
Angiotensin receptor blockers (ARBs) Losartan Candesartan Irbesartan	As for ACEI inhibitors	Block angiotensin II receptor	As for ACE inhibitors (minus cough)
Calcium-channel blockers Dihydropyridine Nifedipine Amlodipine Benzothiazepine Diltiazem Phenylalkylamine Verapamil	Angina Hypertension Rate control of atrial flutter/fibrillation (diltiazem and verapamil only) Nifedipine used safely as antihypertensive in pregnancy	Blockade of L-type calcium channels Dihydropyridines exhibit *in vitro* selectivity for vascular L-type calcium channels Arteriolar vasodilatation, reflex tachycardia Non-dihydropyridines exhibit equivalent binding to vascular and cardiac channels Reduction in heart rate, atrioventricular nodal conduction Negative inosotropic effects and reduction in blood pressure	Flushing Headache Ankle oedema Reflex tachycardia (dihydropyridines) Bradycardia (other types)
Nitrovasodilators Glyceryl trinitrate Isosorbide mononitrate Isosorbide dinitrate Sodium nitroprusside	Angina Unstable angina Heart failure Pain relief post myocardial infarction Treatment of hypertensive encephalopathy (sodium nitroprusside)	Metabolized in vascular smooth muscle to release nitric oxide Relax arteries and veins, effect on veins predominates Reduce myocardial oxygen requirements (by reducing preload and afterload)	Headache, flushing, syncope Co-administration with phosphodiesterase V inhibitors (e.g. sildenafil) can lead to profound hypotension Cyanide toxicity (sodium nitroprusside)

importance. First, most prescribers are unaware of the molecular weights of the drugs they are prescribing, without which it is not possible accurately to compare the potency of drugs; e.g. weight for weight, amlodipine is approximately six times more potent than nifedipine (60 mg of nifedipine is needed to produce the same blood pressure lowering effect as 10 mg of amlodipine), but mole for mole, amlodipine is closer to 10 times more potent because of its greater molecular weight. Second, these differences in potency seldom make a material difference to prescriber or patient, as long as the drugs have the same vasodilator effect (efficacy). Similarly, atorvastatin is approximately four-fold more potent than simvastatin (weight for weight), but for most of the dose-range, the effect of atorvastatin can be reproduced by administering a larger dose of simvastatin [3]. Occasionally the issue of potency may become a problem if other effects of the drug molecule produce unwanted effects and the concentration–response relationship for these differ substantially from the concentration–response relationship for the wanted (therapeutic) effect. However, given that 90% of all adverse reactions to drugs are a consequence of their primary mechanism of action [4], the dose–response curve and the dose–adverse effect curve will usually both be shifted leftward for a more potent drug (Fig. 8.3B). There is evidence that this is the case for statins; the most potent statin, cerivastatin, had its marketing licence withdrawn because of toxicity [5], and

Table 8.4 HMG-CoA reductase inhibitors (statins)

Drugs	Indications	Mechanism	Pharmacokinetics	Interactions	Adverse effects
Simvastatin Pravastatin Lovastatin Fluvastatin Atorvastatin Rosuvastatin	Primary and secondary prevention of coronary heart disease	Inhibition of hepatocyte HMG-CoA reductase leading to increased expression of the hepatocyte LDL-receptor Statins lower total and LDL-cholesterol, as well as triglycerides, and raise HDL-cholesterol	Single daily dose usually administered in the evening Hepatic metabolism most via cytochrome P450 enzymes **Metabolized by CYP3A4** Atorvastatin Simvastatin Lovastatin **Metabolized by CYP2C9** Fluvastatin Rosuvastatin **Metabolized independently of CYP enzymes** Pravastatin	Toxicity may be enhanced by drugs which inhibit metabolism **Drugs which inhibit CYP3A4** Erythromycin Clarithromycin Fluoxetin Verapamil Cyclosporin **Drugs which inhibit CYP2C9** Amiodarone Fluoxetine Metronidazole	Muscle pain ± elevation of creatine kinase to 3–10 times normal (1–5%) Myositis with creatine kinase to > 10 times normal (0.1%) Rhabdomyolysis (0.15 deaths per 10 million prescriptions) Elevation of liver enzymes to less than three times normal (0.5–2.5%) Hepatitis

CK, creatinine kinase; CYP, cytochrome P450; HDL, high density lipoprotein; LDL, low density lipoprotein.

Table 8.5 Miscellaneous

Drugs	Indications	Mechanism	Adverse effects
Beta-blockers *lipid-soluble* Bisoprolol Carvedilol Metoprolol Propranolol *water-soluble* Atenolol Labetalol Sotalol	Hypertension Angina Secondary prevention post myocardial infarction Heart failure Adjunct to digoxin for rate control in atrial fibrillation Prophylaxis of paroxysmal atrial fibrillation (sotalol)	Blockade of β-adrenoreceptors with varying β1 and β2 selectivity Bradycardia Inhibition of renin production contributes to hypotensive response Improve left ventricular function in heart failure	Bronchospasm Bradycardia Cold peripheries Fatigue Impotence Sleep disturbance
Loop diuretics Furosemide	Heart failure	Natriuresis by blocking sodium/chloride co-transporter in ascending limb of the loop of Henle Intravascular volume depletion Intravenous administration may cause pulmonary vasodilatation in acute heart failure	Largely the same as thiazides
Potassium-sparing diuretics Amiloride Spironolactone	Weak antihypertensive effect Heart failure (particularly spironolactone) Diuretic-induced hypokalaemia	Amiloride blocks the sodium/potassium exchanger in the distal tubule; spironolactone blocks the aldosterone site of this transporter	Hyperkalaemia Gynaecomastia (spironolactone)
Thiazide diuretics Bendroflumethiazide	Hypertension Heart failure	Open potassium channels, natriuresis by blocking sodium/chloride co-transporter in proximal tubule Transient fall in cardiac output which returns to normal after 2–3 months; hypotensive effect by vasodilatation	At low doses metabolic adverse effects are minimal and of uncertain significance, postural hypotension, hypokalaemia Polyuria, gout, postural hypotension, hypokalaemia

dose-for-dose, the toxicity of atorvastatin is greater than for simvastatin [6].

Specificity of cardiovascular drug action

Specificity is determined by action on a single receptor or enzyme or subtypes of receptors. Depending on the location of the therapeutic target, it is also possible to achieve a degree of specificity of drug action within the cardiovascular system. For example, voltage-gated calcium channels make only a small contribution to the control of venous smooth muscle tone, and for this reason calcium-channel blockers are selective arterial dilators [7]. Vasoconstricting drugs with a degree of tissue specificity are used in the treatment of migraine; serotonin type 1 (5HT1) agonists targeting a receptor population on the cerebral vasculature. Similarly, vasopressin agonists produce a degree of preferential splanchnic vasoconstriction, and are used in the treatment of portal hypertension [8]. The selective dilator effects of sildenafil (type V phosphodiesterase inhibitor) on the penile and pulmonary vasculature may reflect the expression of this enzyme in these vascular beds [9]. However, many of these receptors are expressed in other cells and tissues, and when activated at these sites result in many of the recognized adverse effects of 5HT1 and vasopressin agonists (coronary spasm), and phosphodiesterase V (PDE V) inhibitors (systemic hypotension). Moreover, loss of specificity is commonly seen as the dose increases; Fig. 8.4 shows the dose–response curves for a drug acting at two receptors but with different potencies; at low doses receptor A is specifically activated but at higher doses where the dose–response curves converge, there is equivalent activation of receptors A and B. Selectivity of drugs is relative, not absolute.

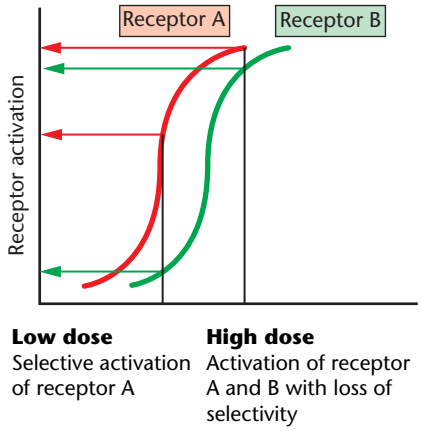

Figure 8.4 The effect of a drug with differing selectivity for two receptor subtypes. At low doses, and therefore low tissue concentrations, there is selective activation of receptor A; with increasing doses selectivity is lost as receptor B is activated. Gradual recruitment of additional molecular targets (receptors on enzymes) with increasing dose accounts for many common dose-dependent adverse effects.

Variation in the response to drug therapy

There appears to be substantial interindividual variation in the dose–response to drug therapy, which can arise because of differences in drug metabolism or elimination (pharmacokinetic), or because of physiological differences in the receptor or systems targeted (pharmcodynamic). At one extreme, a patient may be resistant to the effects of a drug, a good example being low-renin hypertension. This is common in patients of African-Caribbean origin and is responsible for the poor hypotensive response to therapies that block the renin–angiotensin system [beta-blockers, angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers] when used as monotherapy [10]. Similarly, the response to unfractionated heparin is variable because of unpredictable absorption and protein binding following subcutaneous administration, and for this reason therapy needs to be monitored by measuring the activated partial thromboplastin time. Low-molecular-weight heparin has much more reliable absorption and has a predictable interaction with proteins, so it can be administered at a dose based solely on body weight rather than on clotting times. In the majority of cases, variation in response to a drug does not have such potentially catastrophic effects as can occur with poorly controlled anticoagulation, but nevertheless a threshold dose in one patient might be near maximal in another. In the case of warfarin, variation in response may reflect differential antagonism by endogenous vitamin K between individuals. Alternatively, variation may be a consequence of differences in drug metabolism, arising from common genetic variations; cytochrome CYP2C9 activity is a determinant of warfarin metabolism, and variation in the gene for this enzyme might account for a proportion of the variability in warfarin effect and susceptibility to bleeding [11].

The mean dose–response of a drug is in effect the aggregate of individual curves from individual patients. To avoid over-treatment, it is commonplace to perform some degree of dose-titration when initiating therapy; e.g. in elderly patients who are often more sensitive to the effects of vasodilators, it is usually appropriate to start treatment with low doses. Lastly, variation in response may be factitious; a patient might not be adhering to medication, an occurrence that is not uncommon when (as is the case in cardiovascular disease) preventative therapies are being used in combination without any symptomatic benefit apparent to patients.

Genetics as a cause of variation in response to drug therapy

The influence of genetic variation on drug response has been recognized for many years. For example, even before the precise genetic alteration was identified it was clear that the population could be divided into 'fast' or 'slow' acetylators and that this had implications for the metabolism and effects of certain drugs. In cardiovascular medicine, certain adverse responses to hydralazine were more common amongst slow acetylators. Similarly, it is known that a single gene defect can dramatically affect responses to drugs; individuals with deficient glucose-6-phosphatase dehydrogenase are prone to developing haemolytic anaemia in response to oxidizing drugs such as antimalarials [12].

However, in the past few years, interest in pharmacogenetics has increased as the human genetic sequence and its common variations have been identified and the concept of 'personalized medicines' has taken hold. Single gene defects tend to be rare and to be disease-causing mutations. Currently, there are a few examples of important changes that alter responses to cardiovascular drugs. Patients with the monogenic hypertensive syndromes exhibit exquisite hypotensive responsiveness to certain drugs. One example is Liddle's syndrome in which, as a result of activating mutations in the beta- or alpha-subunits of the epithelial sodium channel, amiloride, which targets this channel, reduces blood pressure and normalizes the electrolyte disturbance. Another example is that of glucocorticoid-remediable hyperaldosteronism, which is characterized by abnormal corticotropin-dependent aldosterone production because of the presence of a chimaeric gene; in these patients dexamethasone produces a reduction in blood pressure by suppressing corticotropin synthesis [13].

A more complex issue, and one that may impact significantly on prescribing, relates to common genetic variation. Most (probably all) genes show polymorphic variation with alterations in the base sequence between individuals. These base changes often occur in non-coding regions, when they may cause minor alterations in protein expression or gene transcription. When they occur in a coding region, they may alter the amino acid sequence of the mature protein in a conservative manner that causes subtle alterations in protein function.

These variants are insufficient to cause disease on their own but may alter disease susceptibility to a small degree. They may also alter the metabolizing enzymes, or protein targets of a drug to modify its effect. To date no polymorphic variant has been identified that exerts such a profound effect that it should alter prescribing patterns for cardiovascular drugs. A number of common variants in candidate genes that might influence statin responsiveness have been evaluated. Of these, small effects of polymorphisms in the 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase and apolipoprotein E genes have been reported but, given the inconsistency of genetic association studies of common variants, these findings require validation in very large studies. Even if confirmed, these effects are likely to be small in size, and unlikely to alter prescribing decisions for this group of drugs.

In the field of metabolism, genetic variation in the cytochrome P450 (CYP) enzymes is discussed later in this chapter. In neurology it has been shown that resistance to anti-epileptic medication is predicted in part by common genetic variation in *p*-glycoprotein, and it is conceivable that such changes would also influence responses to antiarrhythmics. As technologies for rapid genotyping emerge, and it becomes possible to identify patterns of relevant polymorphic variations, it may be possible to identify individuals who are at more or less risk of specific unwanted effects, who are resistant to the desired therapeutic effect, or for whom dose adjustment would be beneficial. However, it remains to be determined how important genetic variation will be in determining overall drug effects, compared to the effects of diet, comorbidity, polypharmacy, or even psychosocial factors affecting adherence to therapy [12].

Comparing drugs with identical mechanisms of action

Whilst major advances in therapy follow from the discovery of new molecular targets and new molecules to modulate their function, it is much more common for a new chemical entity to mimic the action of an established drug. In the UK a prescriber can choose from 11 ACE inhibitors, 11 calcium-channel blockers, 7 angiotensin-receptor blockers and 5 statins. The main reason for the proliferation of such similar drugs is the commercial imperative; pharmaceutical companies need market share, especially of large markets (as is the case in cardiovascular disease). An important premise behind the development of a new agent from within the same class is that efficacy is the result of a 'class effect'. The corollary of this is that it is not rational to expect drugs that target the same mechanism to have substantially different pharmacodynamic effects in clinical practice, other than clinically insignificant differences in potency.

Pleiotropic effects of drugs

Additional mechanisms of action may be proposed for a particular class of cardiovascular drugs, often after

licensing. Such multiplicity of effects/action is known as pleiotropic, and pleiotropic effects have been ascribed to ACE inhibitors (not only vasodilators, but antiproliferative, antioxidant, etc.) and statins (not only reduction in low-density lipoprotein cholesterol, but also anti-inflammatory effects). Often these adventitious effects are based solely on the results of *in vitro* or animal studies, so it is often difficult to be certain of their clinical relevance. The cardiovascular effects of ACE inhibitors are just as easily explained by their vasodilator and blood pressure lowering effects [14], and the protective effects of statins by their reduction in blood cholesterol [15].

Pharmacokinetics

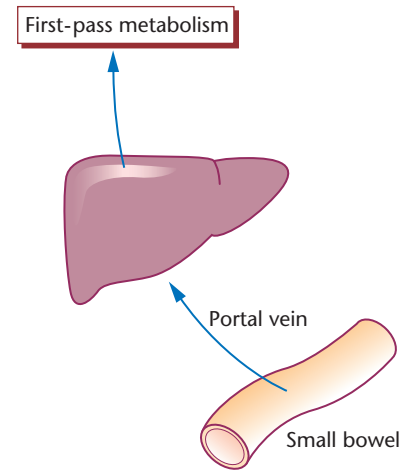
Absorption of drugs

The majority of cardiovascular drugs are administered orally, which is best suited for patients being treated for the conditions outlined in Fig. 8.1. The intravenous route is restricted to drugs that are not readily absorbed through the gastrointestinal tract (heparin) or digested (e.g. proteins such as thrombolytics), when faster onset of action is required (antiarrhythmic drugs in haemodynamically unstable patients), when it is important to rapidly titrate drug dose against effect (intravenous heparin in patients at high risk of bleeding) and when the gut is unavailable (patient is unconscious) or non-functioning (diuretics in severe heart failure to avoid the uncertainties of absorption consequent upon gut oedema). The sublingual route is used for drugs that undergo extensive rapid hepatic metabolism; sublingual absorption of glyceryltrinitrate avoids first-pass metabolism by the liver (which is why it is ineffective when swallowed whole). Dosing interval, although determined by metabolism and excretion (see below), is also influenced by speed of absorption. Dosing interval is important because patients are more likely to adhere to drug therapy if it is administered once or twice daily (these regimens have similar compliance) than drugs with more frequent dosing intervals [16].

Drug distribution

Most cardiovascular drugs distribute freely throughout the cardiovascular system, and will have generalized effects in all vascular beds that contain target receptors and enzymes. Widespread distribution of drugs outside the cardiovascular system is to be expected though there will be differences between water- and lipid-soluble drugs. Amiodarone is sequestered in body fat on account of its very high lipid solubility, which results in the requirement for high loading doses when initiating therapy, and the long time required to elute the drug from the body on cessation of treatment. Penetration of the blood–brain barrier by lipid-soluble beta-blockers may be responsible for some adverse effects (notably sleep disturbance and nightmares), and switching to a water-soluble drug alleviates this problem.

Higher concentrations of aspirin in the portal circulation than the systemic circulation (because of first-pass metabolism; Fig. 8.5) may be important in the effect of aspirin on platelet function. In the time taken to absorb aspirin from the gut, most of the circulating platelets will have traversed the portal circulation and been exposed to concentrations of aspirin sufficient to maximally block cyclo-oxygenase, whilst systemic concentrations, being much lower, may have a lesser effect on endothelial cyclo-oxygenase [17].



Drug	Oral (mg)	i.v. (mg)
Metoprolol	50–100	5–15
Atenolol	50–100	2.5–10

Figure 8.5 Metabolism by the liver reduces the oral bioavailability of beta-blockers and aspirin; consequently, when the first-pass metabolism is bypassed by intravenous administration of beta-blockers, the dose required is substantially smaller than for the oral dose.

Drug metabolism and excretion

Many cardiovascular drugs require metabolism to become active (pro-drugs), with examples including nitrate vasodilators (an as yet unknown process yields the active moiety, nitric oxide), many ACE inhibitors (e.g. enalapril is metabolized to enalaprilat). Otherwise, most drug metabolism increases the water solubility to allow excretion

in the urine. Phase 1 reactions result in oxidation or reduction of drug molecules, inactivating the drug. Subsequent phase 2 reactions (conjugation with glucuronide, sulphate, or acetate) lead to water solubility and excretion in the urine. Phase 1 reactions are of most interest, as many of these are carried out by CYP enzymes. This family of enzymes is responsible for the metabolism of a large number of antiarrhythmic drugs, and genetic variation affecting 10% of Europeans can lead to poor metabolism of these drugs, accumulation and toxicity [18]. One CYP is inhibited by a constituent of grapefruit juice, and is associated with an increased effect of calcium-channel blockers [19]. CYP enzymes exhibit common and potentially important polymorphisms. Several variants influence the metabolism of cardiovascular drugs. Among the most important of these is variation in the CYP2C9 enzyme that metabolizes warfarin. Two common variants (*CYP2C9*2* and *CYP2C9*3*) exist with about 20% of individuals carrying at least one copy. Carriage of these variants is associated with reduced warfarin requirement, and a 1.5-fold to two-fold increase in risk of haemorrhage. However, whether information on *CYP2C9* genotyping will impact on bleeding rates in clinical practice will require prospective evaluation in clinical trials [11].

First-pass metabolism is a determinant of the antiplatelet effect of aspirin, and explains the poor bioavailability of oral nitrates. Beta-blockers also undergo extensive first-pass metabolism, which explains why the intravenous dose of atenolol is 10-fold lower than the oral dose (Fig. 8.5).

Drug interactions

Patients with cardiovascular disease will generally be taking several medications and such polypharmacy predisposes to drug interactions. Whole books have been written about drug interactions, so it is impractical to remember them all (especially when many interactions are clinically unimportant). A few basic concepts will suffice, together with an awareness of the possibility that an interaction may occur in any patient.

Pharmacodynamic interactions

These are amongst the commonest; between vasodilator drugs they result in augmented hypotensive responses, a desirable interaction when treating hypertension, undesirable when patients are taking organic nitrates and phosphodiesterase V inhibitors (e.g. sildenafil). Conversely drugs that cause sodium and water retention (non-steroidal anti-inflammatories, corticosteroids) commonly block the effects of diuretics. Antiplatelet drugs and anticoagulants mutually increase the risk of bleeding in patients taking both types of medication. All classes of antiarrhythmic drugs become more pro-arrhythmic when used together either as causes of ventricular arrhythmias (e.g. amiodarone and flecainide) or bradycardia (concomitant use of beta-blockers, calcium-channel blockers and digoxin). Co-administration of ACE inhibitors, angiotensin-receptor blockers and potassium sparing diuretics predisposes to hyperkalaemia.

Pharmacokinetic interactions

These occur when the metabolism or excretion of drugs is altered. Important examples include the induction (anti-epileptic drugs) or inhibition (certain antibiotics, amiodarone) of CYP enzymes to reduce or enhance respectively the anticoagulant effect of warfarin. Other clinically important interactions include the reduction of renal excretion of digoxin by amiodarone and calcium-channel blockers, or the range of drugs (fibrates, antifungal and antiviral drugs) that impair the metabolism of statins and increase the risk of myositis and rhabdomyolysis. Prescribers should be aware of such common and important problems.

Drugs with a narrow therapeutic index merit special consideration; for such a drug the effective therapeutic plasma concentration is close to the concentration range where adverse effects occur. Therefore even minor changes in plasma concentration can have adverse effects. Good examples are warfarin, digoxin, anti-epileptic drugs and cyclosporin; drug interactions should be anticipated when these therapies are co-prescribed with cardiovascular drugs.

Adverse effects of cardiovascular drugs

The high incidence and prevalence of cardiovascular disease means that the drugs to treat it are widely prescribed often for many years, with the attendant risk of adverse effects. In 2004, it was estimated that between 6000 and 10 000 deaths in general hospitals in the UK per annum might be attributed to an adverse reaction to drugs, and seven of the top 10 culprits were those used for the prevention or treatment of cardiovascular disease [20]. The major reason for the high absolute number of adverse events attributable to the use of cardiovascular medications is not that they are inherently unsafe, but rather that they include some of the most commonly prescribed medications in current use. In the last 10 years xamoterol (beta-agonist for heart failure), and mibefradil (calcium-channel blocker) have had their licences revoked as a result of drug toxicity. Most recently, the cardiovascular toxicity of rofecoxib led to its temporary withdrawal, and raised concerns about all other cyclo-oxygenase-2 inhibitors [21].

The commonest types of adverse event are of type 1 (i.e. they are a consequence of the mechanism of action of the drug, e.g. asthma precipitated by beta-blockers). Type 2 adverse events are unrelated to the mechanism of action of the drug and are unpredictable, often serious but rare. By the time any new agent comes to market, it has usually only been administered to 5000 or so individuals. If serious adverse events occur at a rate of 1 in 5000 or less, it is unlikely that they will come to light until the drug comes to market. Type 2 adverse events are unpredictable in nature, and can only be detected by post-marketing surveillance, which is an integral component of assessment of the performance of any new drug. In the UK, the 'Yellow Card Scheme' has been used since 1964 to detect adverse effects of drugs in clinical use. National Drug Regulatory Authorities in other European countries have their own arrangements for reporting adverse drug reactions, with global co-ordination of reports through the WHO Collaborating Centre for International Drug Monitoring (www.who-umc.org). Within the cardiovascular field, examples of utility of spontaneous reporting include the withdrawal of encainide and flosequinan (excess mortality), mibefradil (multiple drug interactions) and terfenadine (fatal cardiac arrhythmias).

Note that serious but unpredictable adverse effects can occur in just one member of a particular class of drug that targets the same mechanism of action. A good example is practolol, a beta-blocker withdrawn because it increased the risk of retroperitoneal fibrosis, a complication that was not evident with other beta-blockers. More recently, cerivastatin was withdrawn because it had an unacceptably high risk of rhabdomyolysis compared to other statins. The limited safety information that is usually available when a drug is licensed remains a persuasive reason for avoiding prescribing of newer members of a class of drug, until there becomes a compelling reason to take this risk.

Rosuvastatin is the latest statin, with as yet no data on efficacy with respect to hard clinical outcomes, yet uptake into clinical practice has been rapid [22]; since its launch in Holland in 2003, rosuvastatin has acquired 5% of the market share and, in 35% of cases where a statin was newly initiated or changed, rosuvastatin was the statin prescribed. This, despite a concern about a greater risk of adverse events with this agent in comparison to other statins [23].

Prescribing for special groups

Elderly patients make up the largest group of patients in whom special considerations apply. They have a particularly high burden of concurrent cardiovascular and non-cardiovascular disease and are usually taking many different medications. Age-related decline in renal function and a reduction in the rate of drug metabolism can lead to drug accumulation in the elderly. These pharmacokinetic changes with old age underpin the widely held view that drugs should be used at low doses when initiating therapy [24]. However, the pharmacodynamic response to cardiovascular drugs may be diminished in the elderly; e.g. the cardiac effects of calcium-channel blockers and beta-blockers are reduced with age. Therefore it is possible that the resultant drug effect may be similar to that seen in younger subjects. There is a greater incidence of adverse effects of drugs in the elderly, but whether this is caused by polypharmacy, comorbidity or a specific effect of aging is unclear in many cases. Aging seems to increase the risk of non-steroidal anti-inflammatory-induced bleeding and renal impairment, and bleeding on warfarin or following thrombolysis [24].

Prescribing in young women of childbearing potential poses problems related to the real risk of unplanned pregnancy whilst on a teratogenic drug. Organogenesis takes place during the first 8 weeks of pregnancy, the time of maximum risk to a fetus from a drug when a woman might not realize that she is in fact pregnant. To guard against this it is good advice to restrict the choice of medication in such women to those that are not known to be teratogenic. These are typically older drugs, which have been safely used to treat hypertension in early pregnancy (e.g. thiazides and beta-blockers). If a drug has recently been licensed, its teratogenic potential will be unknown (because no studies will have been performed in pregnant women) so using it in young women poses an unknown risk that can be avoided by choosing a safe alternative. If a potentially teratogenic drug is being used such as ACE inhibitors and angiotensin-receptor blockers (responsible for ear and kidney malformation) or statins, then the prescriber must warn the patient of these risks and advise that effective contraception be used. If pregnancy is being planned, then all drugs need to be reviewed for their teratogenic potential and safe alternatives must be substituted. A particular problem is warfarin, which is teratogenic in early pregnancy (facial abnormalities) and poses a high risk of fetal bleeding and peripartum haemorrhage in the third trimester. In these cases, heparin would be the drug of choice because it does not cross the placenta.

In children, particular problems arise because many drugs are unlicensed for use in children, and extrapolation must be made from data in adults. The most obvious problem in this case is that the dose range will not have been established during drug development, and dose adjustments are necessary (either on a body weight or a body surface area basis).

In patients with liver disease, accumulation of calcium-channel blockers, and angiotensin-receptor blockers requires dose reduction because of impaired metabolism.

Special care is needed with anticoagulants, as many patients will have prolonged clotting times because of liver disease. In liver disease, there may be reduced activation of pro-drugs (e.g. many ACE inhibitors including enalapril and ramipril); lisinopril is not a pro-drug and may be preferred. Statins are a recognized cause of transaminitis and it is usual to monitor liver function tests more frequently when being used in patients with established liver disease.

In renal disease, dose modification is indicated if the drug is primarily excreted by the kidney, and dose-related adverse effects are common. As a general principle it is advisable to check for the requirement to reduce the dose of any cardiovascular drug used in renal failure. Specific examples include digoxin, which is not metabolized but is eliminated from the body by renal excretion, and requires dose reduction in the presence of even mild renal impairment (glomerular filtration rate 20–50 ml/min), titrated against plasma concentration. ACE inhibitors and angiotensin-receptor blockers also require dose reduction in mild and moderate renal impairment (glomerular filtration rate 10–20 ml/min), as a result of an increased risk of adverse effects including hyperkalaemia. Similar arguments apply to potassium-sparing diuretics. Many beta-blockers also need dose reduction in moderate renal impairment because of accumulation. It is worth remembering that patients with significant renal impairment are under-represented in many of the large cardiovascular trials. This raises uncertainty when extrapolating the results of these studies to patients with kidney disease, who have a very high risk of cardiovascular disease.

Cardiovascular drugs that impair renal function include diuretics (through volume depletion leading to pre-renal failure if administered at excessive dose), ACE inhibitors and angiotensin-receptor blockers, which can reduce filtration fraction through efferent arteriolar dilatation, a particular problem in the presence of bilateral renal artery stenosis but which can also complicate the use of these drugs in patients with chronic renal failure. Up-to-date guidance on the prescribing of cardiovascular drugs in patients with kidney or liver disease is obtained from http://www.bnf.org/bnf/.

Drug development

Role of the pharmaceutical industry

The cost of developing new medicines is large and, as a society, we have devolved this responsibility to the pharmaceutical industry. In return, the industry is obliged to recoup the costs of development, marketing and distribution, and return a profit for shareholders during the patentable life of the product. An expressed concern with this model is that the profit motive may distort the priorities of drug development at the expense of clinical need. For example, there has been a disproportionate focus on the development of drugs for the management of common, chronic diseases of the Western world, as these treatments are likely to have the largest markets and be the most profitable, though there are signs that this may be changing. Moreover, as the principal funder of most cardiovascular trials world-wide, and given its primary responsibilities to its shareholders, it would be naive in the extreme to gloss over the influence of the pharmaceutical industry in setting the agenda for clinical trial activity, design of studies and dissemination of results.

It was reported in the early 1990s that the pharmaceutical industry spent more on medical research than the National Institutes of Health in the United States [25]. An even larger budget is spent on the dissemination of information about drugs to doctors and, in the United States, to patients themselves. It has been estimated that the 13 largest research-based pharmaceutical companies allocated 13% of their revenues to research and development but nearly 35% to marketing and administration [26]. Although it is difficult to obtain exact figures, in the industry as a whole, there are twice as many employees in marketing as in research and development. Ten years ago these numbers were roughly equivalent. In addition, the sums spent on advertising are huge. In 2000, Merck spent $161 million on direct-to-consumer advertising of rofecoxib in the USA, more than was spent by Pepsi advertising cola ($125 million) or Budweiser advertising beer ($146 million) (http://www.nihcm.org/DTCbrief2001.pdf; accessed 2004). With the shift in focus toward marketing, sometimes at the expense of research and development, true innovation may now be suffering [27]. In 2002, the National Institute of Healthcare Management reported on the licensing of new drugs by the US Food and Drug Administration between 1988 and 2000, and concluded that 76% of all new drugs were no advance over existing products. Between 1995 and 2000 such products accounted for nearly 50% of the increase in the drug budget for the USA (http://www.nihcm.org/innovations.pdf; accessed 2004). These developments are often driven by the need to extend the patent life (evergreening) of an existing product through modest, though patentable, changes in formulation such as extended release, combinations or even chiral forms of existing drugs.

Role of the licensing agencies

The decline in innovation is also in part a consequence of licensing arrangements. In the vast majority of cases, the European Medicines Evaluation Agency and the US Food and Drug Administration grant a licence to new therapies that appear to be as safe as established therapies (though it is clear from earlier in this chapter that safety is only really established once a drug is licensed and used widely), and which demonstrate efficacy when compared to placebo. In addition, it is not generally a requirement that the new therapy has been shown to be an advance over existing treatment, merely that it has efficacy (above placebo) in modifying a surrogate end-point believed to be important in disease pathogenesis. Therefore, where there is an existing effective therapy, subsequent comparator trials are required to establish whether a new product has advantages over existing therapies. Indeed, the evidence required to obtain a licence may be less comprehensive for later than earlier members of a class, with the emphasis on establishing safety rather than obtaining information on drug efficacy. For example, of the ACE inhibitors licensed in the USA, four (captopril, enalapril, ramipril and trandalopril) have licences based on a reduction in cardiovascular events in clinical trials, whereas three others (fosinopril, lisinopril and quinapril) were granted licences on the basis of improvements in haemodynamic indices of potential relevance to heart failure [28].

Many industry-funded studies will therefore be designed to satisfy the minimum requirements for licensing, will be placebo-controlled, and a licence will be awarded if a new therapy has a treatment benefit compared to placebo. Until recently a pharmaceutical company could be confident of a licence for its own HMG-CoA reductase inhibitor without having to demonstrate that the new therapy was a substantial advance over existing statins.

When an established medication seeks approval for an additional licensed indication, again the comparison can be made with placebo. For example, the placebo-controlled HOPE and EUROPA trials examined the effect of fixed doses of ACE inhibitors (ramipril in HOPE; perindopril in EUROPA) on cardiovascular events in patients at high risk (older patients with risk factors or prior stroke or peripheral vascular disease in HOPE; stable coronary disease in EUROPA) [29,30]. In both studies there was a reduction in cardiovascular events in the subjects allocated to ACE inhibitors but, unsurprisingly, treatment was also associated with a reduction in blood pressure (3/2 mmHg in HOPE; 5/2 mmHg in EUROPA). Though both trials have been interpreted by some as providing evidence for a specific atheroprotective effect of ACE inhibition, it is clear that the observed reduction in cardiovascular events could be accounted for, in whole or in large part, by the reduction in blood pressure. If so, a similar reduction in events might have been observed whatever the antihypertensive agent used. It was the absence of a comparator agent in these trials that has engendered uncertainty surrounding this issue. Thus prescribers need to consider carefully the underlying reasons for apparent advantages of one drug over another.

When, for ethical or other reasons, comparison is made with an existing treatment, the choice of comparator drug, its dose, or preparation may favour the new therapy. In the COMET trial, the effect of the beta-blocker carvedilol on mortality in patients with heart failure was compared to that of metoprolol, a beta-blocker whose efficacy when added to standard heart-failure treatment had been demonstrated in previous trials [31]. Mortality was lower among the patients allocated to carvedilol, and this finding has been interpreted as providing evidence for a specific action of carvedilol (perhaps, the argument goes, the result of non-selective beta-blockade, or an additional antioxidant action). However, it has also been suggested that the choice of the comparator dose of metoprolol (lower than in the previous trials with this agent), and the preparation (short-acting compared to long-acting in the previous trials) might have led to the observed difference in outcomes [32,33].

Clinical trials and assessment of evidence

Evidence for drug efficacy: the pre-eminence of randomized controlled trials

Evidence for the efficacy of commonly used cardiovascular drug therapies comes from clinical trials. Indeed, it can be argued that the best clinical trials in cardiovascular disease have informed the development of the basic methodology, and provided an impetus for the conduct of such trials in other areas of medicine. Many have been of the highest quality and have led to important changes in practice that impact on the outcome of thousands of patients. The two critical components of the major clinical trials in cardiovascular disease have been their large size and the use of randomized allocation of patients to the experimental treatment or its comparator.

The value of very large trials is that, by reducing the play of chance, they allow the detection of small to moderate treatment effects with a high degree of reliability.

Table 8.6 Commonly used antiarrhythmic drugs

Drugs	Indications	Mechanism	Pharmacokinetics	Adverse effects
Digoxin	Rate control in atrial fibrillation	Increased vagal tone (central nervous system effect) and direct effect on atrioventricular node	Requires loading dose to achieve steady-state plasma concentrations for rapid control of atrial fibrillation	Pro-arrhythmic (especially if hypokalaemia) Nausea, vomiting and constipation when plasma concentrations in toxic range
Adenosine	Treatment of atrioventricular nodal re-entrant tachycardia Diagnostic evaluation of narrow- and broad-complex tachycardia	Activates adenosine receptors to cause atrioventricular nodal blockade	Half-life is short (seconds) so given intravenously by rapid bolus	Wheezing so contraindicated in asthma
Amiodarone	Supraventricular and ventricular tachyarrhythmias	Prolongs refractory period by blocking potassium rectifier channel	Very long half-life so loading dose required; sequestered in adipose tissue so large apparent volume of distribution	Lung and hepatic fibrosis, hyper/hypothyroidism, photosensitivity, corneal deposits
Flecainide	Supraventricular and ventricular tachyarrhythmias	Blocks sodium channels and increases depolarization threshold	Administered intravenously to rapidly cardiovert atrial fibrillation or orally for long-term prophylaxis	Pro-arrhythmic especially in patients with ischaemic heart disease with poor left ventricular function

Apparently small treatment effects can have considerable impact on the public health when the clinical event prevented is important, and the population at risk is large. In 1988, the ISIS-2 trial of about 17 000 patients with suspected myocardial infarction showed that aspirin (300 mg) reduced mortality at 30 days by about 3% in absolute terms [34]. In other words, for every 100 patients treated with aspirin rather than placebo, three fewer died. A treatment effect of this size might be considered small, and it is clear that a study of several thousand patients was required for it to be demonstrated unequivocally. Nevertheless it was important to ascertain this apparently small treatment effect reliably, because myocardial infarction is such a common clinical event with a high fatality rate. Thus, even though only three more patients survive for every 100 patients treated with aspirin, this translates to many thousands of lives saved annually, at very low cost. It transpires that many other therapies in cardiovascular disease produce treatment effects of similar size (Table 8.8), and their detection relies on very large studies (e.g. MRC/BHF Heart Protection Study, ALLHAT) [35,36].

The counterpoint is that many such therapies (with the exception perhaps of thiazides or beta-blockers for hypertension) are still under patent and cannot match aspirin for cost. The high cost of newer medications with small to moderate treatment benefits minimizes their public-health implications because funding such developments will usually mean that revenue will need to be redirected from other health-care interventions that may have greater treatment benefits. Thus, the 'cost–quality' trade-off is becoming increasingly important in many areas of cardiovascular therapeutics. In the UK, the National Health Service's National Institute for Health and Clinical Excellence (NICE) is charged with making 'recommendations on treatments and care using the best available evidence'. Its evaluations of new treatments commonly include some form of pharmacoeconomic analysis.

The second important element of a clinical trial is the allocation of patients at random to the experimental treatment or its comparator. This process ensures that the patients in the two arms of the trial are, on average, equally healthy (or unhealthy) at the outset and are also automatically matched for other factors (confounders), both measured and unmeasured, which might influence the eventual outcome. Any difference in outcome that is then observed between the two arms of the trial must be the result of the treatment allocation. This design contrasts with studies where the treatment allocation is non-randomized, where any association between treatment and outcome could be subject to bias, such as the preferential uptake of therapies by subjects who are healthier, or by confounding. For example, observational (non-randomized) studies suggested that the use of hormone

replacement therapy (HRT) protected women from cardiovascular disease [37]. In contrast, recent randomized trials have indicated no effect or even a slightly adverse effect of HRT on cardiovascular outcomes [38]. The reasons for this discordance between observational and randomized studies of HRT have been debated, but bias and confounding in the observational data seem the most likely explanations. Women who used HRT in the observational studies were on average less likely to smoke, more likely to come from higher socioeconomic groups, to have a healthy diet and to exercise. While it is possible to perform statistical adjustment to control for these factors, some potential confounders, such as socioeconomic position, are measured with a considerable degree of uncertainty, usually at a single time in the lifecourse, making adequate adjustment difficult and residual confounding a real concern [39]. In contrast, in the randomized controlled trials (RCTs), known confounders (and even unknown or unmeasured ones) were automatically distributed in similar proportions among women allocated to HRT or placebo, by virtue of the randomization process; (readers have only to scrutinize what is usually the first table in any publication reporting the results of a large RCT to be reassured of this). The results of such trials are therefore essentially unbiased and, provided they are of sufficient size, provide a much more reliable assessment of efficacy than observational studies. It is noteworthy that a similar discordance has been noted between the results of observational and randomized studies of antioxidant vitamins in the prevention of cardiovascular disease [40] and similar considerations are likely to apply.

It is for this reason that RCTs are regarded as the highest grade of evidence on the efficacy of a treatment. The Oxford Centre for Evidence-Based Medicine categorizes the hierarchy of medical evidence on a treatment and details can be found at http://www.cebm.net/. The grades of recommendation for use of a treatment that follow from this are also shown and these are now widely used in full or modified form to underpin clinical practice guidelines. See http://www.escardio.org/knowledge/guidelines/ for a full set of guidelines and scientific statements from the European Society of Cardiology.

Statistical aspects of clinical trials

> If your experiment needs statistics, you ought to have done a better experiment

When making this statement, the physicist Ernest Rutherford was probably referring to interventions with large treatment effects. To illustrate, the efficacy of a parachute in preventing fatality following a jump from an aircraft has never been tested in a randomized trial. Nonetheless, observational experience indicates that almost (but not quite) 100% of individuals who have jumped from an aircraft with a parachute survive, whereas almost (but not quite) 100% of individuals who leave a flying aircraft without a parachute die. An RCT of this intervention, as well as being unethical, is probably unnecessary because the effect of the parachute is manifestly large. As we have seen, cardiovascular interventions, such as aspirin, with major impact on the public health exert relatively small treatment effects at an individual level, making very large randomized intervention studies with the appropriate statistical analysis necessary to ascertain their effects reliably.

Rutherford was correct, however, in implying that a clinical trial should be regarded as an experiment designed to test a hypothesis. The usual approach in a trial testing the potentially superior efficacy of a new treatment over placebo (or the existing best therapy) is to develop the null hypothesis that the experimental treatment offers no therapeutic advantage. When complete, the trial provides an estimate of the effect of the treatment with the new agent but, because the participants in a trial form only a sample of the population of all potential participants, and the trial itself is only one of a potentially infinite number of trials that could have been conducted, the estimate of the treatment effect obtained (sometimes called the point estimate) is surrounded by a degree of uncertainty. The usual approach to quantifying the degree of uncertainty is to define a 95% confidence limit for the point estimate, i.e. a boundary within which the point estimates would lie in 95 of every 100 such trials. The size of this confidence limit will depend on the number of subjects studied, the rate of adverse events or outcome measures used to define efficacy (e.g. death, myocardial infarction or stroke), and the size of the treatment effect. If the trial assesses a dichotomous outcome, such as the occurrence or not of acute myocardial infarction, the point estimate of the risk ratio in the treatment arm is less than one (i.e. there is a lower rate of new infarction in the treatment arm), and the upper bound of the confidence limit fails to cross unity, the trial is considered positive and the new agent is considered to offer a therapeutic advantage.

From an alternative perspective of trial design, it is possible to use statistical theory to estimate the minimum number of subjects that would be required for a new trial to detect a treatment effect of a given size with narrow confidence limits. In making this estimate, two constraints are set. The first is the maximum acceptable rate of false-negative results, also referred to as the power or β value. The second is the maximum acceptable rate of false-positive results, also referred to as the level of significance or α value. In a trial that provides 90% power

Table 8.7 Calculation of treatment benefits in three hypothetical clinical trials (see text for explanation)

Profile of trial participants	No. of events in placebo group ($n = 1000$)	No. of events in treatment group ($n = 1000$)	Percentage absolute risk reduction (ARR) (95% CI)	Percentage relative risk reduction (RRR) (95% CI)	χ^2-statistic, *P*-value	Number-needed-to-treat (95% CI)
Trial A High risk	200	100	10 (6.9, 13.1)	50 (37.5, 60)	$\chi^2 = 38.5$, $P < 0.0001$	10 (8, 14)
Trial B Intermediate-risk	100	50	5 (2.7, 7.3)	50 (30.6, 64)	$\chi^2 = 17.3$ $P < 0.0001$	20 (14, 37)
Trial C Low- risk	20	10	1 (−0.1, 2.1)	50 (−6.3, 76.5)	$\chi^2 = 2.74$ $P = 0.098$	100 (48, 1000)

ARR, event rate in control group minus event rate in treatment group; RRR = ARR/control group event rate; NNT = 100/ARR.

to ascertain a given treatment effect, the trial designers accept that 100 – 90 (or 10%) of all such trials would fail to detect a treatment effect of given size when one really existed (a false-negative result). Conversely, in choosing a significance level of 5%, those running the trial accept that 5% of all such studies would provide evidence for a treatment effect of given size when none existed (a false-positive result). Given the intimate link between sample size and the confidence limit, it is unsurprising that the sample size in any clinical trial will vary according to the desirable power and level of significance, the size of the treatment effect deemed clinically important and worth detecting, and the rate of adverse events being examined as the outcome in the group of patients being studied. If a trial is interpreted as positive, it is important to assess if this result is likely to be real or whether it could have arisen by chance. For negative studies, it is important to consider whether the negative result might have arisen because the trial was too small to detect a clinically important treatment effect before ruling out the new therapy. Indeed, when clinical trials are considered in this way, four potential outcomes are possible. The first two are desirable: either the trial detects a real treatment effect or it fails to detect an effect when none exists. The second two are undesirable: they occur when either the trial detects a treatment effect where none exists (false-positive, type I error), or fails to detect a real treatment effect (false-negative, type II error). In a later section, we will discuss how systematic reviews of clinical trial data can help to minimize the possibility of type I and type II errors.

Measuring the size of treatment effects; absolute risk reduction and relative risk reduction

If the trial is considered positive, i.e. the therapy under evaluation offers a therapeutic advantage, the next important question is 'how large is the treatment benefit?' The degree of statistical significance (the '*P*-value') provides no information about the size of the treatment effect. A very small treatment benefit could be detected very precisely by a very large trial and, conversely, a substantial treatment effect might be detected with only marginal levels of significance in a small trial. What then is the best measure of the effect of treatment—an important issue in assessing if the new treatment warrants a change in clinical practice?

Consider a hypothetical clinical trial of an antiplatelet treatment being evaluated among 2000 men and women at high risk of coronary heart disease (CHD). Let us assume that 1000 subjects were allocated to the treatment and 1000 to placebo, and that follow-up was complete at 5 years when the trial closed. The results are presented as Trial A in Table 8.7. Among the group allocated placebo, 200/1000 suffered a CHD event, but among those allocated the treatment only 100/1000 suffered an event. This difference is statistically significant ($P < 0.0001$), but is this an important treatment benefit?

If we first consider the participants allocated to placebo, 200/1000 suffered a CHD event. In other words, the 5-year event rate, or 5-year absolute risk, of CHD was 20%, confirming the high risk of the participants. In the intervention arm of the trial, the treatment lowered the absolute risk to 10% over 5 years. Two measures of the treatment effect can now be derived, the absolute risk reduction (ARR) and the relative risk reduction (RRR). The formulae for deriving these values are simple and are shown in the footnote to Table 8.7. The ARR is simply the difference in risks (or event rates) between the two groups, while the RRR is this difference expressed as a proportion of the control group event rate. It is clear that in our hypothetical trial the ARR is 10% (20 – 10%), and the RRR is 50% [ARR/control group event rate (i.e. 10/20) × 100%]. For completeness, the 95% confidence limits around these values are also shown. By analogy with the previous aspirin example, a 10% ARR equates to 10 fewer events

for every 100 patients treated in this trial for 5 years. The RRR tells us that this treatment halves the event rate. Which of these, the ARR or RRR, provides the best single indication of the treatment benefit? To answer this, consider a second clinical trial of the same drug in a different group of 2000 individuals at lower risk of CHD (Table 8.7, Trial B). In this study, the event rate among the control group over 5 years is lower (10%), but this is still halved by the treatment to 5%. Thus the RRR remains the same (50%) but the ARR is smaller (5%). In a third trial (Trial C, Table 8.7), an even lower risk population has been studied. The corresponding event rates in the placebo and treatment groups are 2% and 1% respectively, the RRR is again unchanged at 50% but the ARR is smaller still at 1%. Some important points emerge from these examples.

First, because the same RRR can be observed in trials with very different ARRs, the RRR does not distinguish trivial from substantial treatment effects. This helps us answer which is the best single measure of the treatment effect—it is the ARR. Second, for a given proportionate reduction in risk, the ARR is highly dependent on the event rate among the participants being studied. Indeed the ARR can be described by the equation ARR = RRR × control group event rate. The higher the event rate, the higher the ARR. Two things follow from this. First, it may make sense to target treatment to those with the highest likely event rate (or risk). This is the strategy currently used to guide statin or antiplatelet therapy in the primary prevention of CHD events. Second, it illustrates why the control group event rate is such an important determinant of sample size and of the confidence limits surrounding the treatment effect. Scrutiny of the χ^2-statistics and *P*-values in Table 8.7 shows that as the control group event rate falls (from Trial A to Trial C), a study of 2000 participants becomes progressively underpowered to detect a 50% RRR.

Numbers needed to treat

Although it is a good indicator of treatment benefit, the ARR can be difficult to conceptualize. In Trial A the ARR of 10% indicates that 10 CHD events are prevented for every 100 subjects treated for 5 years. By extrapolation, one event would be prevented for every 10 subjects treated. The number of subjects that need to receive treatment to prevent one adverse event is defined as the number-needed-to-treat (NNT). In this trial, the NNT is therefore 10. The NNT is related to the ARR by the formula NNT = 100/ARR (when this is expressed as a percentage, as in this case) or 1/ARR if the ARR is expressed as a decimal.

Despite the value of the ARR and NNT, scrutiny of the abstract or promotional material of many clinical trials will reveal a recurring pattern. Treatment benefit will usually be expressed as the RRR (a larger number, with greater immediate impact than the ARR), whereas rates of adverse events will usually be expressed as absolute rather than relative risks, perhaps so as to minimize the impact of information on drug toxicity.

The ideal NNT would be one, i.e. every patient who receives treatment, benefits. NNTs of one are rare. Insulin treatment to prevent ketoacidosis in type I diabetes mellitus, and thyroxine treatment to prevent symptoms in patients with hypothyroidism, might be two examples. NNTs of less than 10 are seen with antimicrobial treatments for certain infections. In cardiovascular disease, however, NNTs to prevent major clinical end-points are substantially higher (Fig. 8.6). Though estimates of treatment benefits are rarely presented to patients in this way in clinical practice (though many argue they should be), studies have shown that when such information is provided patients are reluctant to take medications with NNTs greater than 30 [41].

A related concept is the number needed to harm (NNH), which is a measure of the risks of drug treatment. The Cardiac Arrhythmia Suppression (CAST) trial provides a good example; in patients post myocardial infarction, class I antiarrhythmic drugs increased the relative risk of death by 60%, and the absolute risk by 4.8% [42]. The NNH was therefore 100/4.8 = 21. For every 21 patients treated an additional one patient died who would not otherwise have done so. All drugs carry risks and benefits and a comparison of NNT and NNH is a useful quantitative way of expressing this. A good recent example is the use of cyclo-oxygenase-2 inhibitors to reduce the incidence of peptic ulceration and its complications (NNT = 100) at the cost of increased cardiovascular events (NNH = 100).

The relative risk reduction observed across a wide range of baseline event rates or risks is relatively constant for a number of preventive treatments in cardiovascular disease (Table 8.8). Thus the proportional reduction in risk is fairly similar for antihypertensive agents in the primary prevention of stroke or coronary events, for warfarin in the primary prevention of stroke in atrial fibrillation, and for statins or aspirin in the primary and secondary prevention of coronary events [43], whichever patient group is studied, though, as we have seen the absolute benefits depend on the risk profile of the group being treated.

Survival curve analysis; assessing the time-scale of treatment effects

Effective cardiovascular drugs reduce event rates but do not abolish all events. Whether on placebo or active

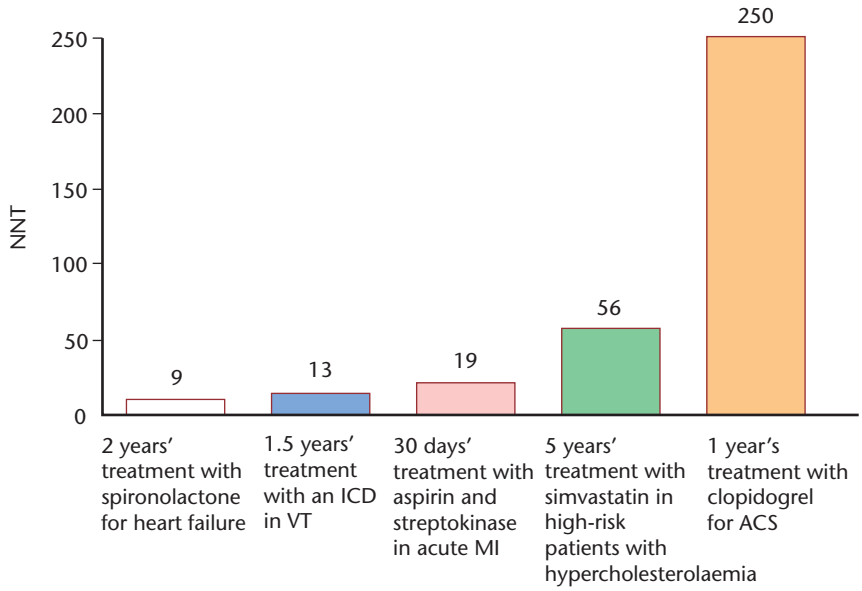


Figure 8.6 Number needed to treat (NNT) of common cardiovascular interventions for mortality reduction. The lower the NNT the more effective the therapy is in preventing death. Note that some interventions are effective in relatively short periods of time [thrombolysis and aspirin in acute myocardial infarction (MI)], some require lengthy treatment (statins) and some are relatively ineffective (clopidogrel; for mortality the absolute risk reduction is not significant (NS) and the confidence intervals for the NNT span infinity). VT, ventricular tachycardia; ACS, acute coronary syndrome.

Table 8.8 Relative risk reductions from some common cardiovascular interventions

Intervention	Outcome	Relative risk reduction	Reference
Thiazide diuretics for primary prevention in hypertension	Myocardial infarction Stroke	22% 31%	61
Statins in secondary prevention	Coronary heart disease mortality or non-fatal myocardial infarction	25%	62
Aspirin in long-term secondary prevention	Any serious vascular event	25%	63
ACE inhibitors in heart failure	Death	20%	48
Beta-blockers in heart failure	Death	37%	64

drug, survival curves inexorably slope downward (Fig. 8.7), and if the trial is long enough (or the death rate is high enough as it is in cancer trials) survival curves will converge when all participants have died. The vertical difference between the curves is a measure of the absolute risk reduction at any given time point (Fig. 8.7A). Note that the absolute risk reduction (and hence the NNT) will vary depending on the time point chosen. The absolute risk reduction reported at the end of the trial will therefore be specific to that particular time point. If the study has a low event rate (as is the case for many cardiovascular trials), the survival curves will be shallow and the trial will only provide data about the early part of the survival curve. Extrapolating beyond the available data will require one of three assumptions to be made. The survival curves will continue to diverge (treatment benefit will increase with time, e.g. the Heart Protection Study [35], the RALES study of spironolactone in heart failure [44]), will separate early and then run parallel (treatment benefit will remain constant; this pattern is expected when a treatment has been administered on a single occasion, e.g. streptokinase in the ISIS-2 cohort [45]), or will converge after the trial has finished (treatment benefit will wane with time; the PROWESS study of activated protein C in bacterial sepsis [46].

The second point to make about survival curves is that the horizontal separation is a measure of the event-free time gained (Fig. 8.7B). In ISIS-2, the combination of aspirin and streptokinase separated the curves (i.e. prolonged life) by approximately 1 year; a similar estimate describes the treatment effect of ACE inhibitors in heart failure [47]. As for estimates of risk reduction, event-free

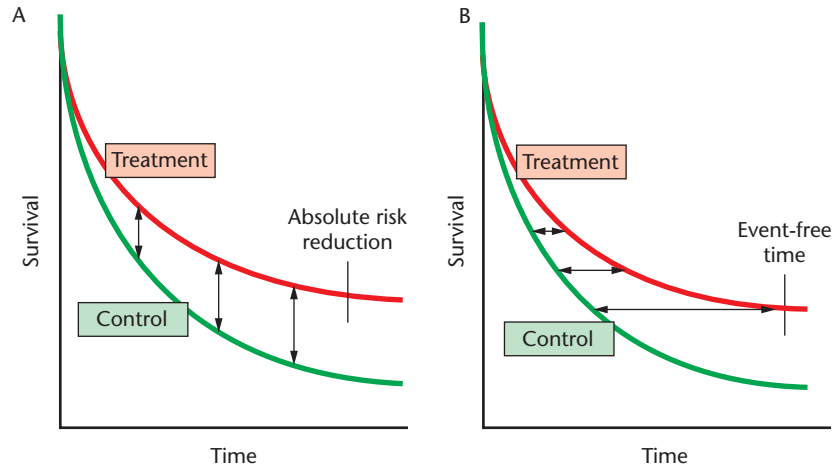

Figure 8.7 Survival curves showing the treatment effect of a cardiovascular drug compared to the placebo group. At the start of the trial survival is 100% in both groups but with time more patients in the placebo group reach the end-point (e.g. death) and the curves diverge. (A) shows that the absolute reduction in death (vertical difference between the two curves) depends on the time point chosen. Similarly, (B) shows how the event-free time (horizontal difference between the two curves) also depends on the time point evaluated.

time will depend on the time point chosen and cannot be extrapolated beyond the trial closure with certainty.

End-points in clinical trials

In the examples considered so far, most of the end-points have been the so-called 'real' end-points of death or major cardiovascular events. However, not all trials consider such end-points. A surrogate outcome measure is an end-point that is easy to measure that is believed to predict an outcome of direct clinical relevance. Examples would be blood pressure, serum cholesterol, carotid artery intima-media thickness, or the number of ectopic beats or periods of ST-segment depression on a 24-hour ECG recording. Because the relationship between the surrogate measure and the real end-point is often uncertain, trials that evaluate surrogate end-points alone must be interpreted with a high degree of caution. In the CAST trial [42], the effects of class 1 antiarrhythmic drugs (including flecainide and encainide) on cardiovascular mortality were examined in patients with myocardial infarction. Although previous studies had shown that these drugs reduced ventricular ectopy following MI, and other studies had shown an association between ventricular ectopy and adverse outcome, there were no firm data prior to the CAST trial on the effect of these agents on mortality. The CAST study showed that arrhythmia suppression notwithstanding, mortality rates over 10 months were higher at 8.3% among the patients receiving antiarrhythmic drugs compared to 3.5% among those receiving placebo, in direct contrast to the expectation from earlier trials that had used surrogate outcome measures.

An increasing trend in more recent clinical trials of cardiovascular drugs has been the use of so-called 'composite' end-points. A composite end-point is constructed by combining several real and/or surrogate end-points to produce a single composite outcome measure. An example might be the composite of death or myocardial infarction or re-hospitalization in an intervention trial of patients with acute coronary syndromes. In reaching any one of these end-points the patient is considered to have achieved the primary end-point, but patients and doctors might attach very different values to the individual components (e.g. death versus hospitalization). This combination of some hard and some soft end-points within the composite one contrasts sharply with the early large trials in cardiovascular disease where hard end-points were the usual primary outcome measures. The reason for this is that event rates in clinical trials of acute coronary syndromes, for example, have fallen because of the widespread application of proven therapies established as effective in prior trials. In the ISIS-2 trial in 1988, the control group 30-day mortality of patients presenting with suspected acute myocardial infarction was 12%. In the GUSTO V trial in 2001, which examined the effect of abciximab or placebo in addition to standard antiplatelet treatment and fibrinolysis in patients with acute myocardial infarction, the 30-day mortality in the control group was only 6% [48].

This reduction in event rate makes the detection of the incremental benefit of any new agent even more challenging. Trials would require truly huge sample sizes if mortality was to be the sole outcome measure. If the event rate is halved, then to detect the same reduction in relative risk, the sample size required may be up to four-fold greater. In an attempt to 'increase' the rate of adverse events, those running the trials have adopted a strategy of a moderate increase in sample size coupled with the use of composite end-points that combine relatively infrequent outcomes. A good example is the CURE study of clopidogrel in acute coronary syndromes, where the primary end-point was non-fatal myocardial infarction

(detected solely by a rise in troponin T in many cases), stroke or cardiovascular death [49]. Accordingly, the CURE study demonstrated that clopidogrel caused an 18% RRR in the rate of non-fatal myocardial infarction, stroke or death. It turns out that in the CURE study, clopidogrel reduced the incidence of non-fatal myocardial infarction alone (ARR 1.5; NNT 67 per year), with no significant effect on death or stroke. Combining these end-points contributes to the common misconception that clopidogrel reduces the risk of myocardial infarction, cardiovascular death *and* stroke rather than myocardial infarction, cardiovascular death *or* stroke [50]. Clopidogrel might reduce these other end-points but we do not have the data to show that it does.

Assessing the risk to benefit ratio of drug therapy

Anticoagulant and antithrombotic drugs are used widely for the treatment and prevention of cardiovascular disease. The therapeutic efficacy of these agents, derived from their effects on platelets or the clotting cascade, is inexorably linked to their potential to cause harm by increasing the risk of gastrointestinal and intracerebral haemorrhage. Net benefits depend on the balance between the reduction in the rate of cardiovascular events and the increase in the rate of bleeding complications. By considering both the NNT and the NNH, it becomes possible to begin to quantify the absolute benefits and risks of a particular intervention. The benefits of treatment are best quantified using data from RCTs (or better still, systematic reviews of several RCTs) as we will discuss. In attempting to balance benefits and risks in an individual patient, however, two additional pieces of data are helpful: the absolute rate of adverse events arising from the treatment (sometimes available from RCTs in which adverse events are recorded), and the absolute risk of the cardiovascular event for which the treatment is being considered (usually obtained from prospective observational studies).

Consider a 70-year-old man with atrial fibrillation, hypertension and type II diabetes. His annual risk of stroke based on prospective observational data incorporated into the CHADS 2 risk score is 5% [51]. We know from a systematic review [52] that warfarin, adjusted to achieve an international normalized ratio (INR) of 2.0–3.0, reduces the risk of stroke by 59%. In other words, we would expect warfarin to reduce our patient's absolute annual risk from 5% to 59/100 × 5% = 2.95%. This equates to an annual absolute risk reduction of 2.05%, equivalent to an annual NNT of about 50. From clinical trials of stroke prevention, the absolute increase in the rate of major extracranial bleeding with adjusted dose warfarin is about 0.3% per annum, and that of intracranial haemorrhage is about 0.2% per annum [53]. Thus the respective NNH values are 333 and 500. We can attempt to quantify the balance of benefits and harm in our patient by considering what would happen to 1000 similar patients treated with warfarin rather than placebo. At the end of 1 year of treatment we would expect that, among the 1000 patients, there would be 20 fewer thromboembolic strokes, but three extra major extracranial bleeds, and two additional intracranial haemorrhages. Absolute benefits of warfarin in the prevention of thromboembolic stroke are much lower in young patients with atrial fibrillation (because the risk of stroke is lower), while the rates of harm may not be substantially different from that in older subjects. For this reason, in many young patients with atrial fibrillation, aspirin may be the preferred intervention to prevent stroke. While its efficacy in stroke prevention is less than that of warfarin (RRR of 30%), the rates of major bleeding are correspondingly lower too. Another illustration of the sometimes fine balance between benefit and harm is the use of aspirin in the primary prevention of coronary disease. In contrast to the clear benefits of aspirin in the prevention of recurrent events in high-risk patients with established vascular disease, the use of aspirin in the primary prevention (in patients who are at much lower risk of events) is more uncertain; in patients at very low risk of vascular events the increased risk of bleeding with aspirin may outweigh any benefit. A threshold coronary heart disease risk of 15% over 10 years (1.5% per annum) has been suggested as an appropriate threshold above which aspirin might provide a net benefit in the primary prevention of coronary events. Quantifying the balance between benefit and harm is thrown into sharpest relief when considering the use of intravenous thrombolysis in acute ischaemic stroke [54].

Systematic review, meta-analysis: RCTs in context

Before the era of the mega-trial that followed the publication of the ISIS-2 and GISSI studies in the late 1980s, which unequivocally established the benefits of aspirin and thrombolysis following myocardial infarction, considerable uncertainty existed about the efficacy of these treatments. A number of RCTs had been conducted up to that point but the findings had been inconsistent. All the trials had been too small to reliably detect the RRR of about 30% produced by each of these treatments alone (40% in combination). Motivated in part by the recognition that RCTs in many fields of medicine were underpowered, the discipline of systematic reviewing has evolved with the aim of obtaining and collating all

available evidence on a treatment. Meta-analysis has been developed in parallel, as a formal statistical method for pooling data from individual RCTs to derive a single summary measure of treatment effect. In 1992, a retrospective meta-analysis of the small RCTs of thrombolysis that predated the ISIS-2 and GISSI studies showed that the summary estimate for the treatment effect obtained by pooling the results of 15 smaller randomized trials published up to 1997 was almost precisely that detected in the subsequent mega-trials [55]. This observation highlighted the potential for meta-analysis of individually underpowered studies to provide reliable risk estimates. Systematic review and meta-analysis are now established as important analytical tools that help inform treatment decisions in clinical practice. The Cochrane Database of Systematic Reviews provides an important function of continually updating systematic reviews of treatments as more evidence accrues. The simplest approach to meta-analysis is to utilize the summary data from several clinical trials. Estimates of the treatment effects are weighted according to the size of the trial (larger trials carrying greater weight than smaller ones) and are then pooled by standard procedures to derive a single summary estimate of the treatment effect.

Sometimes it is important to consider whether there are important differences in the size of the treatment effect in subjects with differing clinical characteristics, or in relation to some aspect of the intervention itself, e.g. the time at which it is administered after the diagnosis is made. To answer these sorts of questions some sort of subgroup analysis becomes necessary. Subgroup analysis within a single clinical trial is fraught with difficulty because any form of data splitting poses two problems. The first is that by reducing the size of the study groups statistical power is lost, rendering subgroup analysis insensitive to the detection of real differences. The converse is perhaps more of a concern, i.e. the detection of a difference in treatment effect in a certain subgroup that arises through the play of chance. A well-publicized example comes from the ISIS-2 trial [34]. A subgroup analysis of the data from the aspirin arm of the trial, conducted to illustrate the dangers of a subgroup analysis even in a very large RCT, indicated an apparent difference in the effect of aspirin on mortality after myocardial infarction by astrological birth sign, aspirin being apparently ineffective for those born under Libra or Gemini [34]. In this situation, meta-analysis may help since pooling data from many trials reduces the play of chance, but an alternative meta-analytical technique is then preferred. Rather than using the aggregate data, the raw data from individual participants in all trials are used. Though more time- and labour-intensive, and requiring many collaborators, this type of analysis allows more reliable inferences to be made about variation in treatment effects in different types of patient. Good examples of this approach are the individual participant data meta-analysis of trials of thrombolysis in acute myocardial infarction [56], ACE inhibitors in heart failure [47] and carotid endarterectomy in patients with transient ischaemic attacks or minor stroke and a carotid stenosis [57]. As a result of these analyses, it is accepted that the benefits of thrombolysis were greatest in patients presenting with ST-segment elevation on the ECG, or new left bundle branch block, that ACE inhibitors are effective in heart failure at all clinical grades of disease, and that endarterectomy should be confined to patients with a greater than 70% stenosis of the carotid artery.

Despite its potential benefits, meta-analysis also has the potential to mislead if the source data are not considered carefully. There are several examples where the results of meta-analyses of smaller trials have subsequently been refuted or modified by the publication of a very large RCT. The most notable example is that of intravenous magnesium in the treatment of acute myocardial infarction, where the results of a meta-analysis published in 1993 [58] were subsequently overturned by the publication of the very large ISIS-4 trial in 1995 [59]. Other examples include the studies of aspirin in the prevention of pre-eclampsia [60]. The most likely explanation in each case is that the meta-analyses of smaller RCTs that predated the very large and definitive mega-trial were biased by the preferential publication of positive results. Publication bias remains one of the greatest obstacles to reliable meta-analysis, but such bias can be minimized by using strategies to actively seek out unpublished data.

Conclusion

To prescribe a drug for a patient with cardiovascular disease, it will be necessary to take into account the efficacy and safety of the therapy in comparison with alternative treatments, and this will rely upon an assessment of aggregate data from clinical trials. However, therapy will have to be individualized to take into account the presence of comorbidity, the potential for drug interactions and perhaps, in the future, genetic variation. The costs of treatment will be a factor, regardless of whether this is borne individually by the patient, or collectively by society.

Personal perspective

Major advances in the treatment of cardiovascular disease have been made in the last 20 years. Notable examples include ACE inhibitors and beta-blockers in the treatment of heart failure, thrombolysis for acute myocardial infarction, and use of aspirin and statins and blood pressure lowering in the prevention of cardiovascular events. Absolute benefits in each case have been small but, because cardiovascular disease is so common, the public-health implications of these interventions have been substantial. Whilst future advances will bring incremental benefits to those already achieved, new treatments are likely to be expensive, and balancing clinical benefits and costs will present a challenge to all health-care systems. Moreover, not all new developments represent a substantial therapeutic advance. In the future, it will become more important than ever to quantify both the treatment effect and the cost, as choices will have to be made that will have an impact on public health as much as on the individual patient.

9 Prevention of Cardiovascular Disease: Risk Factor Detection and Modification

Joep Perk, Annika Rosengren and Jean Dallongeville

Summary

The prevention of cardiovascular disease (CVD) is of major importance because CVD is expected to remain the leading cause of premature death in Europe in the coming decades. The prevalence of symptomatic disease is still increasing. Can this be prevented in clinical practice? What is the role of the physician in preventive cardiology?

A large part of the population at risk can be identified by assessing known risk factors. Risk behaviour can be modified successfully through life-style management. Single risk factors such as hyperlipidaemia and hypertension can be adequately controlled by adding pharmacotherapy. Thus, there are effective tools both for the detection and for the modification of CVD risk.

In this chapter the concept of total-risk calculation based upon the SCORE project is proposed to replace previously used single-risk assessment tools. SCORE risk charts for high- and low-risk regions in Europe are shown and its computer-based application 'HeartScore' is introduced. Prevention strategies and priorities are presented in agreement with the recent guidelines of the Third Joint European Societies Task Force on CVD prevention in clinical practice.

The detection and modification of risk factors is described in the sections on smoking, physical activity and blood pressure and on nutrition, obesity and lipids. It includes specific methods for life-style counselling; drug therapy has been recommended, whenever deemed necessary. Finally, new evidence on the importance of psychosocial risk factors and the influence of gender will be discussed in this chapter.

Introduction

Cardiovascular disease (CVD), including coronary heart disease and stroke, is the major cause of premature death in adults. In Europe it accounts for 49% of all deaths [1]. Almost one in three deaths occurring before the age of 65 is the result of CVD. The disease results in substantial disability and loss of productivity and contributes in large part to the escalating costs of health care. In 2000 CVD accounted for 22% of all disability-adjusted life years (DALYs) lost in Europe [2].

Even though the age-standardized mortality rates have declined over the past decades in most European countries, the prevalence of CVD is increasing because of improved treatment and higher survival rates and because of the increasing elderly population. The prevalence of patients who are at risk of recurrent disease (re-infarction, recurrent stroke, heart failure, sudden death) is likewise on the increase. Furthermore, with the current pandemic of obesity in childhood and adolescence CVD may extend into younger age groups in the future. Thus, CVD is expected to remain the largest burden on health care in Europe in the coming decades.

There are marked gradients in CVD morbidity and mortality within European countries [3,4]. This is partly explained by differences in conventional risk factors such as smoking, blood pressure and blood cholesterol but differences in psychosocial factors related to the work place and to the social environment and in coronary care and secondary prevention may also contribute.

In seeking to prevent CVD in European populations the objectives are to reduce mortality and morbidity and thus improve the chances of a longer life expectancy with preserved quality of life. CVD is strongly related to

Table 9.1 Population-attributable risk associated with life-style-related risk factors in men and women by geographic regions in Europe [8]

	Region	Smoking (%)	Fruits and vegetables (%)	Exercise (%)	Alcohol (%)	All life-styles (%)
Men	Western Europe	39.0	13.3	37.7	14.1	69.6
	Central and Eastern Europe	40.4	7.6	–0.4	10.4	48.9
Women	Western Europe	11.1	8.4	38.3	34.2	65.2
	Central and Eastern Europe	13.1	12.8	42.7	29.9	65.4

life-style characteristics and associated risk factors. There is clear scientific evidence that life-style modification and risk factor reduction can retard the development of the disease both before and after the occurrence of a clinical event.

Traditionally, preventive cardiology has been concerned with unifactorial risk assessment, as in the management of hypertension, hyperlipidaemia or diabetes. This has resulted in emphasis being placed on single high-risk factors rather than on the overall level of risk based on a combination of factors. The total-risk concept, on the other hand, acknowledges that CVD has a multifactorial aetiology and that risk factors can have a multiplicative effect, enhancing the effect of one another.

A genetic predisposition does play a role in the development of CVD and a detailed family history of coronary heart disease (CHD) or other atherosclerotic disease should be part of the assessment of all patients with CVD and in the identification of high-risk individuals. However, except in rare cases, as for example in familial hypercholesterolaemia, the influence of a positive family history is not among the strongest risk factors. Moreover, it is not amenable to intervention and serves alongside other risk factors to identify individuals who are at increased risk. Even with a positive family history CVD only rarely occurs in the absence of other risk factors.

The importance of comprehensive risk factor intervention in patients with established CVD and in high-risk subjects has been emphasized by several expert groups. Previous recommendations were based on reports from the Framingham Study [5]. Because this risk score was based on a limited North American sample its applicability to European populations has been questioned. Accordingly, the development of a risk estimation system based on a large pool of representative European data was instigated: the SCORE (Systematic COronary Risk Evaluation) for total CVD risk [6]. The design of this project allows the development of methods for creating national or regional risk charts based on published mortality data. Thus, there is unanimity on the clinical priorities for coronary prevention and the need to target those at highest risk on the basis of a comprehensive multifactorial risk assessment. Yet, surveys have revealed that there is considerable potential to improve risk factor management [7].

There is a wealth of evidence that tobacco smoking, lack of physical activity, nutritional habits and psychosocial factors play important roles both as causes of the mass occurrence of CVD in populations and as contributing factors to the risk of CVD in individuals within populations. In the INTERHEART study almost 70% of all cases with a first myocardial infarction could be related to life-style factors (Table 9.1), and up to 90% could be related to nine easily identifiable risk factors, thus showing the importance of continuing efforts to prevent CVD [8] (Table 9.2). The cumulative effect of these risk factors on the odds ratio for myocardial infarction is shown in Fig. 9.1.

Table 9.2 Population-attributable risk associated with other risk factors in men and women by geographic regions in Europe [8]

	Region	Hypertension (%)	Diabetes (%)	Abdominal obesity (%)	All psychosocial (%)	Lipids (%)	All nine risk factors (%)
Men	Western Europe	20.5	12.8	68.6	23.7	36.7	92.0
	Central and Eastern Europe	15.9	5.8	31.7	–0.9	38.7	71.9
Women	Western Europe	25.9	21.0	50.6	67.1	47.9	97.1
	Central and Eastern Europe	42.7	15.7	20.0	15.0	26.8	86.1

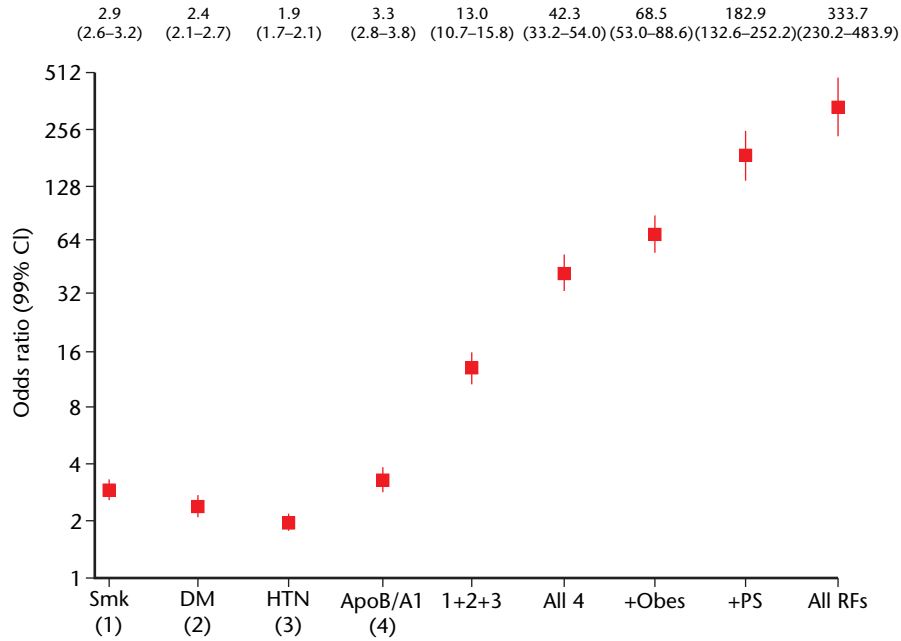

Figure 9.1 Risk of acute myocardial infarction associated with exposure to multiple risk factors [8]. Smk, smoking; Fr/vg, fruits and vegetables; Exer, exercise; Alc, alcohol. Note the doubling scale on the *y*-axis.

For a proper assessment of the total cardiovascular risk each individual risk factor has to be considered and the impact of modifying risk has to be assessed against the background set by the non-modifiable risk characteristics. Therefore the concept of total CVD risk estimation has been proposed as an important principle in the development of preventive strategies aimed at a good match between the intensity of intervention versus magnitude of CVD risk.

Prevention strategies

The 1982 report of the World Health Organization (WHO) Expert Committee on Prevention of Coronary Heart Disease considered that a comprehensive action for prevention has to include three components:

- **Population strategy**—for altering at the population level life-style and environmental factors and their socioeconomic determinants, which are the underlying causes of CHD.
- **High-risk strategy**—identification of high-risk individuals, and action to reduce their risk factor levels.
- **Secondary prevention**—prevention of recurrent events and progression of the disease in patients with clinically established CHD.

The last two correspond to prevention activities targeted at individuals and should be an integral part of clinical practice. They are the focus of this chapter. The population strategy, targeted at entire communities, should be an integral part of food and nutrition, transport, employment, education, health and other policies at European, national, regional and local levels. Table 9.3 summarizes the most important distinctions between the population and the clinical prevention strategies.

Population strategy

The population and clinical approaches are complementary, but the population strategy is fundamental to reducing the burden of CVD in Europe by targeting the social and economic determinants of the disease through political action. The population strategy must lead eventually to changes in life-style: a reduction in the number of people who smoke, enhancement of physical activity and the promotion of adequate and balanced food habits. These goals can be reached in different ways, but political will and development of *ad hoc* policies and investments at all levels are a condition without which they cannot be achieved.

Social inequalities affect cardiovascular health. A population strategy should ensure actions against the determinants of these inequalities. The strategy has to ensure equity of access to preventive advice and to diagnostic and therapeutic interventions, to reduce the social differences in health. A preventive population strategy can be

Table 9.3 Main differences between population and clinical prevention strategies

Prevention in clinical practice	Population strategy: health promotion
The aim is the prevention of onset and progression of disease in an individual	The aim is the reduction of incidence of disease in the population
The targets are individuals	The target is the community
Use quantitative methods	Use quantitative and qualitative methods
Instruments are medical interventions	Instruments are development and implementation of *ad hoc* policies
Standards are randomized controlled trials	Standards are outcome and process evaluation
Easier to treat an individual	Difficult to scale up health promotion programmes that reach the whole population
Outcomes of interventions are individual change	Outcomes are to change the social norms, environments and behaviour of entire populations
Interventions can focus on most factors relevant to the outcome	Interventions take on social determinants external to the community

Modified from the OSAKA declaration [10].

successful, as demonstrated in Finland [9], but is critically dependent on the participating parties such as government, insurance companies, the food industry, etc. Cardiologists, however, should not underestimate the impact that they as professionals can have in the public domain.

High-risk strategy

Prevention targeted at individuals who are at high risk but otherwise healthy should be an integral part of clinical practice. These persons may be identified by their life-style, e.g. smoking cigarettes or obesity, or through the detection of hypertension, hyperlipidaemia, diabetes, or by a combination of risk factors, as in the metabolic syndrome. A substantial number can be identified in daily practice without having to resort to cardiovascular screening of the entire population.

High-risk individuals are defined as those with:

- markedly raised levels of single risk factors, i.e.
  - total cholesterol ≥ 8 mmol/l (320 mg/dl)
  - low-density lipoprotein (LDL)-cholesterol ≥ 6 mmol/l (≥ 240 mg/dl)
  - blood pressure ≥ 180/100 mmHg;
- multiple risk factors
  - resulting in a 10-year fatal CVD risk of ≥ 5% at present according to SCORE
  - or ≥ 5% if extrapolated to age 60;
- diabetes mellitus
  - diabetes mellitus
  - diabetes type 1 with microalbuminuria.

Secondary prevention

Patients who present with CVD have already declared themselves to be at high risk of recurrent ischaemic events and therefore their modifiable risk factors need to be reduced. These include the basic elements of life-style counselling (stopping smoking, modifying food and physical activity habits, taking action against psychosocial stress and depression) and the use of prophylactic medication and are an integral part of post-event cardiological or stroke care.

The treatment goals of prevention in patients with established CVD are:

- stopping smoking;
- daily physical activity;
- adequate nutritional habits aiming at
  - total cholesterol < 5 mmol/l (190 mg/dl)
  - LDL-cholesterol < 3 mmol/l (115 mg/dl);
- blood pressure < 140/90 mmHg.

Patients with established CVD or diabetes, whose untreated values of total and LDL-cholesterol are already close to 5 and 3 mmol/l, respectively, probably benefit from further reduction of total cholesterol to < 4.5 mmol/l (175 mg/dl) and from further reducing LDL-cholesterol to < 2.5 mmol/l (100 mg/dl), with moderate doses of lipid-lowering drugs. In patients with diabetes target levels for blood pressure are < 130/80 mmHg.

Preventive action should lead to contacting close relatives for risk assessment and providing them with preventive advice and intervention if necessary.

Priorities in clinical practice

The number of patients with established CVD and of otherwise healthy individuals who are at high risk is large. This presents a considerable challenge to the medical community for which the tasks of CVD prevention are difficult to accomplish in the context of the daily workload. Therefore, it is useful to define priorities for CVD prevention. The Third Joint European Societies Task Force on CVD prevention in clinical practice [10] has developed guidelines proposing the order in which preventive action should be taken, because with limited resources full-scale action directed to all groups potentially needing preventive advice may not be feasible in the national health-care structure. As soon as progress has been made in the top priority groups, action may be directed to groups with a lower rank order in the list. The highest priority is given to patients with established CVD, the lowest to the general population met in clinical practice.

Furthermore, cardiologists and other physicians should act as opinion leaders and influence public health decisions, aiming at facilitating healthy life-styles at a broad population level.

Proposed list of priorities:

1 Patients with established CHD, peripheral artery disease and cerebrovascular atherosclerotic disease.
2 Asymptomatic individuals who are at high risk of developing atherosclerotic CVD.
3 First-degree relatives of patients with early-onset CVD (defined as males < 55 years, females < 65 years).
4 First-degree relatives of asymptomatic individuals at high risk.
5 Other individuals met in connection with ordinary clinical practice.

Total-risk estimation

Total risk means the likelihood of a person developing a fatal cardiovascular event over a defined period of time. It is well established that risk factor management decisions should not be based on consideration of a single risk factor. Table 9.4 illustrates how a 60-year-old woman with a cholesterol level of 8 mmol/l can have a nine times lower CVD mortality risk than a man with a cholesterol level of 5 mmol/l if the man smokes and is hypertensive. Estimating the combined effect on CVD mortality of several major risk factors is more complex than assessing single risk factors. It is essential for the clinician to be able to assess risk rapidly and with sufficient accuracy to allow evidence-based management decisions. To this end, several risk charts have been published [3,11]. These charts use age, sex, smoking status, total cholesterol and systolic blood pressure to estimate the risk of coronary or cardiovascular events over the next 10 years. In the widely used Framingham risk charts a 10-year risk ≥ 20% was used arbitrarily as a threshold for risk factor intervention. However, the charts had several weaknesses: they were derived from North American data and the applicability of the risk chart to European populations was uncertain. In addition, the dataset used for the chart was small and the definition of non-fatal end-points differed from that used in other studies.

The risk chart presented in the Third Joint Task Force recommendations was developed as part of an EU Concerted Action Project: the SCORE (**S**ystematic **CO**ronary **R**isk **E**valuation) chart. The SCORE risk prediction system is derived from 12 European cohort studies and comprises over 200 000 persons, 3 million person-years of observation and over 7000 fatal cardiovascular events. The main differences from the Framingham charts are:

- CVD mortality, rather than total events, is used as a primary end-point because this allows risk to be calculated for countries or regions where only mortality data are available.
- All atherosclerotic deaths (not only CHD) are included in the risk model by using a calculation method that allows stroke deaths to be considered separately from CHD deaths if required. Stroke deaths may be proportionately more important in low-risk populations.
- The risk chart has been modified to provide more detail for middle-aged subjects in whom risk changes more rapidly with age.

Table 9.4 Examples of how other risk factors may negate the advantages of having a desirable cholesterol level. Risk figures refer to the 10-year risk of CVD death.

Sex	Age (years)	Cholesterol (mmol/l)	Blood pressure (mmHg)	Smoking	Risk (%)
Female	60	8	120	0	2
Female	60	7	140	+	5
Male	60	6	160	0	8
Male	60	5	180	+	19

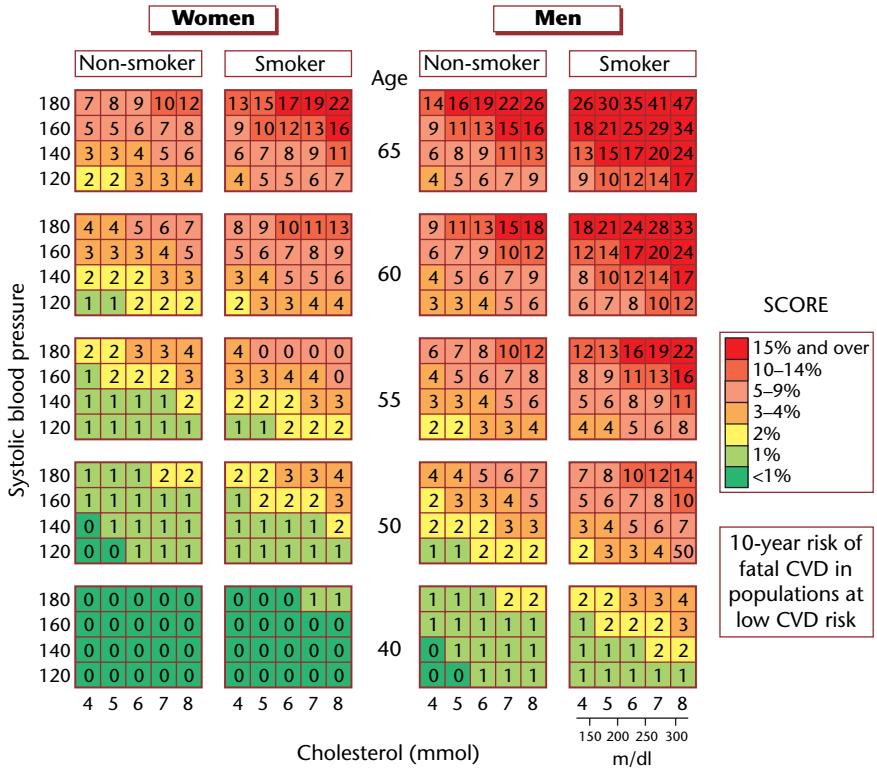

Figure 9.2 Ten-year risk of fatal CVD in high-risk regions of Europe by gender, age, systolic blood pressure, smoking status, total cholesterol or HDL/total cholesterol ratio.

- Separate charts have been prepared for higher and lower risk areas of Europe (see Figs 9.2, 9.3). In the future it will be possible to produce individualized risk charts for individual countries, provided reliable mortality information is available.

It should be stressed that the SCORE charts are only for use in subjects without known vascular disease. Subjects with manifest atherosclerotic vascular disease are already at high risk of vascular events and should be treated accordingly.

The SCORE chart has several functions:

- An individual's total risk of CVD death over the next 10 years can be read from the chart without any calculations.
- Relative risk can readily be estimated by comparing the risk in one cell with any other cell in the same age group.
- The chart can be used to give some indication of the effect of change from one risk category to another, i.e. when the subject stops smoking or reduces other risk factors.
- Although young people are generally at low risk, this will rise as age increases. The chart can be used by following the tables upward to illustrate the effects of lifetime risk by observing the increased risk with an increase in age.

Low-risk individuals should be offered life-style advice to maintain their low-risk status. In the previous chart, based on the Framingham study results, high risk for CHD mortality and morbidity was defined as a level of 20% or more. This equates to a risk of approximately 5% CVD mortality in the SCORE chart. Anybody at or above this level would merit intensive risk factor advice. Because the chart has several practical limitations the European Society of Cardiology has launched an interactive computer-based tool for total risk estimation: HEARTSCORE®.

HEARTSCORE®

HEARTSCORE® is a combination of the PRECARD® program operating with SCORE data, and has been adopted as the standard in European CVD risk management by the Third Joint European Societies Task Force on CVD Prevention. The PRECARD® program is a health educational risk management program which has been developed in Denmark [12]. It is the electronic counterpart to the risk chart and is aimed at supporting both the clinician and the patient in optimizing individual cardiovascular risk management.

The program operates with the same risk factors, endpoints, colours, etc. as the risk chart, but shows total risk

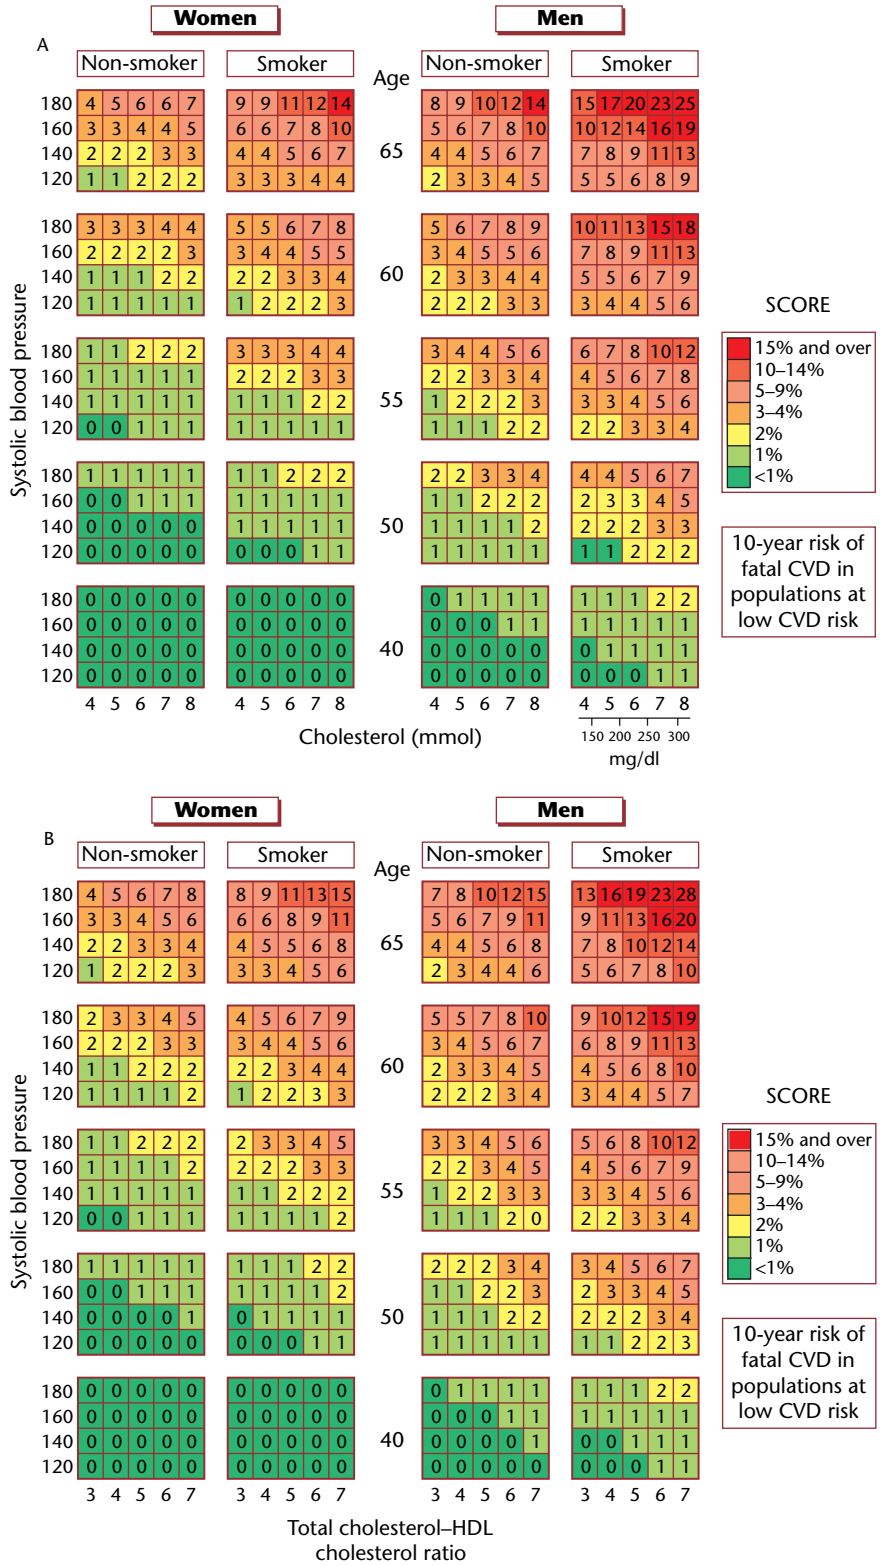

Figure 9.3 Ten-year risk of fatal CVD in low-risk regions of Europe by gender, age, systolic blood pressure, smoking status, total cholesterol or HDL/total cholesterol ratio.

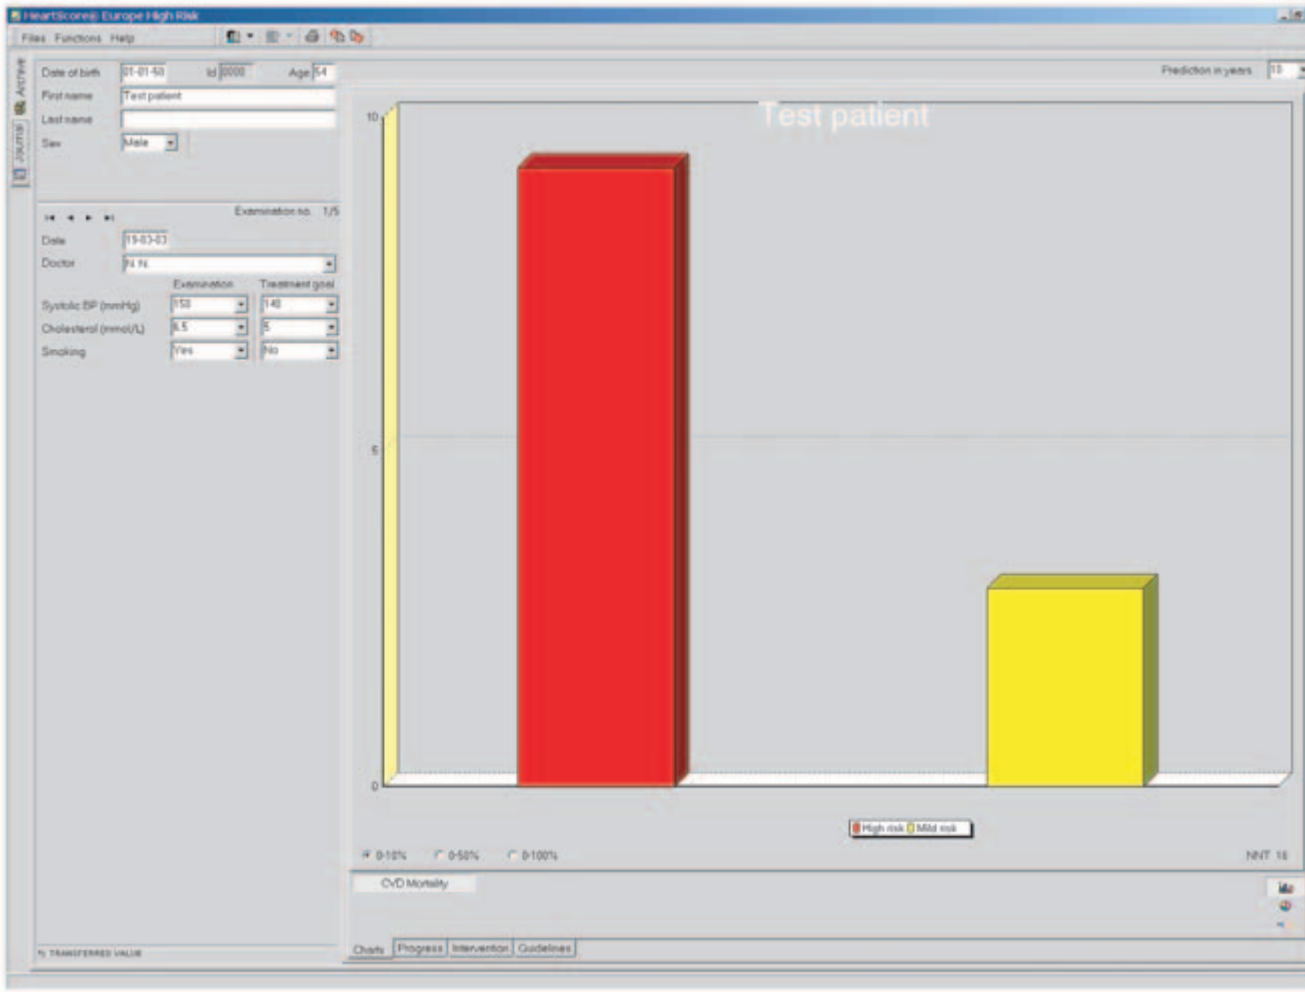

Figure 9.4 Main screen for HEARTSCORE®.

in a bar-chart (left bar in Fig. 9.4) and the distribution of modifiable risk factors in a pie chart (Fig. 9.5). The expected effect of intervention is calculated from large randomized clinical trials in hypertension and hypercholesterolaemia and is also shown in a bar chart (right bar in Fig. 9.4). At the end of the consultation an individual sheet of health advice based on the actual risk profile can be printed. The health promotion texts to the patient are compiled from endorsed sources in each country.

The program is flexible and interactive. It can be updated as new cohort studies become available, and can incorporate new languages, new risk factors and new end-points as knowledge evolves. It can be easily adapted to different countries and settings allowing clinicians to have immediate and interactive access to appropriate local preventive advice.

HEARTSCORE® is available for downloading in a version for low-risk and high-risk regions via the ESC website: www.heartscore.org. National versions will be gradually made available from this website.

Instructions on how to use the chart

- To estimate a person's total 10-year risk of CVD death, find the table for their gender, smoking status and age. Within the table find the cell nearest to the person's systolic blood pressure (mmHg) and total cholesterol (mmol/l or mg/dl).
- The effect of lifetime exposure to risk factors can be seen by following the table upwards. This can be used when advising younger people.
- Low-risk individuals should be offered advice to maintain their low-risk status. Those who are at 5% risk or higher, or who will reach this level in middle age, should be given maximal attention.

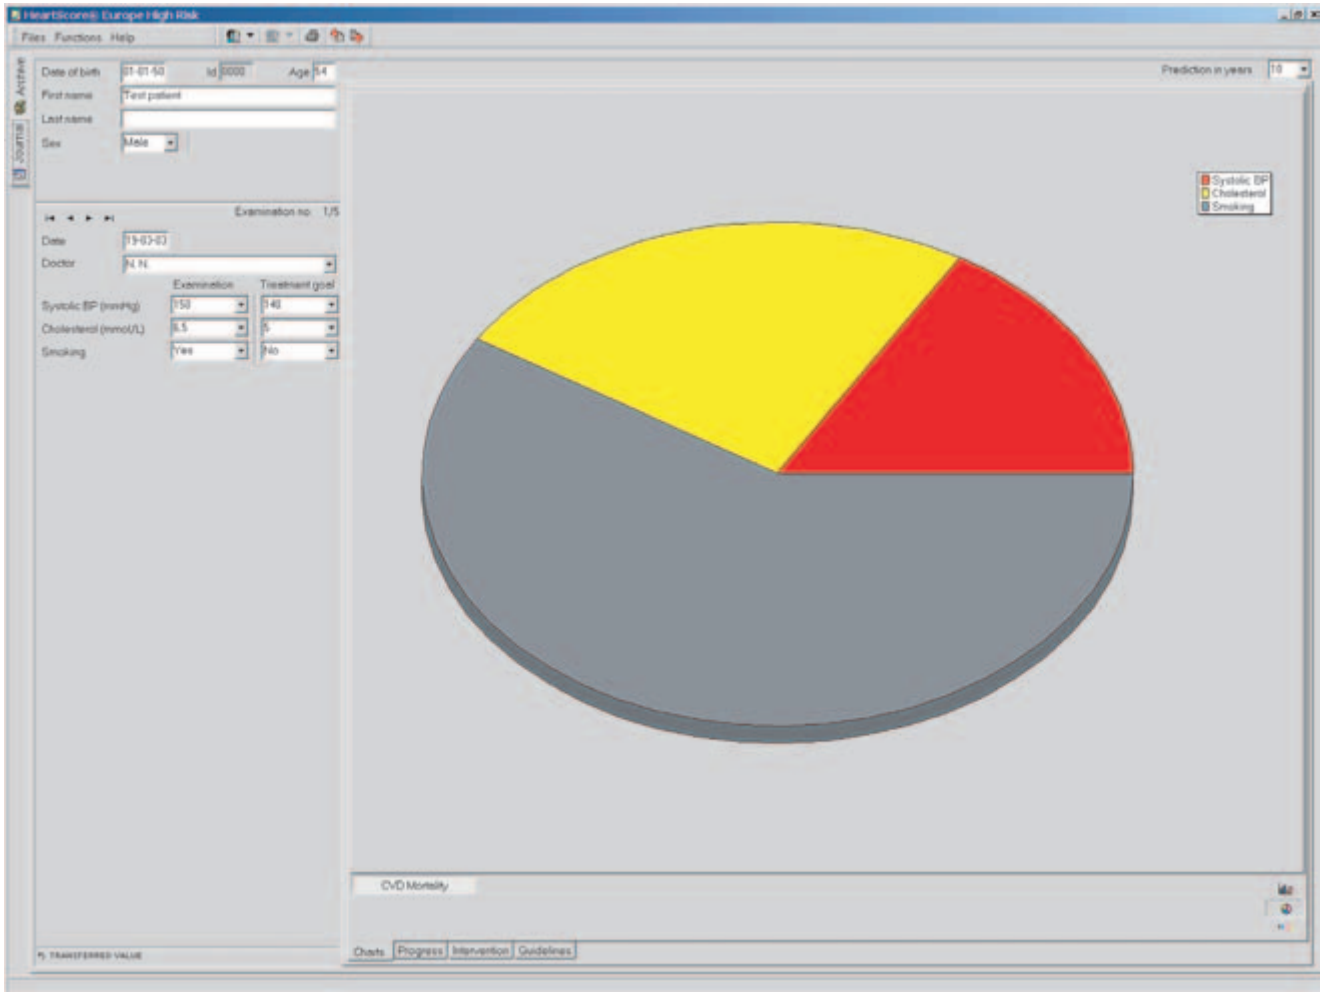

Figure 9.5 Pie chart for HeartScore®.

- To define a person's relative risk, compare their risk category with that of other people of the same age and gender.
- The effect of changing cholesterol, smoking status or systolic blood pressure can be estimated from the chart.

Qualifiers

Total CVD risk may be higher than indicated in the chart:

- as the person approaches the next age category;
- in asymptomatic people with paraclinical evidence of atherosclerosis (e.g. CT scan, ultrasonography);
- in people with a strong family history of premature CVD;
- in people with low high-density lipoprotein (HDL) cholesterol levels, with raised triglyceride levels, with impaired glucose tolerance, with raised C-reactive protein, fibrinogen, homocysteine, apolipoprotein B or lipoprotein(a) levels;
- in obese and sedentary people.

Modifying CVD risk

Smoking

Smoking as a risk factor for cardiovascular disease

Cigarette smoking continues to be a dominant risk factor for both CVD and non-CVD mortality and morbidity. The total number of smokers is expected to reach about 1.6 billion by 2025, with a predicted annual tobacco-related mortality rate of 10 million by 2030. The major part of these deaths will be in the middle- and low-income countries. Thus, smoking remains the single most important preventable cause of disease and early death [13].

The main cardiovascular effects of smoking are shown in Table 9.5, all of which contribute to inflammatory processes in the vascular wall and to thrombotic events.

Table 9.5 Main cardiovascular effects of smoking

Heart rate	↑
Blood pressure	↑
Platelets	Activation → thromboembolism
Endothelium	Dysfunction
Coronary arteries	Provokes arterial spasm
Vascular plaque	Increase in numbers and size
LDL-cholesterol	↑
HDL-cholesterol	↓

These effects are related to the amount of tobacco smoked daily and to the duration of smoking [11]. Genetic disposition is probably important and starting smoking at a young age (< 15 years) significantly increases the risk of premature CVD mortality [14]. In the presence of other risk factors (diabetes, hypertension, dyslipidaemia, overweight) smoking-related risk increases even further. Even passive smoking influences CVD risk.

Quitting smoking is the most effective of all preventive measures for cardiac patients. It leads to a marked reduction in CVD risk: asymptomatic smokers who quit reach the risk level of non-smokers after up to 10 years [11,15]. The effect is more pronounced in patients with CHD: a recent review has shown that quitting smoking is associated with a substantial reduction in risk of all-cause mortality: pooled crude relative risk (RR) 0.64 (95% CI 0.58–0.71). There was also a reduction in non-fatal myocardial infarctions—RR 0.68 (95% CI 0.57–0.82) [15].

Assessment of smoking

A full assessment of the smoking status of the patient is mandatory. This includes: motivation to quit smoking, amount and type smoked, social and family environment, knowledge of nicotine's role in health, signs of nicotine dependence, earlier cessation experience, existing relevant comorbidity, especially chronic obstructive lung disease. A simple lung function test may be valuable. In addition, the degree of addiction and the state of changing smoking habits are highly relevant. Here, the Fagerström test for nicotine dependence can be used (Table 9.6) [16,17]. Motivation and dependency are key elements in the assessment.

Management of smoking, quitting smoking programmes

The doctor's clear and strict advice that a cardiac patient should quit smoking is of decisive importance at the start of the smoking cessation process. At the time of an acute cardiac event or coronary intervention patients may be highly motivated to change life-style, and this is an opportunity to initiate or reinforce anti-smoking advice that should not be missed. Continued reinforcement and encouragement by the physician are also important.

There is a broad variety of options in smoking cessation therapy varying from simple self-help interventions to drug therapy (Table 9.7):

Table 9.6 The Fagerström test for nicotine dependence [19]

Question	Answer	Points
1 How soon after you wake up do you smoke your first cigarette?	Within 5 min	3
	6–30 min	2
	31–60 min	1
	After 60 min	0
2 Do you find it difficult to refrain from smoking in places where it is forbidden?	Yes	1
	No	0
3 Which cigarette would you hate most to give up?	The first in the morning	1
	Any other	0
4 How many cigarettes per day do you smoke?	≤ 10	0
	11–20	1
	21–30	2
	≥ 31	3
5 Do you smoke more frequently during the first hours after waking than during the rest of the day?	Yes	1
	No	0
6 Do you smoke if you are so ill that you are in bed most of the day?	Yes	1
	No	0

Average score in representative samples of smokers: 3–4 points.
Questions 1 and 4 have the highest informative value.

Table 9.7 Success rate of different interventions to stop smoking [20–24]

Type of intervention	Odds ratio	95% Confidence interval	Reference
Self-help interventions	1.24	1.07–1.45	9
Individual behavioural counselling	1.62	1.35–1.94	10
Group therapy programmes	1.95	1.57–2.48	11
Nicotine replacement therapy	1.74	1.64–1.86	12
nicotine gum	1.66		
nicotine patches	1.74		
nasal spray	2.27		
inhaled nicotine	2.08		
sublingual nicotine	2.08		
Antidepressants			13
bupropion	1.97	1.67–2.34	
nortriptyline	2.80	1.81–4.32	
Anxiolytics	–	No consistent evidence	
Community interventions	–	No significant effect	

- **Self-help interventions**—Smokers may give up smoking on their own but leaflets with advice and information may help. Standard self-help materials may increase quitting rates compared to no intervention but the effect is limited. Materials that are tailored for individual smokers may be more effective [18].
- **Individual behavioural counselling**—When compared to control or minimal intervention, individual counselling is more effective and may lead to a quitting smoking rate of up to 40% 6 months after starting the programme [19].
- **Group therapy programmes**—These provide smokers with an opportunity to learn behavioural techniques combined with mutual support within the group, although not all smokers accept this option. Groups are better than self-help and other less intensive interventions. However, there is not enough evidence on their effectiveness, or cost-effectiveness, compared to individual counselling with similar intensity. Addition of group therapy to treatment, such as advice from a health professional or nicotine replacement, has limited additional benefit [20].
- **Nicotine replacement therapy**—The aim is to replace nicotine from cigarettes, thus reducing withdrawal symptoms associated with smoking. Different forms of nicotine replacement are available: chewing gum, transdermal patches, nasal spray, inhalers and tablets. The use of nicotine patches is well tolerated by CVD patients. According to a recent review of 110 trials all of the commercially available forms of nicotine replacement therapy are effective in promoting smoking cessation [21]. They increase quitting rates approximately 1.5- to 2-fold regardless of the setting and largely independent of the intensity of additional support. Provision of more intense levels of support is not essential to the success of nicotine replacement therapy.
- **Antidepressants**—Smoking cessation and nicotine withdrawal may precipitate depression. Nicotine may have an antidepressant action; antidepressants may substitute for this effect. The antidepressants bupropion and nortriptyline can aid smoking cessation. Trials of extended therapy with bupropion to prevent relapse after initial cessation have failed to show a long-term benefit. There is no consistent evidence that anxiolytics aid smoking cessation [22].

Despite these options, many patients who succeed in quitting manage to do this without any special programmes or treatment. Support by the spouse and family is important in smoking cessation.

A community approach will remain an important part of health promotion activities but the largest and best conducted community-based programmes against smoking have thus far failed to diminish the prevalence of smoking. Yet, in several European countries 'smoke-free' environments have been created, including restrictions of smoking at work sites, in public places, restaurants, etc. These changes are important public-health developments that may in the future provide good support to the individual's smoking cessation efforts.

Physical activity

Physical inactivity as a risk factor for CVD

Physical inactivity is a major and growing component in the burden of chronic disease. At least 60% of the global population fails to achieve the minimum recommendation

Table 9.8 Benefits of regular physical activity

- Reduces the risk of premature death
- Reduces the risk of death from CVD
- Reduces the risk of developing diabetes mellitus
- Reduces the risk of developing hypertension
- Reduces the risk of developing colon cancer
- Helps control weight
- Helps build and maintain healthy bones, muscles and joints
- Helps elderly become stronger and better able to move about without falling
- Reduces feelings of depression and anxiety
- Promotes psychological well-being

Table 9.9 Cardiovascular effects of regular physical activity

Antiatherogenic effect		
1	Body fat mass	↓
2	LDL-cholesterol	↓
3	HDL-cholesterol	↑
4	Triglycerides	↓
5	Insulin sensitivity	↑
6	Blood pressure	↓
Antithrombotic effect		
7	Platelet adhesiveness	↓
8	Fibrinolysis	↑
9	Fibrinogen	↓
10	Blood viscosity	↓
Anti-ischaemic effect		
11	Coronary flow	↑
12	Endothelial dysfunction	↓
Antiarrhythmic effect		
13	Vagal tone	↑
14	Adrenergic activity	↓
15	Heart rate variability	↑

of 30 minutes' moderate intensity physical activity daily. The risk of CVD increases by 1.5 times in people who do not follow these recommendations. Physical inactivity is estimated to cause 2 million deaths world-wide annually and 22% of all ischaemic heart disease [23,24]. It will have a major impact as physical activity in the younger generation tends to decrease. In the younger age groups activity patterns decline consistently from ages 12 through 21. In young adulthood (18–29 years) erosion continues whereas in middle age (30–64 years) the activity pattern stabilizes, with a tendency to improve in older age [25]. The combination of excessive caloric intake and insufficient exercise are life-style factors contributing to the development of the metabolic syndrome, which has reached an almost epidemic level in Europe and elsewhere.

Regular physical activity is protective through a wide variety of beneficial effects (Table 9.8). It has a direct effect on vascular lesions and an indirect effect through influencing other risk factors (Table 9.9). Thus, the promotion of regular physical activity and maintenance of fitness at school, at work and during commuting, at home, during leisure time and after old-age retirement is an important task for preventive cardiology.

CHILDREN AND ADOLESCENTS

The risk of a premature onset of atherosclerosis is increasing as children are becoming less active. Today children expend 600 kcal/day less than their counterparts 50 years ago [26]. School children rarely exercise the recommended daily 30–45 minutes. More than half of adolescents become physically inactive after leaving school.

Atherosclerosis begins in childhood: the first stage, a reversible fatty streak, is seen in most children. The harmful later stage, the atheromatous plaque, does not appear until after puberty in boys and much later in girls [27]. Traditional risk factors, such as hypertension, dyslipidaemia and smoking, act in the early stages of this process. At present, blood pressure levels in children are rising, the prevalence and the degree of obesity increases, insulin resistance and type 2 diabetes mellitus (non-insulin dependent diabetes mellitus) are more often found in young individuals [28].

HEALTHY ADULTS

Changes in society and the individual adaptations to these contribute to a mainly sedentary life-style. The exertional demands at the work place have decreased; only a minority of labourers will experience breathlessness in their daily work. Commuting has become less physically demanding. There is lower energy expenditure at home and during leisure time.

Since the landmark studies by the groups of Morris [29] and Pfaffenberger [30] the relation between physical activity and CVD has become well established. Maintaining physical fitness has a direct protective effect independent of other risk factors and exercise capacity, as well as physical activity, are powerful predictors of mortality [31–33]. Regular exercise diminishes the risk of a myocardial infarction under strenuous exertion [34].

ADULTS WITH CVD

CVD patients tend to restrict physical activity for fear of deterioration in the disease or because of symptoms. Overprotection by the family may contribute. Restoration and maintenance of physical fitness are both needed and beneficial.

Many of the beneficial effects of an active life-style observed in the healthy population (Table 9.9) apply to

the CVD patient. Physical activity reduces the progression of atherosclerosis by alleviating endothelial dysfunction. It affects the production of free radicals, protecting patients from oxidative stress; it improves insulin sensitivity and reduces plasma homocysteine levels. Protection against malignant arrhythmias and less myocardial wall stress is obtained through modifying the sympathovagal balance [35–37]. In a recent meta-analysis including 8440 patients a 27% reduction of total mortality as a result of exercise training was estimated, and cardiac mortality was reduced by 31% [38]. In spite of these benefits only a minority of patients are referred to exercise training programmes. Physical inactivity is common in patients with congestive heart failure. The benefit of improving physical fitness in these patients has been demonstrated [39].

THE ELDERLY

Age-related physiological changes may result in physical inactivity: a decrease in maximum heart rate, stroke volume, cardiac output and down-grading of β-adrenergic receptors. Peripheral changes contribute with decreases in muscular strength and coordination, peripheral O_2^- uptake, bone mineral content and lung function. With increasing age the activities of daily life put a greater demand on the person's work capacity. Regular physical activity will counteract or effectively slow down the age-related changes, thereby improving quality of life and extending disease-free survival. As the elderly account for the main part of all myocardial infarctions and coronary interventions, cardiologists should use the therapeutic potential of physical activity.

Assessment of physical activity

In youth, assessment of physical activity remains a challenge for research: differing stages of growth, discrepancies between physical strength and fitness and difficulties with the validity of questionnaires confound assessment. Formal exercise testing including measuring oxygen consumption or direct observation are resource-consuming methods. Yet, assessment is needed to evaluate physical activity programmes. Heart rate monitors, pedometers and accelerometers are used, although they do not register all forms of physical activity in children. Accelerometers may be the preferred choice [40]. In high-risk children, as in hereditary dyslipidaemia, a heavy family CVD burden or diabetes mellitus, standard exercise testing can provide a ground for life-style advice and follow-up.

In healthy adults a brief interview concerning physical activity at work and in leisure time if needed, together with a recall questionnaire, diary or pedometer may act as a base for the physician's advice. This may be completed with an exercise test using a bicycle ergometer or treadmill to obtain an objective assessment of exercise capacity.

In adults with CVD the patient's history usually needs objective assessment by exercise testing to detect myocardial ischaemia, to stratify for risk of a new event, to select for coronary intervention, or to assess the effect of revascularization or the response to medication. We refer to guidelines issued by the European Society of Cardiology (ESC) and the American Heart Association (AHA) [41,42].

In the elderly the patient interview remains the cornerstone in assessing physical activity. The specific problems of deteriorating physical capacity should be addressed, especially regarding the activities of daily living and the need for support. Exercise testing on a bicycle ergometer or treadmill may be indicated in persons with symptoms of CVD. However, less demanding methods, such as the Six-minute Walk Test or the Shuttle Walk Test, may also provide valuable information on the physical capacity of the elderly.

Management of physical activity

CHILDREN AND ADOLESCENTS

Every child should be encouraged to spend a minimum of 30–45 minutes every day in physical activities that increase heart rate to a significant degree, be it in school or during leisure time. Special efforts should be made to maintain activity levels during and after adolescence.

HEALTHY ADULTS

In high-risk individuals the family doctor should specifically promote regular physical exercise. For all healthy adults, regardless of risk, an active life-style should include work, commuting, domestic life and leisure time. Healthy adults are recommended to be active for 30–45 minutes most days of the week in enjoyable activities which fit into their daily routine (Table 9.10). Recommended intensity may be defined as heart rate during exercise at 60–75% of the maximum. As a simple method for estimating maximum heart frequency the formula of '220—age = max. heart rate' can be used. Alternatively the Borg scale of perceived exertion may be applied, using the level of 'moderate exertion' as the target [43]. This level is easily achieved by exercises involving large muscle groups, e.g. brisk walking or jogging, cycling, swimming, aerobic dancing, tennis, golf, or cross-country skiing. The duration of physical activity should preferably be 30–45 minutes, including a 5- to 10-minute warm-up phase, an aerobic phase of 20–30 minutes and a 5- to 10-minute cool-down phase at its end. A frequency of at

Aim	In all age groups: 30–45 minutes of physical activity at least five days a week
Rationale	• To prevent or delay the onset of cardiovascular disease • To limit the progress of existing cardiovascular disease
Method	• Promote daily physical exercise at school • Provide options for regular physical activity at the work site, encourage an active leisure time, e.g. brisk walking, cycling, swimming, gardening or other in/outdoor sports and hobbies • For coronary patients: participation in supervised or home-based programmes of physical training • For elderly: stimulate the maintenance of a physically active life-style, even in higher age groups
Some examples	Moderate activity: • Gardening for 30–45 minutes • Walking 3 km in 30 minutes (10 min/km) • Bicycling 8 km in 30 minutes • Dancing fast (social) for 30 minutes • Water aerobics for 30 minutes • Swimming laps for 20 minutes • Rowing for 20 minutes More strenuous activity: • Running 2.5–3 km in 15 minutes (5–7 min/km) • Stairwalking for 15 minutes • Shovelling snow for 15 minutes

Table 9.10 Recommendations for physical activity

least four or five times weekly is recommended. There is no scientific evidence of further preventive gains of a higher intensity or frequency of exercise.

ADULTS WITH CVD

Recommendations for CVD patients should be based on a clinical examination including exercise testing. Patients with stable angina pectoris or recovering from a myocardial infarction or coronary intervention should be referred to a rehabilitation programme provided by a multidisciplinary team on an ambulatory basis or for selected cases to a specialized in-patient institute. Individual home training programmes and other aids (books, CD-Rom, etc.) are available and effective although regular follow-up and encouragement are needed. Heart-rate monitors or pedometers may be helpful in home-based programmes. We refer to Chapter 26 (Cardiac Rehabilitation) for detailed information. The prescription of physical training programmes in congenital heart disease should remain in the hands of paediatric cardiologists and specially trained physiotherapists.

THE ELDERLY

In healthy elderly persons daily physical activity should be maintained on a moderate level. Brisk walking at a pace at which a conversation still can be held ('walk-and-talk model') is a good example. Senior CVD patients of both genders will benefit equally from rehabilitation programmes: training is safe, improves strength, aerobic fitness, endurance and physical function. It will affect risk factors, mental state and quality of life [44]. Resistance training may be an attractive alternative as it can be used in home-training (thera-band, weight lifting, etc.). The goal should be the prevention of physical inactivity so that the efforts of an active life-style are rewarded by its cardiovascular and other health benefits.

Blood pressure

Hypertension as a risk factor for CVD

Hypertension, defined as a systolic blood pressure ≥ 140 mmHg and/or a diastolic blood pressure ≥ 90 mmHg, is one of the most important preventable causes of premature death world-wide, contributing to approximately half of all global CVD. In many countries, up to 30% of adults have hypertension; a further 50–60% would be in better health if they reduced their blood pressure by increasing physical activity, maintaining an ideal body weight and eating more fruits and vegetables. CVD doubles for every 10 mmHg increase in diastolic blood

pressure or every 20 mmHg increase in systolic blood pressure [45].

Blood pressure usually rises with age, except where salt intake is low, physical activity high, and obesity largely absent. Most natural foods contain salt; processed food may be high in salt; and individuals may add salt for taste. Dietary salt increases blood pressure in most people with hypertension, and in about a quarter of normotensives, especially with increasing age. In addition to effective life-style changes medication may be needed for control of hypertension.

Life-style management

Blood pressure can be reduced either by life-style interventions or by pharmacotherapy. Life-style interventions have been evaluated in mild blood pressure elevation [46]. Blood pressure was moderately reduced in individuals exposed to dietary sodium reduction, increased potassium intake, decreased alcohol consumption, body weight reduction, dietary regimens based on fish oils, increased physical activity and cessation of smoking [47,48]. In compliant individuals life-style changes reduce the total CVD risk, prevent a restart of medication after drug treatment has been stopped and may decrease the number and doses of drugs needed. Treatment based on these interventions alone may be sufficient for patients with mild hypertension and should always be advised even for patients on antihypertensive drugs. Frequent reinforcement is needed because long-term compliance in life-style changes may be lacking.

Life-style recommendations include:

- weight reduction in overweight individuals;
- reduction of salt intake to < 6 g daily;
- restriction of alcohol consumption to < 10–30 g/day (men) and < 10–20 g/day (women);
- regular physical activity in sedentary individuals;
- quitting smoking;
- dietary changes in cases of hyperlipidaemia.

Drug treatment (see Chapter 10)

The decision to start treatment depends both on the level of blood pressure and on the assessment of total CVD risk. Because risk factors may interact, the total cardiovascular risk of hypertensive patients may be high even if blood pressure is only mildly elevated [49].

In patients with established CVD or if target organ damage is present the choice of drugs depends on the underlying disease.

Drug therapy is necessary in case of a sustained systolic blood pressure ≥ 140 mmHg and/or diastolic blood pressure ≥ 90 mmHg despite life-style interventions. Individuals with systolic blood pressure ≤ 140 mmHg and/or diastolic blood pressure ≤ 90 mmHg and no other risk factors do not require drug therapy as a rule.

Nutrition

Nutritional treatment for the prevention of cardiovascular diseases

The relation between nutritional habits and cardiovascular risk is well established. The initial observations of the 'Seven Countries Study' relating food consumption to ischaemic heart disease rates in countries with contrasting nutritional habits and CHD rates showed clear associations between the intake of saturated fats and the incidence of ischaemic heart disease. Since then, the relationship between dietary factors and dyslipidaemia or hypertension has been demonstrated in prospective investigations, confirming the findings from the ecological studies. In continuing research, many epidemiological or clinical studies have demonstrated the close relationships between food or nutriments and cardiovascular risk factors or events. Furthermore, multifactorial or targeted nutritional interventions have clearly demonstrated the beneficial effects of preventive or therapeutic nutritional approaches. In view of this strong evidence nutrition therapy is a full component of cardiovascular risk prevention.

Diet and cardiovascular diseases

The principal properties of foods and nutrients are summarized in Table 9.11.

TOTAL FAT, SATURATED, MONOUNSATURATED AND TRANS FATTY ACIDS

Dietary lipids play a major role in the formation of the atheromatous plaque and thrombotic complications. In Western countries, dietary intake of fat is often over 100 g/day. Dietary fatty acids affect cholesterol and lipoprotein levels [50], arterial blood pressure and haemostasis. In cohort studies, the positive relationship between fat intake and CVDs was linked to their saturated fatty acid content [51,52]. Animal products, industrially manufactured meals and certain cooking fats are the principal sources of saturated fats. These fatty acids increase LDL-cholesterol concentrations. Epidemiological data for monounsaturated fatty acids are scarcer. However, monounsaturated fatty acids have been associated with a reduced coronary risk compared to saturated fatty acids [51].

Trans fatty acids are isomers of monounsaturated or polyunsaturated fatty acids produced by hydrogenation.

Table 9.11 General recommendations for high cardiovascular risk subjects, to be adapted according to local and cultural particularities

Nutrient and food	Goal	Affect cardiovascular risk factors	Affect cardiovascular events
Energy	Keep BMI < 25 kg/m^2 and waist girth < 102 cm in men and < 88 cm in women	Triglycerides, HDL-cholesterol, insulin, glycaemia, blood pressure	Effect of BMI reduction Unknown
Total fat	30% of total energy	LDL-cholesterol and body fat	Little evidence
Saturated fat	10% of total energy	LDL-cholesterol, HDL-cholesterol, body fat, glycaemia	Yes
Trans fatty acids	< 2% of total energy		Yes
Polyunsaturated	≥ 10% of total energy		Yes
Monounsaturated	≥ 10% of total energy		Yes
n-3 fatty acid	1 g/day	Triglyceride, blood pressure, haemostasis, heart rate	Decrease fatal cardiovascular events
Dietary cholesterol	< 300 mg/day	LDL-cholesterol	Little evidence
Fruit and vegetable	≥ five portions a day	LDL-cholesterol and blood pressure	Yes
Salt	< 6 g/day	blood pressure	Little evidence

BMI, body mass index.

They are mainly derived from meat, dairy products, hard margarines and products from the food-processing industry. Compared with oleic acid, trans fatty acids increase blood LDL-cholesterol [53]. Epidemiological studies have shown positive associations between trans fatty acids and cardiovascular morbidity and mortality.

n-6 and n-3 polyunsaturated fatty acids

Linoleic acid is the main representative of the n-6 group. These fatty acids are mainly derived from vegetal oils. Clinical studies have shown that the consumption of n-6 polyunsaturated fatty acids decreases LDL-cholesterol. In cohort studies, the intake of polyunsaturated fatty acids is associated with a reduced coronary risk compared to saturated fatty acids or trans fatty acids. Intervention studies combining a reduction in risk factors and an increase in polyunsaturated fatty acid intake have shown reduced CVD incidence and mortality.

α-Linolenic acid is the precursor of the n-3 fatty acid group. Primary food sources are soya bean, rapeseed, safflower and linseed oils. In cohort studies, the intake of α-linolenic acid is inversely correlated to cardiovascular events and in secondary prevention trials coronary deaths are less frequent in patients randomly assigned to a Mediterranean diet with a high α-linolenic acid content [54].

Eicosapentaenoic acids (EPA) and docosahexaenoic acids (DHA) are two important members of the n-3 group that are mainly derived from oily fish. The intake of EPA and DHA reduces plasma triglycerides, arterial blood pressure, the occurrence of arrhythmias and improves haemostasis. Prospective studies show a reduced risk of fatal cardiovascular events in people who regularly eat fish [55]. In patients with CVD, the intake of fish and of EPA and DHA supplements reduces coronary mortality [54].

Fruits, vegetables, vitamins and vitamin supplements

Fruits and vegetables are important sources of vitamins and fibre. Intervention trials have demonstrated that regular intake of a diet with a high fruit and vegetable content and reduced dairy product content lowers systolic and diastolic blood pressure [56]. Observational studies have shown a lower incidence of cerebral or coronary vascular attacks in regular fruit and vegetable consumers.

Antioxidant vitamins have beneficial effects on cardiovascular risk factors in laboratory experiments. Most epidemiological observation studies have shown negative associations between the intake of vitamin E or carotenoids [57] and CVD. Similarly, leaf vegetable vitamins have a clear impact on homocysteine levels, another vascular risk factor. However, when intervention therapeutic trials were conducted, results were disappointing, showing at best no protective effect of vitamin supplements.

ALCOHOL

In the population, the connection between alcohol use and mortality follows a U- or J-shaped curve. Optimum consumption ranges between 10 and 30 g of alcohol per day for men, and is lower for women [58]. Reduced coronary mortality is the major cause for the reduction in mortality, with no evidence of higher benefit with any specific type of drink [59]. Conversely, 'binge drinking' is associated with a higher risk of sudden death and cerebrovascular stroke. No randomized study proved the benefit of alcohol in the prevention of CVD.

SALT

Sodium intake affects arterial pressure levels. Community-based intervention studies and meta-analyses of randomized trials have shown that a reduction in salt intake resulted in reduced arterial blood pressure in normo- and hypertensive subjects.

ASSESSMENT OF FOOD INTAKE

Quantitative dietary assessment methods consist of recalls or food records designed to measure the quantity of individual foods consumed over a given period. Nutrient intake can be calculated from food consumption data collected by quantitative or semi-quantitative methods using computer programs adapted to each country.

Qualitative dietary assessment methods include food frequency questionnaires and dietary history. Both collect retrospective information of the patterns of food use during a longer, less precise time period. They are most frequently used to assess habitual intake of foods in clinical settings.

Practical aspects of nutritional prevention of cardiovascular diseases

The principal objective of dietary intervention is to control risk factors to prevent the formation and rupture of the atheromatous plaque. Dietary recommendations should be individually adapted taking into account the patient's risk profile and eating habits as well as the cultural characteristics. The general nutritional recommendations for high cardiovascular risk patients are presented in Table 9.12.

Table 9.12 General recommendation on nutrients and foods for high cardiovascular risk subjects

Keep a varied and well-balanced diet
Control body weight by adapting energy intake to needs and perform exercise regularly
Consume fish regularly
Consume fruits and vegetables, cereals and grain products
Choose skimmed milk and low-fat cheeses
Choose lean meat and poultry instead of fat meat and processed meat
Choose vegetal oils and margarines rich in mono- and polyunsaturated fatty acids instead of hard margarines and butter
Reduce salt-rich processed food, salty ready-cooked foods

General issues

- A varied and balanced diet and regular exercise are critical to the preservation of good cardiovascular health.
- It is appropriate to eat fish because the n-3 fatty acids which they contain protect against fatal cardiovascular events.
- It is recommended to eat fruits and vegetables, cereals and grain products, skimmed dairy products and low-fat meat.
- To maintain the ideal weight the intake of calories should be adjusted to energy expenditure by restricting fatty products and products with a high caloric density.
- The total lipid intake should not exceed 30% of calorie intake. The saturated fatty acid intake should not exceed 30% of total lipids and should be replaced by monounsaturated or polyunsaturated fats of vegetal origin.
- The cholesterol intake should be less than 300 mg/day.

Nutritional treatment of dyslipidaemias

- Reduction of blood LDL-cholesterol is the main objective of dietary treatment of subjects at high cardiovascular risk, aiming at less saturated and trans fatty acid intake, and, to a smaller degree, food cholesterol intake. The primary sources of trans and saturated fatty acids are hard margarines and products of animal origin, such as meat and dairy products.
- Increasing intake of omega-3 fatty acids from fish oils and certain vegetal oils to decrease plasma concentrations of triglycerides and prevention of sudden death.
- Increasing intake of polyunsaturated fatty acids, soluble fibres and phytosterols to reduce plasma concentrations of LDL-cholesterol.
- Exercise, body weight reduction in the obese and normalization of glycaemia in diabetic patients to increase blood HDL-cholesterol levels. However, the prescription of exercise should be adapted to the physical condition of the patient.

- Moderate use of alcohol is not contraindicated in cases of hypoalphalipoproteinaemia (low HDL-cholesterol).
- Reduction in the intake of refined sugars, which is associated with reduced concentrations of HDL-cholesterol and increased triglycerides in certain sensitive subjects. They may be replaced by complex sugars from fruits, vegetables and grain products.

Arterial pressure

Diet plays a significant part in the control of arterial pressure.

- The main nutritional targets are the control of the salt and alcohol intake, loss of weight in obese subjects and increase in potassium intake.
- The salt intake should not exceed 6 g/day and the alcohol intake should not exceed 20 g/day (two glasses). Special attention should be paid to insidious salt sources such as industrially prepared food, bread and cheese.
- A varied diet with a high fruit and vegetable content, which is an important source of potassium, and low dairy product content is also associated with lower diastolic and systolic blood pressure.

Excess weight control

A reduction in the weight of obese subjects is associated with improvement of the main risk factors.

- Weight loss is obtained by reducing calorie intake and increasing exercise.
- The calorie intake is obtained by decreasing high energy density food such as dietary lipids (9 kcal/g) and alcohol (7 kcal/g). The reduction of saturated fats of animal origin is the favoured target because of their effects on the lipoprotein profile.
- The lipid intake should be less than 30% of the energy intake.
- Aim at a weight loss from 0.5 to 1 kg/week until target weight has been achieved. Upon weight loss completion, the objective becomes to maintain a stable weight and block weight recovery. Exercise should be adjusted to the physiological condition of the patient.

In conclusion, nutritional strategies have proven to be an efficient means of reducing events in subjects at high cardiovascular risk. Therefore, all patients with manifest CVD and subjects with high cardiovascular risk should receive professional advice on food and dietary choices to lower their risk.

Obesity and problems related to obesity

Obesity and conditions related to obesity are major determinants of cardiovascular morbidity in Europe and world-wide. With technological advances, jobs have become more sedentary and production of large quantities of cheap food has increased. Smoking rates are declining in many countries whereas obesity is a growing problem world-wide; for this reason an increasing number of future cardiovascular events will be attributable to obesity. Figures from the mid-1990s indicate that obesity [defined as body mass index (BMI) at or above 30 kg/m^2] affects more than one in five in several European middle-aged populations, and less than half have normal BMI (< 25 kg/m^2). Even more alarming are reports that show increasing obesity rates in children and young people, indicating that the current favourable trends with respect to smoking and serum cholesterol may be offset by increasing effects of obesity when those who are now young approach middle age.

Despite the fact that overweight and obesity are linked to hypertension, dyslipidaemia, diabetes and thrombotic and fibrinolytic processes, as well as inflammatory reactions, findings with respect to CHD and stroke have not been consistent. Whereas serum cholesterol, smoking and high blood pressure have established roles as predictors of CVD, studies with respect to obesity are more heterogeneous, with many of the early studies showing no, or only a weak, relation with cardiovascular outcomes [60]. In later years, however, several sufficiently large studies have, in fact, demonstrated significant associations between body mass index, the most widely used measure of fatness, and CVD [61,62], although usually at a relatively high body mass index, and thus identifying limited subsets of the population at increased risk.

The inconsistent findings with respect to body mass index are, to some extent, the result of methodological problems, because body mass index does not discriminate between muscle and fat, which may be why moderately elevated levels have generally not been significantly associated with CVD. In addition, BMI does not take the distribution of excess fat into account. Several studies indicate that abdominal fat, as measured by the waist to hip ratio, is a more important predictor than BMI [8]. Another methodological problem is that many studies have used multivariate techniques to investigate whether the effect of obesity is independent of hypertension and dyslipidaemia, conditions that are a result of excess body fat. Even though obesity alone may not be sufficient to produce cardiovascular complications, this is an approach that will lead to an underestimation of the effects of obesity.

In later years there is more than sufficient documentation to support the role of obesity in the pathogenesis of CVD, either directly or via intervening factors. Several studies show increasing risk of myocardial infarction, coronary deaths and stroke with increasing BMI, or abdominal obesity. Recent autopsy studies in young men and women have demonstrated that obesity is associated with more extensive and severe early atherosclerotic lesions [63,64]. Some studies have indicated that the optimal BMI with respect to coronary disease and stroke is probably in the lower reference range [65,66]. Even so, measures of obesity are still not included in cardiovascular risk prediction, probably mostly as a result of the methodological problems and inconsistencies in prior research.

Overweight and abdominal obesity are associated with several adverse factors, such as low HDL-cholesterol, high serum triglycerides, small and dense atherogenic LDL, hypertension, glucose intolerance, insulin resistance and diabetes. The clustering of these factors has been termed the metabolic syndrome [67]. According to a recent definition [68], a diagnosis of metabolic syndrome can be made if a person has three or more of the following five features:

- increased waist circumference (> 102 cm in men and > 88 cm in women);
- elevated triglycerides (> 1.7 mmol/l);
- reduced HDL-cholesterol (< 1 mmol/l in men and < 1.3 mmol/l in women);
- elevated blood pressure (> 130/85 mmHg or on treatment for hypertension);
- elevated glucose (> 6.1 mmol/l).

There is a strong association between multiple metabolic risk factors and insulin resistance, and the metabolic syndrome has alternatively been termed the insulin resistance syndrome. The interactions between the various components of the metabolic syndrome and insulin resistance are complex and partly determined by genetic factors. However, the increasing prevalence of the metabolic syndrome world-wide is predominantly the result of increasing rates of overweight and obesity. In the US population, who have high obesity rates, the prevalence of the metabolic syndrome, using the definition above, was stated to be over 40% back in the early 1990s in people aged 60 years or more [69].

The current rapid increase in the prevalence of obesity is determined by environmental factors but it is equally clear that genetic factors predispose some individuals to develop overweight and obesity in the presence of abundant food. Twin, adoption and family studies have shown that genetic factors play a significant role in the pathogenesis of obesity. However, in the absence of environmental factors, obesity will not develop.

Treatment of obesity, once established, is notoriously difficult. Although there is evidence for short-term effects with medical treatment (orlistat, sibutramine) the relapse rate remains high. New potential anti-obesity drugs currently undergoing phase III trials, such as rimonabant, may produce greater and more prolonged weight loss [70]. Surgical intervention has been demonstrated to be associated with sustained weight loss in patients with a BMI between 35 and 40 kg/m^2 but is an option only in a small proportion of all overweight and obese people. Curbing the effect of the current high prevalence of overweight or obesity will accordingly have to rest with prevention, particularly in children and young people but there is, as yet, little sign of abatement in the current epidemic.

Lipids

Lipid metabolism is complex and regulated by several processes [71]. Most of the cholesterol in blood plasma is normally carried as LDL, and, over a wide range of cholesterol concentrations, there is a strong and graded positive association in men and women between total as well as LDL-cholesterol and the risk of CVD [72]. A 25-year follow-up of the populations of the Seven Countries Study [73] showed that the relative risk associated with high as opposed to low serum cholesterol was virtually identical in men from Finland, Italy, Greece, the Netherlands, and the former Yugoslavia, with Japan, which had only very few cases, as the only exception. However, the absolute risk associated with any particular level of serum cholesterol varied markedly between different countries. Coronary artery disease is rare in populations with total cholesterol less than 3–4 mmol/l, even in the presence of other risk factors, but even in a very-low-risk population with low cholesterol levels, such as the Chinese, an association has been found between serum cholesterol and coronary mortality [74].

By itself, hypercholesterolaemia produces no symptoms; it is only an indicator of elevated risk. Except in those rare cases with inherited lipid disorders, such as familial hypercholesterolaemia, an elevated serum cholesterol can be associated with almost any risk of developing coronary disease. In an otherwise healthy non-smoking woman the risk may be next to negligible, but the risk increases with the number of other risk factors and can be up to 10 times higher in a man of the same age who is also a smoker [75]. The highest absolute risk associated with high serum cholesterol is run by people who already have manifest coronary disease or who have diabetes.

In contrast to LDL-cholesterol, increased concentrations of HDL-cholesterol protect against atherosclerotic

disease in populations at high risk. The cardioprotective effects of HDL-cholesterol have been attributed to reverse cholesterol transport, positive effects on endothelial cells, and to antioxidant activity [76]. Elevated serum triglycerides are associated with increased risk of CVD but the association is not as strong, nor as consistent, as it is for serum cholesterol. Low HDL levels and increased triglycerides are both components of the metabolic syndrome, and are also associated with a number of other adverse factors, for example type 2 diabetes, hypertension, low physical activity, obesity and low consumption of fruits and vegetables. Statistically, lipid fractions in the blood are highly intercorrelated; in particular, there is an inverse correlation between serum triglycerides and HDL-cholesterol. Accordingly, an independent role for serum triglycerides has been difficult to establish. However, given the complex pathophysiology concerning lipids and atherosclerotic disease, the concept of statistical independence does little to enhance our understanding of the role of triglycerides in risk. Even so, a meta-analysis of 17 population-based studies, comprising more than 46 000 men and more than 10 000 women, showed that risk of CVD in fact does increase with increasing degrees of hypertriglyceridaemia, independently of serum cholesterol [77]. The effect of serum triglycerides seems to be stronger for women than for men [72].

Drug treatment of dyslipidaemia

Pharmacological agents that reduce serum cholesterol have long been available. However, the WHO clofibrate trial published in the early 1980s [78], which showed that patients on active treatment, although they had significantly fewer coronary events, had higher all-cause mortality, led to therapeutic nihilism that lasted for more than a decade. In 1994, the 4S study was published [79]. This was the first large study that unequivocally demonstrated a survival advantage in coronary patients on active treatment with a statin. This study, and several more large placebo-controlled trials, have clearly demonstrated that patients with coronary disease benefit from cholesterol-lowering treatment, with an estimated 20–40% reduction in coronary events, almost regardless of initial serum cholesterol level [80]. Likewise, recent primary prevention trials have demonstrated significant reductions in coronary events [81] (Fig. 9.6).

Data derived from several sources show a log-linear relation between LDL-cholesterol and risk of coronary disease. As the absolute reduction in LDL-cholesterol induced by cholesterol-lowering drugs will be larger with higher initial levels and, as the relation between LDL-cholesterol is curvilinear, this larger reduction will result in a proportionately greater net reduction in coronary events. In terms of reduction in absolute risk in a particular individual, the reduction will be determined as much by his or her overall coronary risk, as by the initial cholesterol level. The presence of coronary disease, diabetes, or an accumulation of other risk factors means a higher absolute risk and the same net benefit in terms of reduced coronary events can therefore be expected at lower lipid levels in patients with any of these conditions. In contrast to findings for CHD, plasma cholesterol is not associated with overall rates of stroke [83].

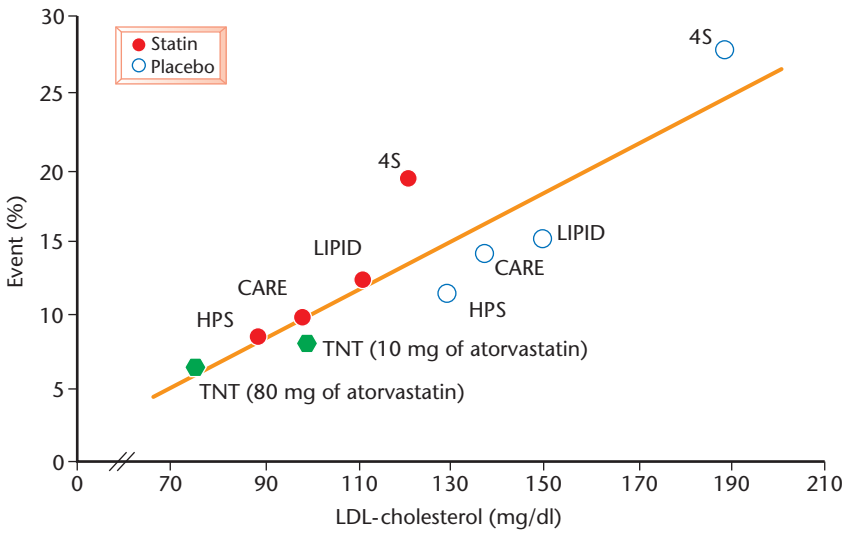

Figure 9.6 Event rates plotted against LDL-cholesterol levels during statin therapy in secondary-prevention studies. HPS denotes the Heart Protection Study, CARE denotes the Cholesterol and Recurrent Events Trial, LIPID denotes the Long-term Intervention with Pravastatin in Ischaemic Disease study and 4S denotes the Scandinavian Simvastatin Survival Study. Event rates for HPS, CARE and LIPID are for death from CHD and non-fatal myocardial infarction. Event rates for 4S and the TNT Study (82) also include resuscitation after cardiac arrest. To convert values for LDL-cholesterol to mmol/l, multiply by 0.02586. Reproduced with permission from LaRosa JC *et al*. Intensive lipid lowering with atorvastatin in patients with stable coronary disease. *N Engl J Med* 2005; **352**: 1425–1435.

From a population perspective, pharmacological treatment of a subset of the population with high cholesterol levels will achieve comparatively little. Several Western countries have, in fact, experienced important decreases in mortality from CHD during the last decades, resulting from life-style changes. One example is Finland, which has experienced a very large decrease in CHD mortality since 1970. During the same period serum cholesterol levels in middle-aged men decreased from approximately 7 mmol/l to below 6.5 mmol/l and intake per day of saturated fat from liquid dairy products and spreadable fat decreased from 45 to 16 g in men [84].

In terms of life-years saved or coronary events avoided a population strategy makes more sense as the reduction in risk factors and attack rate will also involve those with moderately increased levels and the intervention will be targeted at more than one risk factor. Optimal serum cholesterol, as defined by the European guidelines as being a serum cholesterol < 5 mmol/l, is found in a minority of European middle-aged populations. If normotension, normal weight and non-smoking are added, only a tiny fraction have truly optimal risk factor status [85]. Most cases of coronary disease occur in the large group in the population with combinations of moderately elevated levels of risk factors. From a population perspective, intervention only in persons with high cholesterol will achieve comparatively little with respect to reduction in coronary disease incidence and mortality.

When faced with an individual patient with high serum cholesterol, however, the aim must be to attempt to minimize risk in that individual patient. Evidence from the trials shows unequivocally that treatment prevents coronary disease in patients at high risk. In accordance with the recommendations on prevention of coronary disease from the Joint European Societies and other national recommendations this will mean not only treatment with a statin in an important number of patients, but also aiming for reducing overall risk. This will involve anti-smoking advice, treatment of hypertension, weight-reducing regimens and advice on physical activity, whenever appropriate. Although the reduction in risk achieved by treatment is more or less the same regardless of initial risk the gain in terms of absolute risk is greater the higher the risk in the individual.

Current European recommendations hold that, in general, total plasma cholesterol should be < 5 mmol/l (< 190 mg/dl), and LDL-cholesterol should be < 3 mmol/l (< 115 mg/dl). Concentrations of HDL-cholesterol and triglycerides are not used as goals of therapy, but as markers of increased risk [HDL-cholesterol < 1.0 mmol/l (< 40 mg/dl) in men and < 1.2 mmol/l (> 46 mg/dl) in women; fasting triglycerides > 1.7 mmol/l (> 150 mg/dl)]. A recent small study found that a combination regimen (gemfibrozil, niacin and cholestyramine) aimed at increasing HDL-cholesterol levels prevented angiographic progression of coronary stenosis, and may have helped towards preventing cardiovascular events, when added to regular exercise and a low-fat diet [86].

Patients with established CVD, and patients at high risk of developing CVD, whose untreated values of total and LDL-cholesterol are already close to 5 and 3 mmol/l, respectively, benefit from further reduction of total cholesterol and LDL-cholesterol with moderate doses of lipid-lowering drugs. Use of higher doses of lipid-lowering agents has not yet been sufficiently well documented in unselected patients who are close to treatment targets.

In asymptomatic subjects (see Fig. 9.7), the first step is to assess total cardiovascular risk. If the 10-year risk of cardiovascular death is < 5%, even if projected to age 60, advice concerning diet, physical activity and smoking should be given to keep the cardiovascular risk low. If the 10-year risk of cardiovascular death is ≥ 5%, or will

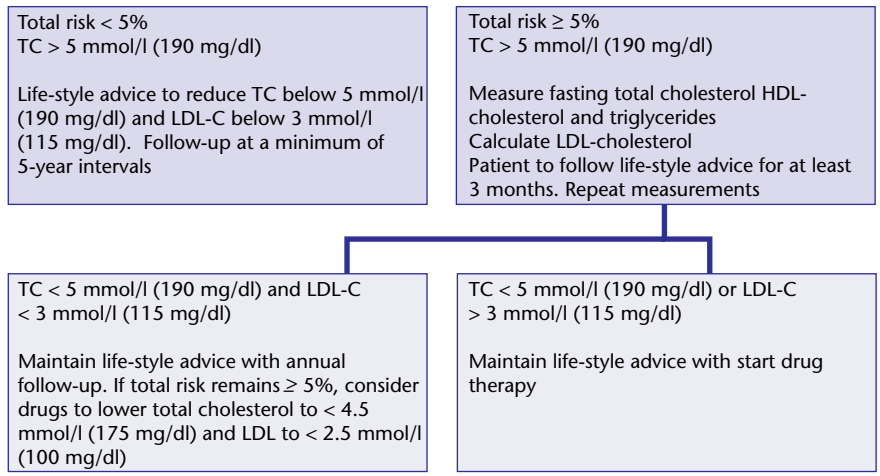

Figure 9.7 Guide to lipid management in asymptomatic subjects.

become ≥ 5% if the subjects' risk factor combination is projected to age 60, serum LDL-cholesterol, HDL-cholesterol and triglyceride should be analysed and intensive life-style advice should be given. If total and LDL-cholesterol levels < 5 mmol/l and < 3 mmol/l, respectively, are achieved, and the total CVD death risk estimate has become < 5%, yearly follow-up is warranted to ensure that cardiovascular risk remains low. If total CVD risk remains elevated or progresses to ≥ 5%, lipid-lowering drug therapy should be considered to lower total and LDL-cholesterol. Current European recommendations in high-risk individuals are to lower total cholesterol to < 4.5 mmol/l and to lower LDL-cholesterol to < 2.5 mmol/l. However, these values are not therapy targets for patients with lower untreated values. To achieve target values combination therapy will have to be used in some patients. Even with maximal therapy, targets will not be achieved in some patients, but they will still benefit from treatment.

Psychosocial factors

During the last two decades, considerable evidence has accumulated with respect to the association of markers of stress and other psychosocial factors with coronary disease [87,88]. However, compared to other major risk factors, psychosocial variables are more difficult to define objectively because several different dimensions are involved. Despite this, several separate constructs within the broad conceptual framework of psychosocial factors are increasingly considered as being causally related to CHD. Stress at work and in family life, life events, low perceived control, lack of social support, socioeconomic status, and depression are some of the dimensions that have been shown to either influence the risk of CHD or affect prognosis in CHD patients [3,88–99].

There are several methodological problems in the study of psychosocial factors and health outcomes. First, compared to other biological and life-style risk factors, psychosocial factors represent a more problematic construct in that there is little uniformity with respect to either definition or measurement of these factors. Second, most of the dimensions involved are subjective, and hence potentially open to biases and confounding. Third, even though some persons may be more vulnerable than others with respect to adverse circumstances, exposure probably varies considerably over a lifetime, and hence, prospective follow-up studies with extended follow-up may not adequately capture short-term influences.

According to popular opinion, stress is one of the most important risk factors for CHD but this view has not so far been altogether accepted by the medical profession. However, accumulating evidence does, in fact, demonstrate that it is likely that stress is causally related to CHD, and possibly even to stroke. To date, most studies have dealt with stress at work, with stress outside the workplace receiving less attention. Both cross-sectional and prospective studies have demonstrated a positive association between level of work stress and disease [92,94,100–102]. Even so, not all studies have found an association between indices of job stress [103]. It has also been held that associations between stress and coronary disease are mainly the result of confounding by low socioeconomic status [103] or may be spurious, because people with stress tend to report more symptoms [104].

Shift work has been described as increasing future risk of CHD, both in women and men. Decreased heart-rate variability, a marker of autonomic imbalance, has been related to exposure to shift work [105]. In the Helsinki Heart Study shift workers, who had a 50% excess risk of CHD over day workers, exhibited large increases in perceived job stress, suggesting a direct stress-related mechanism explaining part of the CHD risk [106].

In addition to perceived stress at work, stressful conditions in family life have been shown to increase CHD risk. In women in Stockholm, marital discord was found to worsen prognosis in acute coronary syndrome and reduce event-free survival over and above the effects of standard clinical prognostic factors [97]. Although all women were employed outside the home, the hazards of marital stress were stronger than those of stress at work in these women. Other measures of stress have also been used. In a prospective survey of middle-aged Swedish men, self-reported permanent stress was associated with an increased risk of incident CHD (OR 1.5; 95% CI 1.2–1.9) after adjustment for conventional coronary risk factors during a 12-year follow-up [95]. Similar results were observed in a large prospective study involving 281 cases in 73 424 Japanese men and women, which reported an association between perceived mental stress and CHD mortality [93].

Clinical depression, depressive symptoms and other negative emotions have been associated with an increased risk of CHD incidence in both men and women [89,107]. In established CHD, clinical depression is associated with a three-fold risk for recurrent major cardiac events [108], particularly if there was also a lack of social support [109].

Some studies have investigated the effect of external influences such as financial stress or life events on risk of coronary disease. In a previous case–control study, having experienced one life event or more during the year preceding an acute myocardial infarction study and dissatisfaction with one's financial situation was twice as common among cases than controls in men, but no significant relation was found in women [100]. An extreme external stressor such as the death of a child was

demonstrated to be associated with increased risk of future acute myocardial infarction in a Danish registry-based study [91].

Men and women with low socioeconomic status have an increased risk of coronary disease. Several population-based studies have examined this question [96,110,111]. Controlling for standard risk factors reduced the size of the gradient, but a relevant proportion of the variance according to socioeconomic status was explained by distinct psychosocial factors which either mediate or modify the effect of socioeconomic status on CHD [112,113].

People with poor social networks have been demonstrated to have higher mortality from several causes [114]. However, data are less consistent with respect to the effect of social ties and activities on CVD, but some studies have reported an association with coronary disease [89]. Similarly, lack of social support leads to decreased survival and poorer prognosis among people with clinical manifestations of CVD [115].

The mechanism by which psychosocial factors increase the risk of CVD is complex. In experimental studies worsened coronary atherosclerosis [116] and endothelial dysfunction [117] occur in response to social disruption. Several studies have demonstrated links between psychosocial variables and vascular function, inflammation, increased blood clotting and decreased fibrinolysis. The exact pathophysiological nature of the influence of psychosocial factors remains to be determined, as does the temporal sequence of events.

Gender aspects in cardiovascular disease, risk factors and prevention

In both men and women, acute myocardial infarction arises as a complication of coronary atherosclerosis. Although the incidence of acute myocardial infarction increases sharply with age, women are less prone to develop it than men at any given age, with an approximate 9- to 10-year difference between the sexes. Below the age of 65, approximately four times as many men as women develop acute myocardial infarction, with corresponding differences in coronary death rates. The difference in mortality and morbidity diminishes with age, but even at ages between 75 and 85, the incidence is almost two-fold in men compared to women. Eventually, however, almost as many women as men die from coronary disease and in large parts of the world, CHD is the most important single cause of death in both men and women. After acute myocardial infarction, the prognosis is by and large similar, however, women stand to lose more because of their longer life expectancy. The sex difference with respect to stroke is less marked, but at least in the age span below 65, stroke is twice as common in men as in women.

Smoking may be a stronger risk factor for acute myocardial infarction in middle-aged women than in men, but relative risks associated with serum total cholesterol and blood pressure are similar [75]. However, serum triglycerides, which are strongly related to obesity, have been demonstrated to be a better predictor of future coronary events in women, compared to men [72]. Risk factors for stroke are similar in women and men [118]. The INTERHEART case–control study demonstrated similar odds ratios for acute myocardial infarction in women and men for most risk factors, including smoking, but the increased risk associated with hypertension and diabetes seemed to be greater in women than in men [8]. Because smoking is more prevalent among men than in women in most nations of the world, more cases of acute myocardial infarction are attributable to this factor among men, compared to women, whereas hypertension and diabetes cause proportionately more acute myocardial infarctions among women than among men.

In primary prevention, the higher absolute risk among men in a 5- or 10-year perspective should be taken into account, for example when pharmacological treatment of hypertension or hypercholesterolaemia is being considered. In a lifetime perspective, however, the absolute risk among women is not much different from that among men. Hence, life-style modifications with respect to anti-smoking advice, diet, physical activity and avoidance of obesity should be the same, irrespective of gender. Among people who already have manifest CVD, or diabetes, preventive efforts should be the same for men and women.

Personal perspective

Genetic disposition and behavioural and environmental factors are the main contributors to the onset or to the recurrence of cardiovascular disease. Ameliorating the last two is a rewarding challenge for the physician as effective and evidence-based methods are available.

Prevention commences with detecting and assessing risk: marked raised levels of single risk factors (total cholesterol, LDL-cholesterol, blood pressure) or of total risk as a result of multiple risk factors (using the SCORE algorithm or HeartScore), the presence of CVD, type 2 diabetes mellitus, or type 1 diabetes mellitus with microalbuminuria.

Modification of risk should be tailored to the needs of the individual patient. It includes life-style management and the use of pharmacotherapy, if considered appropriate. This may demand the efforts of a multidisciplinary team, which should act under the guidance of a cardiologist. The main targets of risk modification are a cessation of smoking, an active life-style with daily 30–60 minutes of physical activity on at least a moderate level, making healthy food choices and reducing excess weight, preserving normal levels of blood pressure and lipids. Psychosocial support and stress-coping techniques may be needed and gender differences should be considered.

The cardiologist has a decisive initial role in motivating the patient to commit to a healthy life-style once significantly raised risk and/or the presence of cardiovascular disease has been confirmed. Yet, special attention should be paid to a lasting maintenance of risk reduction, for which long-term follow-up in cooperation with the family doctor is mandatory.

10 Hypertension

Sverre E. Kjeldsen, Henrik M. Reims, Robert Fagard and Giuseppe Mancia

Summary

Hypertension, usually defined as persistent blood pressure at 140/90 mmHg or higher, affects about a quarter of the adult population in many countries and particularly in Western societies. Hypertension is a risk factor for most, if not all, cardiovascular diseases and renal failure. While blood pressure should be measured repeatedly for the diagnosis, new techniques such as 24-hour ambulatory blood pressure and self-measured home blood pressure taking are increasingly being used for diagnosis and assessment during treatment. Modern work-up of hypertensive patients focuses on the detection of target organ damage, i.e. left ventricular hypertrophy and renal effects including microalbuminuria.

While diagnosis of secondary causes of hypertension should be kept in mind, the detection of concomitant diseases or risk factors should be clearly identified for the purposes of assessing total cardiovascular risk and choosing the optimal treatments. While life-style changes may be appropriate, i.e. increase physical exercise, reduce body weight if needed, and eat healthily, these kinds of interventions should not unnecessarily delay initiation of drug treatment for hypertension when clearly indicated. Drug treatment has repeatedly proven effective in outcome studies in preventing stroke, heart failure, deteriorated renal function, new onset diabetes and, to some extent, coronary heart disease and other complications. Modern drug treatment of hypertension usually contains a combination of well-tolerated doses of two or more drugs aiming at blood pressure below 140/90 mmHg and below 130/80 mmHg in patients with diabetes and already established cardiovascular disease. Acetylsalicylic acid and statins are recommended as add-on treatment if total 10-year cardiovascular risk is above 20%.

Introduction

This chapter is based on the 2003 ESH-ESC *Guidelines for Detection, Prevention and Treatment of Arterial Hypertension* jointly issued by the European Society of Hypertension (ESH) and the European Society of Cardiology (ESC) [1]. A concise summary of these guidelines has also been published [2]. For in-depth reading of the pathophysiology and aetiology of *essential hypertension*, the most common form of hypertension, there are extensive reviews recently published [3,4].

Definition and classification of hypertension

Systolic, diastolic and pulse pressures as predictors

Both systolic and diastolic blood pressures show a continuous graded independent relationship with risk of stroke and coronary events [5]. The relationship between systolic blood pressure and relative risk of stroke is steeper than that for coronary events, reflecting a closer aetiological relationship with stroke, but the attributable risk—

Category	Systolic	Diastolic
Optimal	< 120	< 80
Normal	120–129	80–84
High–normal	130–139	85–89
Grade 1 hypertension (mild)	140–159	90–99
Grade 2 hypertension (moderate)	160–179	100–109
Grade 3 hypertension (severe)	≥ 180	≥ 110
Isolated systolic hypertension	≥ 140	< 90

When a patient's systolic and diastolic blood pressures fall into different categories, the higher category should apply. Isolated systolic hypertension can also be graded (grades 1, 2, 3), according to systolic blood pressure values in the ranges indicated, provided that diastolic values are < 90.

Table 10.1 Definitions and classification of blood pressure levels (mmHg)

excess deaths due to raised blood pressure—is greater for coronary events than stroke. However, with population ageing the relative incidence of stroke is increasing, as shown in recent randomized controlled trials [6].

The apparently simple direct relationship between increasing systolic and diastolic blood pressure levels and increasing cardiovascular risk is complicated by the relationship that normally prevails between blood pressure and age, namely systolic blood pressure rises throughout the adult age range, whereas diastolic blood pressure peaks at about age 60 years in men and 70 years in women, and falls gradually thereafter [7]. Although both the continuous rise in systolic blood pressure and the rise and fall in diastolic blood pressure with age are usual, they represent the results of some of the pathological processes that underlie 'hypertension' and cardiovascular diseases [8].

These observations help to explain why, at least in elderly populations, a wide pulse pressure (systolic blood pressure minus diastolic blood pressure) has been shown in some observational studies to be a better predictor of adverse cardiovascular outcomes than either systolic or diastolic pressures individually [9,10]. However, in the largest compilation of observational data in almost 1 million patients from 61 studies [11], both systolic and diastolic blood pressures were independently predictive of stroke and coronary mortality, and more so than pulse pressure.

In practice, given that we have randomized controlled trial data supporting the treatment of isolated systolic hypertension [12,13] and treatment based purely on diastolic entry criteria [14], we should continue to use both systolic blood and diastolic blood pressures as part of guidance for treatment thresholds.

Classification of hypertension

The continuous relationship between the level of blood pressure and cardiovascular risk makes any numerical definition and classification of hypertension arbitrary.

The real threshold of hypertension should therefore be considered a mobile one, being higher or lower on the basis of the global cardiovascular risk profile of each individual (Table 10.1). Accordingly, the definition of high normal blood pressure in Table 10.1 includes blood pressure values that may be considered as 'high' (i.e. hypertension) in high-risk subjects or fully normal in low-risk individuals.

Total cardiovascular risk

Because of the clustering of risk factors in individuals and the graded nature of the association between each risk factor and cardiovascular risk [15], a contemporary approach has been to determine threshold, at least for cholesterol and blood pressure lowering, on the basis of estimated global coronary or cardiovascular (coronary plus stroke) [16] risk over a defined relatively short-term (e.g. 5- or 10-year) period. It should be noted that although several methods may be used, most risk estimation systems are based on the Framingham study [17]. Although this database has been shown to be reasonably applicable to some European populations [18], estimates require recalibration in other populations [19] owing to important differences in the prevailing incidence of coronary and stroke events. The main disadvantage associated with intervention threshold based on relatively short-term absolute risk is that younger adults (particularly women), despite having more than one major risk factor, are unlikely to reach treatment thresholds despite being at high risk relative to their peers. By contrast, most elderly men (e.g. > 70 years) will often reach treatment thresholds although being at very little increased risk relative to their peers. This situation results in most resources being concentrated on the oldest subjects, whose potential lifespan, despite intervention, is relatively limited, and young subjects at high relative risk remain untreated despite, in the absence of intervention, a predicted significant shortening of their otherwise much longer potential lifespan [20,21].

On the basis of these considerations, total cardiovascular risk classification may be stratified as suggested in Table 10.2. The terms *low*, *moderate*, *high* and *very high*

Table 10.2 Stratification of risk to quantify prognosis

	Blood pressure (mmHg)				
Other risk factors and disease history	**Normal SBP 120–129 or DBP 80–84**	**High normal SBP 130–139 or DBP 85–89**	**Grade 1 SBP 140–159 or DBP 90–99**	**Grade 2 SBP 160–179 or DBP 100–109**	**Grade 3 SBP ≥ 180 or DBP ≥ 110**
No other risk factors	Average risk	Average risk	Low added risk	Moderate added risk	High added risk
One or two risk factors	Low added risk	Low added risk	Moderate added risk	Moderate added risk	Very high added risk
Three or more risk factors or TOD or diabetes	Moderate added risk	High added risk	High added risk	High added risk	Very high added risk
ACC	High added risk	Very high added risk	Very high added risk	Very high added risk	Very high added risk

ACC, associated clinical conditions; DBP, diastolic blood pressure; SBP, systolic blood pressure; TOD, target organ damage.

Table 10.3 Factors influencing prognosis

Risk factors for cardiovascular disease used for stratification
Levels of systolic and diastolic BP
Men > 55 years
Women > 65 years
Smoking
Dyslipidaemia (total cholesterol > 6.5 mmol/l, > 250 mg/dl*; or LDL-cholesterol > 4.0 mmol/l, > 155 mg/dl*; or HDL-cholesterol M < 1.0, W < 1.2 mmol/L, M < 40, W < 48 mg/dl)
Family history of premature cardiovascular disease (at age < 55 years M, < 65 years W)
Abdominal obesity (abdominal circumference M ≥ 102 cm, W ≥ 88 cm)
C-reactive protein ≥ 1 mg/dl

Target organ damage
Left-ventricular hypertrophy (electrocardiogram: Sokolow–Lyon > 38 mm; Cornell > 2440 mm × ms; echocardiogram: LVMI M ≥ 125, W ≥ 110 g/m^2)
Ultrasound evidence of arterial wall thickening (carotid IMT ≥ 0.9 mm) or atherosclerotic plaque
Slight increase in serum creatinine (M 115–133, W 107–124 µmol/L; M 1.3–1.5, W 1.2–1.4 mg/dl)
Microalbuminuria (30–300 mg/24 h; albumin–creatinine ratio M ≥ 22, W ≥ 31 mg/g; M ≥ 2.5, W ≥ 3.5 mg/mmol)

Diabetes mellitus
Fasting plasma glucose 7.0 mmol/l (126 mg/dl)
Postprandial plasma glucose > 11.0 mmol/l (198 mg/dl)

Associated clinical conditions
Cerebrovascular disease: ischaemic stroke; cerebral haemorrhage; transient ischaemic attack
Heart disease: myocardial infarction; angina; coronary revascularization; congestive heart failure
Renal disease: diabetic nephropathy; renal impairment (serum creatinine M > 133, W > 124 µmol/L; M > 1.5, W > 1.4 mg/dl); proteinuria (> 300 mg/24 h)
Peripheral vascular disease
Advanced retinopathy: haemorrhages or exudates; papilloedema

HDL, high-density lipoprotein; IMT, intima media thickness; LDL, low-density lipoprotein; LVMI, left-ventricular mass index; M, men; W, women.
*Lower levels of total and LDL-cholesterol are known to delineate increased risk, but they were not used in the stratification.

added risk are calibrated to indicate, approximately, an absolute 10-year risk of cardiovascular disease of < 15%, 15–20%, 20–30% and > 30%, respectively, according to Framingham criteria [17] or an approximate absolute risk of fatal cardiovascular disease < 4%, 4–5%, 5–8%, and > 8% according to the SCORE chart [22].

Table 10.3 indicates the most common risk factors, target organ damage (TOD), diabetes and associated clinical conditions (ACCs) to be used to stratify risk.

1 Obesity is indicated as 'abdominal obesity' in order to give specific attention to an important sign of the metabolic syndrome [23].
2 Diabetes is listed as a separate criterion in order to underline its importance as risk, at least twice as large as in absence of diabetes [24].
3 Microalbuminuria is indicated as a sign of TOD, but proteinuria as a sign of renal disease (ACC).
4 Slight elevation of serum creatinine as sign of TOD

is indicated as a serum creatinine concentration of 115–133 μmol/l (1.3–1.5 mg/dl) in men and 107–124 μmol/l (1.2–1.4 mg/dl) in women, and concentrations > 133 μmol/L (> 1.5 mg/dl) in men and > 124 μmol/l (> 1.4 mg/dl) in women as ACC [25,26].

5 Generalized or focal narrowing of the retinal arteries is omitted among signs of TOD, as too frequently seen in subjects aged 50 years or older [27], but retinal haemorrhages and exudates as well as papilloedema are retained as ACCs.

Diagnostic evaluation

In hypertension, diagnostic procedures are aimed at (1) establishing the blood pressure levels, (2) excluding or identifying secondary causes of hypertension and (3) evaluating the overall cardiovascular risk of the subject by searching for other risk factors, TOD and concomitant diseases or accompanying clinical conditions.

The diagnostic procedures consist of:

- repeated blood pressure measurements;
- medical history;
- physical examination;
- laboratory and instrumental investigations, some of which should be considered essential in all subjects with high blood pressure, some are recommended and may be used extensively, some are useful only when suggested by some of the more widely recommended examinations or the clinical course of the patient.

Blood pressure measurement

Blood pressure is characterized by large spontaneous variations both within the 24 h and between days. The diagnosis of hypertension should thus be based on multiple blood pressure measurements, taken on separate occasions. If blood pressure is only slightly elevated, repeated measurements should be obtained over a period of several months to define as accurately as possible the patient's 'usual' blood pressure. If, on the other hand, the patient has a more marked blood pressure elevation, evidence of hypertension-related organ damage or a high or very high cardiovascular risk profile, repeated measurements should be obtained over shorter periods of time, i.e. weeks or days. Blood pressures can be measured by the doctor or the nurse in the office or in the clinic (office or clinic blood pressure), by the patient at home or automatically over the 24 h. These procedures can be summarized as follows [28].

Office or clinic blood pressure measurement

Blood pressure can be measured by a mercury sphygmomanometer, whose various parts (rubber tubes, valves, quantity of mercury, etc.) should be kept in proper condition. Other non-invasive devices (aneroid and auscultatory or oscillometric semi-automatic devices) can also be used and will indeed become increasingly important because of the progressive banning of medical use of mercury. These devices, however, should be validated according to standardized protocols [29] and their accuracy should be periodically checked by comparison with mercury sphygmomanometric values.

Ambulatory blood pressure measurement

Several devices (mostly oscillometric) are available for automatic blood pressure measurements in patients who are allowed to conduct a near-normal life. This allows information to be obtained on 24-h average blood pressure, as well as on average blood pressure values on more restricted portions of the 24 h, such as the day, the night and the morning [28]. This information should not be regarded as a substitute for information derived from conventional blood pressure measurements. It may be considered, however, of additional clinical value because cross-sectional and longitudinal studies have shown that office blood pressure has a limited relationship with 24-h, and thus daily life, blood pressure [30]. These studies have also shown that ambulatory blood pressure: (1) correlates with the TOD of hypertension more closely than office blood pressure [31–34], (2) predicts, both in populations and in hypertensive patients, the cardiovascular risk more and above the prediction provided by office blood pressure values [35–38] and (3) measures more accurately than office blood pressure the extent of blood pressure reduction induced by treatment, because of the absence of a 'white coat' [39], a placebo [40] effect and a higher reproducibility over time [41]. Although some of the above advantages can be obtained by increasing the number of office blood pressure measurements [42], 24-h ambulatory blood pressure monitoring before and during treatment can be recommended at the time of diagnosis and, occasionally, during treatment, whenever the facilities make it possible.

When measuring 24-h blood pressure [28] care should be taken to:

- Use only devices validated by international standardized protocols.
- Use cuffs of appropriate size and compare the initial values with those from a sphygmomanometer to check that the differences are not greater than ± 5 mmHg.
- Set the automatic readings at no more than 30-min intervals to obtain an adequate number of values and

have most hours represented if some readings are rejected because of artefacts.
- Instruct the patients to engage in normal activities but to refrain from strenuous exercise, and to keep the arm extended and still at the time of cuff inflations.
- Ask the patient to provide information in a diary on unusual events, and on duration and quality of night sleep; although in the population and the hypertensive patients at large day and night blood pressures normally show a close correlation, there is evidence that subjects in whom nocturnal hypotension is blunted and thus exhibit a relatively high night blood pressure may have an unfavourable prognosis [43].
- Obtain another ambulatory blood pressure monitoring if the first examination has less than 70% of the expected values because of a high number of artefacts.
- Remember that ambulatory blood pressure is usually several mmHg lower than office blood pressure [44–46]. As shown in Table 10.4, in the population office values of 140/90 mmHg correspond to about 125/80 mmHg 24-hour systolic and diastolic blood pressure average values, and to about 135/85 mmHg daytime average values. These values may be approximately taken as the threshold values for diagnosing hypertension by ambulatory blood pressure.
- Base clinical judgement on average 24-h, day or night values only; other information derivable from ambulatory blood pressure (e.g. blood pressure standard deviations, trough–peak ratio, smoothness index) is clinically promising but is still in the research phase.

Table 10.4 Blood pressure thresholds (mmHg) for definition of hypertension with different types of measurement

	Systolic	Diastolic
Office or clinic	140	90
24-hour ambulatory	125	80
Daytime ambulatory	135	85
Night-time ambulatory	120	70
Home (self)	135	85

Home blood pressure

Self-measurements of blood pressure at home cannot provide the extensive information on 24-h blood pressure values provided by ambulatory blood pressure monitoring. It can provide, however, values on different days in a setting close to daily life conditions. When averaged over a period of a few days these values have been shown to share some of the advantages of ambulatory blood pressure, i.e. to have no white coat effect and to be more reproducible and predictive of the presence and progression of organ damage than office values [31,47]. Home blood pressure measurements for suitable periods (e.g. a few weeks) before and during treatment can therefore be recommended also because this relatively cheap procedure may improve the patient's adherence to treatment regimens [48].

When advising self-measurement of blood pressure at home, care [28] should be taken to:
- Advise only use of validated devices; not one of the present available wrist devices for measurement of blood pressure is satisfactorily validated—should any of these wrist devices become validated, the subject should receive recommendation to keep the arm at heart level during measurement.
- Use semi-automatic devices rather than mercury sphygmomanometer to avoid the difficulty posed by patient's instruction and the error originated from hearing problems in elderly individuals.
- Instruct the patient to perform measurement in the sitting position after several minutes' rest—inform him or her that values may differ between measurements because of spontaneous blood pressure variability.
- Avoid asking for an excessive number of values to be measured and ensure that measurements include the period prior to drug intake to have information on duration of the treatment effect.
- Remember that, as for ambulatory blood pressure, normality values are lower for home than office blood pressure—take 135/85 mmHg as the values of home blood pressure corresponding to 140/90 mmHg measured in the office or clinic (Table 10.4).
- Give the patient clear instructions on the need to provide the doctor with proper documentation of the measured values and to avoid self-alterations of the treatment regimens.

Isolated office or white coat hypertension

In some patients, office blood pressure is persistently elevated, whereas daytime or 24-h blood pressure falls within their normality range. This condition is widely known as '*white coat hypertension*' [49], although the more descriptive and less mechanistic term '*isolated office (or clinic) hypertension*' is preferable because the office ambulatory blood pressure difference does not correlate with the office blood pressure elevation induced by the alerting response to the doctor or the nurse, i.e. the true '*white coat effect*' [50]. Regardless of the terminology, evidence is now available that isolated office hypertension is not infrequent (about 10% in the general population) [51] and that it accounts for a noticeable fraction of individuals in whom hypertension is diagnosed. There is also

evidence that in individuals with isolated office hypertension cardiovascular risk is less than in individuals with both office and ambulatory blood pressure elevations [51]. Several, although not all, studies, however, have reported this condition to be associated with a prevalence of organ damage and metabolic abnormalities greater than those of normal subjects, which suggests that it may not be an entirely innocent phenomenon [52].

Physicians should diagnose isolated office hypertension whenever office blood pressure is >140/90 mmHg at several visits, whereas 24-h and daytime ambulatory blood pressure are <125/80 and <135/85 mmHg respectively. Diagnosis can also be based on home blood pressure values (average of several day readings <135/85 mmHg). Identification should be followed by search for metabolic risk factors and TOD. Drug treatment should be instituted when there is evidence of organ damage or a high cardiovascular risk profile. However, lifestyle changes and a close follow-up should be implemented in all patients with isolated office hypertension in whom the doctor elects not to start pharmacological treatment.

Although less frequently, the reverse phenomenon of 'white coat hypertension' may occur, namely individuals with normal office blood pressure (< 140/90 mmHg) may have elevated ambulatory blood pressure values ('isolated ambulatory or masked hypertension') [52–55]. These individuals have been shown to display a greater than normal prevalence of TOD [56] and may have a greater cardiovascular risk than truly normotensive individuals [54,55].

Family and clinical history

A comprehensive family history should be obtained, with particular attention to hypertension, diabetes, dyslipidaemia, premature coronary heart disease, stroke or renal disease.

Clinical history should include: (1) duration and previous levels of high blood pressure, (2) symptoms suggestive of secondary causes of hypertension and intake of drugs or substances that can raise blood pressure, such as liquorice, cocaine, amphetamines; oral contraceptives, steroids, non-steroidal anti-inflammatory drugs, erythropoietin and cyclosporins, (3) lifestyle factors, such as dietary intake of fat (animal fat in particular), salt and alcohol, quantification of smoking and physical activity, weight gain since early adult life, (4) past history or current symptoms of coronary disease, heart failure, cerebrovascular or peripheral vascular disease, renal disease, diabetes mellitus, gout, dyslipidaemia, bronchospasm or any other significant illnesses, and drugs used to treat those conditions, (5) previous antihypertensive therapy, its results and adverse effects; and (6) personal, family and environmental factors that may influence blood pressure and cardiovascular risk, as well as the course and outcome of therapy.

Physical examination

In addition to blood pressure measurement, physical examination should search for evidence of additional risk factors (in particular abdominal obesity), for signs suggesting secondary hypertension, and for evidence of organ damage.

Laboratory investigations

Laboratory investigations are also aimed at providing evidence of additional risk factors, at searching for hints of secondary hypertension and at assessing absence or presence of TOD. The younger the patient, the higher the blood pressure and the faster the development of hypertension, the more detailed the diagnostic work-up will be.

Essential laboratory investigations should include: blood chemistry for fasting glucose, total cholesterol, HDL-cholesterol, triglycerides, urate, creatinine, sodium, potassium, haemoglobin and haematocrit; urinalysis (dipstick test complemented by urine sediment examination); and an electrocardiogram. Whenever fasting glucose is above 6.1 mmol/l (110 mg/dl), post-prandial blood glucose should also be measured or a glucose tolerance test performed [57]. A fasting glucose of 7.0 mmol/l (126 mg/dl) or a 2-h post-prandial glucose of 11 mmol/l (198 mg/dl) is now considered threshold value for diabetes mellitus [57].

Searching for target organ damage

Owing to the importance of TOD in determining the overall cardiovascular risk of the hypertensive patient, evidence of organ involvement should be sought carefully. Recent studies have shown that without ultrasound cardiovascular investigations for left-ventricular hypertrophy and vascular (carotid) wall thickening or plaque, up to 50% of hypertensive subjects may be mistakenly classified as at low or moderate added risk, whereas presence of cardiac or vascular damage stratifies them within a higher risk group. Likewise, searching for microalbuminuria can be strongly recommended because of the mounting evidence that it may be a sensitive marker of organ damage, not only in diabetes, but also in hypertension.

Heart

Electrocardiography should be part of all routine assessment of subjects with high blood pressure. Its sensitivity

to detect left-ventricular hypertrophy is low but, nonetheless, hypertrophy detected by the Sokolow–Lyon index or of the Cornell voltage QRS duration product is an independent predictor of cardiovascular events [58]. Electrocardiography can also be used to detect patterns of ventricular overload ('strain'), known to indicate more severe risk [58], ischaemia, conduction defects and arrhythmias. Echocardiography is undoubtedly much more sensitive than electrocardiography in diagnosing left-ventricular hypertrophy [59] and predicting cardiovascular risk [60]. An echocardiographic examination may help in more precisely classifying the overall risk of the hypertensive patient and in directing therapy. The best evaluation includes measurements of interventricular septum and posterior wall thickness and of end-diastolic left-ventricular diameter, with calculation of left-ventricular mass according to available formulae [61]. Classifications in concentric or eccentric hypertrophy, and concentric remodelling by also using the wall–radius ratio have been shown to have risk predicting value [62]. Echocardiography also provides means of assessing left-ventricular diastolic distensibility (diastolic function) by Doppler measurement of the ratio between the E and A waves of transmitral blood flow (and, more precisely, by adding measurement of early diastolic relaxation time and evaluating patterns of pulmonary vein outflow into the left atrium) [63].

There is current interest to investigate whether patterns of 'diastolic dysfunction' can predict onset of dyspnoea and impaired effort tolerance without evidence of systolic dysfunction, frequently occurring in hypertension and in the elderly ('diastolic heart failure') [64]. Finally, echocardiography can provide evidence of left-ventricular wall contraction defects due to ischaemia or previous infarction and, more broadly, of systolic dysfunction. Other diagnostic cardiac procedures, such as nuclear magnetic resonance, cardiac scintigraphy, exercise test and coronary angiography, are obviously reserved for specific indications (diagnosis of coronary artery disease, cardiomyopathy, etc.). On the other hand, a radiograph of the thorax may often represent a useful additional diagnostic procedure, when information on large intrathoracic arteries or the pulmonary circulation is sought.

Blood vessels

Ultrasound examination of the carotid arteries with measurement of the intima media complex thickness and detection of plaques [65] has repeatedly been shown to predict occurrence of both stroke and myocardial infarction. A recent survey indicates that it can usefully complement echocardiography in making risk stratification of hypertensive patients more precise.

The increasing interest in systolic blood pressure and pulse pressure as predictors of cardiovascular events [66] has stimulated the development of techniques for measuring large artery distensibility or compliance [67,68]. This has been further supported by the observation that a reduction of arterial distensibility per se may have a prognostic significance [69]. One of these techniques, the pulse wave velocity measurement [69], may be suitable because of its simplicity for diagnostic use. Another technique, the augmentation index measurement device [70], has also raised wide interest as a possible tool to obtain an assessment of aortic blood pressure from peripheral artery measurement in view of the claim that aortic blood pressure (and therefore the pressure exerted on the heart and brain) may be different from that which is usually measured at the arm, and may be differently affected by different antihypertensive drugs.

Finally, there has been widespread interest in investigating endothelial dysfunction or damage as an early marker of cardiovascular damage [71,72]. The techniques used so far for investigating endothelial responsiveness to various stimuli are either invasive or too laborious and time consuming to envisage their use in the clinical evaluation of the hypertensive patient. However, current studies on circulating markers of endothelial activity, dysfunction or damage may soon provide simpler tests of endothelial dysfunction and damage to be investigated prospectively.

Kidney

The diagnosis of hypertension-induced renal damage is based on the finding of an elevated value of serum creatinine, of a decreased (measured or estimated) creatinine clearance or the detection of an elevated urinary excretion of albumin below (microalbuminuria) or above (macroalbuminuria) the usual laboratory methods to detect proteinuria. The presence of mild renal insufficiency has recently been defined as serum creatinine values equal or above 133 μmol/l (1.5 mg/dl) in men and 124 μmol/l (1.4 mg/dl) in women [73,74] or by the finding of estimated creatinine clearance values below 60–70 ml/min [26]. An estimate of creatinine clearance in the absence of 24-h urine collection can be obtained based on prediction equations corrected for age, gender and body size [74]. A slight increase in serum creatinine and urate may sometimes occur when antihypertensive therapy is instituted or potentiated, but this should not be taken as a sign of progressive renal deterioration. Hyperuricaemia, defined as a serum urate level in excess of 416 μmol/l (7 mg/dl), is frequently seen in untreated hypertensives and has also been shown to correlate with the existence of nephrosclerosis [75].

Although an elevated serum creatinine concentration points to a reduced rate of glomerular filtration, an increased rate of albumin or protein excretion points to a derangement in the glomerular filtration barrier [76]. Microalbuminuria has been shown to predict the development of overt diabetic nephropathy in both type 1 and type 2 diabetics [77], whereas the presence of proteinuria generally indicates the existence of established renal parenchymatous damage [76]. In non-diabetic hypertensive patients, microalbuminuria, even below the threshold values currently considered [78], has been shown to predict cardiovascular events, and a continuous relation between urinary albumin excretion and cardiovascular, as well as non-cardiovascular, mortality has recently been found in a general population study [79].

The finding of deranged renal function in a hypertensive patient, expressed as any of the above-mentioned alterations, is frequent and constitutes a very potent predictor of future cardiovascular events and death [25,26]. It is therefore recommended that serum creatinine (possibly with estimated creatinine clearance calculated on the basis of age, gender and body size) [74] and serum urate levels are measured, and urinary protein (by dipstick) searched in all hypertensive patients. Whenever possible, microalbuminuria may also be measured (in dipstick-negative patients) by using one of the validated commercial methods on urine samples collected during the night, and possibly related to creatinine excretion.

Fundoscopy

In contrast with the 1930s, when the Keith Wagener and Barker classification of hypertensive eye ground changes in four grades [80] was formulated, nowadays most hypertensive patients present early in the process of their illness, and haemorrhages and exudates (grade 3), or even papilloedema (grade 4), are very rarely observed. A recent evaluation of 800 hypertensive patients attending a hypertension outpatient clinic [27] showed that the prevalence of grades 1 and 2 retinal changes was as high as 78% (in contrast with 43% for carotid plaques, 22% for left-ventricular hypertrophy and 14% for microalbuminuria). It is therefore doubtful whether grades 1 and 2 retinal changes can be used as a sign of TOD to stratify global cardiovascular risk, whereas grades 3 and 4 are certainly markers of severe hypertensive complications.

Brain

In patients who have suffered a stroke, imaging techniques allow improved diagnosis of the existence, nature and location of a lesion [81,82]. Cranial computerized tomography (CT) is the standard procedure for diagnosis of a stroke but, with the exception of prompt recognition of an intracranial haemorrhage, CT is progressively being replaced by magnetic resonance imaging (MRI) techniques. Diffusion-weighted MRI can identify ischaemic injury within minutes after arterial occlusion. Furthermore, MRI, particularly in fluid attenuated inversion recovery (FLAIR) sequences, is much superior to CT in discovering silent brain infarctions, the large majority of which are small and deep (lacunar infarction). As cognition disturbances in the elderly are, at least in part, hypertension related [83,84], suitable cognition evaluation tests, such as the Mini Mental State Evaluation, should be used more often in the clinical assessment of the elderly hypertensive.

Screening for secondary forms of hypertension

A specific cause of blood pressure elevation can be identified in a minority (from < 5% to 10%) of adult patients with hypertension. Therefore, screening for secondary forms of hypertension is indicated, if possible before initiation of antihypertensive therapy. Findings suggesting a secondary form of blood pressure elevation are severe hypertension, sudden onset of hypertension and blood pressure responding poorly to drug therapy.

Renal parenchymal hypertension

Renal parenchymal disease is the most common cause of secondary hypertension, detected in about 5% of all cases of hypertension. The finding of bilateral upper abdominal masses at physical examination is consistent with polycystic kidney disease and should lead to an abdominal ultrasound examination. Renal ultrasound has now almost completely replaced intravenous urography in the anatomical exploration of the kidney. Although the latter requires the injection of nephrotoxic contrast media, ultrasound is non-invasive and provides all necessary anatomic data about kidney size and shape, cortical thickness, urinary tract obstruction and renal masses, in addition to evidence of polycystic kidneys. Assessment of the presence of protein, erythrocytes and leucocytes in the urine and measurement of serum creatinine concentration are the proper functional screening tests for renal parenchymal disease [85,86], and should be performed in all patients with hypertension. Renal parenchymal disease may be excluded if urinalysis and serum creatinine concentration are normal at repeated determinations. The presence of erythrocytes and leucocytes should be confirmed by microscopic examination of the urine. If the screening tests for renal parenchymal hypertension are positive, a detailed work-up for kidney disease should ensue.

Renovascular hypertension

Renovascular hypertension is caused by one or several stenoses of the extrarenal arteries and is found in about 2% of adult patients with blood pressure elevation. In about 75% of the patients, the renal artery stenosis is caused by atherosclerosis (particularly in the elderly population). Fibromuscular dysplasia accounts for up to 25% of total cases (and is the most common variety in young adults). Signs of renal artery stenosis are an abdominal bruit with lateralization, hypokalaemia and progressive decline in renal function. However, these signs are not present in many patients with renovascular hypertension. Determination of the longitudinal diameter of the kidney using ultrasound can be used as a screening procedure. However, a difference of more than 1.5 cm in length between the two kidneys—which is usually considered as being diagnostic for renal stenosis—is only found in about 60–70% of the patients with renovascular hypertension. Colour Doppler sonography is able to detect stenosis of the renal artery, particularly stenosis that is localized close to the origin of the vessel [87], but the procedure is highly observer dependent. There is evidence that investigations of the renal vasculature by breath-hold three-dimensional, gadolinium-enhanced magnetic resonance angiography may become the diagnostic procedure of choice for renovascular hypertension in the future [88]. Another imaging procedure with similar sensitivity is spiral computerized tomography, which requires the application of contrast media and relatively high X-ray doses. Once there is a strong suspicion of renal artery stenosis, intra-arterial digital subtraction angiography should be performed for confirmation. This invasive procedure is still the gold standard for the detection of renal artery stenosis.

Phaeochromocytoma

Phaeochromocytoma accounts for less than 0.1% of all cases of elevated blood pressure. The determination of catecholamines (noradrenaline and adrenaline) as well as of metanephrines in several 24-h urine samples is a reliable method for detection of the disease. In most patients with phaeochromocytoma, no further confirmation is required [89]. If the urinary excretion of catecholamines and their metabolites is only marginally increased or normal despite a strong clinical suspicion of phaeochromocytoma, the glucagon stimulation test can be applied. This test requires the measurement of catecholamines in plasma and should be performed after the patient has been effectively treated with an alpha-blocker. This pretreatment prevents marked blood pressure rises after injection of glucagon. The clonidine suppression test is used to identify patients with essential hypertension, who have slight elevations of the excretion of catecholamines and their metabolites in urine [90]. Once the diagnosis of phaeochromocytoma has been established, localization of the tumour is necessary. As phaeochromocytomas are often big tumours localized in, or in the close vicinity of, the adrenal glands, they often are detected by ultrasound. A more sensitive imaging procedure is CT. The meta-iodobenzylguanidine scan is useful in localizing extra-adrenal phaeochromocytomas and metastases of the 10% of phaeochromocytomas that are malignant.

Primary aldosteronism

Primary aldosteronism accounts for about 1% of all patients with hypertension. The determination of serum potassium levels is considered to be a screening test for the disease. However, only about 80% of the patients have hypokalaemia in an early phase [91], and some authorities maintain that hypokalaemia may even be absent in severe cases. Particularly in patients with bilateral adrenal hyperplasia, serum potassium levels may be normal or only slightly decreased [92]. The diagnosis is confirmed by a low plasma renin activity (< 1 ng/ml/h) and elevated plasma aldosterone levels (after withdrawal of drugs influencing renin, such as beta-blockers, ACE inhibitors, angiotensin receptor antagonists and diuretics). A plasma aldosterone (pg/ml)–plasma renin activity (ng/ml/h) ratio of > 50 is highly suggestive of primary aldosteronism [92]. The diagnosis of primary aldosteronism is confirmed by the fludrocortisone suppression test [93]. Imaging procedures such as CT and MRI are used to localize an aldosterone-producing tumour, but adrenal morphology correlates poorly with function, and adrenal venous sampling, although invasive and difficult to perform, is considered by some investigators to be a more reliable procedure [94].

Cushing's syndrome

Cushing's syndrome affects less than 0.1% of the total population. On the other hand, hypertension is a very common finding in Cushing's syndrome, affecting about 80% of such patients. The syndrome is suggested by the typical habitus of the patient. The determination of 24-h urinary cortisol excretion is the most practical and reliable index of cortisol secretion and a value exceeding 110 nmol (40 µg) is highly suggestive of Cushing's syndrome. The diagnosis is confirmed by the 2-day, low-dose dexamethasone suppression test or the overnight dexamethasone suppression test. A normal result of either of the two suppression tests excludes the possibility of

Cushing's syndrome [95]. Further tests and imaging procedures have to be used to differentiate the various forms of the syndrome [96].

Coarctation of the aorta

Coarctation of the aorta is a rare form of hypertension in children and young adults. The diagnosis is usually evident from physical examination. A mid-systolic murmur, which may become continuous with time, is heard over the anterior part of the chest and also over the back. Hypertension is found in the upper extremities concomitantly with low or not measurable blood pressure in the legs.

Genetic analysis

There is often a family history of high blood pressure in hypertensive patients, suggesting that inheritance contributes to the pathogenesis of this disorder. Essential hypertension has a highly heterogeneous character, which points to a multifactorial aetiology and polygenic abnormalities [97,98]. Variants in some genes might render an individual sensitive to a given factor in the environment. A number of mutations in the genes encoding for major blood pressure controlling systems has been recognized in humans, but their exact role in the pathogenesis of essential hypertension is still unclear. The search for candidate gene mutations in the individual hypertensive is therefore not useful at present. However, the patient's genetic disposition might influence drug-metabolizing enzymes, which might translate into differences in drug effects or tolerability, and several extremely rare monogenic forms of inherited hypertension have been described.

Therapeutic approach

When to initiate antihypertensive treatment

Guidelines for initiating antihypertensive treatment are based on two criteria: (1) the level of total cardiovascular risk, as indicated in Table 10.2 and (2) the level of systolic and diastolic blood pressure, as classified in Table 10.1. Consideration of subjects with systolic blood pressure of 120–139 mmHg and diastolic blood pressure of 80–89 mmHg for possible initiation of antihypertensive treatment is so far limited to subjects with stroke [99], coronary artery disease [100] and diabetes [101]. Antihypertensive treatment is recommended within this blood pressure range only for patients at least at high total risk. Close monitoring of blood pressure and no blood pressure intervention is only recommended for patients at moderate or low total risk, who are considered to mostly benefit from lifestyle measures and correction of other risk factors (e.g. smoking).

In patients with grade 1 and 2 hypertension, antihypertensive drug treatment should be initiated promptly in subjects who are classified as at high or very high risk, whereas in subjects at moderate or low added risk blood pressure, as well as other cardiovascular risk factors, should be monitored for extended periods (from 3 to 12 months) under non-pharmacological treatment only. If after extended observation systolic values ≥ 140 mmHg or diastolic values ≥ 90 mmHg persist, antihypertensive drug treatment should be initiated in patients at moderate risk, and considered in patients at lower risk. In the latter group, decision as to whether to adopt drug treatment should be influenced by the patient's preference and/or resources rather than a higher blood pressure threshold (systolic ≥ 150 or diastolic ≥ 95 mmHg).

Table 10.5 also includes recommendations about initiation of treatment in patients with grade 3 hypertension. In these subjects confirmation of elevated blood pressure values should be obtained within a few days, and treatment instituted immediately, without the preliminary need of establishing the absolute risk (high even in absence of other risk factors). Complete assessment of other risk factors, TOD or associated disease can be carried out after institution of treatment, and lifestyle measures can be recommended at the same time as initiation of drug therapy.

Several studies have shown that in high or very high risk patients, treatment of hypertension is very cost-effective, i.e. the reduction in the incidence of cardiovascular disease and death largely offsets the cost of treatment despite its lifetime duration. Some pharmacoeconomical studies suggest that treatment may be less cost-effective in grade 1 or 2 hypertensives who are at low or moderate added risk. This may be more apparent than real, however, because in these patients the purpose of treatment is not to prevent an unlikely morbid or fatal event in the subsequent few years but rather to oppose appearance and/or progression of organ damage that will make the patient a high risk in the long term. Several trials of antihypertensive therapy, foremost the HDPP [102] and HOT [103] studies, have shown that under these circumstances and despite intensive blood pressure lowering, residual cardiovascular risk remains higher than in patients with initial moderate risk. This suggests that some of the major cardiovascular risk changes may be difficult to reverse and that restricting antihypertensive

Table 10.5 Initiation of antihypertensive treatment

	Blood pressure (mmHg)				
Other risk factors and disease history	**Normal SBP 120–129 or DBP 80–84**	**High normal SBP 130–139 or DBP 85–89**	**Grade 1 SBP 140–159 or DBP 90–99**	**Grade 2 SBP 160–179 or DBP 100–109**	**Grade 3 SBP ≥ 180 or DBP ≥ 110**
No other risk factors	No BP intervention	No BP intervention	Lifestyle changes for several months then drug treatment if preferred by the patient and resources available	Lifestyle changes for several months then drug treatment	Immediate drug treatment and lifestyle changes
One or two risk factors	Lifestyle changes	Lifestyle changes	Lifestyle changes for several months, then drug treatment	Lifestyle changes for several months then drug treatment	Immediate drug treatment and lifestyle changes

ACC	Drug treatment and lifestyle changes	Immediate drug treatment and lifestyle changes	Immediate drug treatment and lifestyle changes	Immediate drug treatment and lifestyle changes	Immediate drug treatment and lifestyle changes

therapy to patients at high or very high risk may be far from an optimal strategy.

Goals of treatment

The primary goal of treatment of the patient with high blood pressure is to achieve the maximum reduction in the long-term total risk of cardiovascular morbidity and mortality. This requires treatment of all the reversible risk factors identified, including smoking, dyslipidaemia or diabetes and the appropriate management of associated clinical conditions, as well as treatment of the raised blood pressure per se.

As to the blood pressure goal to be achieved, randomized trials comparing less with more intensive treatment [101,104–106] have shown that in diabetic patients more intensive blood pressure lowering is more protective [101,103,105,107]. This is not yet conclusively established in non-diabetic subjects. This is because the only trial not exclusively involving diabetics is the HOT study [103,104], which, because of the small diastolic blood pressure differences achieved (2 mmHg) among the groups randomized to = 90, 85 or 80 mmHg, was unable to detect significant differences in the risk of cardiovascular events (except for myocardial infarction) between adjacent target groups. However, the results of the HOT study have confirmed that there is no increase in cardiovascular risk in the patients randomized to the lowest target group, which is relevant to clinical practice because setting lower blood pressure goals allows a greater number of subjects to at least meet the traditional ones. Furthermore, a recent subgroup analysis of the HOT study [108] suggests that except for smokers a reduction of diastolic blood pressure to an average of 82 mmHg rather than 85 mmHg significantly reduces major cardiovascular events in non-diabetic patients at high or very high risk (50% of HOT study patients), as well as in patients with previous ischaemic heart disease, in patients older than 65 years and in women. Finally, in patients with a history of stroke or transient ischaemic attack, the PROGRESS trial [99] showed less cardiovascular mortality and morbidity by reducing diastolic blood pressure to 79 mmHg (active treatment group) rather than 83 mmHg (placebo group). Similar observations has been made in patients with coronary disease, although the role of blood pressure reduction in these trials has been debated [109]. As far as systolic blood pressure is concerned, evidence of a greater benefit by a more aggressive reduction is limited to the UKPDS study, which has shown, through retrospective analysis of the data, fewer cardiovascular morbid events at values below 130–120 compared with 140 mmHg. Most trials, however, have been unable to reduce systolic blood pressure below 140 mmHg, and in no trials on diabetic and non-diabetic patients have values below 130 mmHg been achieved [109].

As for patients with non-diabetic renal disease, data about the effects of more or less intensive blood pressure lowering on cardiovascular events are scanty: the HOT study was unable to find any significant reduction in cardiovascular events in the subset of patients with plasma creatinine > 115 μmol/l (> 1.3 mg/dl) [108] or > 133 μmol/l (> 1.5 mg/dl) [26] when subjected to more vs. less intensive blood pressure lowering (139/82 vs. 143/85 mmHg). However, not one of these trials suggests an increased cardiovascular risk at the lowest blood pressure achieved.

In conclusion, on the basis of current evidence from trials, it can be recommended that blood pressure, both systolic and diastolic, can be intensively lowered at least below 140/90 mmHg and to definitely lower values if tolerated, in all hypertensive patients, and below 130/80 mmHg in diabetics. The achievable goal may depend on the pre-existing blood pressure level, and systolic values below 140 mmHg may be difficult to achieve, particularly in the elderly.

When home or ambulatory blood pressure measurement are used to evaluate the efficacy of treatment, it must be remembered that daytime values provided by these methods (compared with office measurement) are on average at least 10 mmHg lower for systolic and 5 mmHg lower for diastolic blood pressure, although these differences tend to become smaller at lower office blood pressure values, such as those recommended as treatment goals [45].

Lifestyle changes

Lifestyle measures should be instituted whenever appropriate in all patients, including subjects with high/normal blood pressure and patients who require drug treatment. The purpose is to lower blood pressure and to control other risk factors and clinical conditions present. However, lifestyle measures are undocumented in preventing cardiovascular complications in hypertensive patients and should never delay the initiation of drug treatment unnecessarily, especially in patients at higher levels of risk, or detract from compliance to drug treatment.

Smoking cessation

Smoking cessation is probably the single most powerful lifestyle measure for the prevention of a large number of non-cardiovascular and cardiovascular diseases, including stroke and coronary heart disease [110]. Those who quit before middle age typically have a life expectancy that is not different to that of lifelong non-smokers. Although smoking cessation does not lower blood pressure [111], smoking may predict a future rise in systolic blood pressure [112], and global cardiovascular risk is greatly increased by smoking [110]. For several reasons, therefore, hypertensive smokers should be counselled on smoking cessation. In addition, some other data suggest that smoking may interfere with the beneficial effects of some antihypertensive agents, such as beta-blockers, or may prevent the benefits of more intensive blood pressure lowering [108]. Where necessary, nicotine replacement or buspirone therapy should be considered, as they appear to facilitate other interventions for smoking cessation [113].

Moderation of alcohol consumption

There is a linear relationship between alcohol consumption, blood pressure levels and the prevalence of hypertension in populations [114]. Beyond that, high levels of alcohol consumption are associated with high risk of stroke [115]; this is particularly so for binge-drinking. Alcohol attenuates the effects of anti-hypertensive drug therapy, but this effect is at least partially reversible within 1–2 weeks by moderation of drinking by around 80% [116]. Heavier drinkers (five or more standard drinks per day) may experience a rise in blood pressure after acute alcohol withdrawal and are more likely to be diagnosed as hypertensive at the beginning of the week if they have a weekend drinking pattern. Accordingly, hypertensive patients who drink alcohol should be advised to limit their consumption to no more than 20–30 g of ethanol per day for men, and no more than 10–20 g per day for women. They should be warned against the heightened risks of stroke that are associated with binge-drinking.

Weight reduction and physical exercise

Excess body fat predisposes to raised blood pressure and hypertension [117]. Weight reduction reduces blood pressure in overweight patients and has beneficial effects on associated risk factors, such as insulin resistance, diabetes, hyperlipidaemia and left-ventricular hypertrophy. The blood pressure lowering effect of weight reduction may be enhanced by simultaneous increase in physical exercise [118], by alcohol moderation in overweight drinkers [119] and by reduction in sodium intake [120]. Physical fitness is a rather strong predictor of cardiovascular mortality, independent of blood pressure and other risk factors [121]. Thus, sedentary patients should be advised to take up modest levels of aerobic exercise on a regular basis, such as walking, jogging or swimming for 30–45 min, three to four times per week [122]. The extent of the pre-training evaluation will depend on the extent of the envisaged exercise and on the patient's symptoms, signs, overall cardiovascular risk and associated clinical

conditions. Even mild exercise may lower systolic blood pressure by about 4–8 mmHg [123]. However, isometric exercise such as heavy weightlifting can have a pressor effect and should be avoided. If hypertension is poorly controlled, and always in severe hypertension, heavy physical exercise should be discouraged or postponed until appropriate drug treatment has been instituted and found to work.

Reduction of high salt intake and other dietary changes

Epidemiological studies suggest that dietary salt intake is a contributor to blood pressure elevation and to the prevalence of hypertension [124]. The effect appears to be enhanced by a low dietary intake of potassium-containing foods. Randomized controlled trials in hypertensive patients indicate that reducing sodium intake by 80–100 mmol (4.7–5.8 g) per day from an initial intake of around 180 mmol (10.5 g) per day will reduce blood pressure by an average of 4–6 mmHg [125] or even more if combined with other dietary counselling [126]. Patients should be advised to avoid added salt, to avoid obviously salted food, particularly processed foods, and to eat more meals cooked directly from natural ingredients containing more potassium. Counselling by trained dietitians may be useful. Hypertensive patients should also be advised to eat more fruit and vegetables [127], to eat more fish [128] and to reduce their intake of saturated fat and cholesterol.

Pharmacological therapy

Introduction

Recommendations about pharmacological therapy are here preceded by analysis of the available evidence (as provided by large randomized trials based on fatal and non-fatal events) of the benefits obtained by antihypertensive therapy and of the comparative benefits obtained by the various classes of agents. This is the strongest type of evidence available. It is commonly recognized, however, that event-based randomized therapeutic trials have some limitations; among these, the special selection criteria of the subjects included: the frequent selection of high-risk patients in order to increase the power of the trial, so that the vast majority of uncomplicated and lower risk hypertensives are rarely represented; the therapeutic programmes that often diverge from usual therapeutic practice; and the stringent follow-up procedures enforcing patients' compliance well beyond that obtained in common medical practice. The most important limitation is perhaps the necessarily short duration of a controlled trial, in most cases 4–5 years, whereas additional life expectancy and hence expectancy of therapeutic duration for a middle-aged hypertensive is of 20–30 years [20,129].

Long-term therapeutic benefits and long-term differences between benefits of various drug classes may also be evaluated by using intermediate end-points (i.e. subclinical organ damage changes), as some of these changes have predictive value of subsequent fatal and non-fatal events. Several of the recent event-based trials have also used 'softer' end-points, such as congestive heart failure (certainly clinically relevant, but often based on subjective diagnosis), hospitalization, angina pectoris and coronary revascularization (highly subjected to local clinical habits and facilities), etc. Treatment-induced alterations in metabolic parameters, such as serum LDL- or HDL-cholesterol, serum potassium, glucose tolerance, induction or worsening of the metabolic syndrome or diabetes, although they can hardly be expected to increment cardiovascular event incidence during the short term of a trial, may have some impact during the longer course of the patient's life.

Trials based on mortality and morbidity end-points comparing active treatment with placebo

The results of trials performed in mostly systolic–diastolic hypertension and in elderly with isolated systolic hypertension have been included in meta-analyses [5,129–132]. Antihypertensive treatment resulted in significant and similar reductions of cardiovascular and all-cause mortality in both types of hypertension. With regard to cause-specific mortality, Collins and colleagues [14] observed a significant reduction in fatal stroke (–45%, $P < 0.001$), but not in fatal coronary heart disease (–11%, NS). This could be related to age because coronary mortality was significantly reduced by 26% ($P < 0.01$) in a meta-analysis on elderly with systolic–diastolic hypertension [133]. Fatal and non-fatal strokes combined and all coronary events were significantly reduced in the two types of hypertension. The Blood Pressure Lowering Treatment Trialists Collaboration (BPLTTC) [107] performed separate meta-analyses of placebo-controlled trials in which active treatment was initiated by a calcium antagonist or by an ACE inhibitor and showed the reductions in cardiovascular end-points were similar to those found in the trials in which active treatment was based on diuretics or beta-blockers. The proportional reduction of the cardiovascular risk appears to be similar in women and in men [134].

Additional information has more recently been provided by other trials, not yet included in the previously mentioned meta-analysis. Placebo-controlled trials addressed the effect of the angiotensin receptor antagonists

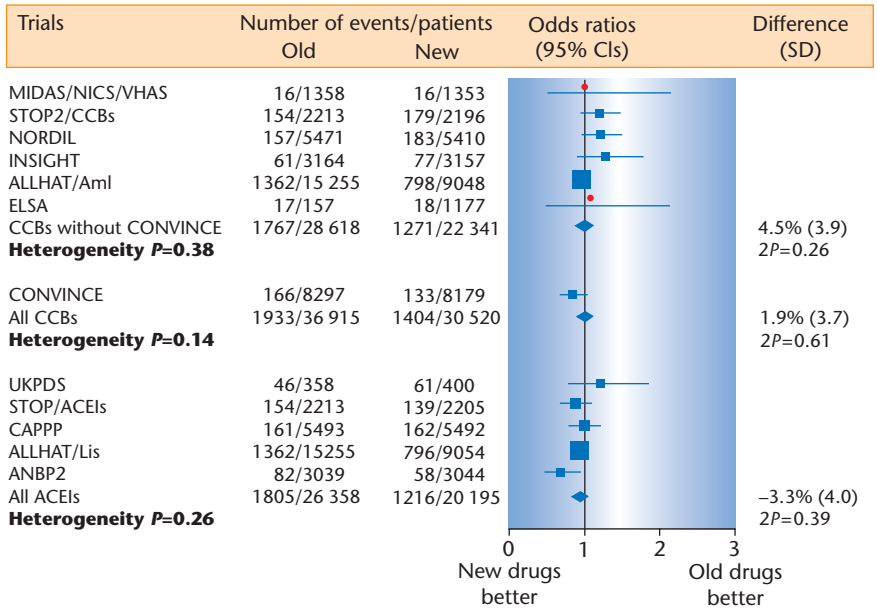

Figure 10.1 Fatal and non-fatal myocardial infarction in randomized clinical trials comparing 'newer' with 'old' antihypertensive drugs.

losartan [135] and irbesartan [136,137] in patients with type 2 diabetes and nephropathy. All studies concluded that the drug treatment was renoprotective but that there was no evidence of benefit in secondary cardiovascular end-points (for the evaluation of which, however, these trials had insufficient power). It can be concluded from these recent placebo-controlled trials that blood pressure lowering by angiotensin II antagonists can also be beneficial, particularly in stroke prevention, and, in patients with diabetic nephropathy, in slowing down progression of renal disease.

Trials based on mortality and morbidity end-points comparing treatments initiated by different drug classes

During the last 5 years, a large number of controlled randomized trials has compared antihypertensive regimens initiated with different classes of antihypertensive agents, most often comparing older (diuretics and beta-blockers) with newer ones (calcium antagonists, ACE inhibitors, angiotensin receptor antagonists, alpha-blockers), and occasionally comparing newer drug classes. Several trials [138–146] with > 67 000 randomized patients, comparing calcium antagonists with older drugs, have recently been reviewed [147]. For none of the outcomes considered in this analysis, including all-cause and cardiovascular mortality, all cardiovascular events, stroke, myocardial infarction and heart failure, did the *P*-values for heterogeneity reach statistical significance ($0.11 \leq P \leq 0.95$). The pooled odds ratios expressing the possible benefit of calcium antagonists over old drugs were close to unity and non-significant for total mortality, cardiovascular mortality, all cardiovascular events and myocardial infarction (Fig. 10.1). Calcium antagonists provided slightly better protection against fatal and non-fatal stroke than old drugs (Fig. 10.2). For the trials combined, the odds ratio for stroke reached formal significance (0.90, 95% confidence interval 0.82–0.98, $P = 0.02$) after CONVINCE [146], the only large trial based on verapamil, was excluded. For heart failure, calcium antagonists appeared to provide less protection than conventional therapy, regardless of whether or not the CONVINCE trial was incorporated in the pooled estimates.

Six trials with about 47 000 randomized patients compared ACE inhibitors with old drugs [139,142,148,149]. The pooled odds ratios expressing the possible benefit of ACE inhibitors over conventional therapy were close to unity, and non-significant for total mortality, cardiovascular mortality and myocardial infarction (Fig. 10.1). Compared with old drugs, ACE inhibitors provided slightly less protection against stroke (Fig. 10.2), heart failure and all cardiovascular events. For all-cause and cardiovascular mortality, stroke and myocardial infarction, *P*-values for heterogeneity among the trials of ACE inhibitors were non-significant ($0.16 \leq P \leq 0.88$). In contrast, for all cardiovascular events and heart failure, heterogeneity was significant owing to the ALLHAT [139] findings. Compared with chlorthalidone, ALLHAT patients allocated to lisinopril had a greater risk of stroke, heart failure and hence combined cardiovascular disease [139]. Similar findings were previously reported for the comparison of the alpha-blocker doxazosin with chlorthalidone, an ALLHAT arm that was interrupted prematurely

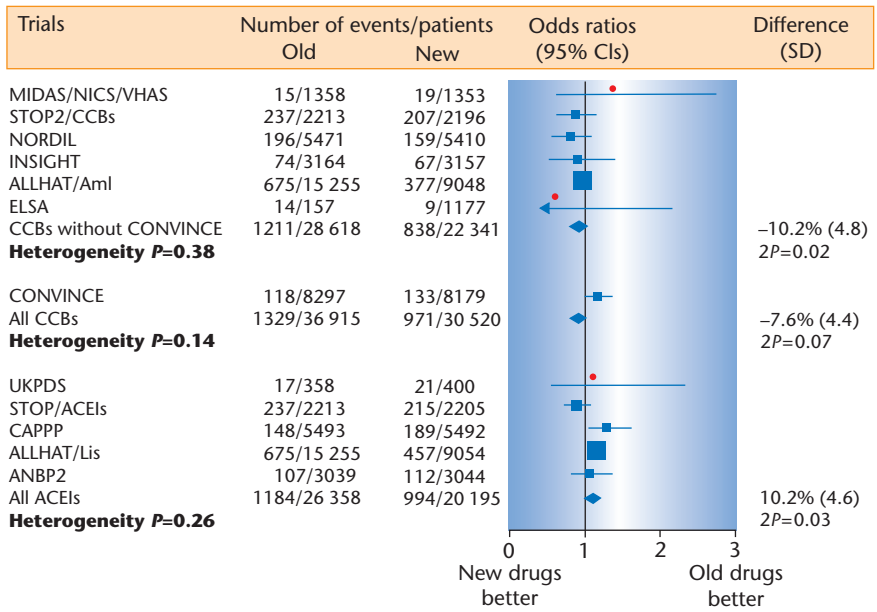

Figure 10.2 Fatal and non-fatal stroke in randomized clinical trials comparing 'newer' with 'old' antihypertensive drugs.

[138]. Although ALLHAT [139] stands out as the largest double-blind trial undertaken in hypertensive patients, interpretation of its results is difficult in several aspects, which may account for the heterogeneity of ALLHAT results with respect to those of the other trials.

1 In ALLHAT, 90% of the patients at randomization were already on antihypertensive treatment, most often diuretics, thus ALLHAT tested 'continuing a diuretic' vs. 'switching drug classes'. Patients on diuretics with latent or compensated heart failure were deprived of their therapy when they were not randomized to chlorthalidone.
2 The achieved systolic pressure was higher on doxazosin, amlodipine and lisinopril than on chlorthalidone. Presumably, these factors explain why the Kaplan–Meier curves started to diverge immediately after randomization for heart failure and approximately 6 months later also for stroke.
3 The sympatholytic agents used for step-up treatment (atenolol, clonidine and/or reserpine at the physician's discretion) led to a somewhat artificial treatment regimen, which does not reflect modern clinical practice, is not usually recommended and is known to potentiate the blood pressure response to diuretics much more than to ACE inhibitors or alpha-blockers.
4 ALLHAT did not include systematic end-point evaluation, which may have particularly affected evaluation of 'softer' end-points, such as congestive heart failure.

These limitations notwithstanding, ALLHAT [138,139], either alone or in combination with the other trials, supports the conclusion that the benefits of antihypertensive therapy largely depend on blood pressure lowering, thus being in line with the preliminary and most recent findings of the meta-analysis of the BPLTTC [107,150]. The conclusion that a substitution of portion of the benefit of antihypertensive treatment depends on BP reduction per se is also supported by the recent findings of the INVEST study [151], in which cardiovascular disease was similarly frequent in patients treated with verapamil compared with those treated with atenolol (± hydrochlorotiazide). It is not entirely supported by the data of the Second Australian Blood Pressure study [152], in which ACE inhibitor-based treatment was found to be more protective against cardiovascular disease than diuretic-based treatment. The difference was modest, however, and significant only when the second morbid event in the same patient was included in the analysis. Finally, the conclusion of the paramount importance of blood pressure control for prevention of cardiovascular complications is supported by the results of the recently published VALUE trial [153,154], in which cardiac disease (the primary end-point) was similarly frequent in high-risk hypertensive patients who were treated with valsartan or amlodipine. Amlodipine reduced blood pressure to a greater degree in the months that followed randomization than using two drug-regimens, and this was accompanied by a lower risk of events.

Apart from the VALUE trial, two other recent trials have studied the new class of angiotensin receptor antagonists. The LIFE study [155] has compared losartan with the beta-blocker atenolol in hypertensive patients with left-ventricular hypertrophy for an average of 4.8 years, and found a significant 13% reduction in major cardiovascular

events, mostly due to a significant 25% reduction in stroke incidence. There were no blood pressure differences between the treatment groups. The SCOPE study [156] was initiated as a comparison of elderly patients receiving candesartan or placebo but, because for ethical reasons 85% of the placebo-initiated patients received antihypertensive therapy (mostly diuretics, beta-blockers or calcium antagonists), the study is a comparison of antihypertensive treatment with or without candesartan. After 3.7 years of treatment there was a non-significant 11% reduction in major cardiovascular events, and a significant 28% reduction in non-fatal strokes among candesartan-treated patients, with an achieved blood pressure slightly lower (3.2/1.6 mmHg) in the candesartan group.

In the most recent meta-analysis of the BPLTTC [150], it was concluded that ARB-based regimens showed a greater effect than other control regimens on the risk of stroke, heart failure and major cardiovascular events, but not on coronary heart disease, cardiovascular death and total mortality. However, it is likely that only the effect on heart failure will persist when the results of the VALUE trial, which only became available after the BPLTTC publication, are considered together with the results from the BPLTTC meta-analysis.

Randomized trials based on intermediate end-points

LEFT-VENTRICULAR HYPERTROPHY

The studies that have tested the effects of various antihypertensive agents on hypertension-associated left-ventricular hypertrophy, mostly evaluated as left-ventricular mass at the echocardiogram, are almost innumerable, but only a few of them have followed strict enough criteria to provide reliable information. The very few studies adhering to these strict criteria do not yet provide uncontrovertible answers, although their most recent meta-analysis suggests that, for a similar blood pressure reduction, newer agents (ACE inhibitors, calcium antagonists and angiotensin II antagonists) may be more effective than conventional drugs [157]. The large and long-term (5 years) LIFE Study is particularly relevant, as the greater regression of electrocardiographically determined left-ventricular hypertrophy (LVH) with losartan was accompanied by a reduced incidence of cardiovascular events [155]. The same findings were obtained in a LIFE substudy in which LVH was determined by echocardiography. Future studies should investigate treatment-induced effects on indices of collagen content of the ventricular wall rather than on its mass only.

ARTERIAL WALL AND ATHEROSCLEROSIS

A number of randomized trials have compared the long-term (2–4 years) effects of different antihypertensive regimens on carotid artery wall intima media thickness. The most convincing evidence has been obtained for calcium antagonists, which comes from trials with different agents, concluding with a long-term study on more than 2000 patients [158]. The data show [158–160] that for a similar reduction in blood pressure these drugs slow down carotid artery wall thickening and plaque formations more than conventional drugs. Evidence of a greater benefit is also available for ACE inhibitors [161], although less consistently.

RENAL FUNCTION

The most abundant evidence concerns renal function in diabetic patients [162]. Progression of renal dysfunction can be retarded by adding an angiotensin receptor antagonist [135,136] (compared with placebo) in diabetic patients with advanced nephropathy. Consistent effects of more intensive blood pressure lowering were found on urinary protein, both overt proteinuria and microalbuminuria. Of several studies in diabetic patients comparing treatments initiated by different agents, some [101,145,148] did not show a difference in the renal protective effect of the drugs that were being compared, whereas one indicated the angiotensin antagonist irbesartan to be superior to the calcium antagonist amlodipine in retarding development of renal failure [136], and the other indicated the angiotensin antagonist losartan to reduce incidence of new overt proteinuria better than the beta-blocker atenolol [163].

As to patients with non-diabetic renal disease, a recent meta-analysis of 11 randomized trials comparing antihypertensive regimens including or excluding an ACE inhibitor [164] indicates a significantly slower progression in patients achieving blood pressure of 139/85 mmHg rather than 144/87 mmHg. It is not clear, however, whether the benefit should be ascribed to ACE inhibition or to the lower blood pressure achieved. Some light on the matter is shed by the recently completed AASK study [165]. ACE inhibitors were shown to be somewhat more effective than beta-blockers [165] or calcium antagonists [166] in slowing glomerular filtration rate decline. It appears, therefore, that in patients with non-diabetic renal disease the use of an ACE inhibitor may be more important than an aggressive blood pressure reduction, whereas in diabetic patients aggressive lowering of blood pressure may be equally important as blockade of the renin–angiotensin system.

NEW-ONSET DIABETES

Several trials have monitored the incidence of new-onset diabetes during the treatment follow-up (Fig. 10.3). With few exceptions [142,143], studies have shown a lower incidence in patients treated with an ACE inhibitor, a

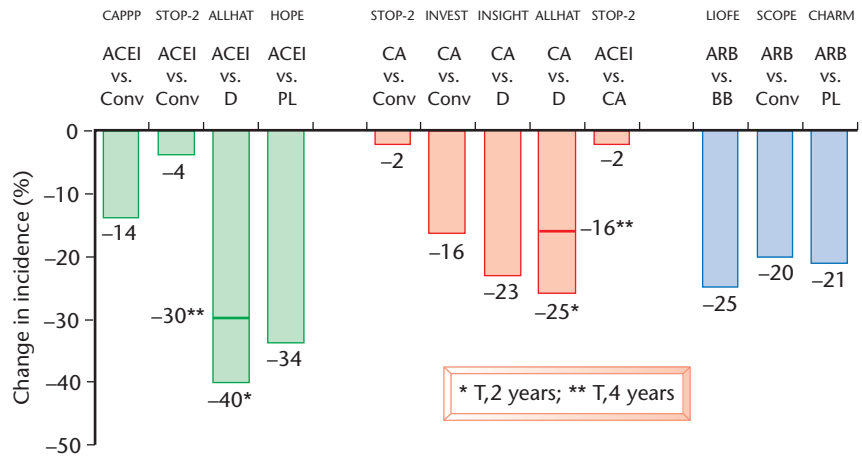

Figure 10.3 Prevention of new-onset diabetes with 'newer' vs. 'old' antihypertensive drugs in recent randomized clinical trials.

calcium antagonist or an angiotensin II antagonist compared with diuretics or beta-blockers [139,145,149,151, 156,167]; treatment with an ACE inhibitor has resulted in a lower incidence of new-onset diabetes than with placebo [100], and administration of the angiotensin II antagonist valsartan has been more beneficial on this end-point than administration of amlodipine [153]. There are thus differences between different antihypertensive drugs on this end-point. This is likely to be clinically relevant because, in the long term, treatment-induced diabetes is accompanied by an increased incidence of cardiovascular disease as much as native diabetes [168,169].

Therapeutic strategies

Principles of drug treatment: monotherapy vs. combination therapy

In most, if not all, hypertensive patients, therapy should be started gently, and target blood pressure values achieved progressively through several weeks. To reach target blood pressure, it is likely that a large proportion of patients will require combination therapy with more than one agent. The proportion of patients requiring combination therapy will also depend on baseline blood pressure values. In grade 1 hypertensives, monotherapy is likely to be successful more frequently [104,138,139]. In trials on diabetic patients, the vast majority of patients were on at least two drugs, and in two recent trials on diabetic nephropathy [135,136] an average of 2.5 and 3.0 non-study drugs were required in addition to the angiotensin receptor antagonist used as study drug.

According to the baseline blood pressure and the presence or absence of complications, it appears reasonable to initiate therapy either with a low dose of a single agent or with a low-dose combination of two agents (Fig. 10.4). If low-dose monotherapy is chosen and blood pressure control is not achieved, the next step is to switch to a low dose of a different agent or to increase the dose of the first compound chosen (with a greater possibility of eliciting adverse disturbances) or to make recourse to combination therapy. If therapy has been initiated by a low-dose combination, a higher dose combination can subsequently be used or a low dose of a third compound added.

The following two-drug combinations have been found to be effective and well tolerated, but other combinations are possible (Fig. 10.5):

- diuretic and beta-blocker;
- diuretic and ACE inhibitor or angiotensin receptor antagonist;
- calcium antagonist (dihydropyridine) and beta-blocker;
- calcium antagonist and ACE inhibitor or angiotensin receptor antagonist;
- calcium antagonist and diuretic;
- alpha- and beta-blockers;
- other combinations can be used if necessary, and three or four drugs may be required in special cases.

The use of long-acting drugs or preparations providing 24-h efficacy on a once-daily basis is recommended. The advantages of such medications include improvement in adherence to therapy and minimization of blood pressure variability, thus possibly providing greater protection against the risk of major cardiovascular events and the development of TOD [170,171].

Particular attention should be given to adverse events, even purely subjective disturbances, because they may be an important cause of non-compliance. Patients should always be asked about adverse effects, and dose or drug changes made accordingly. Even within the same drug class, there may be compounds less prone to induce a specific adverse effect (e.g. among beta-blockers, less fatigue or Raynaud's phenomenon with vasodilating

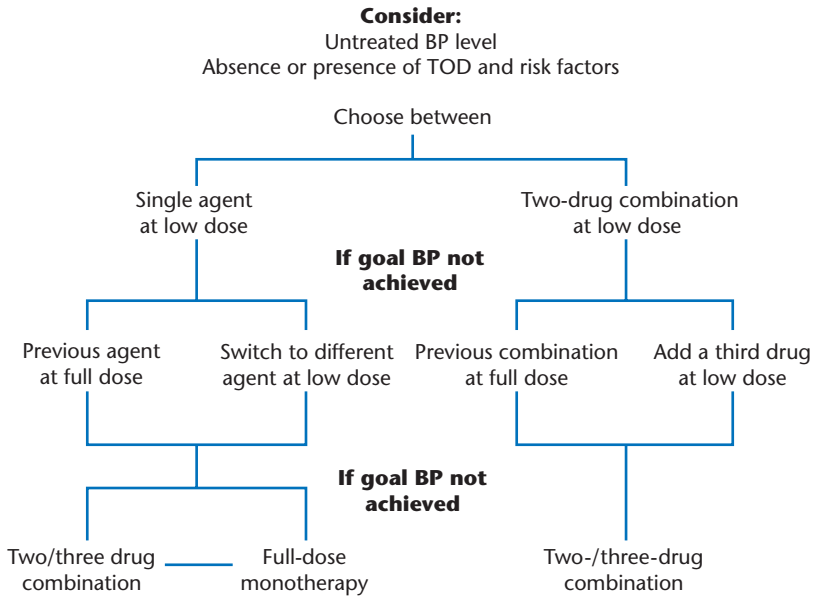

Figure 10.4 Monotherapy vs. combination therapy against hypertension.

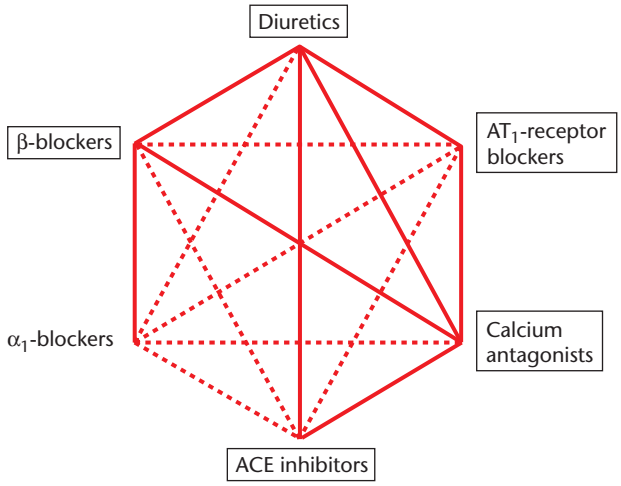

Figure 10.5 First-line treatments and choices of drug combinations.

compounds; among calcium antagonists, no constipation with dihydropyridines, no tachycardia with verapamil and diltiazem, variable degree of dependent oedema with different compounds).

CHOICE OF ANTIHYPERTENSIVE DRUGS

A large number of randomized trials confirm that the main benefits of antihypertensive therapy are due to lowering of blood pressure per se, largely independently of the drugs used to lower blood pressure.

There is also evidence, however, that specific drug classes may differ in some effect or in special groups of patients. Finally, drugs are not equal in terms of adverse disturbances, particularly in individual patients, and patients' preference is a prerequisite for compliance and therapy success.

It can therefore be concluded that the major classes of antihypertensive agents—diuretics, beta-blockers, calcium antagonists, ACE inhibitors and angiotensin receptor antagonists—are suitable for the initiation and maintenance of antihypertensive therapy. Evidence favouring the use of alpha-blockers is less than evidence of the benefits of other antihypertensive agents, and it appears prudent to use alpha-blockers mostly for combination therapy. Emphasis on identifying the first class of drugs to be used is probably outdated by the awareness that two or more drugs in combination are necessary in the majority of patients, particularly those with higher initial blood pressures or TOD or associated diseases, in order to achieve target blood pressure.

Within the array of available agents, the choice of drugs will be influenced by many factors including:

1. the previous, favourable or unfavourable experience of the individual patient with a given class of compounds;
2. the cost of drugs, either to the individual patient or to the health provider, although cost considerations should not predominate over efficacy and tolerability in any individual patient;
3. the cardiovascular risk profile of the individual patient;
4. the presence of TOD, clinical cardiovascular disease, renal disease and diabetes;
5. the presence of other coexisting disorders that may either favour or limit the use of particular classes of antihypertensive drugs;

Table 10.6 Indications and contraindications for the major classes of antihypertensive drugs

		Contraindications	
Class	**Conditions favouring the use**	**Compelling**	**Possible**
Diuretics (thiazides)	Congestive heart failure Elderly hypertensives Isolated systolic hypertension Hypertensives of African origin	Gout	Pregnancy
Diuretics (loop)	Renal insufficiency Congestive heart failure		
Diuretics (anti-aldosterone)	Congestive heart failure Post myocardial infarction	Renal failure Hyperkalaemia	
Beta-blockers	Angina pectoris Post myocardial infarction Congestive heart failure (up-titration) Pregnancy Tachyarrhythmias	Asthma Chronic obstructive pulmonary disease Atrioventricular block (grade 2 or 3)	Peripheral vascular disease Glucose intolerance Athletes and physically active patients
Calcium antagonists (dihydropyridines)	Elderly patients Isolated systolic hypertension Angina pectoris Peripheral vascular disease Carotid atherosclerosis Pregnancy		Tachyarrhythmias Congestive heart failure
Calcium antagonists (verapamil, diltiazem)	Angina pectoris Carotid atherosclerosis Supraventricular tachycardia	A-V block (grade 2 or 3) Congestive heart failure	
ACE-inhibitors	Congestive heart failure Left-ventricular dysfunction Post myocardial infarction Non-diabetic nephropathy Type 1 diabetic nephropathy Proteinuria	Pregnancy Hyperkalaemia Bilateral renal artery stenosis	
Angiotensin II-receptor antagonists (AT1-blockers)	Diabetic nephropathy Diabetic microalbuminuria Proteinuria Left-ventricular hypertrophy ACE inhibitor cough	Pregnancy Hyperkalaemia Bilateral renal artery stenosis	
Alpha-blockers	Prostatic hyperplasia (BPH) Hyperlipidaemia	Orthostatic hypotension	Congestive heart failure

6 the possibility of interactions with drugs used for other conditions present in the patient.

The physician should tailor the choice of drugs to the individual patient, after taking all these factors, together with patient preference, into account. Indications and contraindications of specific drug classes are listed in Table 10.6, and therapeutic approaches to be preferred in special conditions are discussed in the next section.

Therapeutic approaches in special conditions

Elderly

There is little doubt from randomized controlled trials that older patients benefit from antihypertensive treatment in terms of reduced cardiovascular morbidity and mortality, whether they have systolic–diastolic hypertension

[133] or isolated systolic hypertension [132]. Whereas trials in the elderly usually include patients who are at least 60 years old, a recent meta-analysis concluded that fatal and non-fatal cardiovascular events combined were significantly reduced in participants in randomized, controlled trials of antihypertensive drug treatment, who were aged 80 years and over, but all-cause mortality was not reduced [172]. The larger randomized controlled trials of antihypertensive treatment vs. placebo or no treatment in elderly patients with systolic–diastolic hypertension used a diuretic or a beta-blocker as first-line therapy [133]. In trials on isolated systolic hypertension, first-line drugs consisted of a diuretic [12] or a dihydropyridine calcium channel blocker [13,173,174]. In all of these trials, active therapy was superior to placebo or no treatment. Other drug classes have only been used in trials in which 'newer' drugs were compared with 'older' drugs [139,142,155,156,175]. It appears that benefit has been shown in older patients for at least one representative agent of several drug classes, i.e. diuretics, beta-blockers, calcium channel blockers, converting enzyme inhibitors and angiotensin receptor antagonists.

Initiation of antihypertensive treatment in elderly patients should follow the general guidelines. Many patients will have other risk factors, TOD and associated cardiovascular conditions, to which the choice of the first drug should be tailored. Furthermore, many patients will need two or more drugs to control blood pressure, particularly due to the fact that it is often difficult to lower systolic pressure to below 140 mmHg [109,176].

Diabetes mellitus

The prevalence of hypertension is increased in patients with diabetes mellitus [177]. Type 2 diabetes is by far the most common form, occurring about 10–20 times as often as type 1. Hypertensive patients frequently exhibit a condition known as 'metabolic syndrome', i.e. a syndrome associating insulin resistance (with the concomitant hyperinsulinaemia), central obesity and characteristic dyslipidaemia (high plasma triglyceride and low HDL-cholesterol) [23,178]. These patients are prone to develop type 2 diabetes.

In type 1 diabetes, hypertension often reflects the onset of diabetic nephropathy [179], whereas a large fraction of hypertensive patients have still normoalbuminuria at the time of diagnosis of type 2 diabetes [180]. The prevalence of hypertension (defined as a blood pressure ≥ 140/90 mmHg) in patients with type 2 diabetes and normoalbuminuria is very high, at 71%, and increases even further to 90% in the presence of microalbuminuria [181].

The coexistence of hypertension and diabetes mellitus (either of type 1 or 2) substantially increases the risk of macrovascular complications, including stroke, coronary heart disease, congestive heart failure and peripheral vascular disease, and is responsible for an excessive cardiovascular mortality [179,182]. The presence of microalbuminuria is both an early marker of renal damage and an indicator of increased cardiovascular risk [183,184]. There is also evidence that hypertension accelerates the development of diabetic retinopathy [185]. The level of blood pressure achieved during treatment greatly influences the outcome of diabetic patients. In patients with diabetic nephropathy, the rate of progression of renal disease is in a continuous relationship with blood pressure until a level of 130 mmHg systolic and 70 mmHg diastolic is reached. Aggressive treatment of hypertension protects patients with type 2 diabetes against cardiovascular events. The primary goal of antihypertensive treatment in diabetics should be to lower blood pressure below 130/80 mmHg whenever possible, the best blood pressure being the lowest one that remains tolerated.

Weight gain is a critical factor in the progression to type 2 diabetes. It is therefore key to fight against overweight by all possible means, particularly by calorie restriction and a decrease in sodium intake, as a strong relationship exists between obesity, hypertension, sodium sensitivity and insulin resistance [186].

No major trial has been performed to assess the effect of pharmacological blood pressure lowering on cardiovascular morbidity and mortality in hypertensive patients with type 1 diabetes. There is, however, good evidence that beta-blocker and diuretic-based antihypertensive therapy delays the progression of nephropathy in these patients [187]. In albuminuric patients with type 1 diabetes the best protection against renal function deterioration is obtained by ACE inhibition [188]. It remains unknown whether angiotensin II receptor antagonists are equally effective in this indication.

As to antihypertensive treatment in type 2 diabetes [162], evidence of the superiority or inferiority of different drug classes is still vague and contradictory. Superiority of ACE inhibitors in preventing the aggregate of major cardiovascular events is limited to two trials, one against diuretics/beta-blockers [149] and the other against a calcium antagonist [106], or on analyses of cause-specific events for which the trial power was even less. The recent ALLHAT trial [139] has also failed to find differences in cardiovascular outcomes in the larger number of type 2 diabetes patients included in the trial, randomized to a diuretic, a calcium antagonist or an ACE inhibitor. Recent evidence concerning angiotensin II receptor antagonists has shown a significant reduction of cardiovascular events, cardiovascular death and total mortality in diabetics when losartan was compared with atenolol [163], but not when irbesartan was compared

with amlodipine [136]. If renal end-points are also considered, the benefits of angiotensin II receptor antagonists become more evident, as the IDNT [136] showed a reduction in renal dysfunction and failure by the use of irbesartan rather than amlodipine, and LIFE [163] indicated losartan reduced incidence of new proteinuria better than atenolol. In conclusion, in view of the consensus that blood pressure in type 2 diabetic patients must be lowered, whenever possible, to < 130/80 mmHg, it appears reasonable to recommend that all effective and well-tolerated antihypertensive agents can be used, generally in multiple combinations in diabetic patients. Available evidence suggests that renoprotection may be improved by the regular inclusion of an angiotensin receptor antagonist in these associations, and that in patients with high normal blood pressure, who may sometimes achieve blood pressure goal by monotherapy, the first drug to be tested should be an angiotensin II receptor antagonist.

Concomitant cerebrovascular disease

Evidence of the benefits of antihypertensive therapy in patients who had already suffered a stroke or a transient ischaemic attack (TIA) (secondary prevention) was equivocal [189], and no definite recommendation could be given until recent trials have clearly shown the benefits of lowering blood pressure in patients with previous episodes of cardiovascular disease, even when their initial blood pressure was in the normal range [99].

The other issue, whether elevated blood pressure during an acute stroke should be lowered at all, or to what extent and how, is still a disputed one, for which there are more questions than answers, but trials are in progress. A statement by a special International Society of Hypertension (ISH) panel has recently been published [190].

Concomitant coronary heart disease and congestive heart failure

The risk of a recurrent event in patients with coronary heart disease is significantly affected by the blood pressure level [191], and hypertension is frequently a past or present clinical problem in patients with congestive heart failure [192]. However, few trials have tested the effects of blood pressure lowering in patients with coronary heart disease or congestive heart failure. The HOT Study showed a significant reduction of strokes when the target blood pressure in hypertensives with previous signs of ischaemic heart disease was lowered, and found no evidence of a J-shaped curve [104,108].

Apart from the INVEST study [151], many of the more common blood pressure-lowering agents have been assessed in patients with coronary heart disease or heart failure with objectives other than reduction of blood pressure. Beta-blockers, ACE inhibitors and anti-aldosterone compounds are well established in the treatment regimens for preventing cardiovascular events and prolonging life in patients after an acute myocardial infarction and with heart failure, but how much of the benefit is due to concomitant blood pressure lowering and how much to specific drug actions has never been clarified. There are also data in support of the use of angiotensin receptor antagonists in congestive heart failure as alternatives to ACE inhibitors, especially in ACE inhibitor intolerance or in combination with ACE inhibitors [193,194]. The role of calcium antagonists in prevention of coronary events has been vindicated by the ALLHAT trial, which showed a long-acting dihydropyridine to be equally effective as the other antihypertensive compounds [139]. Calcium antagonists are possibly less effective in prevention of congestive heart failure, but a long-acting compound such as amlodipine may be used, if hypertension is resistant to other compounds [195].

Hypertensive patients with deranged renal function

Renal vasoconstriction is found in the initial stages of essential hypertension and this is reversed by the administration of calcium channel blockers and angiotensin-converting enzyme inhibitors. In more advanced stages of the disease, renal vascular resistance is permanently elevated as a consequence of structural lesions of the renal vessels (nephrosclerosis). Before antihypertensive treatment became available, renal involvement was frequent in patients with primary hypertension. Renal protection in diabetes requires two main accomplishments: first, to attain a very strict blood pressure control (< 130/80 mmHg and even lower, < 125/75 mmHg, when proteinuria > 1 g per day is present) and, second, to lower proteinuria or albuminuria (micro- or macro-) to values as near to normalcy as possible. In order to attain the latter goal, blockade of the effects of angiotensin II (either with an ACE inhibitor or with an angiotensin receptor blocker) is required. In order to achieve the blood pressure goal, combination therapy is usually required, even in patients with high normal blood pressure [162]. The addition of a diuretic as second-step therapy is usually recommended (a loop diuretic if serum creatinine > 2 mg/dl), but other combinations, in particular with calcium antagonists, can also be considered. To prevent or retard development of nephrosclerosis, blockade of the renin–angiotensin system has been reported to be more important than attaining very low blood pressure [165]. On the whole, it seems prudent to start antihypertensive therapy in patients (diabetic or non-diabetic) with reduced renal function, especially if accompanied by proteinuria, by

an ACE inhibitor or an angiotensin receptor antagonist, and then add other antihypertensive agents in order to further lower blood pressure.

Resistant hypertension

Hypertension may be termed resistant to treatment, or refractory, when a therapeutic plan that has included attention to lifestyle measures and the prescription of at least three drugs in adequate doses has failed to lower systolic and diastolic blood pressure sufficiently. In these situations, referral to a specialist should be considered.

There are many cases for resistance to treatment including cases of previous hypertension, such as isolated office (white coat) hypertension, and failure to use large cuffs on large arms. One of the most important causes of refractory hypertension may be poor compliance or adherence to therapy, and in this situation, after all else fails, it can be helpful to suspend all drug therapy while continuing to monitor blood pressure frequently. A fresh start with a new and simpler regimen may help break a vicious cycle.

High risk in general

In the VALUE trial [153], as many as 15 245 hypertensive patients with high cardiovascular risk for various reasons were randomized to valsartan- vs. amlodipine-based treatment for an average of 4.2 years and until 1599 primary end-points, defined as the composite of serious cardiac morbidity or cardiac mortality. There was no difference between the treatment arms with respect to the primary end-point; however, amlodipine lowered blood pressure more effectively than valsartan, and the difference in blood pressure was associated with less stroke and myocardial infarction early in the study. Towards the end of the study, valsartan reduced new-onset diabetes [153] and serious heart failure, particularly if the data were adjusted for the difference in blood pressure [154].

Personal perspective

Modern antihypertensive treatment should usually be given as a combination of well-tolerated drugs, not withholding lifestyle changes when appropriate. There is solid documentation of cardiovascular protection; although most benefit is related to the blood pressure reduction per se, there is evidence in certain patient groups, such as diabetics and patients with left-ventricular hypertrophy, that benefits may be better with certain drugs. However, blood pressure control among patients is still on average suboptimal or even poor, and this applies even more so to patients with complicated hypertension and particular high risk. The challenge for the future is to implement the knowledge from the research and provide equal levels of care for all hypertensive patients. Newer drugs seem better tolerated than the old ones, but they have not been studied in the vast majority of patients, namely those with mild blood pressure elevation only. It is a challenge for all to document more solid prognostic improvements among these patients, including examining the cost–benefit of treating these patients. Full implementation of ambulatory and home blood pressure assessments in clinical practice still needs better documentation. Isolated office or white coat hypertension, and also the reversed phenomenon in patients with high ambulatory but low office blood pressure, need better understanding. Prevention of certain not so 'hard' but still important end-points, such as new-onset diabetes, atrial fibrillation and vascular dementia, needs extensive investigations. The breakthrough of genetic stratification in the field of hypertension research is also still to come.

11 Diabetes Mellitus and Metabolic Syndrome

Francesco Cosentino, Lars Ryden and Pietro Francia

Summary

This chapter reviews an evidence-based approach to diagnosis and treatment of diabetes mellitus and metabolic syndrome according to the most recent scientific evidence, recommendations of the European Society of Cardiology, and world-wide institutional guidelines. The pathophysiology and clinical management of atherosclerotic complications of diabetes and metabolic syndrome are considered as a continuum rather than separate issues, according to the need for merging basic and clinical sciences into a real 'bench-to-bedside' approach.

Diabetes mellitus affects more than 150 million people world-wide, with an expected doubling of this number in the next 25 years. Furthermore, approximately 50% of persons above the age of 60 years will meet current diagnostic criteria for metabolic syndrome in the near future. Hyperglycaemia, insulin resistance and the consequent cellular shift to an increased oxidative stress metabolism carry a high risk for the development of comorbidities and cardiovascular risk factors, mainly hypertension, lipid disorders, proinflammatory state, and impairment of coagulation and thrombosis. As a consequence, the incidence of and mortality from all forms of cardiovascular disease are two- to eightfold higher in persons with diabetes, and coronary artery disease accounts for 75% of all deaths in individuals with diabetes. The impressive burden of the disease supports the employment of highly sensitive risk stratification systems to identify patients who will benefit from pharmacological interventions aside from glycaemic control (mainly statins, aspirin, and renin–angiotensin system antagonists) to prevent cardiovascular and cerebrovascular events, and new percutaneous intervention strategies, including drug-eluting stents and anti-thrombotic agents, that currently provide evidence of efficacy in treating target vessels and reducing the rate of restenosis.

Modification of diabetes-associated risk factors for cardiovascular disease, together with a combined approach of medical and interventional strategies to increase long-term vessel patency after percutaneous intervention, is our challenge for the future.

Introduction

Diabetes mellitus is characterized by a state of long-standing hyperglycaemia, hyperinsulinaemia and excess circulating free fatty acids resulting from environmental and genetic factors. The prevalence of diabetes is increasing rapidly, and individuals with diabetes are at high risk for cardiovascular disorders that affect the heart, brain and peripheral vessels. Although cardiovascular disease (CVD) accompanying diabetes is on the rise, many open issues remain concerning the temporal relations between diabetes and CVD, the contribution of conventional risk factors, and the role of diabetes-specific risk factors. The major CVD risk factors, including elevated low-density lipoprotein (LDL)-cholesterol, hypertension, smoking, remain important determinants of CVD in patients with diabetes. In addition, the emerging risk factors—hyperglycaemia, insulin resistance, albuminuria, fibrinogen and enhanced inflammatory activation—further appear to affect risk in individuals with diabetes. Hence the significant clustering of atherogenic risk factors links the current epidemic of diabetes and CVD. Indeed, diabetes

mellitus magnifies the risk of cardiovascular morbidity and mortality [1]. Besides the well-recognized microvascular complications of diabetes, such as nephropathy and retinopathy, macrovascular complications, including diseases of coronary, peripheral and carotid vessels, cause important and common problems in the type 2 diabetic population.

This chapter will consider the pathophysiology and management of atherosclerotic complications of diabetes as a continuum and not—traditionally—as separate sections. Nowadays, physicians caring for patients with CVD must have a working knowledge of the effects of diabetes mellitus and the morbid constellation of risk factors on the heart and blood vessels. Therefore, early detection and intervention with regard to the atherogenic metabolic abnormalities and glucose intolerance that precede development of diabetes is mandatory. A high priority is given to the modification of the major risk factors for CVD. Increasing evidence indicates that controlling CVD risk factors will reduce onset of CVD and its complications in patients with diabetes.

Diagnostic criteria

The clinical diagnosis of diabetes is often prompted by symptoms such as increased thirst, urine volume, recurrent infections, unexplained weight loss and glycosuria. A single blood glucose estimation in excess of the diagnostic values indicated in Table 11.1 establishes the diagnosis in such cases [2]. A blood glucose determination after an 8-h fast (fasting plasma glucose, FPG) of < 6.1 mmol/l (< 110 mg/dl) is considered normal. Impaired fasting glucose encompasses FPGs > 6.1 mmol/l but < 7 mmol/l (< 126 mg/dl). An FPG > 7.0 mmol/l establishes the diagnosis of diabetes mellitus. Among routine tests of glucose metabolism, the 2-h oral glucose tolerance test (OGTT) most closely reflects postprandial glucose disposal. Patients fast overnight, then have blood drawn for serum glucose immediately before and 2 h after the ingestion of an oral load of 75 g of dextrose. Impaired glucose tolerance (IGT) corresponds to a 2-h glucose concentration between 7.8 mmol/l (140 mg/dl) and 11.1 mmol/l (199 mg/dl), while diabetes is defined as a value > 11.1 mmol/l (> 200 mg/dl) [2,3]. For clinical purposes, an OGTT to establish diagnostic status should be considered if causal blood glucose values lie in the uncertain range (i.e. between the levels that establish or exclude diabetes) and FPG levels are below those which establish the diagnosis of diabetes. In this regard, despite the recent lowering by the American Diabetes Association [4] of the value of normal FPG concentration to 5.5 mmol/l and impaired fasting glucose (IFG) (from > 5.5 mmol/l to < 7.0 mmol/l), there is evidence that some of the individuals identified by the new fasting values differ from those identified from their 2-h post-glucose challenge values. Indeed, in less obese subjects and the elderly, lower fasting glucose levels may be seen in persons who have 2-h post-load glucose values that are diagnostic for diabetes. On the other hand, middle-aged, more obese patients are more likely to have diagnostic fasting values. Diagnosis requires the identification of people at risk for development of complications in whom early preventive strategies are indicated. Ideally therefore both the 2-h and the fasting value should be used [2]. These recommendations contrast with those of the American Diabetes Association Expert Committee which gives primacy to

	Venous glucose concentration in mmol/l (mg/dl)	
	Whole blood	**Plasma**
Diabetes mellitus

the FPG. IGT or IFG are not clinical entities, but rather risk categories for future diabetes and/or cardiovascular disease. IGT is often associated with the metabolic syndrome (insulin-resistance syndrome). Thus, IGT may not be directly involved in the pathogenesis of cardiovascular disease, but rather may serve as a marker of enhanced risk. Self-evidently, those individuals with IGT manifest glucose intolerance only when challenged with an oral glucose load.

In this chapter, the focus is on type 2 diabetes, characterized by insulin resistance and/or inadequate beta-cell insulin secretion, because these patients represent more than 90% of those with diabetes and atherosclerosis. However, those with type 1 diabetes (previously known as insulin-dependent or juvenile diabetes) also have an independently higher risk of cardiovascular events, and their disease generally develops at a much younger age than in the type 2 diabetic population.

Atherosclerotic burden associated with diabetes

Diabetes mellitus is estimated to affect more than 150 million people world-wide, with an expected doubling number in the next 25 years, reaching 5.4% of the total adult population [5]. In the United States 17 million people are diabetics, 95% of whom have type 2 diabetes. Among these, 5–6 million are unaware of their condition and do not receive treatment [6,7]. An additional 35 million—20% of all people in the middle-adult years and 35% of the entire older population—have some degree of abnormal glucose tolerance and show signs of insulin resistance; this higher-risk group will account for a significant proportion of CVD and premature mortality. The increasing frequency of obesity and sedentary life-styles, major underlying risk factors for type 2 diabetes in both developed and developing countries, portends that diabetes will continue to be a growing world-wide entity. The incidence of and mortality from all forms of CVD are two- to eightfold higher in persons with diabetes than in those without diabetes. Coronary artery disease (CAD) accounts for 75% of all deaths in individuals with diabetes [8,9] and as many as 30% of patients presenting with acute coronary syndromes have the disease [7]. Both in-hospital and long-term mortality rates after an acute myocardial infarction (MI) are twice as high for patients with diabetes as for those without diabetes (Fig. 11.1). In one population-based study [10], the 7-year incidence of first myocardial infarction or death for patients with diabetes was 20% but was only 3.5% for non-diabetic patients. A history of myocardial infarction increased the rate of recurrent myocardial infarction or cardiovascular death events for both groups (18.8% in non-diabetic persons and 45% in those with diabetes). Thus patients

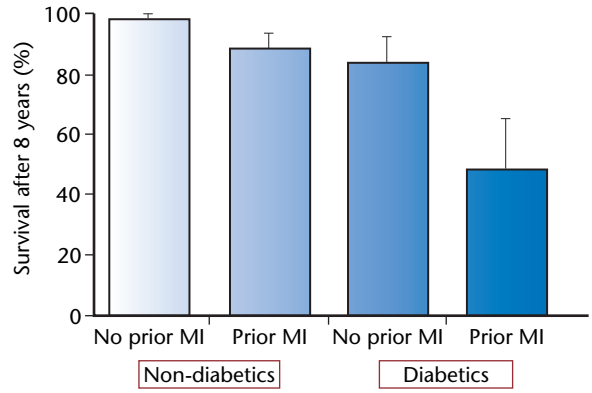

Figure 11.1 Mortality in diabetics after myocardial infarction. Redrawn with permission from [10].

with diabetes but without previous myocardial infarction carry the same level of risk for subsequent acute coronary events as non-diabetic patients with previous myocardial infarction. Such results led the Adult Treatment Panel III of the National Cholesterol Education Program to establish diabetes as a CAD risk equivalent mandating aggressive antiatherosclerotic treatment [11]. Comorbidities —including renal insufficiency, peripheral and cerebral vascular disease—that are more prevalent in patients with diabetes often worsen outcomes. The increase in the incidence of diabetes, its association with CVD, and the accompanying high morbidity and mortality make diabetes a serious public-health issue.

Vascular disease risk factors: from pathophysiology to clinical management

Hyperglycaemia, insulin resistance and oxidative stress

Hyperglycaemia

Hyperglycaemia characterizes both type 1 and type 2 diabetes mellitus. Since a number of studies closely linked elevated blood glucose levels to excess mortality and morbidity from vascular disease [12], growing efforts currently focus on clarifying the effects of glucose on vascular function, in particular endothelial function and nitric oxide (NO) bioavailability.

Indeed, the endothelium contributes to the control of vascular smooth muscle tone by the release of NO. The NO causes vasodilatation and platelet inhibition and thereby prevents vasoconstriction and thrombus

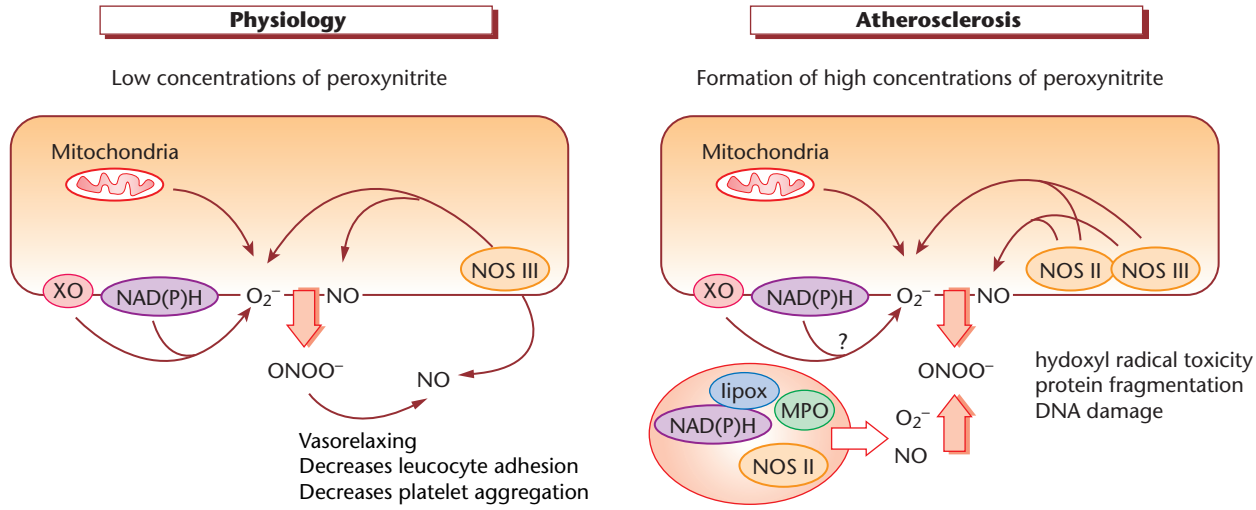

Figure 11.2 In the atherosclerotic setting, an excessive production of O_2^- occurs. O_2^- rapidly inactivates NO, leading to the formation of high concentrations of peroxynitrite ($ONOO^-$), a condition associated with cellular toxicity. Please note the putative sources of O_2^- in the left panel. Reproduced with permission [192].

formation. It is generated from a terminal guanidino nitrogen of L-arginine and is catalysed by a family of enzymes called NO synthases [13,14]. One of these enzymes, endothelial NOS (eNOS), is Ca^{2+}-dependent and is constitutively present in various cell types, including endothelial cells. The activity of the L-arginine/NO pathway is a balance between synthesis and breakdown of NO by its reaction with the superoxide anion (O_2^-). Under physiological conditions the production of this molecule is not markedly affected by O_2^-. Hence, NO may exert its well-known vascular protective effects favouring an antiatherosclerotic environment. However, in the presence of cardiovascular risk factors, an excessive production of O_2^- occurs rapidly, inactivating NO and leading to the formation of high concentrations of peroxynitrite ($ONOO^-$), a very powerful oxidant (Fig. 11.2).

Several lines of evidence support the concept that hyperglycaemia decreases endothelium-derived NO availability and affects vascular function [15,16] via a number of mechanisms mainly involving overproduction of reactive oxygen species (ROS), namely O_2^- [17] (Fig. 11.3).

The mitochondrial electron transport chain is probably one of the first targets of high glucose, with a direct net increase in superoxide anion formation. A further increase in superoxide production is driven by a vicious circle involving ROS-induced activation of protein kinase C (PKC) [15] and vice versa. Indeed, activation of PKC by glucose has been implicated in the regulation and activation of membrane-associated NAD(P)H-dependent oxidase, this latter leading to subsequent production of superoxide anion [18]. Indeed, NAD(P)H activity and subunit protein expression are enhanced in the internal mammary arteries and saphenous veins of diabetic patients [19]. Moreover, high glucose-dependent PKC activation induces an upregulation of inducible cyclo-oxygenase 2 and eNOS expression as well as a selective increase of thromboxane production and reduced NO release. Hence, activation of the PKC pathway represents a proximal node in the intracellular signalling leading to hyperglycaemia-induced oxidative stress and endothelial dysfunction [20] (Fig. 11.4).

Oxygen-derived free radical excess affects endothelial function via a number of different pathways:

- Superoxide anion rapidly inactivates NO to peroxynitrite [21], a powerful oxidant which easily penetrates across phospholipid membranes and produces substrate nitration, thereby inactivating regulatory receptors and enzymes, such as free radical scavengers [22,23] and key NOS co-factors, for instance tetrahydrobiopterin [24].
- Mitochondrial production of superoxide increases intracellular formation of advanced glycation end-products (AGEs) which adversely affect endothelial function by increasing ROS production and inflammatory cytokines from vascular cells thereby enhancing endothelial expression of various adhesion molecules implicated in atherogenesis [25].
- Activation of the receptor for AGEs (RAGE) increases intracellular superoxide anion production [26] and seems to represent a key step in atherosclerotic lesion development [27].
- Superoxide anion production activates the hexosamine pathway, which lowers protein kinase Akt-induced NOS activation [28]. Akt activation is

further limited by PKC-dependent inhibition of phosphatidylinositol-3 kinase (PI-3K) pathway.

- High glucose-induced oxidative stress increases the levels of dimethylarginine, a competitive antagonist of NOS [29].

The impact of diabetes mellitus on vascular function is not limited to the endothelium. In patients with type 2 diabetes mellitus, the vasodilator response to exogenous NO donors is diminished [30]. Dysregulation of vascular smooth muscle function is further enhanced by impairments in sympathetic nervous system function. Diabetes increases PKC activity, NF-κB production, and generation of oxygen-derived free radicals in vascular smooth muscle, akin to these effects in endothelial cells.

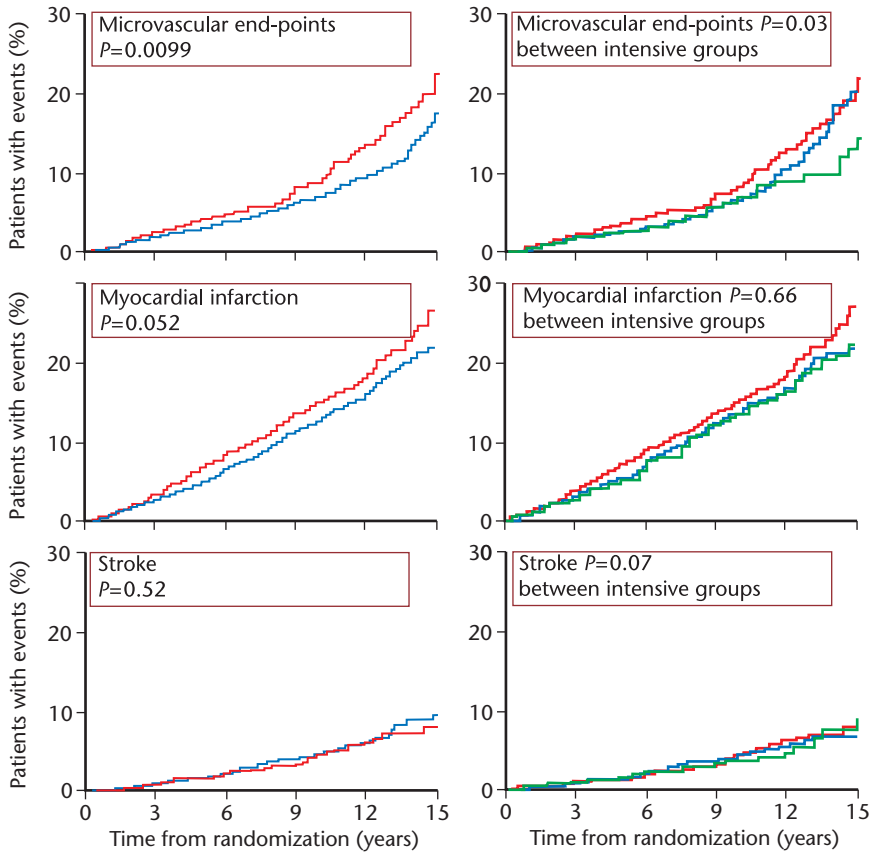

Figure 11.5 Kaplan–Meier plots of aggregate end-points: microvascular disease, myocardial infarction and stroke for intensive and conventional treatment and by individual intensive therapy. Microvascular disease = renal failure, death from renal failure, retinal photocoagulation, or vitreous haemorrhage. Myocardial infarction = non-fatal, fatal, or sudden death. Stroke = non-fatal and fatal. Reprinted with permission [33].

Moreover, diabetes heightens migration of vascular smooth muscle cells into nascent atherosclerotic lesions, where they replicate and produce extracellular matrix —important steps in mature lesion formation [31]. Vascular smooth muscle cell apoptosis in atherosclerotic lesions is also increased, such that patients with diabetes tend to have fewer smooth muscle cells in the lesions, which increases the propensity for plaque rupture [32]. In persons with diabetes, elaboration of cytokines diminishes the vascular smooth muscle synthesis of collagen and increases production of matrix metalloproteinases, yielding an increased tendency for plaque destabilization and rupture.

Given the above-mentioned effects of hyperglycaemia on vascular function, one might speculate that tight glycaemic control warrants preservation from micro- and macrovascular damages and favourably impacts prognosis in diabetic patients. Epidemiological studies support the notion that increasing blood glucose levels proportionally relates to cardiovascular events. Less is known on the effect of a really strict glycaemic control. In the United Kingdom Prospective Diabetes Study (UKPDS) [33] the risk of death, stroke, or amputation did not change while there was a trend towards fewer myocardial infarctions in the most actively treated group. Glycaemic control was, however, rather modest, with a glycated haemoglobin A1c (HbA1c) of 7% in the intervention group and only a small difference of 0.9% between the intervention and the control groups. Still, improved treatment of hyperglycaemia lowered the incidence of diabetic retinopathy and nephropathy (Fig. 11.5). Considering the established close relationship between glucose levels and cardiovascular risk, a strict control of glycaemia is at present highly recommended in diabetic patients. A HbA1c < 6.0% (Diabetes Control and Complications Trial standard), fasting glucose < 6.0 mmol/l (venous plasma, < 110 mg/dl) and postprandial glucose < 10.0 mmol/l (< 180 mg/dl) should be considered as targets for glycaemic control [34]. Risks and benefits of more stringent goals are currently under evaluation.

Insulin resistance

Insulin resistance is a typical characteristic of type 2 diabetes. Insulin stimulates NO production from endothelial cells by increasing the activity of NOS via activation of PI-3K and Akt kinase. Thus, in healthy subjects, insulin increases endothelium-dependent (NO-mediated)

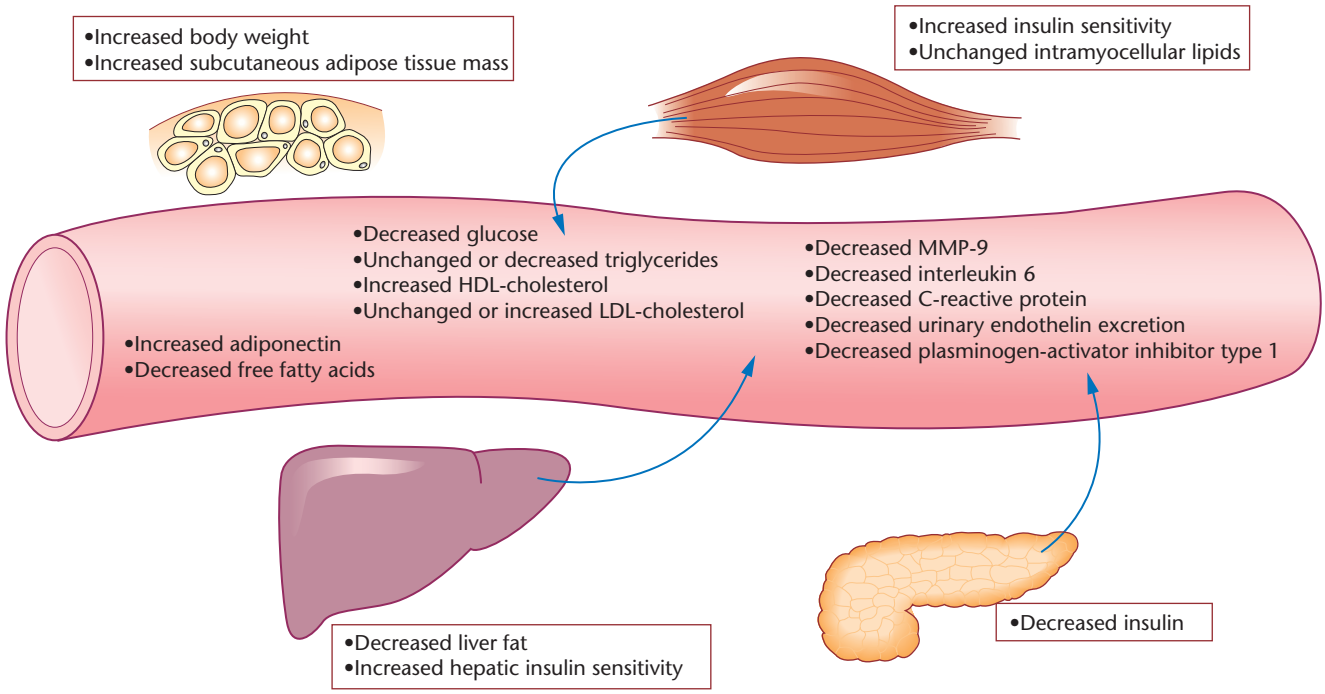

Figure 11.6 Mechanism of action of thiazolidinediones *in vivo* in humans. MMP-9, matrix metalloproteinase-9; HDL, high-density lipoprotein; LDL, low-density lipoprotein. Reproduced with permission [38].

vasodilatation. On the contrary, endothelium-dependent vasodilatation is reduced in insulin-resistant subjects. Furthermore, insulin-mediated glucose disposal correlates inversely with the severity of the impairment in endothelium-dependent vasodilatation. Abnormal endothelium-dependent vasodilatation in insulin-resistant states may be explained by alterations in intracellular signalling that reduce the production of NO. Insulin signal transduction via the PI-3K pathway is impaired and insulin is less able to produce NO. On the other hand, insulin signals via the mitogen-activated protein kinase pathway (MAPK) remain intact. MAPK activation is associated with increased endothelin production and a greater level of inflammation and thrombosis.

Insulin resistance is a distinct trait of diabetes mellitus, and its magnitude directly relates to cardiovascular outcomes [35,36]. In the UKPDS, a likely reason that the biguanide metformin decreased macrovascular events is enhanced insulin sensitivity. However, the addition of metformin to a sulphonylurea increased cardiovascular risk [37].

The recently introduced thiazolidinediones offer another approach to decrease insulin resistance [38] (Fig. 11.6). These compounds activate the peroxisome proliferator-activated receptor-γ (PPAR-γ), a nuclear receptor that takes part in vascular cell and adipose differentiation [39]. They also seem to have an anti-inflammatory property, a feature that may favourably impact the natural history of the atherosclerotic process [40]. Drug therapies that increase insulin sensitivity, such as metformin and the thiazolidinediones, improve endothelium-dependent vasodilatation. At present, and after elimination of troglitazone because of hepatotoxic effects, rosiglitazone and pioglitazone are approved in most countries for the treatment of hyperglycaemia in patients with type 2 diabetes. Whether the hypothetical benefits of these drugs hold true in clinical practice is presently being studied in large clinical trials.

Oxidative stress

Given the pivotal role of oxidative stress in endothelial function and atherosclerotic processes in diabetes, growing efforts focus on the putative effects of antioxidant therapy. Despite evidence indicating the reversal of endothelial dysfunction by different antioxidant agents [41], data from clinical trials are still inconclusive and do not support compelling indications for antioxidant therapy in diabetes mellitus [42,43]. These data would seem to refute a role of oxidative stress in the pathogenesis of atherosclerosis. There are several reasons to believe that this conclusion is not justified but rather that treatment with antioxidative is perhaps not the best approach for reducing oxidative stress. First, the rate of costant for

reactions between vitamin E and superoxide is several orders of magnitude less than the rate of constant for the reaction of superoxide with NO. Second, many of the oxidative events occur in the cytoplasm and in the extracellular space, and would not be affected by lipid-soluble antioxidants, which are concentrated in lipid membranes and lipoproteins. Third, antioxidants may become pro-oxidants after scavenging a radical, vitamins E and C become tocopheroxyl and ascorbyl radicals, respectively. The tocopheroxyl radical can be regenerated by other antioxidants such as vitamin C or co-enzyme Q10. For this reason, the use of cocktails of antioxidants rather than high doses of a selected one may be more effective. Given the above considerations, it is quite possible that use of antioxidant vitamins will never prove to be the best approach to limit vascular oxidant stress. To prevent the development of the earliest stages of diabetic vascular disease, future research should focus on identifying substances which have antioxidant effects not because they scavenge radicals but because they block their production.

Lipid disorders

Classically, diabetes mellitus induces elevation of triglycerides and LDL-cholesterol, and decline of high-density lipoprotein (HDL) plasma levels. These changes clearly affect the natural history of the atherosclerotic disease, and render patients with diabetes more prone to developing CAD, stroke and peripheral vascular disease. Recent evidence confers to diabetes-related enhanced free fatty acid liberation a crucial role in producing the well-described changes in lipid profile. Excess circulating levels of free fatty acids result from both enhanced release from adipose tissue and reduced uptake from skeletal muscle [44]. The liver responds to free fatty acid excess by increasing very-low-density lipoprotein (VLDL) production and cholesteryl ester synthesis [45]. The accumulation of triglyceride-rich lipoproteins, depending also on their reduced clearance by lipoprotein lipase, triggers hypertriglyceridaemia and lowers HDL levels by promoting exchanges from HDL to VLDL via cholesteryl ester transfer protein [45]. HDL are not only reduced in quantity, but also impaired in function. Indeed, HDL from poorly controlled type 2 diabetic patients are less effective in preventing LDL oxidation compared to those from non-diabetic subjects [46]. Moreover, increased VLDL production and abnormal cholesterol and triglyceride transfer between VLDL and LDL enhance the plasma levels of small and dense proatherogenic LDLs [47], which are in addition more prone to oxidation because of impaired antioxidant defence mechanisms in the plasma of diabetics [48]. Since their pro-atherosclerotic effects on coronary, carotid and peripheral arteries, the above-mentioned changes in lipid profile have important clinical consequences, thus representing an important treatment target. Non-pharmacological approaches, including glycaemic control, dietary modifications, weight loss, physical exercise and cessation of smoking [49] represent the first mode of therapy. However, life-style modifications are mostly inadequate and a drug-based therapeutic regimen is mandatory, especially in patients who experience poor glycaemic control. The 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (or statins), by increasing LDL clearance and decreasing VLDL secretion, currently represent the cornerstone of lipid-lowering therapy. In the Scandinavian Simvastatin Survival Study [50], simvastatin reduced the risk of total mortality and myocardial infarction by 43% and 55%, respectively, in diabetic patients, compared to 29% and 32% in non-diabetic patients. Accordingly, the Cholesterol and Recurrent Events (CARE) trial [51] demonstrated a 24% reduction in cardiovascular events in diabetic patients with CAD and elevated or average LDL-cholesterol with statins. In the Heart Protection Study (HPS) [43], which enrolled 3000 diabetic subjects without evidence of atherosclerosis at entry, simvastatin reduced the combined end-point of acute coronary syndrome, stroke or revascularization by 34% over a 5-year follow-up period in the diabetic subgroup. The primary preventive Collaborative Atorvastatin Diabetes Study (CARDS) [52] assessed atorvastatin for primary prevention of major cardiovascular events in patients with type 2 diabetes and LDL-cholesterol below 4.14 mmol/l. In this study, 2838 patients without a history of cardiovascular disease were randomized to placebo or 10 mg of atorvastatin daily if they had at least one further risk factor (retinopathy, albuminuria, current smoking, or hypertension). The trial was terminated after a median duration of follow-up of 3.9 years because of the beneficial effects of atorvastatin. Acute coronary heart disease events were reduced by 36%, coronary revascularizations by 31% and stroke by 48%. Moreover, atorvastatin reduced the death rate by 27%, which was borderline significant.

As a result of its ability to increase HDL and decrease triglyceride levels without affecting glucose control, niacin would be an ideal drug in dyslipidaemic diabetic patients [53]. However, the effect on cardiovascular outcomes is still unproven in diabetics. This and well-known side-effects [54] still make niacin a second-line agent.

Fibric acid derivatives, as PPAR-α agonists, also raise HDL and lower triglyceride levels. The Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT) [55] showed a 24% risk reduction in death from

CAD, non-fatal myocardial infarction and stroke in diabetic patients with normal LDL and low HDL levels treated with gemfibrozil. As a result of the potential risk of myositis [56] the joint use of fibric acid derivatives and statins requires careful monitoring and should be considered only in selected patients.

Hypertension

Hypertension is a common comorbidity of diabetes. Indeed, high blood pressure is more common in patients with type 2 diabetes than in matched controls [57]. While in type 1 diabetes hypertension is often the result of underlying nephropathy, the association of type 2 diabetes and high blood pressure is a typical feature of the metabolic syndrome. In 1998, UKPDS [58] first documented the benefits of tight blood pressure control in diabetic patients. Both atenolol and captopril decreased the risk of stroke and death with comparable magnitude [59]. Of note, the majority of enrolled subjects required two or three drugs to control blood pressure at follow-up.

According to the European Society of Cardiology guidelines on cardiovascular disease prevention, a target blood pressure < 135/80 mmHg is the goal in diabetic hypertensive patients [34]. Although diuretics, beta-blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs) and calcium-channel blockers are all effective in lowering blood pressure in diabetics (Table 11.2), the modern approach in diabetic patients starts with modulation of the renin–angiotensin system (Fig. 11.7). Modulation of the renin–angiotensin system by ACE inhibitors, and more recently by ARBs, seems to exert vascular protective effects beyond blood pressure control, and to limit target organ damage [60–63]. In the HOPE trial, ramipril significantly reduced death, myocardial infarction and stroke in more than 3000 high-risk non-hypertensive diabetic patients [64]. Interestingly, ramipril treatment was also associated with a 34% reduction in new-onset diabetes [65]. More recently, the LIFE study showed that losartan was superior to atenolol in reducing the combined end-point of cardiovascular death, stroke, or myocardial infarction and total mortality in a large subgroup of hypertensive diabetic patients [66,67]. Of note, because the blood pressure-lowering of the two drugs was equivalent, the reported effect seems to be largely independent of blood pressure lowering. Such benefits support the front-line use of ACE inhibitors and ARBs in high-risk diabetic patients, probably regardless of whether they are hypertensive. A further reason to stress the key role of renin–angiotensin system modulation in diabetic hypertensive patients is the well-demonstrated ability of ACE inhibitors and ARBs to slow the deterioration of renal function and rate of progression to end-stage renal disease [60,62]. The putative added value of combining an ACE inhibitor with an ARB in diabetic patients is still under evaluation [68].

From a practical perspective, prehypertensive (systolic blood pressure of 130–140 mmHg or diastolic blood pressure of 80–90 mmHg) diabetic patients may benefit from life-style and behavioural therapy for a maximum

Table 11.2 Relationship between blood pressure lowering and risk of cardiovascular disease in patients with diabetes

of 3 months. If target blood pressure < 135/80 mmHg is not achieved, a pharmacological intervention with a regimen that includes either an ACE inhibitor or an ARB should be established. Careful monitoring of potassium serum levels is necessary in diabetics treated with ACE-inhibitors, particularly in those with moderate-to-severe impairment of glomerular filtration rate.

Thrombosis and coagulation

Platelet function is crucial in determining the natural history of atherosclerosis and the consequences of plaque rupture. It is therefore not surprising that cardiovascular risk is closely linked to platelet function abnormalities and coagulation disorders in the diabetic patient. The intracellular platelet glucose concentration mirrors the extracellular environment and is associated with increased superoxide anion formation, PKC activity and decreased platelet-derived NO [69,70]. Moreover, diabetic patients show increased expression of glycoprotein Ib and IIb/IIIa, which enhances both platelet–von Willebrand factor and platelet–fibrin interactions [69] (Fig. 11.8). Hyperglycaemia further affects platelet function by impairing calcium homeostasis [71] and thereby altering platelet conformation, secretion and aggregation, and thromboxane formation. Further abnormalities affecting platelet function include impaired endothelial production of nitric oxide and prostacyclin, and increased production of fibrinogen, thrombin and von Willebrand factor [69].

Moreover, blood coagulability is enhanced in diabetic patients. Indeed, plasma coagulation factors (e.g. factor VII and thrombin), lesion-based coagulants (e.g. tissue factor) and atherosclerotic lesion content of plasminogen activator inhibitor-1 (a fibrinolysis inhibitor) are increased, and endogenous anticoagulants (e.g. thrombomodulin and protein C) are decreased [72–76]. Thus, a propensity for platelet activation and aggregation, coupled with a tendency for coagulation, amplify the risk that plaque rupture results in thrombotic occlusion of arteries (Fig. 11.8).

Results from several trials have consistently demonstrated that increased propensity for platelet aggregation in diabetics strongly relates to cardiovascular outcomes. The Antiplatelet Trialists' Collaboration analysed the results of 195 trials of > 135 000 patients at high risk of arterial disease and found that platelet antagonists lowered the risk of stroke, myocardial infarction and vascular death [77] (Fig. 11.9). In the Early Treatment of Diabetic Retinopathy Study (ETDRS), aspirin reduced the risk of myocardial infarction in patients with type 1 or

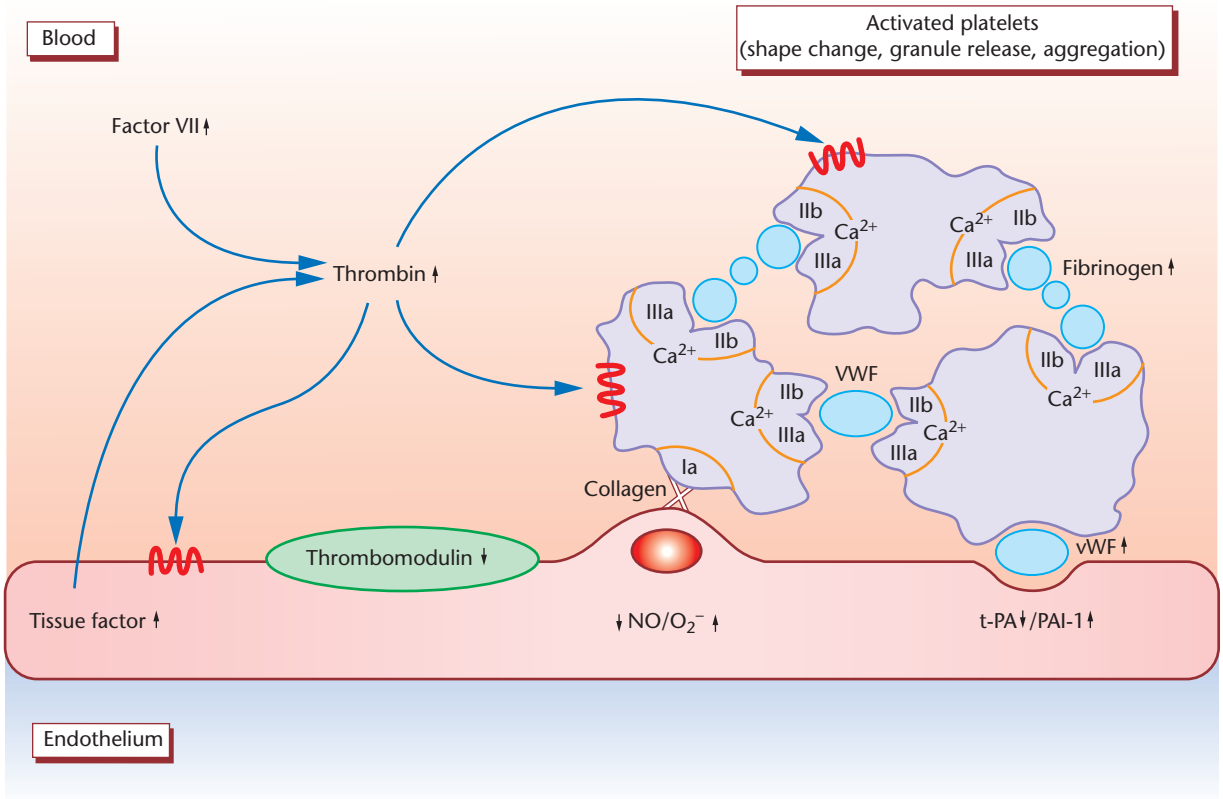

Figure 11.8 Platelet function and plasma coagulation factors are altered in diabetes, favouring platelet aggregation and a propensity for thrombosis. There is increased expression of glycoprotein Ib and IIb/IIIa, augmenting both platelet–von Willebrand factor (vWF) and platelet–fibrin interaction. The bioavailability of NO is decreased. Coagulation factors, such as tissue factor, factor VII and thrombin, are increased; plasminogen activator inhibitor (PAI-1) is increased; and endogenous anticoagulants such as thrombomodulin are decreased. t-PA, tissue plasminogen activator. type 2 diabetes without increasing the risk of vitreous or retinal bleeding, even in patients with retinopathy [78]. In acute coronary syndromes, platelet antagonists seem to be particularly effective in diabetics. The PRISM-PLUS study showed that addition of tirofiban (a platelet glycoprotein IIb/IIIa antagonist) to heparin decreased the risk of death and myocardial infarction particularly in diabetics [79]. A meta-analysis of six large-scale trials of intravenous glycoprotein IIb/IIIa inhibitors in the management of acute coronary syndromes in diabetics showed that these agents reduce mortality by 25% at 30 days in diabetic patients [80]. In the Clopidogrel in Unstable Angina to Prevent Recurrent Ischaemic Events (CURE) study the addition of clopidogrel to aspirin led to a reduction in death, myocardial infarction, or stroke in patients with unstable angina/non-ST-segment-elevation myocardial infarction (NSTEMI), irrespective of their diabetes status [81]. In addition, specific and amplified benefits of clopidogrel treatment have been reported in diabetics [82].

Given the above reported evidence, it is appropriate to recommend the use of aspirin both as a secondary prevention strategy in diabetics already affected by myocardial infarction, cerebrovascular disease or peripheral artery disease, and as a primary prevention strategy in diabetics who have additional risk factors for cardiovascular disease.

Clinical presentation and management of cardiovascular disease

Coronary artery disease

The short- and long-term prognosis in patients with diabetes presenting with acute coronary syndrome (ACS) has been evaluated in several randomized clinical trials. The first Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries trial (GUSTO I) enrolled 41 021 patients presenting with STEMI, including insulin-treated and non-insulin-treated patients with diabetes [8]. The 30-day mortality rate was significantly higher for diabetic than non-diabetic patients. A meta-analysis was also performed with data from six large-scale trials enrolling patients without and with diabetes hospitalized for NSTEMI and/or unstable angina [80]. The 30-day mortality rate was found to be significantly higher in the diabetic subgroup. In the Organization to Assess Strategies for Ischaemic Syndromes (OASIS) registry, a six-nation NSTEMI/unstable angina outcome study, diabetes increased mortality by 57% [9]. The recently published Euro Heart Survey on diabetes and the heart [83] studied the prevalence of abnormal glucose regulation in adults with CAD. The survey involved 110 centres in 25 countries recruiting 4196 patients with CAD. An OGTT was used for the characterization of glucose metabolism. In patients with acute CAD, 36% had impaired glucose regulation and 22% had newly detected diabetes. In patients with stable CAD these proportions were 37% and 14%, respectively. The survey showed that normal glucose regulation is indeed less common than abnormal glucose regulation in CAD patients. Based on these studies, an aggressive treatment strategy with maximization of life-saving therapies is crucial for patients with diabetes and CAD. The importance of this is underlined by recently published follow-up data from the Glucose Abnormalities in patients with Myocardial Infarction (GAMI) study. This study demonstrated that abnormal glucose regulation detected a few days after an acute myocardial infarction is an independent predictor of a dismal prognosis [84].

Glycaemic control

The Diabetes and Insulin–Glucose Infusion in Acute Myocardial Infarction (DIGAMI) study [85] demonstrated that tight glycaemic control can further improve outcomes in diabetic individuals after acute myocardial infarction. Of 620 diabetic patients with acute myocardial infarction, 306 were randomly assigned to a ≥ 24-hour insulin–glucose infusion followed by multidose subcutaneous insulin. Three hundred and fourteen patients were randomized as controls, receiving routine glucose-lowering therapy. During an average follow-up of 3.4 years, 33% of patients in the intensive insulin group and 44% in the control group died ($P = 0.011$). Metabolic control, mirrored by blood glucose and HbA1c, improved significantly more in patients on intensive insulin treatment than in the control group. Therefore, intensive insulin treatment reduced long-term mortality in addition to standard therapy with aspirin, ACE inhibitors, and beta-blockers. While the intensive-treatment group had a lower mortality than the usual-care group, it was unclear whether the benefit was the result of the initial insulin–glucose infusion or the chronic insulin therapy.

The second DIGAMI trial [86] compared the following three management protocols: acute insulin–glucose infusion followed by insulin-based long-term glucose control; insulin–glucose infusion followed by standard glucose control; and routine metabolic management according to local practice, in 1253 patients with type 2 diabetes and suspected acute myocardial infarction. The DIGAMI 2 trial did not show that an acutely introduced,

long-term intensive insulin treatment strategy improves survival in type 2 diabetic patients following myocardial infarction and did not demonstrate that initiating treatment with an insulin–glucose infusion is superior to conventional management. However, the overall mortality in DIGAMI 2 was lower than expected, probably because of the very aggressive use of evidence-based treatment, including revascularization. Moreover, glucose control was better than in DIGAMI 1 at the onset and continuation of DIGAMI 2 and the three glucose management strategies did not result in significantly different metabolic control. Indeed, target glucose levels were not reached in the intensive insulin group. The DIGAMI 2 trial did, however, clearly confirm that glucose level is a strong, independent predictor of long-term mortality following myocardial infarction in patients with type 2 diabetes.

Taking these studies together, it is reasonable to initiate glucose control by means of insulin infusions, at least in patients with high blood glucose levels on admission. Furthermore, continued strict glucose control is mandatory, but the therapeutic regimen to accomplish this goal may be oral agents or insulin. Yet there is no definite answer to which is the best choice, so today this decision is based on practical reasons from patients and physicians but most importantly on the effect of the long-term glucose levels.

Revascularization strategies

Over the last 25 years, percutaneous coronary intervention (PCI) has evolved considerably from its early use in patients with focal lesions in the proximal coronary vessels to its application in more complex lesions and in patients with multivessel disease. In the National Heart, Lung and Blood Institute PTCA registry [87], patients with diabetes had a greater incidence of three-vessel disease and more diffuse disease in both proximal and distal coronary artery segments when compared with patients without diabetes. In the Fast Revascularization during Instability in Coronary Artery Disease (FRISC-II) trial it did, however, seem as if the presence of diabetes in itself, rather than a diffuse or multivessel disease, was related to an unfavourable prognosis as regards new coronary events or mortality [88].

Randomized controlled trials comparing PCI with coronary artery bypass grafts (CABG) [89,90] have not revealed any difference in terms of mortality between the two revascularization strategies within non-diabetic populations. In contrast, data from randomized trials and non-randomized studies suggest that diabetics have a higher mortality with PCI than with CABG. The Bypass Angioplasty Revascularization Investigation (BARI) [89] is the largest of the randomized trials. BARI enrolled 1829 patients with multivessel disease of whom 19.5% were medically treated diabetic patients. In patients without diabetes the cumulative survival was virtually identical for CABG and PCI. Patients with diabetes did, however, have a clinically and statistically significant survival advantage after CABG compared with PCI. The 7-year survival rate was 76% for diabetic patients assigned to CABG and 56% for those assigned to PCI. Moreover there was a significantly higher need for repeated revascularization among diabetic PCI-treated patients than in the group without diabetes (Fig. 11.10). Following CABG the survival rate was better in diabetic patients who received an internal mammary artery graft than those given saphenous vein grafts only.

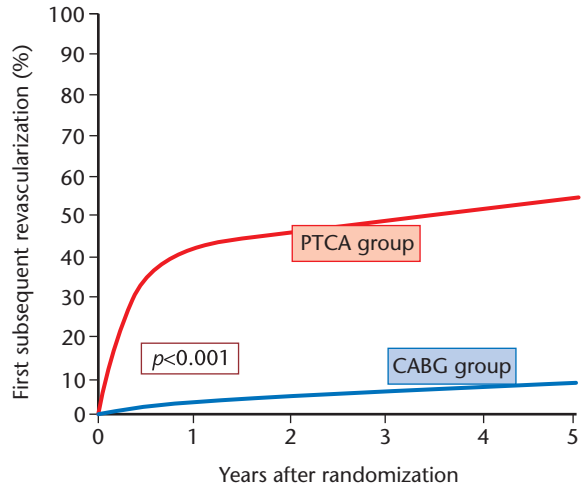

Figure 11.10 In the BARI trial, percutaneous transluminal coronary angioplasty (PTCA) patients had significantly higher need for repeated revascularization than did CABG patients. CABG, coronary artery bypass graft. Reproduced with permission from [89].

In the Emory Angioplasty versus Surgery Trial (EAST) [91], 392 patients with multivessel CAD were randomized to PCI or CABG. The survival rates were nearly identical after 3 years and the long-term survival at 8 years was not significantly different between the PCI and the surgical groups (79.3% vs. 82.7%, $P = 0.40$).

Revascularization of diabetic patients in the setting of acute coronary syndromes has been evaluated in a subgroup analysis of the FRISC-II trial. This revealed that early revascularization, either by CABG or PCI, was at least as effective among diabetic as in non-diabetic patients, with an almost 40% reduction of the combined endpoint re-infarction and mortality during the first year of follow-up. Since the risk for events was higher in the diabetic subgroup, fewer diabetic than non-diabetic patients needed to be treated to save one event (11 vs. 32).

A management strategy based on early coronary angiography and, if possible, an early coronary intervention is therefore recommended for diabetic patients [88].

Diabetes restenosis and coronary stenting

Coronary stenting has become the predominant method of PCI. Currently, up to 80% of interventions are accomplished with stent placement. Better angiographic results and prevention of adverse coronary remodelling despite the increase in neo-intimal hyperplasia justify the expectation of better outcome in diabetic patients; however, there are conflicting reports to date.

Short-term angiographic success rates of stenting in diabetics (92–100%) are often similar to those observed in non-diabetic patients [92]. The composite end-point of mortality, non-fatal myocardial infarction and urgent CABG is similar in diabetic and non-diabetic patients in most series. These in-hospital complications after stent implantation compare favourably with the rates reported after balloon PCI in diabetics. However, a clear trend toward higher rates of subacute stent thrombosis was found in diabetics. It was also reported that insulin-treated diabetics were at higher risk for in-hospital mortality when compared with non-insulin treated type 2 diabetics and non-diabetics.

Turning to long-term results, Van Belle *et al*. [93] found a lower angiographic restenosis rate in diabetic patients treated with coronary stents compared with those treated with balloon angioplasty and restenosis rates were similar in diabetics and non-diabetics treated with stents. Event-free survival is, however, often lower in diabetics. As reported by Elezi *et al*. [94], diabetics have a less favourable clinical outcome and a lower event-free survival than non-diabetic patients even after successful stent placement. The incidence of both restenosis and stent-vessel occlusion was significantly higher in diabetic patients. Diabetes was identified as an independent risk factor for adverse clinical events and restenosis in multivariate analysis. A subgroup analysis of the Arterial Revascularization Therapy Study (ARTS) trial [95], including 112 diabetic patients, revealed that surgical revascularization with routine use of arterial bypass conduits provides a superior 1-year clinical outcome compared with PCI in patients with diabetes and multivessel CAD even when a strategy of stented angioplasty is applied. Diabetic patients treated with stenting had the lowest event-free survival rate (63.4%) because of the higher demand of repeated revascularization compared with diabetic patients treated with CABG (84.4%, $P < 0.001$) and non-diabetic patients treated with stents (76.2%, $P < 0.04$) (Fig. 11.11).

Thus, long-term outcome after PCI is hampered in the diabetic population even after stenting, mainly because restenosis remains a major limitation. Several studies did indeed reveal that diabetes is an independent risk factor for in-stent restenosis after balloon angioplasty, ranging from 35% to 71% [96]. Coronary stenting with bare metal stents reduces this risk, but restenosis remains more frequent in diabetics with a restenosis rate of 24–40% [93]. Tight glycaemic control, aggressive risk factor modification, and the use of glycoprotein IIb/IIIa inhibitors have been attempted to improve the outcome of coronary stenting in diabetics, with some success. Different percutaneous interventions have been used to treat in-stent restenosis, including balloon angioplasty, repeat stenting, rotational or directional atherectomy, and intracoronary radiation (brachytherapy).

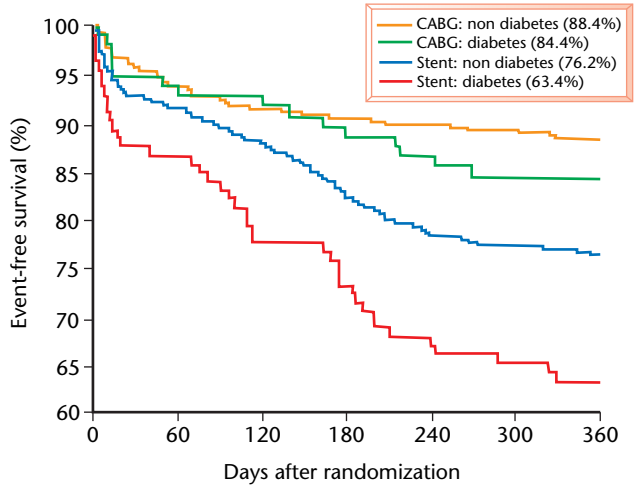

Figure 11.11 In the ARTS Trial, diabetic patients treated with stenting had the lowest event-free survival rate (63.4%) because of a higher incidence of repeat revascularization compared with both diabetic patients treated with coronary artery bypass grafts (CABG) (84.4%, $P < 0.001$) and non-diabetic patients treated with stents (76.2%, $P < 0.04$). Reproduced with permission from [95].

Stents coated with biodegradable and non-biodegradable polymers for local delivery of pharmacological agents have been proposed as a method to reduce in-stent restenosis. Sirolimus (rapamycin), a cytostatic macrocyclic lactone with both anti-inflammatory and antiproliferative properties, reduces restenosis significantly in several prospective, multicentre, randomized trials [97,98]. However, among patients receiving sirolimus-eluting stents, there remains a trend toward a higher frequency of repeat intervention in diabetic patients compared with non-diabetic patients, particularly in the insulin-requiring group. A recent meta-analysis comparing drug-eluting stents to bare metal stents in diabetic subpopulations in several clinical trials revealed that drug-eluting stents

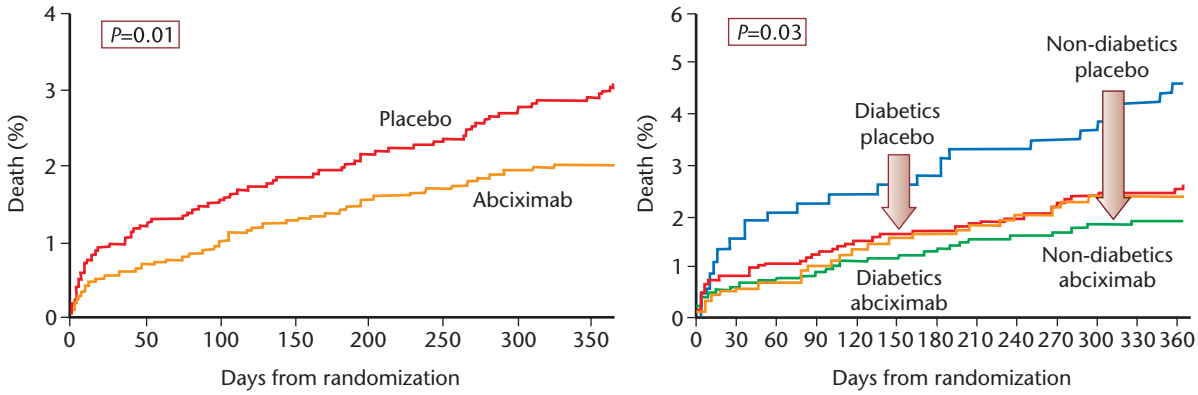

Figure 11.12 Pooled data from the EPIC, EPILOG and EPISTENT trials showed that abciximab decreases the 1-year mortality of diabetic patients to that of placebo-treated non-diabetic patients. Reprinted from [104], with permission from American College of Cardiology Foundation.

were associated with an 80% relative risk reduction for restenosis during the first year of follow-up [99]. Future clinical trials comparing drug-eluting stents with coronary arterial bypass surgery are certainly needed to determine the optimal revascularization strategy in diabetic patients with multivessel disease.

Diabetes and glycoprotein IIb/IIIa inhibitors

Potent platelet inhibition by glycoprotein IIb/IIIa inhibitors has been demonstrated to improve outcomes after PCI. There is evidence to suggest that glycoprotein IIb/IIIa receptor blockade has an even greater effect in diabetics with less need for repeat intervention among stented patients [100]. Abciximab, tirofiban and eptifibatide achieved similar levels of inhibition of platelet aggregation and similar reduction in the platelet–monocyte interaction in patients undergoing coronary stenting. Their effects in patients undergoing PCI have been reported in numerous trials.

The EPISTENT trial was the largest study evaluating the benefit of abciximab therapy in patients undergoing coronary stenting [100]. It demonstrated a significant reduction of major cardiac events at 30 days and at 6 months in the abciximab groups compared with the stent-plus-placebo group. In addition, the combination of stenting and abciximab therapy among diabetic patients resulted in a significant reduction in 6-month rates of death, myocardial infarction and target vessel revascularization compared with stent plus placebo or balloon angioplasty plus abciximab therapy. Abciximab has not been consistently shown to reduce angiographic restenosis in prior balloon angioplasty studies. In the EPIC trial, abciximab therapy showed a 35% reduction in the primary end-point of death, myocardial infarction and urgent revascularization at 1 month, with a similar risk reduction in diabetic and non-diabetic patients [101]. At 3 years, however, the clinical benefits were sustained in the total population [102], whereas diabetics experienced a progressive deterioration with more clinical events than non-diabetics. In the EPILOG trial, abciximab therapy in diabetic patients undergoing elective PCI led to a significant reduction of death and myocardial infarction at 30 days and at 6 months [103]. However, target vessel revascularization at 6 months was reduced only in the non-diabetic subgroup, and diabetics treated with abciximab and standard-dose heparin had a marginally greater benefit than those assigned to abciximab and low-dose heparin.

Pooled data from the EPIC, EPILOG and EPISTENT trials [104], including 1462 diabetic patients, showed that abciximab decreases the 1-year mortality of diabetic patients to that of placebo-treated non-diabetic patients (Fig. 11.12). In the PRISM-PLUS Study, a comparison of treatment outcomes in the diabetic subgroup revealed that the combination therapy (tirofiban and heparin) compared with heparin alone was associated with reductions in the incidence of cardiac adverse events, but these results did not reach statistical significance [105]. Furthermore, there is increasing evidence that glycoprotein IIb/IIIa inhibitors are of particular value in the diabetic patients with non-ST-elevation acute coronary syndromes during PCI [80].

Cerebrovascular disease

Diabetes increases the risk of stroke [106]. As an example, the risk of stroke among patients taking hypoglycaemic medications was increased three-fold among the nearly 350 000 men in the Multiple Risk Factor Intervention

Trial [107]. In the Baltimore-Washington Cooperative Young Stroke Study, stroke risk increased more than 10-fold in diabetic patients younger than 44 years, ranging as high as 23-fold in young Caucasian men [108]. Diabetes also increases stroke-related mortality and doubles the rate of recurrent stroke [109,110].

Diabetic patients with cerebrovascular atherosclerosis should receive platelet antagonists, statins and ACE inhibitors. A strategy of surgical revascularization combined with medical therapy for asymptomatic and symptomatic patients with haemodynamically significant internal carotid artery atherosclerosis resulted in fewer strokes than medical therapy alone [111,112]. Diabetic subjects represented 23% of the total population in the Asymptomatic Carotid Atherosclerosis Study (ACAS) [111] and 19% in the North American Symptomatic Carotid Endarterectomy Trial (NASCET) [112]. Consequently, they should be managed in accordance with non-diabetic patients with carotid artery disease. Cardiovascular mortality following carotid endarterectomy is increased in diabetic patients after both 30 days and 1 year because of an increased rate of coronary events [113,114]. The rates of perioperative major and minor stroke, however, do not differ between diabetic and non-diabetic patients [115] even if the need for hospitalization was somewhat longer. Thus, despite a lack of direct outcome data in diabetic patients, evidence suggests that the use of stenting for the treatment of carotid artery atherosclerosis is as rational in patients with diabetes as in those without diabetes [116].

Peripheral arterial disease

Diabetes increases the incidence and severity of limb ischaemia approximately two- to fourfold [117]. Data from the Framingham cohort and Rotterdam studies show increased rates of absent pedal pulses, femoral bruits, and diminished ankle–brachial indices [118]. Diabetic peripheral arterial disease often affects the distal limb vessels, such as the tibial and peroneal arteries, limiting the potential for collateral vessel development and reducing options for revascularization [119]. As such, patients with diabetes are at a particularly high risk to develop symptomatic forms of peripheral artery disease, such as intermittent claudication and critical limb ischaemia, and to undergo amputation. In the Framingham cohort, the presence of diabetes increased intermittent claudication more than threefold in men and more than eightfold in women. Diabetic persons have a particular propensity to develop foot ulcers with male sex, hyperglycaemia and diabetes duration as important risk factors. Foot ulcers often result from severe macrovascular disease, and diabetic neuropathy exacerbates the risk [120,121]. Once ulceration occurs, patients with diabetes have a much higher risk of amputation, highlighting the importance of prevention. Two non-invasive therapies have demonstrated benefit in improving walking distance in patients with peripheral artery disease: exercise and cilostazol [122,123]. Supervised exercise therapy produces impressive increases in walking distance. Patients with progressively disabling claudication and those with critical limb ischaemia should be considered for revascularization. Decisions regarding endovascular or open surgical procedures depend in large part on the severity and distribution of the arterial lesions. Outcomes of iliac artery percutaneous transluminal angioplasty and stenting in patients with diabetes have been reported as being similar to or worse than those in non-diabetic patients [124] and the long-term patency rates after femoral-popliteal percutaneous transluminal angioplasty are less in diabetic than non-diabetic patients [125]. The long-term patency rates of tibio-peroneal artery percutaneous transluminal angioplasty are low in both diabetic and non-diabetic patients, but may be sufficient in the short term to facilitate healing of foot ulcers. Graft patency rates are similar in diabetic and non-diabetic patients following surgical revascularization. Still there is a greater rate of limb loss in diabetic patients with critical limb ischaemia as a result of persistent foot infection and necrosis [126]. Moreover, the risk of perioperative cardiovascular events is increased in patients with diabetes [127].

Selected issues

Cardiac autonomic neuropathy and silent myocardial ischaemia

Autonomic neuropathy is a serious and common complication of diabetes. It has been estimated that about 20% of asymptomatic diabetic patients have abnormal cardiovascular autonomic function [128,129]. The risk for cardiovascular autonomic neuropathy depends on the duration of diabetes and the degree of glycaemic control. It is caused by injury to the autonomic nerve fibres that innervate the heart and blood vessels. The hypotheses concerning its aetiology include metabolic insult to nerve fibres, neurovascular insufficiency, neurohormonal growth factor deficiency and autoimmune damage [130]. The main consequences are dysfunctional heart rate control, abnormal vascular dynamics and cardiac denervation, which become clinically overt as exercise intolerance [131], orthostatic hypotension [132],

intraoperative cardiovascular lability [133] and silent myocardial ischaemia.

The earliest sign is often a vagal deficiency leaving sympathetic innervation unopposed. A manifestation of this is that diabetic patients tend to have higher resting heart rate and less heart rate variability during the day than their non-diabetic counterparts. A clinical setting where this may be particularly unfavourable is at the onset of a myocardial infarction causing unnecessary myocardial oxygen consumption in a situation with decreased nutritional blood supply.

The autonomic nervous system influences coronary blood flow regulation independently of endothelial cell function. Diabetic patients with sympathetic nervous system dysfunction have impaired dilatation of coronary resistance vessels in response to cold pressure testing when compared with diabetics without defects in cardiac adrenergic nerve density. Global myocardial blood flow and coronary flow reserve, studied by positron emission tomography in response to adenosine provocation, were subnormal in diabetics with cardiovascular autonomic neuropathy. It is obvious that cardiovascular autonomic neuropathy may provoke ischaemic episodes by upsetting the balance between myocardial supply and demand. As a result of autonomic neuropathy, silent myocardial ischaemia is prevalent in diabetic patients but is often symptomatically apparent only in advanced stages of disease. Instead of typical angina, patients often complain of shortness of breath, diaphoresis, or profound fatigue.

Knowledge on the actual prevalence of cardiovascular autonomic neuropathy and its related mortality rates is conflicting. However, different studies and meta-analyses reveal that mortality rates among diabetic subjects with cardiovascular autonomic neuropathy are many times higher than among those without. Subjects with diabetes and low levels of autonomic function parameters (baroreflex sensitivity, heart rate variability and classical Ewing tests) had an approximately doubled risk of mortality in the Hoorn Study [134]. In the Detection of Ischaemia in Asymptomatic Diabetics (DIAD) study [135], cardiac autonomic dysfunction, assessed by the Valsalva manoeuvre, was a strong predictor of ischaemia, whereas traditional and emerging risk factors were not. Impaired angina perception largely accounts for such an increased mortality. Indeed, silent myocardial ischaemia delays treatment of acute coronary events and makes it more difficult to monitor anti-ischaemic treatment or determine whether restenosis has occurred after a coronary intervention. Although silent myocardial ischaemia has a reported prevalence of 10–20% in diabetic populations compared with only 1–4% in non-diabetic populations, routine screening for silent myocardial ischaemia in diabetics remains debatable. In the DIAD study [135], 22% of 522 type 2 diabetic patients randomized to adenosine stress testing with myocardial perfusion imaging by means of single photon emission computerized tomography (SPECT) had silent ischaemia. This would indicate that asymptomatic diabetic patients have at least an intermediate probability of CAD, a prevalence that may justify routine screening for CAD by non-invasive testing. In a series of 203 diabetic patients [136], the prevalence of functional silent myocardial ischaemia, assessed by stress ECG and thallium myocardial scintigraphy, was 15.7%. In this study, the positive predictive value of exercise ECG was 90%, compared with 63% of thallium myocardial scintigraphy. Thus, available evidence highlights the need for non-invasive screening by means of stress-testing in diabetic subjects, especially considering the high sensitivity, feasibility and low costs of exercise ECG.

Based on cardiovascular autonomic neuropathy-associated coronary blood flow impairment, misdiagnosed CAD, and the consequently higher risk of mortality, it is presently recommended that a baseline determination of cardiovascular autonomic function is performed upon diagnosis in type 2 diabetes and within 5 years of diagnosis for type 1 diabetes, followed by yearly repeated tests [137].

The diabetic cardiomyopathy

The existence of a unique diabetic cardiomyopathy has been debated for decades. In the early 1970s, epidemiological evidence from the Framingham Heart Study [138] showed that, after adjustment for age, blood pressure, blood cholesterol, obesity and a history of CAD, the presence of diabetes quadrupled the risk for chronic heart failure in men aged from 35 to 64 years and doubled the risk in men aged 65 years or older. In women aged 35–64 years, diabetes entailed an eightfold increase in chronic heart failure and this increase was fourfold in older women. Further analysis of the Framingham Cohort showed that diabetic individuals, particularly women, had greater left ventricular wall thickness and cardiac mass than control subjects [139]. More recent studies reported a solid link between diabetes and some forms of 'idiopathic' dilated cardiomyopathy [140,141], and confirmed that diabetes-related cardiac myopathy is independent from CAD [142].

Diabetic cardiomyopathy often manifests itself with diastolic dysfunction. Doppler echocardiographic studies have demonstrated that diastolic dysfunction is an early feature of diabetes in animal models [143] and in humans [144,145]. The reduction of left ventricular compliance is associated with severity and duration of diabetes, and negatively correlates with the ability to

perform treadmill exercise. The frequent coexistence of hypertension and diabetes does, however, cloud the actual contribution of the diabetic state to the diastolic dysfunction. The fact that impaired left ventricular diastolic filling in animal models of type 2 diabetes occurs early, even before the onset of hypertension and vasculopathy, suggests that diastolic dysfunction is an effect of diabetes itself. After the onset of diastolic dysfunction, progressive myocardial dysfunction occurs in a time-dependent fashion, leading not only to a cardiomyopathy characterized by increased ventricular stiffness, but also to cavitary dilatation, mural thinning and depressed contractile behaviour. Because of the common coexistence of diabetes, hypertension and CAD, it is currently being debated whether left ventricular dilatation and systolic dysfunction are primarily triggered by the glucometabolic disorder itself rather than by the synergistic action of these factors. From a clinical perspective, prevention of the development of left ventricular systolic dysfunction and subsequent heart failure is currently focused on pharmacological treatment of the comorbidities. It may also explain why meticulous antihypertensive treatment seems to be particularly effective in the diabetic subject. More specific, metabolically oriented treatment modalities are, however, tested.

Further evidence for the existence of a distinct diabetes-specific cardiomyopathy emerges from basic reports of changes in cardiac structure and cardiomyocyte ultrastructure plausibly attributable to the diabetic milieu. In diabetic patients, as well as in animal models, the heart displays a reduction in cardiac mass, myocardial hypertrophy, interstitial fibrosis, and cell loss over time [146]. Although similar patho-anatomical changes may be seen even in the hypertensive heart, cardiac cell death is still believed to be a direct consequence of hyperglycaemia-induced metabolic abnormalities, subcellular defects and abnormal gene expression [147]. A prominent role is currently conferred to enhanced intramyocardial deposition of collagen [148], abnormalities in calcium handling [149], changes in troponin T [150], and PKC-mediated cardiac hypertrophy and failure [151]. Moreover, recent evidence in diabetic patients [152] and in streptozotocin-induced diabetic mice [153] suggests that increased incidence of cell apoptosis occurs in the diabetic heart, mainly as a consequence of oxidative stress-triggered receptor-independent cell death pathway activation [154]. Thus, oxidative stress rather than hyperglycaemia per se may account for subcellular remodelling, cardiomyocyte apoptosis and the subsequent onset of cardiomyopathy. Accordingly, a significant increase in 3-nitrotyrosine-containing proteins, typical end-products of the reaction of peroxynitrite with biological compounds [155], has been reported in cardiomyocytes from diabetic patients and streptozotocin-induced diabetic animals. This evidence suggests a causative link between hyperglycaemia, oxidative/nitrosative stress, cardiomyocyte apoptosis and diabetic cardiomyopathy.

The metabolic syndrome

Insights from pathophysiology for better clinical management

In 1988, Reaven [156] noted that several risk factors (e.g. dyslipidaemia, hypertension, hyperglycaemia) commonly cluster together. He defined this clustering as syndrome X, and identified it as a risk factor for cardiovascular disease.

Nowadays, extended panels of metabolic risk factors have been identified to better understand pathogenesis, predict outcomes and improve clinical management of the so-called metabolic syndrome (MS). Two independent efforts to identify definition criteria have been carried out by the National Cholesterol Education Program's Adult Treatment Panel III (ATP III) [157] and the World Health Organization (WHO) [158].

ATP III identified six components of the MS that relate to CVD:

- abdominal obesity;
- atherogenic dyslipidaemia;
- raised blood pressure;
- insulin resistance and/or glucose intolerance;
- proinflammatory state;
- prothrombotic state.

All of these components are part of a larger body of risk factors for CVD that ATP III identifies as underlying (obesity, physical inactivity, atherogenic diet), major (cigarette smoking, hypertension, elevated LDL-cholesterol, low HDL-cholesterol, family history of premature coronary heart disease, aging) and emerging (elevated triglycerides, small LDL particles, insulin resistance, glucose intolerance, proinflammatory state and prothrombotic state).

To facilitate diagnosis and preventive interventions, ATP III proposed a clinical definition based on having at least three of five criteria (Table 11.3) [159]. Using ATP III definition, the estimated prevalence of the MS among men and women in NHANES III [160] ranges from 5% (normal weight) to 60% (obese) in men, and from 6% (normal weight) to 50% (obese) in women. Currently it exceeds 20% of individuals who are at least 20 years of age, and 40% of the population > 40 years [161].

Table 11.3 ATP III clinical identification of the metabolic syndrome

Risk factor	Defining level
Abdominal obesity (given as waist circumference)*†	
men	> 102 cm (> 40 inches)
women	> 88 cm (> 35 inches)
Triglycerides	≥ 150 mg/dl
HDL-cholesterol	
men	< 40 mg/dl
women	< 50 mg/dl
Blood pressure	≥ 130/≥ 85 mmHg
Fasting glucose	≥ 110 mg/dl‡

*Overweight and obesity are associated with insulin resistance and metabolic syndrome. However, the presence of abdominal obesity is more highly correlated with the metabolic risk factors than is an elevated body mass index. Therefore, the simple measure of waist circumference is recommended to identify the body weight component of the metabolic syndrome.
†Some male patients can develop multiple metabolic risk factors when the waist circumference is only marginally increased, e.g. 94–102 cm (37–39 inches). Such patients may have a strong genetic contribution to insulin resistance. They should benefit from changes in life habits, similarly to men with categorical increases in waist circumference.
‡The American Diabetes Association has recently established a cut-off point of ≤ 100 mg/dl, above which persons have either pre-diabetes (impaired fasting glucose) or diabetes. This new cut-off point should be applicable for identifying the lower boundary to define an elevated glucose as one criterion for the metabolic syndrome.
Reproduced with permission [159].

The WHO criteria (Table 11.4) require insulin resistance for diagnosis, by demonstrating the presence of type 2 diabetes, IFG or IGT by OGTT in patients without IFG. In addition to insulin resistance, two other risk factors are sufficient for a diagnosis of MS.

On the contrary, ATP III claims that information obtained from an OGTT does not outweigh the inconveniences and costs of applying this test in the clinical routine.

Notably, both ATP III and WHO recognize CVD as the primary outcome of the MS. In the Framingham Study the MS alone predicted 25% of all new-onset CVD. In the absence of diabetes the MS generally did not raise the 10-year risk for CAD to > 20% (the threshold for the CAD risk equivalent in ATP III). Notably, the 10-year cardiovascular risk in men with MS ranged from 10 to 20%, whereas it did not exceed 10% in most women, who also displayed a lower rate of CAD events during the eight-year follow-up.

Table 11.4 WHO clinical criteria for metabolic syndrome

Insulin resistance, identified by one of the following:
- type 2 diabetes
- impaired fasting glucose
- impaired glucose tolerance
- or for those with normal fasting glucose levels (< 110 mg/dl), glucose uptake below the lowest quartile for background population under investigation under hyperinsulinaemic, euglycaemic conditions

Plus any two of the following:
- Antihypertensive medication and/or high blood pressure (≥ 140 mm Hg systolic or ≥ 90 mm Hg diastolic)
- Plasma triglycerides ≥ 150 mg/dl (≥ 1.7 mmol/l)
- HDL-cholesterol < 35 mg/dl (< 0.9 mmol/l) in men or < 39 mg/dl (< 1.0 mmol/l) in women
- Body mass index > 30 kg/m^2 and/or waist : hip ratio > 0.9 in men, > 0.85 in women
- Urinary albumin excretion rate ≥ 20 mg/min or albumin : creatinine ratio ≥ 30 mg/g

Reproduced with permission [159].

In this section, specific risk factors and new emerging and contributing conditions will be analysed in the attempt to identify a continuum between pathogenesis, clinical management and treatment of MS risk factors.

Obesity

In ATP III, abdominal obesity, recognized by increased waist circumference, is the first criterion listed. Its inclusion reflects the pivotal role assigned to abdominal obesity as a contributor to the MS: obesity contributes to hypertension, high serum cholesterol, low HDL-cholesterol and hyperglycaemia, and it associates with higher CVD risk. Excess visceral adipose tissue releases several products that apparently exacerbate these risk factors, including:
- non-esterified fatty acids, which overload muscle and liver with lipid, thus enhancing insulin resistance
- plasminogen activator inhibitor type 1 (PAI-1), which contributes to a prothrombotic state
- C-reactive protein (CRP), which may signify cytokine excess and a proinflammatory state.

The strong connection between abdominal obesity and risk factors led ATP III to define the MS essentially as a cluster of metabolic complications of obesity.

As stated by the National Heart, Lung, and Blood Institute (NHLBI) and the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) [162], overweight and obesity are defined by a body mass index (BMI) of 25–29.9 kg/m^2 and ≥ 30 kg/m^2, respectively.

Abdominal obesity, defined as a waist circumference ≥ 102 cm (≥ 40 inches) in men and ≥ 88 cm (≥ 35 inches) in women, is associated with several of the components of the MS. In ATP III, the rationale for using waist criteria rather that BMI arises from data showing that measures of overall obesity are relatively insensitive indicators of the risk for metabolic and cardiovascular complications of obesity, as compared with measures of central or abdominal adiposity [163]. Waist circumference reflects both abdominal subcutaneous adipose tissue and abdominal visceral adipose tissue. The visceral adipose tissue is supposed to be the major determinant of metabolic and cardiovascular complications of obesity [164]. It is presently unclear whether more accurate measures of specific abdominal subcutaneous and visceral adipose tissue using computerized tomography or magnetic resonance imaging may provide superior information regarding obesity complications [165].

It is generally accepted that obesity should be the primary target of intervention in MS. First-line therapy should be weight reduction obtained by lowering caloric intake and reinforcing physical activity. Weight loss lowers serum cholesterol and triglycerides, raises HDL-cholesterol, lowers blood pressure and glucose, and reduces insulin resistance. Recent data further show that weight reduction can decrease serum levels of CRP and PAI-1.

Extreme diets are often ineffective in producing long-term results. More effective and healthful for long-term weight loss are reduced-energy diets, consisting of a modest calories/day reduction. General recommendations for diet composition include low intake of saturated fats, trans fats and cholesterol; reduced consumption of simple sugars; increased intake of fruits, vegetables and whole grains. Regular physical activity is highly recommended, with a daily minimum of 30 minutes of moderate-intensity activity [166]. More exercise (i.e. 1 hour daily) is even more efficacious for weight control. A realistic goal is to reduce body weight by 7–10% over 6–12 months. Long-term maintenance of weight loss is best achieved when regular exercise is included in the weight-reduction regimen, and professional support (such as nutrition counselling) and group training is often helpful (see Chapter 9).

Insulin resistance

Insulin resistance per se is believed to play a significant role in the pathogenesis of MS, and many investigators claim that insulin resistance is the pathophysiological process behind the clustering of cardiovascular risk factors in the MS [167]. Insulin resistance predicts atherosclerosis and cardiovascular events independently of other risk factors, including fasting glucose and lipid levels [168]. However, so far there is little evidence that a reduction in insulin resistance will substantially improve any of the components of the MS other than glucose intolerance. Moreover, identifying a unique role for insulin resistance is complicated by the fact that it is often linked to obesity. Thus, the putative mechanistic link between insulin resistance and most of the components of the MS remains unclear and does not meet general consensus. Mechanisms by which insulin resistance impacts other MS risk factors are:

- diversion of excess non-esterified fatty acids from lipid-overloaded insulin-resistant muscles to the liver, thus promoting fatty liver and atherogenic dyslipidemia;
- enhanced output of very-low-density lipoprotein;
- predisposition to glucose intolerance, which can be worsened by increased hepatic gluconeogenesis in the insulin-resistant liver;
- blood pressure raising, by a variety of mechanisms (see below for details).

Insulin resistance generally rises with increasing body fat and most people with a BMI ≥ 30 kg/m^2 have postprandial hyperinsulinaemia/reduced insulin sensitivity [169] while persons with a BMI between 25 and 29.9 kg/m^2 exhibit a spectrum of insulin sensitivities as well. In some populations (such as South Asians), insulin resistance is common even with BMI < 25 kg/m^2, a condition termed primary insulin resistance.

Various measures have been used to define insulin sensitivity [170]. While hyperinsulinaemic clamp and glucose tolerance testing-based approaches accurately define insulin resistance, prolonged insulin infusion and/or repeated blood sampling are required, which may be undesirable in routine clinical practice. Surrogate measures of insulin sensitivity including the Homeostasis Model Assessment (HOMA) and Quantitative Insulin Sensitivity Check Index (QUICKI) have been developed, showing a good correlation with direct gold-standard measures [171] and predicting the development of cardiovascular disease and type 2 diabetes mellitus [172].

The reduction of insulin resistance is an attractive pharmacological target to prevent CVD in MS patients and there are currently two classes of drugs available: metformin and insulin sensitizers, such as thiazolidinediones. Both drugs reduce insulin resistance and favourably impact different metabolic risk factors. However, no clinical trial has documented the efficacy of metformin and thiazolidinediones in reducing CVD risk, thus limiting recommendation for their use in preventing CVD in patients with either MS or diabetes.

Atherogenic dyslipidaemia

Atherogenic dyslipidaemia is often recognized in MS and manifests itself by raised triglycerides, low HDL-cholesterol, increased remnant lipoproteins, elevated apolipoprotein B, and small LDL and HDL particles. It is commonly believed that hypertriglyceridaemia is the result of enhanced triglyceride hepatic synthesis driven by an increased flux of free fatty acids from the periphery to the liver in an insulin-resistant setting [173]. The causes of hypertriglyceridaemia in the MS are, however, most likely multifactorial and the increased free fatty acid flux hypothesis is one side of this issue. In the same view, low HDL-cholesterol, often ascribed to elevated triglycerides because of increased transfer of triglycerides to HDL and cholesterol from HDL [174], are likely to have a more complex origin, because HDL-cholesterol levels are often reduced in patients with insulin resistance even when fasting triglyceride levels are normal.

More recently, activation of innate immunity and immunity-related inflammation have been proposed as potential links between insulin resistance and dyslipidaemia. In animal models activation of innate immunity leads to changes in lipoproteins, enzymes, transfer proteins and receptors [175] commonly seen also in human MS. Inflammation-driven increase in lipase production has been proposed as a mechanism promoting reduction of lipid content of HDLs [176].

While lipid-lowering therapy is mandatory in dyslipidaemic MS patients, most of them do not display elevated LDL-cholesterol levels, and there is no consensus on the appropriate LDL target in the MS. It is conceivable that in the presence of additional traditional (smoking, family history of CAD) or new (high CRP levels, evidence of a prothrombotic state) risk factors, the MS should be considered a cardiovascular disease equivalent rather than a 'sum' of risk factors. Statin therapy with a target LDL-cholesterol < 100 mg/dl (or even lower, based on evidence in 'very-high-risk patients') would then be the appropriate target.

Several drugs are available for patients with atherogenic dyslipidaemia. Statins reduce all apolipoprotein B-containing lipoproteins, often achieving ATP III goals for LDL/non-HDL-cholesterol. Their impact on CV events is well documented [158]. Fibrates improve all components of atherogenic dyslipidaemia, and *post hoc* analysis of recent trials strongly suggests that they reduce CVD end-points in patients with atherogenic dyslipidaemia and MS [177]. Since clinical studies demonstrate that abnormal lipoprotein patterns are better controlled by statin–fibrate therapy, a combined therapeutic strategy would seem attractive. However, both fibrates and statins have the potential to produce myopathy, and their combined use enhances this risk [55]. Nicotinic acid shares some features with fibrates, and is considered especially efficacious for raising HDL-cholesterol levels. Its combined use with statins is promising. Still awaiting proven efficacy confirmation from randomized clinical trials is the category of dual PPAR agonists. They are promising agents targeting both PPAR-α and PPAR-γ, thereby simultaneously treating insulin resistance, glucose intolerance, elevated triglycerides and low HDL-cholesterol levels.

High blood pressure

In obese patients, blood pressure is sensitive to sodium intake, and this sensitivity is related to fasting insulin levels [178]. The antinatriuretic effect of insulin, together with its ability to activate the sympathetic nervous system [179] and to drive abnormal vascular function, contributes to the development of hypertension. Moreover, both hyperglycaemia and insulin activate the renin–angiotensin system by enhancing the expression of angiotensin, angiotensin II, and angiotensin I receptor, which contribute to raising the blood pressure of patients with insulin resistance (Fig. 11.13).

The majority of MS patients fall into the categories of normal and high–normal blood pressure levels (systolic blood pressure: 120–139 mmHg or diastolic blood pressure: 80–89 mmHg) or stage 1 hypertension (systolic blood pressure: 140–159 mmHg or diastolic blood pressure: 90–99 mmHg). Life-style modification is the cornerstone of management in all patients with high–normal blood pressure levels or with the MS. If blood pressure exceeds 140/90 mmHg, pharmacological therapy is indicated according to both JNC7 [180] and ESH-ESC [181] recommendations. In patients with established diabetes, antihypertensive drugs should be introduced at even lower blood pressures (> 130/> 80 mmHg) (see Chapters 6 and 9). No class of antihypertensive drugs has been identified as being uniquely efficacious in patients with MS. Diuretics and beta-blockers in high doses can worsen insulin resistance and atherogenic dyslipidaemia. However, beta-blockers are cardioprotective in patients with established CAD and are no longer contraindicated in patients with type 2 diabetes.

As mentioned, a rationale for antagonizing the renin–angiotensin system in MS has been proposed [182]. ACE inhibition improves insulin sensitivity and glycaemic control in diabetic patients [183] and was shown to induce a 14% relative reduction in the incidence of new-onset type 2 diabetes in the Captopril Prevention Project (CAPPP) [184]. This was confirmed by the Heart Outcomes Prevention Evaluation (HOPE) trial, in which

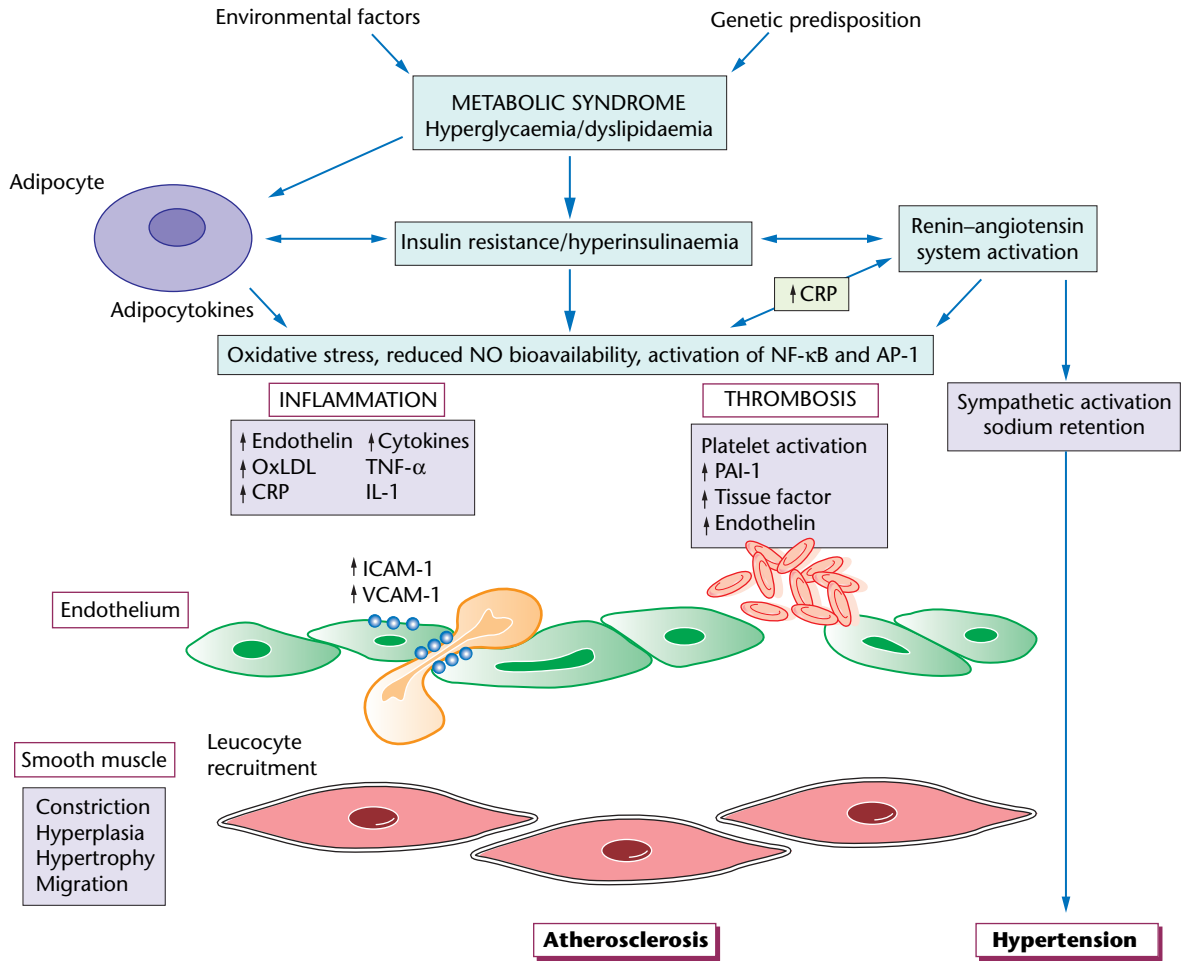

Figure 11.13 Pathophysiology of cardiovascular disease in metabolic syndrome. AP-1, activator protein-1; ICAM-1, intercellular adhesion molecule 1; OxLDL, oxidized LDL; VCAM-1, vascular cell adhesion molecule 1; CRP, C-reactive protein; TNF-α, tumour necrosis factor-α; IL-1, interleukin-1; PAI-1, plasminogen activator inhibitor-1. Reproduced with permission from [182].

ramipril significantly reduced by 34% the incidence of new-onset diabetes [185]. Moreover, in the Losartan Intervention for Endpoint Reduction (LIFE), conducted on patients with hypertension and left ventricular hypertrophy, losartan reduced the composite cardiovascular event rate by 13% and the incidence of new-onset diabetes by 25% compared with atenolol [66,67]. Similarly, treatment with valsartan, compared with amlodipine, was associated with a reduction in the incidence of diabetes in high-risk hypertensive patients in the Valsartan Antihypertensive Long-term Use Evaluation (VALUE) [186]. ACE inhibitors and angiotensin receptor antagonists also have a reno-protective capacity, not least in the diabetic patient.

In summary, ACE inhibitors and ARBs are useful, first-line antihypertensives. Some evidence exists that they carry advantages over other drugs in patients with diabetes.

Proinflammatory and prothrombotic state

Chronic subclinical inflammation is part of the MS [187]. This condition is characterized by elevated cytokines (e.g. tumour necrosis factor-α and interleukin-6) and acute-phase reactants (CRP and fibrinogen). Of interest, recent studies suggest that immunity and inflammation play a role in the development of insulin resistance and predict the development of type 2 diabetes mellitus [188,189]. Thus, the pathogenesis of insulin resistance and MS risk factors may have a common inflammatory basis which closely relates to the occurrence of atherosclerotic cardiovascular events. Since measures of inflammatory activity do not presently provide additional insights into the risk of events in MS patients, the current clinical approach to the MS does not incorporate measurement of inflammatory markers. However, as elevated CRP levels (≥ 3 mg/l) have been outlined as an emerging risk

factor for CVD, its inclusion together with traditional MS risk factors into a single algorithm is likely to provide a useful approach to risk prediction in MS patients. Indeed, in a recently published study [190], plasma CRP levels provided prognostic information regarding the risk of cardiovascular events in apparently healthy women at all levels of severity of the MS. From a practical perspective, the finding of high CRP levels in a MS patient should intensify life-style therapies, make certain that low-dose aspirin is used, and set lower LDL goals.

A prothrombotic state in patients with the MS is characterized by elevations of fibrinogen, PAI-1, and possibly other coagulation factors. In MS, activation of NF-κB promotes synthesis of PAI-1, a natural inhibitor of tissue plasminogen activator, and leads to impaired fibrinolysis. PAI-1 levels correlate with plasma insulin levels and insulin resistance, and appear to predict the likelihood of developing diabetes [191]. Since no drugs are available that target PAI-1 and fibrinogen, the alternative approach to the prothrombotic state is antiplatelet therapy. Use of aspirin is recommended in most patients whose 10-year risk for CHD is ≥10% as determined by Framingham risk scoring.

Personal perspective

The cardiology community should be aware of the important relationship between diabetes and atherosclerosis and be prepared to institute appropriate medical and interventional treatments to reduce the growing burden of cardiovascular disease and death among patients with diabetes. Unfortunately, the available evidence indicates that strict glycaemic control reduces microvascular disease to a greater extent than macrovascular manifestations. The relatively small reduction in glycaemia that can be achieved may explain the inability to show decreases in macrovascular events. Furthermore, interventions that improve glucose utilization or reduce insulin resistance have proven to be more promising for limiting cardiovascular complications. The multifactorial complexity of diabetic vascular disease may explain how pharmacological interventions that target dyslipidaemia, hypertension and the prothrombotic state associated with type 2 diabetes reduce the risk of macrovascular complications in such patients. Although we look forward to the development of new treatments for diabetic macrovascular disease, the implementation of aggressive medical management directed at optimizing glucose control, achieving normal blood pressure, correcting dyslipidaemia, and inhibiting platelet function is undoubtedly able to reduce the likelihood of adverse cardiovascular events.

Moreover, in the near future, approximately 50% of persons above the age of 60 years will meet current diagnostic criteria for metabolic syndrome with an estimated excess of cardiovascular risk which raises human, social and economic concerns. While a concerted effort with focus on dietary education and increased physical activity is mandatory to face off the medical and social burden of the disease, identifying and targeting primary pathogenetic abnormalities of metabolic syndrome is our challenging future. Statins, fibrates, metformin, thiazolidinediones, and possibly dual peroxisome proliferator-activated receptor agents will probably represent the cornerstone of pharmacological intervention. The increasing epidemic of metabolic syndrome is, however, not an isolated medical problem. To handle it on a population basis necessitates societal reforms including agricultural and food-processing political considerations.

12 Acute Coronary Syndromes: Pathophysiology, Diagnosis and Risk Stratification

Christian W. Hamm, Christopher Heeschen, Erling Falk and Keith A.A. Fox

Summary

Acute coronary syndrome (ACS) is the clinical manifestation of the critical phase of coronary artery disease. Based on ECG and biochemical markers it is distinguished from ST elevation myocardial infarction (STEMI), non-ST elevation myocardial infarction (NSTEMI) and unstable angina. The common underlying pathophysiology is related to plaque rupture or erosion with subsequent thrombus formation. Despite the decreasing age-adjusted mortality for myocardial infarction, the disease prevalence for non-fatal components of ACS remains high and the economic costs are immense. The effective treatment of ACS is guided by early diagnosis and risk stratification, and is based on the ECG and biochemical markers.

Introduction and definition

As early as 2600 BC, Egyptian papyrus scrolls recorded that patients with acute chest pain were at high risk of death. Today, the term acute coronary syndrome (ACS) is used to denote the acute phases of ischaemic coronary artery disease with or without myocardial cell necrosis. This term is preferred to earlier symptom-related terminology because it encompasses the common underlying pathophysiology.

ACS describes the spectrum of clinical manifestations which follow disruption of a coronary arterial plaque, complicated by thrombosis, embolization and varying degrees of obstruction to myocardial perfusion. The clinical features depend upon extent and severity of myocardial ischaemia. Complete coronary occlusion in the absence of collateral perfusion results in ST-segment elevation (STEMI) or non-ST-segment elevation myocardial infarction (NSTEMI). Transient or partial coronary occlusion may also result in myocyte necrosis as a result of embolization of thrombus and plaque fragments into the distal coronary circulation and changes in vascular tone. The release of sensitive markers of myocardial necrosis (e.g. troponins) is regarded as indicative of myocardial cell necrosis and fulfils the definition of myocardial infarction (NSTEMI) [1]. If no rise in markers is detected, the term unstable angina is used and non-cardiac differential diagnoses must be considered [2].

In the clinical setting the term 'acute coronary syndrome' is used as an initial working diagnosis (Fig. 12.1). According to the ECG and biomarker results the diagnosis is later refined. The first therapeutic steps are based on the ST-segment in the initial ECG.

Japan	57	19

Adapted from British Heart Foundation [4].

Incidence and prevalence of acute coronary syndromes

Internationally, robust information is documented for coronary heart disease deaths and for acute myocardial infarction (AMI) with specific ECG and enzyme/marker characteristics (Table 12.1). The American Heart Association estimates that 1.1 million myocardial infarctions occur in the United States alone and that 40% of these patients will die. Approximately half of the deaths occur prior to the patient receiving medical attention [3]. Taken together with corresponding figures for myocardial infarction in the UK [4], these data suggest that the incidence of AMI is in the range of 1 per 250 to 1 per 500 of the population per year.

Based on registry data, the incidence for all ACS is approximately threefold the incidence of STEMI [5]. Thus, the annual incidence of ACS in Europe is estimated at between 1 per 80 to 1 per 170 of the population per year. However, the incidence of chest pain leading to hospital assessment, of suspected ACS, is substantially higher and varies regionally, depending on the threshold for referral or presentation to an emergency department.

An apparent paradox exists with respect to the prevalence of ACS. Although age-adjusted death rates from coronary artery disease are falling in many economically developed communities, the prevalence appears to be rising. This apparent contradiction is explained by increased awareness in both the public and primary-care physicians of ACS, especially suspected myocardial infarction, together with lowered thresholds for presentation and evaluation of suspected ACS. This now includes patients of advanced age and those with significant comorbidity. Previously, many of these patients may not have presented for evaluation of suspected ACS. Thus, although the true incidence of ACS may follow the declining trends for myocardial infarction, the higher prevalence is accounted for by more patients being evaluated for the condition.

Within the spectrum of ACS the relative prevalence of STEMI, NSTEMI and unstable angina can be determined from registry studies which include the entire spectrum of the disease condition. Among patients presenting with suspected ACS the working diagnosis is unstable angina in 44% and suspected or 'rule-out' AMI in 45%, with uncertain chest pain in the remainder [5]. By hospital discharge, STEMI is confirmed in 30%, NSTEMI in 25%, unstable angina in 38%, and other cardiac or non-cardiac diagnoses in the remainder. Thus, for each patient with STEMI there are approximately two further patients with either NSTEMI or unstable angina (the latter diagnosed by the presence of the clinical syndrome and ECG changes but without enzyme/marker elevations above the diagnostic threshold). The data on the prevalence of components of ACS are entirely consistent between the GRACE registry and the Euro Heart Survey [6]. In the Euro Heart Survey, 42% of the population had an initial diagnosis of ST-elevation ACS, and on discharge, Q-wave myocardial infarctions were identified in 33% of the patients, non-Q-wave myocardial infarction in 25% of patients, and unstable angina in 42% of the patients. Thus, the prevalence of ACS can be estimated in a specific population with reference to the frequency of STEMI or a Q-wave myocardial infarction in that cohort. Only one-third of patients with the syndrome manifest STEMI or Q-wave infarction by the time of hospital discharge.

In-hospital death rates are significantly higher among unselected registry populations (8% in GRACE and 8.4% in Euro Heart Survey for STEMI) compared with clinical trials (GUSTO V study: 5.6–5.9%) [7]. The incidence of myocardial infarction in the UK for men aged 30 to 69 years is approximately 6 per 1000, and 2 per 1000 for women [4]. Estimates for the prevalence of myocardial infarction vary across populations and study designs. However, the combined data from prevalence studies suggest that approximately 4% of men and 2% of women in the community have sustained a myocardial infarction [4]. In the UK in 2002/3, diseases of the circulatory system accounted for 1.1 million hospitalizations out of a total of 12.7 million hospitalizations (9%), and of these, coronary heart disease accounted for 4% [8].

Time trends

Analysis of data from the MONICA centres over a 10-year trend indicates an average 4% annual reduction

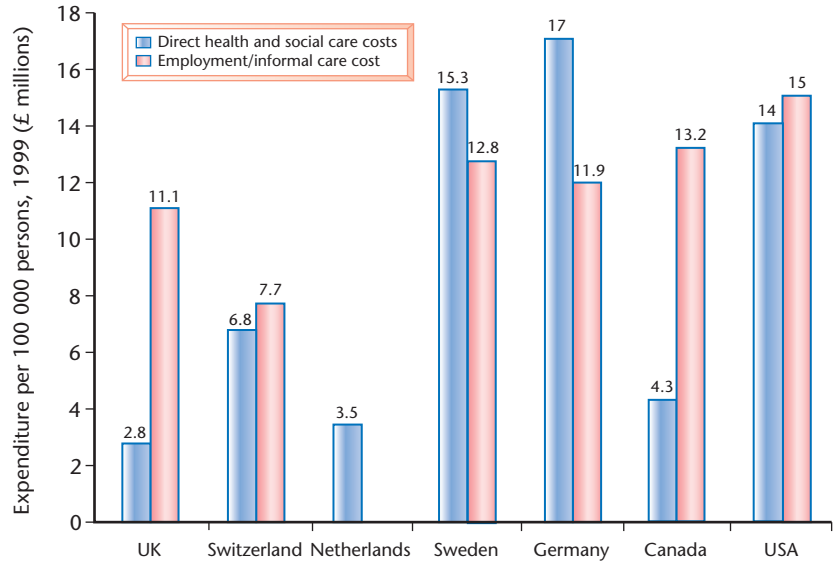

Figure 12.2 Expenditure on coronary heart disease per 100 000 persons in selected OECD countries. Adapted from Liu *et al*. [13].

in coronary artery disease mortality for men and women. However, this varies from a 7–8% annual reduction in some countries, for example Australia, Finland and Sweden, to annual increases in some geographic regions [9]. The decline in death rates from coronary heart disease amongst developed economies in Europe, North America, Australia and New Zealand (between 39 and 52% fall in age-adjusted death rates in men and women from 1989 to 1999) is contrasted with an increase in mortality in several countries of Eastern and Central Europe, most notably countries of the former USSR. For example, in Ukraine between 1989 and 1999 age-adjusted death rates rose by 60% in both men and women [4].

In the UK a 36% fall in age-adjusted death rates has occurred over the past decade; for men aged 35 to 74 years the death rate from coronary heart disease per 100 000 of the population fell from 364 to 199 [4]. The most rapid fall in death rates has occurred amongst men aged 55–64 years and women aged 55–64 years with lesser falls demonstrated in older and younger age groups. Recent large-scale multinational surveys and registries have used predefined case definitions and methods to minimize the influence of bias on patient inclusion and have provided robust information for the full spectrum of ACS [5,6].

Longitudinal studies within specific regions can provide important insights into changes over the course of time. In south-western France, for example, the 28-day case fatality rate has fallen between 1985 and 1993 by about 3% a year for first myocardial infarction [10]. It was concluded that this mainly reflects improvements in acute management rather than in prevention. Similarly, longitudinal studies in Sweden between 1984 and 1991 demonstrated that 2-year mortality after AMI fell from 36% to 25%. Most of the reduction in mortality occurred during the in-hospital phase [11]. In considering the decline in coronary heart disease mortality in Scotland, it was estimated that 40% of the decline was attributed to improved therapeutic treatments and 51% to measurable risk factor reductions [12].

Health economic implications

Despite the falling age-adjusted mortality for myocardial infarction, the disease prevalence for non-fatal components of ACS remains high and the economic costs are immense. The annual cost of coronary heart disease ranks highest of all diseases for which comparable analyses have been performed (Fig. 12.2) [13].

The economic cost of coronary heart disease relates not only to the direct cost to the health-care system but also to loss of productivity and to the provision of formal and informal care of patients. For example, in the UK, the economic burden of coronary heart disease has been estimated at 2.6 billion euros for direct health-care costs in 1999 and a further 3.6 billion euros for the provision of care for coronary artery disease subjects, and 4.4 billion euros for loss of productivity.

General risk factors for acute coronary syndromes

A series of modifiable risk factors (e.g. hyperlipidaemia, hypertension, diabetes and metabolic syndrome) and non-modifiable risk factors (e.g. gender and age) relate to

the development of atherosclerosis and the risk of presenting with ACS.

Age and gender

The most powerful independent predictor for the development of ACS, including presentation with myocardial infarction, is age. Among men, risk increases with each decile of age and comparisons between men and women demonstrate that for premenopausal women the risk corresponds with that of men approximately 10 years younger [4]. Post menopause, the risks increase for women but remain lower than for men of corresponding age [14]. However, interpretations of the impact of gender in ACS are complex and potentially influenced by referral bias and by differences in diagnostic sensitivity of the ECG and stress tests with gender. On angiography of suspected ACS a higher proportion of women do not have significant obstructive coronary heart disease. For example, in the RITA 3 study, 37% of women who fulfilled symptomatic and ECG criteria for non-ST elevation ACS did not have a stenosis greater than 50%, whereas the corresponding figure for men was 12%. Similarly, 26% of men but only 16% of women had significant disease in three or more vessels [15]. Adjusted for age, women have higher rates of diabetes and hypertension but are less frequently smokers [16].

Family history

Having accounted for all known risk factors, family history remains a significant independent risk factor for the development of coronary heart disease. In addition, genetic traits contribute to the specific risk phenotypes, including those related to hyperlipidaemia and hypertension. Twin studies reveal higher concordance among identical than non-identical twins.

Diabetes and metabolic syndrome

Clinical and animal studies demonstrate the importance of diabetes as a risk factor for the development of atherosclerosis as well as for ACS, and the increasing prevalence of obesity in specific populations is implicated in the increased frequency of metabolic syndrome and type 2 diabetes. Patients with type 2 diabetes mellitus have a risk of death from cardiovascular causes that is two- to sixfold elevated compared to those without diabetes. The development of ACS or cardiovascular death accounts for more than one-quarter of all new cardiovascular events among those with diabetes. Intensive intervention involving multiple risk factor reduction among patients with type 2 diabetes and microalbuminuria demonstrates that five patients need to be treated to prevent one cardiovascular event over the course of 8 years [17].

The dramatic increase in the prevalence of obesity among children and adolescents has been demonstrated across many economically developed and developing communities. In the year 2000, more than 20% of the US adult population from 22 states had a body mass index $> 30\ kg/m^2$. In contrast, none of the states had more than 20% of the population with this level of obesity in 1990 [18]. This rise has serious implications for future coronary events, including ACS. Among obese children and adolescents, the prevalence of metabolic syndrome approaches 50% (38.7% in moderately obese subjects and 49.7% in severely obese subjects) [19]. C-reactive protein (CRP) and interleukin-6 are markers of inflammation and their levels can be used as predictors for future cardiovascular events; the concentrations of these markers rise with the extent of obesity. In addition, adiponectin, a biomarker of insulin sensitivity which also has a role in preventing atherosclerosis development, is decreased in obesity [19]. The findings provide a link between obesity, metabolic syndrome and future risk of acute coronary events.

In the third National Health Nutrition Examination Survey (TNHNES) of more than 10 000 subjects, the presence of the metabolic syndrome independently increased the risk of myocardial infarction twofold [odds ratio (OR) 2.01; 95% confidence interval (CI) 1.53–2.64] [29]. Other independent predictors of cardiac events were low levels of high-density lipoprotein (HDL)-cholesterol (OR 1.35), hypertension (OR 1.44) and hypertriglyceridaemia (OR 1.66). A target-driven long-term intensified intervention aimed at modifying several risk factors in patients with type 2 diabetes and microalbuminuria reduces the risk of cardiovascular and microvascular events by approximately 50% [17].

Hypertension

There is a strong association between hypertension and coronary heart disease and there is a particularly strong influence of elevated blood pressure on stroke. Approximately two-thirds of cerebrovascular disease burden and half of ischaemic heart disease burden are attributable, at least in part, to elevated blood pressure [14]. The Blood Pressure Lowering Treatment Trialists' Collaboration has examined the influence of blood pressure lowering on mortality and the development of major cardiovascular events [20]. The overview examined data from 29 randomized trials ($n = 162\ 341$ patients) and the key finding was that the larger the reduction in blood pressure

(irrespective of the regimen used) the greater the reduction in risk of cardiovascular events. Thus, blood pressure lowering is critically important not only in secondary prevention but in the primary prevention of major cardiovascular events including the development of ACS.

Lipid abnormalities

Extensive studies have demonstrated that elevated low-density lipoprotein (LDL) cholesterol and very-low-density lipoprotein (VLDL) cholesterol are associated with atherogenesis and that lowering total cholesterol and LDL cholesterol is associated with reduced atherogenesis. Reduced cardiovascular complications have been demonstrated in primary and secondary prevention clinical trials [21]. Elevated levels of HDL-cholesterol are protective whereas reduced levels of HDL confer increased risk.

Multiple large-scale cholesterol-lowering trials have demonstrated a reduced number of cardiovascular events among treated individuals without manifest coronary artery disease at the time of inclusion (WOSCOPS, AFCAPS, TEXCAPS). Among those patients with hypertension at baseline, a 3-year treatment with a statin (atorvastatin) reduced the risk of major cardiovascular events by approximately one-third (hazard ratios for myocardial infarction or fatal coronary heart disease 0.64, $P < 0.01$) [22]. More detailed consideration of hyperlipidaemia and coronary risk is described elsewhere.

Other modifiable and potentially modifiable risk factors

Up-regulation of systemic inflammation provides a plausible mechanism for accelerating atherogenesis and its acute complications. A series of risk factors may be directly or indirectly related to increased coronary and vascular risk (for example elevated homocysteine, CRP, fibrinogen, plasminogen activator inhibitor type 1 and altered platelet reactivity).

A series of additional 'environmental factors' are influenced by life-style but may also interact with the genetically influenced factors listed above. These include high-fat, low-antioxidant diets (experimentally and clinically), smoking, a lack of exercise, and obesity. Infectious agents may also contribute to the up-regulation of the inflammatory response and acceleration of atherogenesis.

Individuals born with low birth weight exhibit a two- to threefold increased risk in later life of non-fatal coronary heart disease compared with normal birth weight infants [23]. Low birth weight is also associated with several coronary risk factors including the subsequent development of hypertension, type 2 diabetes and elevated cholesterol and fibrinogen concentrations. The risk factors are related not only to birth weight but to other indicators of restriction of fetal growth including small head circumference and altered placental development. The associations between size at birth and coronary heart disease are not explained by premature birth. They are also independent of the risks of subsequent obesity, smoking and socioeconomic classification. The findings have led to the hypothesis that coronary heart disease is programmed in fetal life ('the Barker hypothesis') [24]. *In-utero* programming of steroid metabolism may explain, at least in part, the re-setting of vascular tone in the arterial system and insulin sensitivity [25,26].

Based upon the INTERHEART case–control study in 52 countries, nine potentially modifiable risk factors account for more than 90% of the risk of AMI, consistently across geographic regions and ethnic groups [27]. Identified risk factors include abnormal lipids reflected by the apolipoprotein B–apolipoprotein A1 ratio, smoking, hypertension, diabetes, abdominal obesity, psychosocial factors, consumption of fruits and vegetables, alcohol and regular physical activity. The findings suggest that these phenotypes are potentially amenable to modification across countries and diverse ethnic populations. This has major implications for primary and secondary prevention strategies.

Genetic influences in atherothrombosis and the initiation of acute coronary syndromes

Common forms of atherosclerosis are multifactorial and relate principally to polygenic disorders rather than to single gene defects. Nevertheless, rare Mendelian disorders have provided insights into disease mechanisms. These include familial hypercholesterolaemia with abnormalities of the LDL receptor and familial disorders of apolipoprotein B-100. Similarly, there are single gene defects associated with low HDL, including apolipoprotein A-1 deficiency and ABC transporter defects (Tangier disease). Specific genetic traits relate to disorders of haemostasis and elevated homocysteine is linked to a defect of cystathionine β-synthase (a regressive metabolic disorder with severe occlusive vascular disease). Type 2 diabetes is associated with altered expression of hepatocyte nuclear factor 4α, hepatocyte nuclear factor 1α and glucokinase. Hypertension is linked with 11β-hydroxylase abnormalities and mineralocorticoid receptor defects.

In contrast, a series of relatively common genetic variations contribute to coronary heart disease and to coronary heart disease risk factors. These include the apolipoprotein E defects which explain about 5% of the variance in cholesterol levels (LDL and VLDL). Various

polymorphisms influence HDL through hepatic lipase, lipoprotein lipase and defects in transfer proteins. A series of alleles explain more than 90% of the variance in lipoprotein (a). Polymorphisms influence tetrahydrofolate reductase and hence homocysteine levels. Specific polymorphisms influence fibrinogen, plasminogen activator inhibitor type 1 and coagulation factor VIII and hence defects in coagulation and endogenous fibrinolysis. Similarly, polymorphisms of angiotensinogen, the beta-2 receptor, and α-adducin affect blood pressure. Specific defects influence angiotensin-converting enzyme and endothelial nitric oxide synthase, contributing to vascular tone [28]. A series of polymorphisms influence the risk of plaque rupture, including those regulating matrix metalloproteinases. As further data emerge, unravelling the contribution of groups of polymorphisms may allow a more accurate genetic basis of risk for atherogenesis and its acute complications to be established. Genetic and environmental factors interact to produce specific clinical phenotypes where underlying genetic risk is amplified or modified by environmental and therapeutic interventions.

Many of the risk factors for the development of ACS also predict subsequent myocardial infarction and death. Such factors include increasing age, male gender, diabetes, hypertension and previous manifestations of coronary disease including angina, myocardial infarction and impaired contractile function heart failure.

Pathophysiology of acute coronary syndromes

Atherosclerosis is by far the most frequent cause of coronary artery disease, carotid artery disease and peripheral artery disease, but atherosclerosis alone is rarely fatal [29,30]. Life-threatening manifestations of atherosclerosis such as ACS are usually precipitated by acute thrombosis, superimposed on a ruptured or eroded atherosclerotic plaque, with or without concomitant vasoconstriction, causing a sudden and critical reduction in blood flow [30–32]. In rare cases, ACS may have a non-atherosclerotic aetiology such as arteritis, trauma, dissection, thromboembolism, congenital anomaly, cocaine abuse, or complications of cardiac catheterization.

Atherothrombosis

Atherosclerosis is a chronic and multifocal immunoinflammatory, fibroproliferative disease of medium-sized and large arteries mainly driven by lipid accumulation [33]. Atherosclerosis begins to develop early in life and progresses with time, but the speed of progression is unpredictable and varies markedly among different subjects. At every level of risk factor exposure, there is substantial variation in the amount of evolved atherosclerosis, probably because the individual vulnerability to atherosclerosis and its risk factors varies greatly. However, even in vulnerable individuals, it usually takes several decades to develop obstructive or thrombosis-prone plaques, so there should in principle be ample time to inhibit plaque development and its complications by timely screening and, where necessary, risk-reducing interventions (Fig. 12.3) [34,35].

Serial angiographic and pathoanatomical observations indicate that the natural progression of coronary artery disease involves two distinct processes: a fixed and hardly reversible process that causes gradual luminal narrowing slowly over decades (atherosclerosis), and a dynamic and potentially reversible process that punctuates the slow progression in a sudden and unpredictable way, causing rapid coronary occlusion (thrombosis or vasospasm, or both). Thus, symptomatic coronary lesions contain a variable mix of chronic atherosclerosis and acute thrombosis but, because the exact nature of the mix is unknown in the individual patient, the term atherothrombosis is frequently used. Generally, atherosclerosis predominates in lesions responsible for chronic stable angina, whereas thrombosis constitutes the critical component of culprit lesions responsible for the ACS [29,30,32].

Abnormal coronary vasoreactivity is common in ACS, but 'spasm' is usually confined to the culprit lesion, suggesting that it is caused by locally released vasoactive substances [36]. The plaque, particularly the inflamed and disrupted plaque responsible for an ACS, may contain potent vasoconstrictors such as endothelin-1, and superimposed thrombosis may also contain or generate vasoconstrictors such as thrombin and platelet-derived serotonin and thromboxane A.

Systemic and local inflammation

Three key pathophysiological mechanisms link vascular inflammation with the early development of ACS. Inflammation within the atherosclerotic plaque is reflected by monocyte recruitment, macrophage activation and the release of free radicals. The consequence is metalloproteinase activation and destabilization of plaques. Second, paradoxical vasoconstriction is linked with endothelial dysfunction, triggered by platelet aggregation, the release

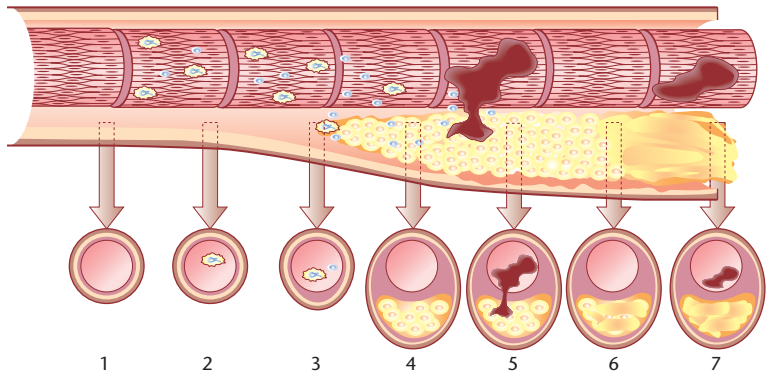

Figure 12.3 Development of the vulnerable plaque. Top, Longitudinal section of artery depicting 'timeline' of human atherogenesis from normal artery (1) to atheroma that causes clinical manifestations by thrombosis or stenosis (5, 6, 7). Bottom, Cross-sections of artery during various stages of atheroma evolution. 1, Normal artery. 2, Lesion initiation occurs when endothelial cells, activated by risk factors such as hyperlipoproteinaemia, express adhesion and chemoattractant molecules that recruit inflammatory leucocytes such as monocytes and T lymphocytes. Extracellular lipid begins to accumulate in intima at this stage. 3, Evolution to fibrofatty stage. Monocytes recruited to artery wall become macrophages and express scavenger receptors that bind modified lipoproteins. Macrophages become lipid-laden foam cells by engulfing modified lipoproteins. Leucocytes and resident vascular wall cells can secrete inflammatory cytokines and growth factors that amplify leucocyte recruitment and cause smooth muscle cell migration and proliferation. 4, As lesion progresses, inflammatory mediators cause expression of tissue factor, a potent pro-coagulant, and of matrix-degrading proteinases that weaken fibrous cap of plaque. 5, If fibrous cap ruptures at point of weakening, coagulation factors in blood can gain access to thrombogenic, tissue factor-containing lipid core, causing thrombosis on non-occlusive atherosclerotic plaque. If balance between prothrombotic and fibrinolytic mechanisms prevailing at that particular region and at that particular time is unfavourable, occlusive thrombus causing ACS may result. 6, When thrombus resorbs, products associated with thrombosis such as thrombin and mediators released from degranulating platelets, can cause healing response, leading to increased collagen accumulation and smooth muscle cell growth. In this manner, the fibrofatty lesion can evolve into an advanced fibrous and often calcified plaque, one that may cause significant stenosis, and produce symptoms of stable angina pectoris. 7, In some cases, occlusive thrombi arise not from fracture of fibrous cap but from superficial erosion of endothelial layer. Resulting mural thrombus, again dependent on local prothrombotic and fibrinolytic balance, can cause acute myocardial infarction. Superficial erosions often complicate advanced and stenotic lesions, as shown here. Superficial erosions do not necessarily occur after fibrous cap rupture. Adapted from Libby [32].

of thrombin and endothelin-1, and sympathetic stimulation. Third, thrombogenicity arises from an imbalance between endogenous concentrations of nitric oxide, prostacyclin, protein C/S and tissue plasminogen activator, and the prothrombotic stimulus from plaque components including tissue factor and apoptotic microparticles of endothelial origin [37].

The endothelium plays a critical role not only in the regulation of vasomotor tone, but is responsible for release of prostacyclin, endothelin-1, hyperpolarizing factor and nitric oxide, all of which influence thrombotic risk and vascular tone. Endothelial dysfunction is associated with enhanced oxidative stress and reduced nitric oxide bioavailability. Nitric oxide is synthesized from L-arginine under the influence of the enzyme nitric oxide synthase and is the key endothelium-derived relaxing factor, playing a pivotal role in the maintenance of vascular tone and reactivity [38]. In addition to being the main determinant of basal vascular smooth muscle tone, nitric oxide opposes the actions of potent endothelium-derived contracting factors such as angiotensin-II and endothelin-1. Furthermore, nitric oxide inhibits platelet and leucocyte activation and maintains the vascular smooth muscle in a non-proliferative state.

Although pathological findings associate ACS with the rupture or erosion of specific plaques, evidence exists for more widespread inflammation both in the systemic circulation and the arterial wall. Neutrophil activation has been demonstrated in both non-culprit and culprit coronary arteries in ACS, as evidence of general inflammatory up-regulation [39]. In contrast, such changes were not present in patients with stable angina, despite a similar extent of coronary artery disease. Furthermore, there is clinical evidence that acute systemic inflammation influences endogenous endothelium-dependent tissue plasminogen activator release in clinical studies [40]. The findings suggest that more extensive inflammation exists in the arterial wall in the context of ACS with increased susceptibility to ACS events in more than one vascular territory [41].

Although studies often report endothelial dysfunction as a loss of the vasodilatory capacity (in response to a

nitric oxide-releasing stimulus such as acetylcholine), the term encompasses a generalized defect in all the homeostatic mechanisms. Endothelial dysfunction is a broad term that implies diminished production of or availability of nitric oxide and/or an imbalance in the relative contribution of endothelium-derived relaxing and contracting factors (such as endothelin-1, angiotensin and oxidants). For example, endothelial dysfunction in diabetes may result from a decreased bioavailability of nitric oxide (secondary to insulin resistance) coupled with an exaggerated production of endothelin-1 (stimulated by hyperinsulinaemia or hyperglycaemia) [42]. Endothelial dysfunction has been implicated in the pathogenesis and clinical course of all known cardiovascular diseases and is associated with future risk of adverse cardiovascular events [43]. Systemic endothelial dysfunction is a major predictor of recurrence of instability in patients with acute coronary syndromes [44]. Assessment of the vascular phenotype might provide an integrated index of systemic inflammatory activation of the vascular wall and thus enable the identification of the inflamed, 'vulnerable' patient at risk. The implications are that treatment of obstructive target lesions in ACS should be accompanied by measures to reduce thrombotic consequences of up-regulated inflammation elsewhere in the arterial system.

In consideration of the important role that inflammatory processes play in determining plaque stability, recent work has focused on whether plasma markers of inflammation may help improve risk stratification in these patients. Even in the early phase of atherogenesis as well as after manifestation of atherosclerosis, elevated levels of inflammatory markers (e.g. intercellular and vascular adhesion molecules, selectins and pregnancy-associated plasma protein A) and downstream acute-phase reactants (e.g. CRP, serum amyloid A and fibrinogen) can be detected in the peripheral blood (Fig. 12.4).

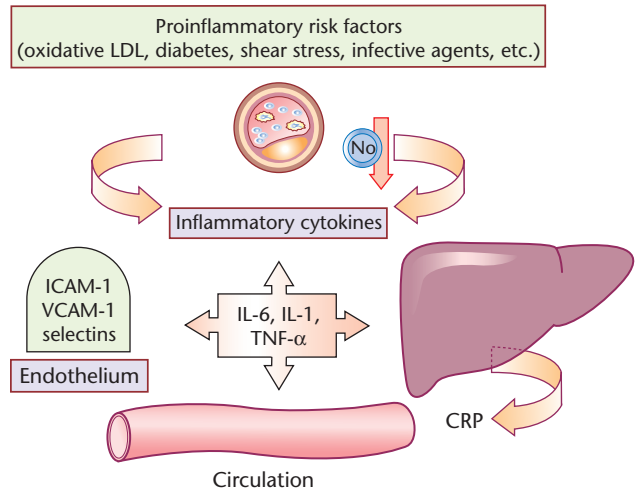

Figure 12.4 The pathophysiology of atherosclerosis with respect to lesion development, progression and destabilization. Biomarkers with distinct pathophysiological profile can be used to assess disease activity.

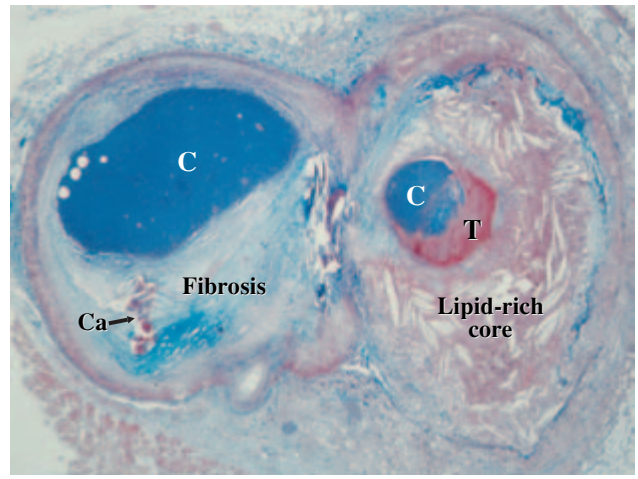

Figure 12.5 Atherothrombosis: a variable mix of chronic atherosclerosis and acute thrombosis. Ca, calcification; T, thrombus; C, contrast in the lumen.

Vulnerable plaques

Coronary atherosclerotic plaques are very heterogeneous structurally as well as biologically, and even neighbouring plaques in the same artery may differ markedly (Fig. 12.5). The great majority of coronary plaques are, and will remain, quiescent, at least from a clinical point of view. In fact, during a lifetime, none or only few coronary plaques become complicated by clinically significant thrombosis, and these rare but dangerous thrombosis-prone plaques are called vulnerable. Thus, a vulnerable plaque is a plaque assumed to be at high short-term risk of thrombosis, i.e. causing an ACS [45]. The challenge is to find the thrombosis-prone plaques, treat them (or rather the patients harbouring them), and thus avoid ACS [46].

Approximately 75% of all coronary thrombi responsible for ACS are precipitated by plaque rupture [29,30]. In plaque rupture, there is a structural defect (a gap) in the fibrous cap that separates the lipid-rich core of an inflamed plaque from the lumen of the artery (Fig. 12.6). Based on the morphological appearance of ruptured plaques, it is assumed that a rupture-prone plaque will possess the features outlined in Table 12.2

Table 12.2 Features of ruptured plaques*

Thrombus
Large lipid-rich core (> 30–40% of plaque)
Fibrous cap covering the lipid-rich core
• thin (thickness < 100 μm)
• many macrophages (inflammation)
• few smooth muscle cells (apoptosis)
Outward remodelling preserving the lumen
Neovascularization from vasa vasorum
Adventitial/perivascular inflammation

*By inference, the same features, except thrombus, are assumed to characterize rupture-prone (vulnerable) plaques.

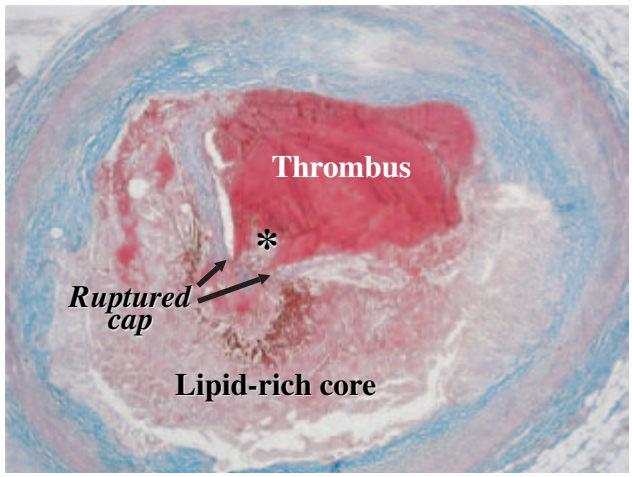

Figure 12.6 Plaque rupture. Cross-sectioned coronary artery containing a lipid-rich atherosclerotic plaque with occlusive thrombosis superimposed. The fibrous cap covering the lipid-rich core is ruptured (between arrows) exposing the thrombogenic core to the blood in the lumen. Atheromatous plaque content is displaced through the gap in the cap into the lumen (cholesterol crystals at asterisk), clearly indicating the sequence of events: plaque rupture preceded thrombus formation. Trichrome stain, rendering luminal thrombus and intraplaque haemorrhage red and collagen blue.

and illustrated in Figs 12.7 and 12.8. Lipid accumulation [47], thinning of the plaque's fibrous cap with local loss of smooth muscle cells [48] and inflammation with many macrophages and few mast cells and neutrophils [32,49,50], and intraplaque haemorrhage [51] destabilize plaques, making them vulnerable to rupture. In contrast, smooth muscle cell-mediated healing and repair processes stabilize plaques, protecting them against rupture [52]. Plaque size or stenosis severity reveals nothing, or only a little, about a plaque's vulnerability [53]. Many rupture-prone plaques are invisible angiographically, because of compensatory vascular remodelling, and they

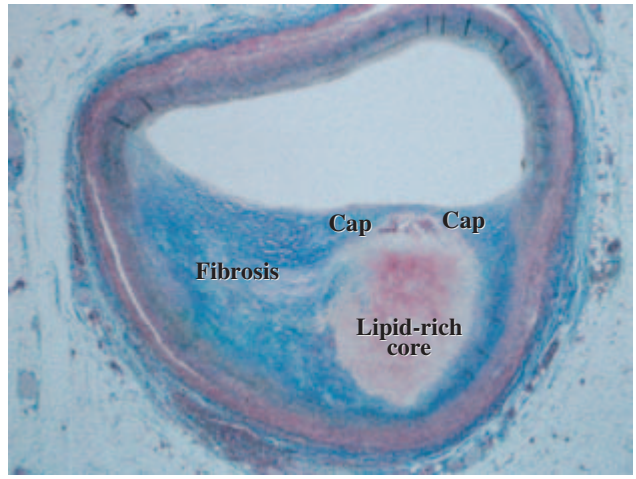

Figure 12.7 Vulnerable plaque. Cross-section of a coronary artery containing a plaque assumed to be rupture-prone, consisting of a relatively large lipid-rich core covered by a thin and fragile fibrous cap. Trichrome stain, rendering collagen blue and lipid colourless.

appear to be highly thrombogenic after rupture, probably because of a high content of tissue factor [54].

Clinical observations suggest that culprit lesions responsible for acute coronary syndromes generally are less calcified than plaques responsible for stable angina, indicating that calcium confers stability to plaques rather than the opposite [55]. The total amount of calcification (the calcium score) is a marker of plaque burden (and thus a marker of cardiovascular risk) rather than a marker of risk conferred by the individual calcified plaque [56].

The term plaque erosion is generally used for intact plaques with superimposed thrombosis, i.e. there is no underlying plaque rupture but the endothelium is missing at the plaque–thrombus interface (Fig. 12.9) [57]. These plaques have identified themselves as being relatively thrombogenic, but the precipitating factor or condition may, in fact, be found outside rather than inside the plaque (e.g. a hyperthrombotic tendency or so-called vulnerable blood).

Plaque vulnerability and remodelling

Arterial remodelling is bidirectional. Plaques responsible for ACS are usually relatively large and associated with compensatory enlargement that tends to preserve a normal lumen despite the presence of significant, and potentially dangerous, vessel wall disease [53,58]. Such lesions, hidden in the arterial wall, may not be seen by angiography. As many as three-quarters of all infarct-related thrombi appear to evolve over plaques causing only mild-to-moderate stenosis prior to infarction, partly because their propensity for outward remodelling, partly

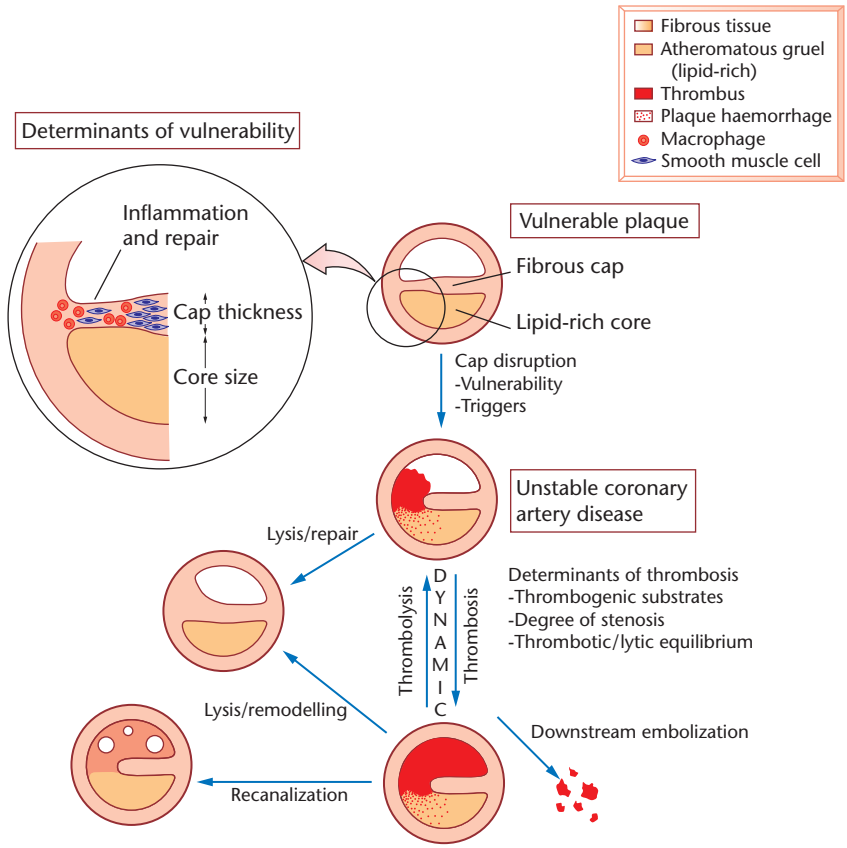

Figure 12.8 Plaque vulnerability, rupture and thrombosis. Lipid accumulation, cap thinning, macrophage infiltration, and local loss of smooth muscle cells destabilize plaques, making them vulnerable to rupture. It is unknown whether rupture of a vulnerable plaque is a random (spontaneous) or triggered event. The thrombotic response to plaque rupture is dynamic and depends on local (e.g. exposed substrate and shear forces) as well as systemic factors (e.g. platelets, coagulation and fibrinolysis).

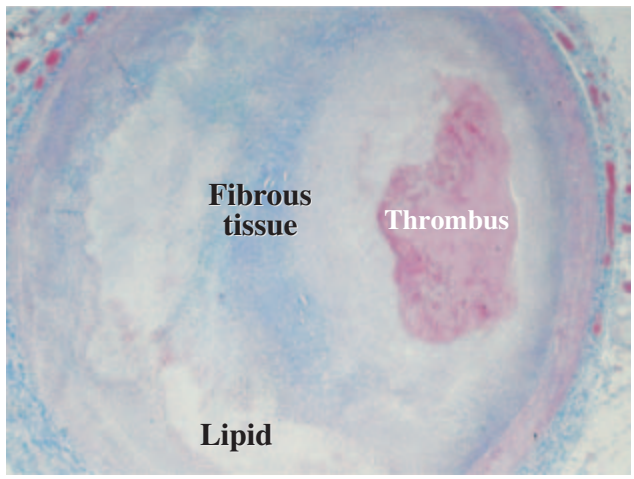

Figure 12.9 Plaque erosion. Cross-section of a coronary artery containing a severely stenotic atherosclerotic plaque with occlusive thrombosis superimposed. The lipid located deeply in the plaque is covered by a thick and intact fibrous cap. The endothelium is missing at the plaque–thrombus interface but the plaque surface is otherwise intact. Thus, there is no obvious local cause (no ruptured plaque) of thrombosis. Trichrome stain, rendering thrombus red, collagen blue, and lipid colourless.

because of their much greater prevalence compared to stenotic plaques [29]. Thus, the great majority of myocardial infarctions originate from atherosclerotic lesions that, prior to the acute events, were haemodynamically insignificant and probably asymptomatic. In contrast, plaques responsible for stable angina are usually smaller but, nevertheless, may cause more severe luminal narrowing because of concomitant local shrinkage of the artery (inward remodelling).

Onset of acute coronary syndrome: vulnerability versus triggers

Sudden rupture of a thin and inflamed fibrous cap may occur spontaneously but triggering could also play a role and thus help explain the non-random onset of ACS [59]. Potential triggers may include extreme physical activity, especially in someone unaccustomed to regular physical activity, severe emotional trauma, sexual activity, exposure to illicit drugs such as cocaine or amphetamines, cold exposure, and acute infections—or simply normal daily activities [59]. The fact that exercise stress testing in individuals with advanced coronary atherosclerosis rarely triggers an ACS suggests that plaque vulnerability

ultimately plays a more important role in plaque rupture than physiological stresses or other potential triggers.

After an ACS, the risk of a recurrent ischaemic event is high during the following 3–6 months. Many of these 'new' events are probably caused by reactivation of the original culprit lesion (rethrombosis), but both post-mortem and clinical observations indicate that patients with acute coronary syndromes often have many ruptured and/or 'active' plaques in their coronary arteries, indicating widespread disease activity [60]. The role of active non-culprit lesion (vulnerable plaques) for subsequent ischaemic events is unknown.

Coronary thrombosis caused by plaque rupture

A world-wide search revealed 18 autopsy studies in which 1460 coronary thrombi were identified and studied carefully with the purpose of characterizing the surface of the underlying atherosclerotic plaque [29]. Plaque rupture was the major cause of coronary thrombosis, being responsible for approximately 76% of the fatal thrombotic events world-wide, regardless of clinical presentation (myocardial infarction or sudden death). Plaque rupture is a more frequent cause of coronary thrombosis in males (81%) than in females (59%). It is rare in one extremely small subgroup of patients, namely premenopausal females, who constitute less than 1% of heart attack victims. A few studies have reported that diabetes (predominantly type 2), smoking and hyperlipidaemia tend to favour a particular type of thrombosis but, except for sex and menopause, no particular risk factors have consistently been connected with a particular type of plaque or mechanism of thrombosis [29]. Even in China, where the average plasma cholesterol level is low, rupture of a lipid-rich plaque is the major cause of coronary thrombosis [61].

Coronary thrombosis not caused by plaque rupture

The term plaque erosion has gained popularity for the minority of thrombi not precipitated by plaque rupture (~20% in males and ~40% in females) [29,57]. It refers to a heterogeneous group of atherothrombotic plaques where no deep injury is present to explain the overlying thrombus, only the endothelium is missing at the plaque–thrombus interface.

The precise mechanisms of thrombosis over eroded plaques are not known but probably reflect the heterogeneity of these plaques. It is conceivable that systemic thrombogenic factors such as platelet hyperaggregability, hypercoagulability, circulating tissue factor, and/or depressed fibrinolysis play a major role in thrombosis over plaques that are only eroded (vs. ruptured). Recent studies have suggested that activated circulating leucocytes may transfer active tissue factor by shedding microparticles and transferring them onto adherent platelets [54,62]. Accordingly, such circulating sources of tissue factor rather than plaque-derived tissue factor can contribute to thrombosis at sites of endothelial denudation as seen in plaque erosion.

Thrombotic response

Rupture of the plaque surface occurs frequently during plaque growth [63]. Most frequently, a small 'resealing' mural thrombus forms at the rupture site, and only occasionally does a major and life-threatening luminal thrombosis evolve. There are three major determinants of the thrombotic response to plaque rupture (or the amount of thrombosis formed on top of an eroded plaque): the local thrombogenic substrate, local flow disturbances, and the systemic thrombotic propensity.

Local thrombogenic substrate

Ongoing inflammation, in particular macrophage infiltration and activation, and lipid accumulation not only destabilize plaques, making them vulnerable to rupture, these plaque components also appear to be highly thrombogenic when exposed to the flowing blood after plaque rupture [64]. Activated macrophages express tissue factor, and the lipid-rich atheromatous core contains high amounts of active tissue factor, probably originating from dead macrophages [54,65]. Culprit lesions responsible for the acute coronary syndromes contain more tissue factor than plaques responsible for stable angina [66]. Oxidized lipids in the lipid-rich core may also directly stimulate platelet aggregation.

Local flow disturbances

In contrast to venous thrombosis, rapid flow and high shear forces promote arterial thrombosis, probably via shear-induced platelet activation [67]. A platelet-rich thrombus may indeed form and grow within a severe stenosis, where the blood velocity and shear forces are highest. Irregularities of the exposed surface also increase the platelet-mediated thrombus formation.

Systemic thrombotic propensity

The state (activation) of platelets, coagulation, and fibrinolysis is critical for the outcome of plaque rupture, documented by the protective effect of antiplatelet agents and anticoagulants in patients at risk of coronary thrombosis. Tissue factor probably plays an important

prothrombotic role both locally (expressed by macrophages in the culprit lesion) and systemically (expressed by activated leucocytes in the peripheral blood) [54,62,66].

Platelets, fibrin and thrombotic burden

In coronary thrombosis, the initial flow obstruction is usually caused by platelet aggregation, but fibrin is important for the subsequent stabilization of the early and fragile platelet thrombus. Thus, both platelets and fibrin are involved in the evolution of a stable and persisting coronary thrombus.

If the platelet-rich thrombus (macroscopically white) at the site of plaque disruption occludes the lumen totally —as is usually the case in STEMI—the blood proximal and distal to the occlusion will stagnate and may coagulate, giving rise to a secondarily formed venous-type stagnation thrombosis (macroscopically red) (Fig. 12.10). Stagnation thromboses may contribute significantly to the overall thrombotic burden, particularly in occluded vein grafts (no side branches), and thus hamper recanalization. Clinical observations indicate that it is indeed very difficult to recanalize an occluded vein graft rapidly by intravenous thrombolytic therapy alone.

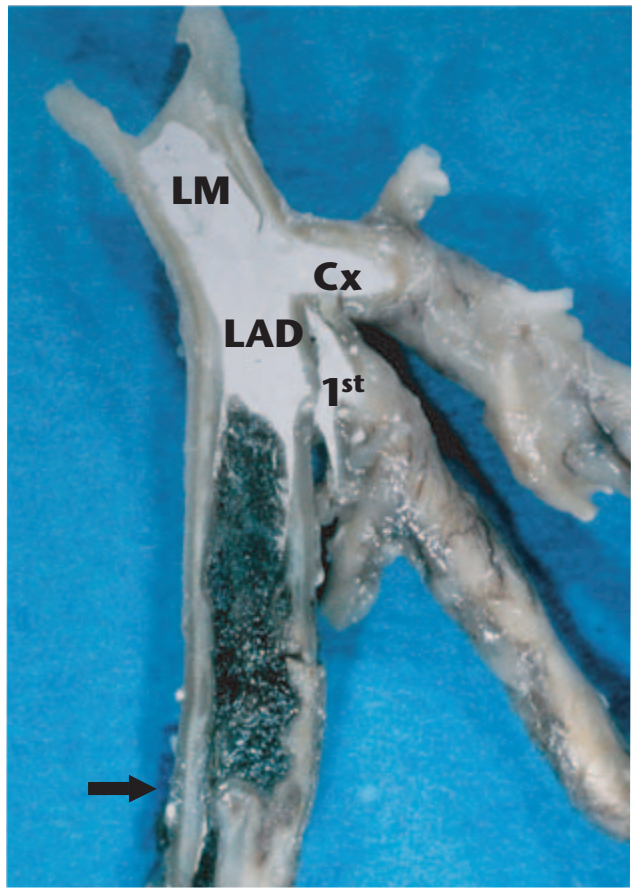

Figure 12.10 Thrombotic burden. Thrombosed coronary artery cut open longitudinally, illustrating a voluminous erythrocyte-rich stagnation thrombosis (dark black on screen) that has developed secondarily to blood stagnation caused by an occlusive platelet-rich thrombus (white) formed on top of a severely stenotic and ruptured plaque (arrow). The white material in the lumen is contrast medium injected post-mortem. LM, left main stem; LAD, left anterior descending coronary artery; Cx, circumflex branch; 1st; first diagonal branch.

Dynamic thrombosis and microembolization

The thrombotic response to plaque rupture is dynamic: thrombosis and thrombolysis, often associated with vasospasm, tend to occur simultaneously, causing intermittent flow obstruction and distal embolization (Fig. 12.11) [29]. The latter leads to microvascular obstruction which may prevent myocardial reperfusion despite a 'successfully' recanalized infarct-related artery [68].

The purpose of coronary recanalization is, of course, to provide oxygenated blood to the ischaemic myocardium, and 'successful' recanalization (a patent culprit artery with brisk flow angiographically) is assumed to improve the perfusion at the tissue level. However, mechanical crushing and fragmentation of atherothrombotic lesion during percutaneous coronary intervention has emerged as a major cause of intracoronary (micro) embolization leading to downstream microvascular occlusion and thus preventing optimal reperfusion of the ischaemic myocardium despite 'successful' recanalization of the infarct-related artery [68]. Both spontaneous as well as iatrogenic coronary microembolization appear to be associated with an unfavourable long-term prognosis.

Development of myocardial infarction

Myocardial infarction (i.e. irreversible injury) caused by complete coronary artery occlusion begins to develop after 15–20 minutes of severe ischaemia (no forward or collateral flow). Within the perfusion area of the occluded artery, flow deprivation and myocardial ischaemia are usually most severe subendocardially (apart from the innermost 10 or so cell layers nourished from the cavity) and, at least in dogs, cell death progresses from the subendocardium to the subepicardium in a time-dependent fashion, the 'wavefront phenomenon' (Fig. 12.12) [69]. Although the susceptibility to ischaemic necrosis differs significantly among patients (related to, for example, variability in preconditioning and oxygen demand/consumption), there are two well-characterized major determinants of the ultimate extent of infarction:

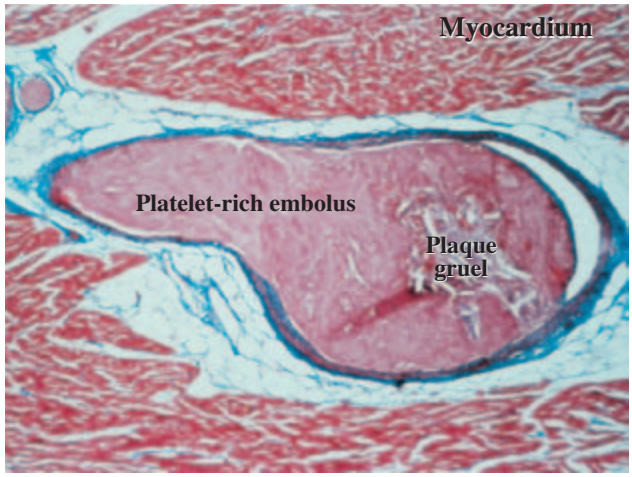

Figure 12.11 Distal embolization. Microvascular occlusion, caused by embolized platelet-rich thrombus and atheromatous 'gruel', in the myocardium downstream of a thrombosed epicardial coronary artery. If extensive, microvascular obstruction may prevent myocardial reperfusion despite 'successful' recanalization of the infarct-related artery.

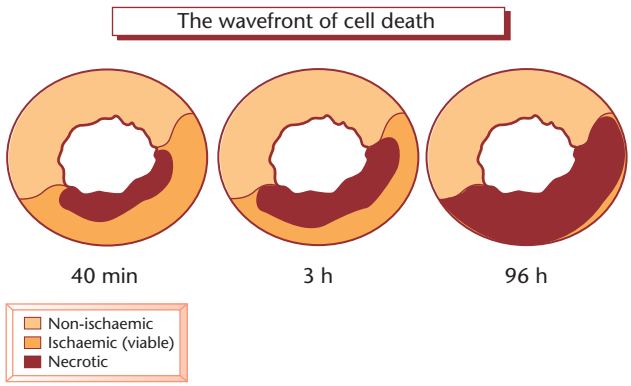

Figure 12.12 The wavefront phenomenon. Following coronary occlusion in dogs, ischaemic cell death progresses from the subendocardium to the subepicardium in a time-dependent fashion—the wavefront phenomenon. Adapted from Reimer and Jennings [69].

- Location of the occlusion, defining the 'area at risk' (amount of jeopardized myocardium).
- Severity and duration of myocardial ischaemia (residual flow and rapidity of recanalization).

The speed and completeness of infarct development and, consequently, the potential for myocardial salvage by reperfusion therapy is difficult to assess in the individual patient presenting with an evolving AMI. The amounts of residual or spontaneously restored forward flow and collateral flow differ substantially among AMI patients. Rapid recruitment of collateral flow at the time of coronary occlusion (via pre-existing collaterals) does not exist in some patients with myocardial infarction because they do not have such protective collaterals. They rapidly develop a transmural AMI, (like rabbits and pigs, which lack collaterals), whereas other myocardial infarction patients have collaterals, probably because of the presence of severe collateral-promoting atherosclerotic stenoses prior to the acute occlusion. Patients in this second set slowly develop a relatively small myocardial infarction, or possibly none at all, in the same way as cats and guinea-pigs, which possess native collaterals.

Collaterals

The available collateral flow, at the time of occlusion, may limit or even avert the development of myocardial infarction. In unstable angina with pain at rest, about 10% of patients have an occluded culprit artery at the time of presentation, but no definite infarction evolves because of well-developed collateral circulation [29]. In infarction without Q-wave development, about 25% of patients have an occluded culprit artery at early angiographic examination, increasing to 40% in the subsequent few days, but a significant amount of myocardium is salvaged because of parallel development of collateral vessels [29]. Conversely, in STEMI, nearly all patients initially have an occluded culprit artery. Unless recanalization occurs rapidly, these patients usually develop extensive transmural infarction with Q-waves on the ECG because of poor collateral circulation. Thus, collaterals may save myocardium at risk, and improve clinical outcome.

Reperfusion and no reflow

Timely, complete and sustained reperfusion may save myocardium at risk of undergoing necrosis in patients with evolving STEMI. Such infarcts nearly always remain anaemic and pale if not reperfused. Therapeutic reperfusion is, however, associated with extravasation of erythrocytes in the ischaemic tissues that have already passed the point of no return, giving rise acutely to a haemorrhagic red infarct. In addition, reperfusion is not homogeneous and, in particular, 'no reflow' may be a cause and/or a consequence of infarction [68].

No reflow in human AMI is more complex than that seen after ligation of a normal coronary artery in animals (classical no reflow model), because the clinical setting involves an atherothrombotic dynamic occlusion with both an innate risk of distal embolization and an embolization risk when crushed or fragmented mechanically during percutaneous coronary intervention [68]. Thus, coronary no reflow and myocardial hypoperfusion after

otherwise successful recanalization of infarct-related arteries do not simply represent non-reperfusion confined to myocardium that is already dead. No reflow may also result from percutaneous coronary intervention-induced (micro)vascular obstruction caused by distal (micro)embolization and/or microvascular spasm [68]. Because emboli necessarily stream preferentially to well-perfused and viable myocardium, potentially salvageable myocardium may vanish. Percutaneous coronary intervention-induced (micro)embolization may, in fact, not only prevent optimal reperfusion, it may worsen the ischaemia if distal branches receiving collateral flow are occluded. Thus, the vital question is, of course: how much of the coronary no reflow and myocardial hypoperfusion seen after primary percutaneous coronary intervention reflects the classical no reflow phenomenon caused by necrosis, and how much reflects percutaneous coronary intervention-induced distal microembolization (and perhaps microvascular spasm) causing more necrosis? The thrombotic burden may prove to be critical.

Clinical implications

Atherothrombosis with ruptured and eroded coronary plaques is common and can be clinically silent for long periods of time. However, acute thrombosis (with or without vasospasm) may cause sudden flow obstruction, giving rise to an ACS. The culprit lesion is frequently 'dynamic', causing intermittent flow obstruction, and the clinical presentation and the outcome depend on the location of the obstruction and the severity and duration of myocardial ischaemia. A non-occlusive or transiently occlusive thrombus—modified overall by vascular tone and collateral flow—most frequently underlies ACS without ST-segment elevation, whereas a more stable and occlusive thrombus prevails in STEMI. A critical thrombotic component is also frequent in culprit lesions responsible for out-of-hospital cardiac arrest and sudden coronary death.

For the prevention and treatment of the ACS, it is important to keep in mind that they are the result of an interaction between two distinct processes: atherosclerosis and thrombosis. Atherosclerosis is a chronic and fixed process that sets the limit for what is achievable by antithrombotic and thrombolytic therapies. Atherosclerosis persists after thrombolysis and may, if severe, prevent optimal and durable reperfusion. The atherosclerotic obstruction may, however, be eliminated by mechanical intervention or bypass surgery. In contrast, thrombosis is an acute and dynamic process that is highly susceptible to treatment with drugs. Thrombosis may appear and disappear rapidly, either spontaneously or accelerated by treatment. Vasospasm and thrombosis often coexist. Overall, drug therapy and mechanical intervention may complement each other in the treatment of the ACS, to obtain rapid, complete and sustained reperfusion.

An invasive approach (percutaneous coronary intervention) may be needed to obtain rapid, complete and sustained reperfusion of infarct-related arteries or to 'passivate' one or a few complex lesions that pose a particularly high short-term risk in ACS, but a target lesion-based approach alone will not eliminate the threat posed by all the other existing coronary plaques, and their overall risk determines the long-term prognosis. Therefore, lifelong systemic therapy is important in patients with diseases caused by atherosclerosis.

Diagnosis and risk stratification of ACS

Diagnosis and risk stratification in patients with ACS are closely linked. The leading complaint is usually chest pain which initiates a diagnostic cascade. Before an ECG is recorded or laboratory test results are available ACS remains the working diagnosis and the presence of a myocardial infarction must be considered.

Clinical presentation

An accurate history is essential in distinguishing the onset of ACS from alternative diagnoses. The prodrome is characterized by anginal type chest discomfort, but usually at rest or on minimal exertion. Of patients with STEMI and prodromal symptoms, two-thirds have symptoms in the preceding week and one-third have symptoms for up to 4 weeks. Overall, only 20% have symptoms for less than 24 hours.

The clinical presentation of patients with ACS encompasses a large variety of symptoms. The cardinal symptom is the ischaemic chest pain which is typically described by the patient as burning, tightness, or heaviness. Patients often have associated symptoms of nausea and fatigue. Chest pain can be graded according to the Canadian Cardiovascular Society Classification (CCS): prolonged (> 20 minutes) anginal pain at rest, new onset (*de novo*) severe (CCS Class III) angina, or recent destabilization of previously stable angina with at least CCS III angina characteristics (crescendo angina). Prolonged pain is observed in 80% of patients while *de novo* or accelerated angina is observed in only 20% of patients [70].

To recognize subgroups of patients with unstable angina who are at different levels of cardiac risk, the Braunwald classification was introduced [71]. This

Table 12.3 Braunwald classification of unstable angina

	Clinical circumstances		
Severity	**A—develops in presence of extracardiac condition that intensifies myocardial ischaemia (secondary UA)**	**B—develops in absence of extra-cardiac condition (primary UA)**	**C—develops within 2 weeks of acute myocardial infarction (post-infarction UA)**
I—new onset of severe angina or accelerated angina, no rest pain	IA	IB	IC
II—angina at rest within past month but not within preceding 48 h (angina at rest, subacute)	IIA	IIB	IIC
III—Angina at rest within 48 h (angina at rest, acute)	IIIA	IIIB-T_{neg} IIIB-T_{pos}	

Adapted from Hamm and Braunwald [74].

empirically developed classification is based on symptoms with respect to pain severity and duration as well as the pathogenesis of myocardial ischaemia and was validated in prospective studies [72,73]. Patients with unstable angina at rest within the last 48 hours (class IIIB) have been shown to be at highest risk of an adverse cardiac event (11% in-hospital event rate). The Braunwald classification has become an accepted standard for grading patients, designing study protocols, and improving the comparability of study results. For further risk assessment troponins have been introduced to this classification (Table 12.3) [74].

Patients with STEMI usually have severe chest pain with fear of dying, whereas in non-ST elevation ACS the pain is more waning and waxing, is dependent on the level of exertion, but usually lasts no longer than 20 minutes. The pain is typically located in the centre or the left lateral chest and radiates to the left shoulder, arm, neck and jaw. Pain may also be epigastric, particularly in inferior myocardial infarctions. Perception of pain in the right side of the chest does not exclude myocardial ischaemia. If the pain is related to inspiration (pleuritic pain), or radiates to the back, other differential diagnoses including aortic dissection must be considered (Table 12.4). Pain that persists over many days or pain that can be provoked mechanically is not ischaemic.

In up to one-half of patients with STEMI physical and or emotional factors are identified in the prodrome and may have influenced plaque rupture. A circadian periodicity of presentation with STEMI is observed. The peak incidence of events coincides with the early waking hours, possibly associated with rises in catecholamines and cortisol and increases in platelet aggregability.

Table 12.4 Differential diagnoses: acute chest pain

Cardiovascular diseases
- arrhythmias
- pericarditis
- myocarditis
- aortic dissection

Pulmonary diseases
- pulmonary embolism
- pleuritis
- pneumothorax

Skeletal disorders
- rip fracture/contusion
- spine diseases
- Tietze syndrome

Gastrointestinal disorders
- oesophagitis/oesophageal rupture
- pancreatitis
- gall bladder dysfunction

Others
- herpes zoster
- malignant diseases involving chest/bones

Population studies reveal that approximately 30% of myocardial infarctions occur silently or with less severe symptoms. They are detected only by chance on subsequent ECG recordings [75].

Atypical presentations of ACS are not uncommon. They are often observed in younger (25–40 years) and older (> 75 years) patients, diabetic patients and in women. In the Multicenter Chest Pain Study, acute myocardial ischaemia was diagnosed in 22% of patients presenting

to emergency departments with sharp or stabbing chest pain, 13% of those with chest pain that had some pleuritic features, and in only 7% of those whose chest pain was fully reproduced by palpation [76]. In addition, variant angina, as a result of coronary spasm, forms part of the spectrum of unstable angina and may not be recognized at initial presentation. Accordingly, the assessment of clinical symptoms alone is insufficient for risk stratification as symptoms may be difficult to assess objectively and can easily be subject to misinterpretation.

Physical examination

Physical examination of patients with chest pain includes chest examination, auscultation, and measurement of heart rate and blood pressure. The major purpose of the examination is to exclude non-cardiac causes of chest pain, non-ischaemic cardiac disorders (e.g. pericarditis, valvular disease), potential precipitating extracardiac causes, pneumothorax, and to look for signs of potential haemodynamic instability and left ventricular dysfunction. In patients with myocardial infarctions particular attention has to be drawn to systolic murmurs indicative of mitral regurgitation or ventricular septal defects.

The electrocardiogram

The resting ECG plays a central role in the early assessment of patients with suspected ACS. In all patients admitted with acute chest pain a 12-lead ECG should be recorded and evaluated by an experienced physician within 10 minutes. If a pre-hospital fibrinolysis programme exists a complete recording has to be obtained at the site of first contact with the patient. Exercise testing is contraindicated in symptomatic patients and in patients with elevated troponins. After stabilization and where there is a lack of high-risk features (Table 12.5), treadmill testing is useful for risk assessment.

The ECG remains an important screening tool also in patients with atypical presentations and it may provide evidence of alternative diagnoses such as pericarditis, pulmonary embolism, or cardiomyopathy. Ideally, a tracing should be obtained when the patient is symptomatic and compared with a tracing obtained when symptoms have resolved. Comparison with a previous ECG, if available, is extremely valuable, particularly in patients with coexisting cardiac pathology such as left ventricular hypertrophy or a previous myocardial infarction [76,77].

ST-segment shifts and T-wave changes are the most reliable electrocardiographic indicators of unstable coronary disease and associated with elevated risk [78,79]. Dynamic changes, particularly during episodes of chest pain, have a very high diagnostic value. Continuous ST-segment monitoring was shown to provide better ECG prediction, but should not delay invasive management in symptomatic patients [77].

ST-segment depression of > 1 mm in two or more contiguous leads, in the appropriate clinical context, are highly suggestive of ACS. Inverted T-waves (greater than 1 mm) in leads with predominant R-waves are also suggestive, although the latter finding is less specific. Deep symmetrical inversion of T-waves (≥ 0.2 mV) in the anterior chest leads is often related to significant proximal left anterior descending coronary artery stenosis. Non-specific ST-segment shift and T-wave changes of < 1 mm are much less specific. In the Multicenter Chest Pain Study such non-specific changes were often noted in patients in whom an ACS was ultimately ruled out. Transient episodes of bundle branch block occasionally may occur during ischaemic attacks.

Giant T-waves are a rare finding in the very early phase of AMI. New ST-segment elevations in the presence of appropriate symptoms indicates transmural ischaemia as a result of acute coronary occlusion. Persistent ST-segment elevation at the J-point with the cut-off points ≥ 0.2 mV in V1 through V3 and ≥ 0.1 mV in other leads characterizes evolving myocardial infarction (STEMI). The ST-segment vector points to the region of injury, which allows the infarct-related artery to be identified in many cases (Table 12.5). Right precordial leads (V3r to V6r) may be useful in identifying right ventricular involvement and V7 to V9 in detecting true posterior infarctions.

Transient ST-segment elevation may be observed in ACS and particularly in Prinzmetal's angina. To detect or to rule out transient ST-segment changes during recurrent episodes of chest pain or in silent ischaemia, continuous multi-lead ST-segment monitoring can be useful.

ST-segment depression may occur in reciprocal leads (Figs 12.13, 12.14) as an electrical mirror or as the result of true ischaemia in another territory ('ischaemia at a distance'). In the absence of ST-segment elevation, depression of the ST-segment is indicative of subendocardial ischaemia. Only biochemical markers of myocardial cell injury (e.g. troponins) will determine whether this patient is having a NSTEMI in the absence of typical ST-segment elevations. Isolated ST-segment depression in the right precordial leads may occur in strictly posterior myocardial infarctions. ST-segment elevations confined to leads V1 and V2 may be the result of early repolarization and should critically be interpreted when typical clinical symptoms are lacking.

During the evolution of cell necrosis the amplitude of the R-wave is reduced, T-waves become negative, and Q-waves develop. Clinically established myocardial infarction is defined by any Q-wave in leads V1 through V3, or

Table 12.5 Acute myocardial infarction based on electrocardiographic entry criteria with angiographic correlation

Location	Anatomy of occlusion	ECG	1-year mortality (%)*
Proximal left anterior descending	Proximal to first septal perforator	ST↑ V1–6, I, aVL and fascicular bundle or bundle branch block	25.6
Mid left anterior descending	Proximal to large diagonal but distal to first septal perforator	ST↑ V1–6, I, aVL	12.4
Distal left anterior descending or diagonal	Distal to large diagonal or to diagonal itself	ST↑ V1–V4 or ST↑ I,V5,6 aVL, V5–V6	10.2
Moderate to large inferior (posterior, lateral, right ventricular)	Proximal right coronary artery or left circumflex	ST↑ II, III, aVF and any or all of the following: 1) V1, V3R, V4R 2) V5V6 3) R > S in V1, V2	8.4
Small inferior sdsds	Distal righ coronary artery or left circumflex branch occlusion	ST↑ II, III, aVF only	6.7

*Based on GUSTO-I cohort population in each of the 5-year categories, all receiving reperfusion therapy.

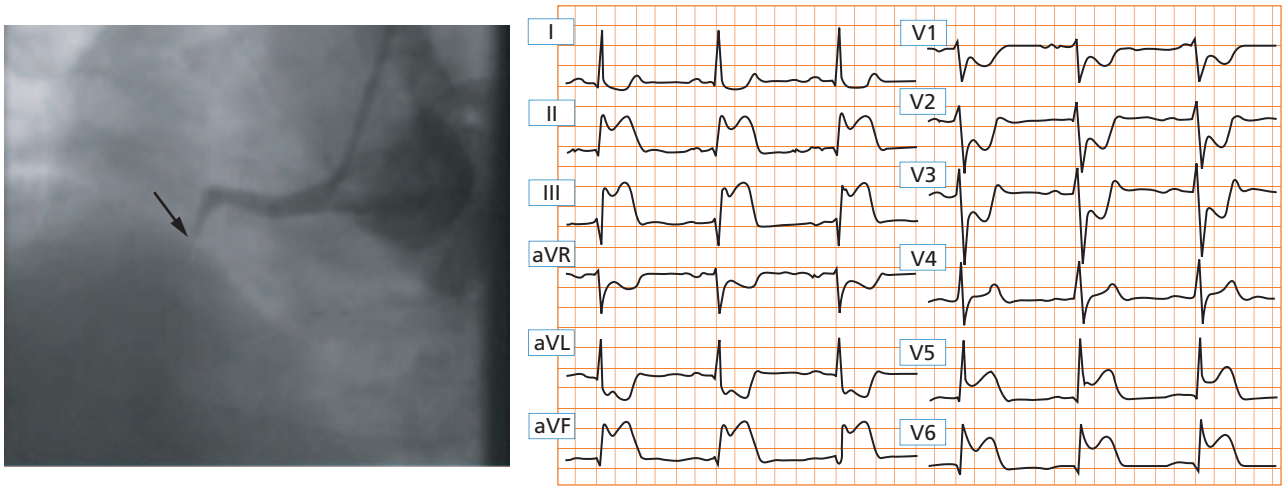

Figure 12.13 Inferior AMI: occluded right coronary artery, ST-segment elevation in leads II, III and aVF; ST depression in V1 to V4.

Q-wave ≥ 0.03 s and ≥ 0.3 mV in leads I, II, aVL, aVF, V4, V5, or V6. However, the absence or presence of Q-waves is not a reliable sign of a transmural or non-transmural infarct expansion. In addition, creatine kinase (CK) levels do not always correlate with the development of Q-waves. Accordingly, the terms Q-wave and non-Q-wave myocardial infarction should be used critically [80].

It is important to note that even a completely normal ECG in patients presenting with suspicious symptoms does not exclude the possibility of an ACS. In several studies about 5% of patients with normal ECG who were discharged from the emergency department were ultimately found to have either an AMI or unstable angina [81–83]. However, a completely normal ECG recording during an episode of significant chest pain should direct attention to other possible causes for the patient's complaints.

Biochemical markers

Biochemical markers play a central role in evaluating patients with chest pain. Besides routine laboratory measurements (haemoglobin, white blood cell count, thyroid hormones, etc.) special markers reflecting distinct pathophysiological processes must be obtained in this high-risk group of patients.

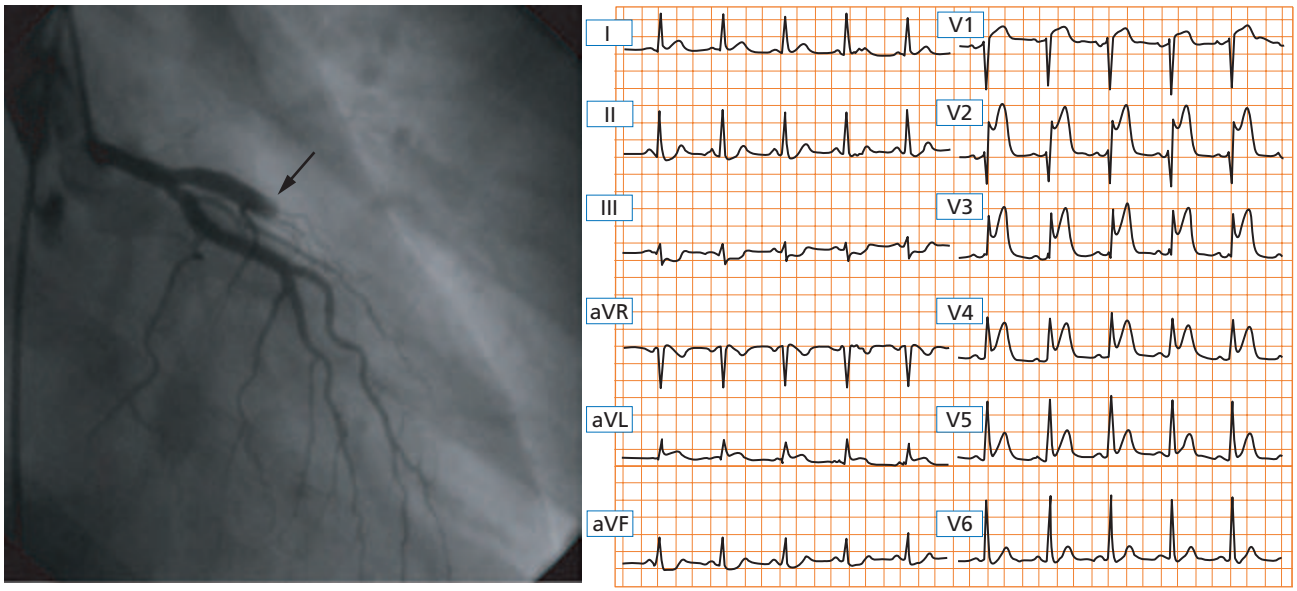

Figure 12.14 Anterior AMI: occluded left anterior descending coronary artery, ST-segment elevation.

Table 12.6 Biochemical markers for the detection of myocardial necrosis

	MW (kDa)	Specificity	Sensitivity	First rise after AMI	Peak after AMI	Return to normal
CK-MB mass	85.0	++	+	4 h	24 h	72 h
Myoglobin	17.8	+	+	2 h	6–8 h	24 h
Troponin T	33.0	+++	+++	4 h	24–48 h	5–21 days
Troponin I	22.5	+++	+++	3–4 h	24–36 h	5–14 days

Markers of myocardial necrosis

Pathohistological studies in patients with unstable angina have disclosed focal cell necroses in the myocardium distal to the culprit artery. These were attributed to repetitive thrombus embolization [84,85]. Focal cell necroses, or so-called minor myocardial injuries, are very infrequently detectable by routine creatine kinase (CK) and CK-MB measurements. Even improved test systems for the quantitative determination of CK-MB based on immunological determination, which are superior to enzyme activity measurements, did not substantially increase the sensitivity for the detection of minor myocardial injury. Myoglobin is a marker which rises earlier than CK-MB in AMI but has similar limitations with respect to specificity (Table 12.6).

These biochemical limitations of CK-MB and myoglobin measurements for the detection of minor myocardial injury have been overcome by the introduction of troponin measurements (Fig. 12.15). In the early 1990s, the cardiac isoforms of troponin T and troponin I were introduced into clinical practice. The troponin complex is formed by three distinct structural proteins (troponins I, C and T) and is located on the thin filament

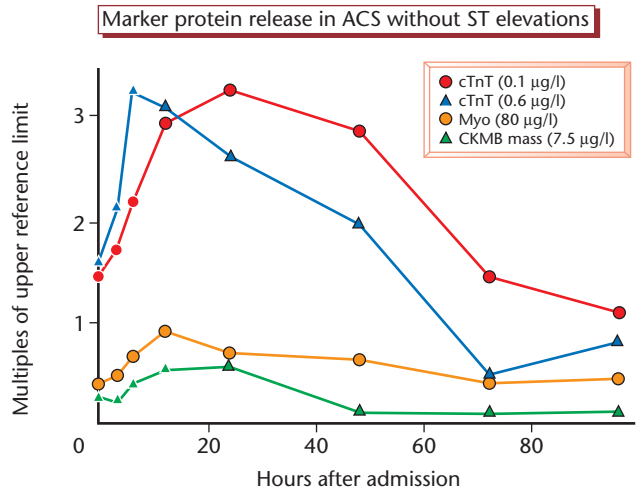

Figure 12.15 Biomarker levels in a typical patient with ACS without ST-segment elevation.

of the contractile apparatus in both skeletal and cardiac muscle tissue regulating the calcium-dependent interaction of myosin and actin. Cardiac isoforms for all three troponins, however, are encoded each by different genes

and can be distinguished by monoclonal antibodies recognizing the amino acid sequence distinct for the cardiac isoform [86]. However, only the cardiac isoforms of troponin T and troponin I are exclusively expressed in cardiac myocytes. Accordingly, the detection of cardiac troponin T and troponin I is highly specific for myocardial damage, attributing these markers the role of a new gold standard. In conditions of 'false-positive' elevated CK-MB, such as skeletal muscle trauma, troponins will clarify any cardiac involvement.

In patients with a myocardial infarction, a first rise of troponins in peripheral blood can be observed as early as 3–4 hours because of its release from a cytosolic pool, followed by a prolonged appearance of up to 2 weeks related to continuous proteolysis of the contractile apparatus in the necrotic myocardium. The high proportional rise of troponins, relative to the low plasma troponin concentrations in healthy controls, allows the detection of myocardial damage in about one-third of patients presenting with unstable angina even without elevated CK-MB [87–95].

Definition of acute myocardial infarction

The traditional clinical definition of myocardial infarction by WHO did not require elevations of biochemical markers, and hence was revised by the Joint European Society of Cardiology/American College of Cardiology Committee. Today, the AMI definition is based on biochemical criteria, namely troponin elevation as a result of irreversible cell damage, combined with clinical features (Table 12.7) [1]. This change in definition increases the frequency of the diagnosis of myocardial infarction and has important implications for the interpretation of epidemiological research and clinical trials as well as for clinical care. Although many physicians currently have conceptual difficulties with the translation of this change in paradigm into clinical practice, the increased risk in patients with elevated troponin levels justifies the revised criteria.

Table 12.7 Definition of AMI according to ESC/ACC/AHA consensus

Typical rise or fall of troponin or CK-MB with at least one of the following:
Ischaemic symptoms
New Q-waves on the ECG
ECG changes indicative of ischaemia (ST elevation/depression)
Coronary artery intervention (e.g. percutaneous coronary intervention)

Adapted from [1].

Troponins for risk stratification

It has been demonstrated in numerous clinical trials that troponin T and troponin I are strongly associated with increased risk both in the acute phase of hospitalization and during long-term follow-up. In the first report on troponin T in a small cohort of patients with unstable angina, it was demonstrated that the risk of death and myocardial infarction during hospitalization was increased even in the presence of antiplatelet therapy with aspirin and heparin [88]. In a substudy of the FRISC (FRagmin during InStability in Coronary artery disease) trial the prognostic value was shown to correlate with the absolute concentrations of troponin T over a 5-month period [91]. The peak value during the first 24 hours provided the best independent prognostic information and the absence of troponin T was superior to CK-MB for identification of the low-risk group [96]. Furthermore, the combination of the troponin T test with a predischarge exercise test represents an excellent risk assessment for unstable coronary disease [97]. During the 5-month follow-up, death and myocardial infarction occurred at a rate of only 1%, if both the troponin test and the predischarge exercise test were normal, whereas the event rate was as high as 50% when both tests were abnormal. Moreover, the prognostic potential of troponin T in the entire spectrum of patients with ACS, including myocardial infarctions, was evaluated in a substudy of the GUSTO (Global Use of Strategies To Open occluded coronary arteries) IIA trial [98]. A single measurement within 2 hours after admission was highly predictive of 30-day mortality and other major complications. The prognostic value was independent of ECG findings and was superior to CK-MB measurements.

For elevations of cardiac troponin I, a similar prognostic impact was evidenced as for troponin T elevations. In the TIMI IIIB trial including patients with unstable angina and non-Q-wave myocardial infarction, the mortality rate was closely related to troponin I levels reaching 7.5% after 42 days follow-up in patients with the highest troponin I values [90].

Analytical aspects of troponin measurements

Quantitative and semi-quantitative bedside troponin test systems for whole blood allow the prognostic potential of the troponins to be independent of clinical chemistry laboratory facilities. To establish the correct diagnosis and for prompt triage, point-of-care or bedside testing for biochemical markers may be advantageous. Point-of-care tests are characterized as assays to be performed either directly at the bedside or at 'near-patient' locations such as the emergency department, chest pain evaluation centre, or intensive-care unit. Therefore, the rationale

behind point-of-care testing is the improvement in analytical turnaround time. Suspected ACS represents a possibly life-threatening condition in which savings in time for therapeutic decision-making and further patient management may be decisive. The National Academy of Clinical Biochemistry as well as the ESC Task Force Report advise implementation of point-of-care testing systems if the hospital logistics cannot consistently deliver cardiac marker results within 1 hour [66,99–101]. Point-of-care techniques must be analytically accurate and equivalent to centralized laboratory methods. In large series, bedside tests results were validated against quantitative measurements and could be reliably performed by paramedical staff [92,93,102–104]. It was shown prospectively that risk stratification based on a protocol scheduling rapid testing of troponin on the patient's arrival in the emergency room, and again 4–6 hours later, provides a more reliable risk stratification than the previous more time-consuming protocols [92]. However, a single test result obtained on admission of the patient is inappropriate for risk stratification, because up to 10% of high-risk patients will be missed.

The difficulty with defining the appropriate diagnostic threshold for troponins is compounded by the availability of multiple assays for troponin I for which different reference ranges have been developed. For troponin I, many manufacturers report two decision limits: a 'diagnostic' limit for the definitive diagnosis of myocardial infarction based on prior comparisons to CK-MB and a lower limit 'suggestive' of myocardial injury that is important for the patients' prognosis. Though the challenge of developing terminology and diagnostic thresholds around low-level troponin elevation has been a source of debate, the clinical importance of increased troponin levels in suspected ACS is firmly established.

There is no fundamental clinical difference between troponin T and troponin I. Differences between study results are predominantly explained by varying inclusion criteria, differences in sampling patterns and use of assays with different diagnostic cut-offs. The decision limits must be based on carefully conducted clinical studies for individual troponin I assays and should not be generalized between different troponin I assays. For troponin T, levels as low as 0.01 μg/l have recently been shown to be associated with adverse cardiac outcomes in ACS [105]. From the FRISC studies a troponin T level of 0.03 μg/l appears to be the appropriate threshold [106]. Low levels of troponins appear to carry the highest risk in patients with ACS. However, the application of this threshold among more heterogeneous populations of patients presenting to the emergency department will require prospective evaluation. Currently, the diagnostic threshold for troponin T may be maintained between 0.06 and 0.10 μg/l, depending on the local laboratory performance.

Non-cardiac causes of elevated cardiac troponins

One initial barrier to the universal acceptance of troponins as the gold standard for the detection of myocardial injury has been the observation that troponin concentrations are increased rarely in non-cardiac conditions, but are more commonly elevated in patients with renal failure. Although measurements of cardiac troponins are generally assessed as highly specific for myocardial injury, elevated cardiac troponin, unrelated to myocardial damage, has been reported in a number of conditions including cerebrovascular accidents, subarachnoid haemorrhage, endocrine disease, polymyositis, dermatomyositis, and haematological malignancies [107,108]. Studies in intensive-care units have demonstrated increased troponin levels in septic patients. Importantly, troponin concentrations in these patients correlated with left ventricular dysfunction and the presence of multiorgan failure. However, it remains unclear whether troponin elevation affected either hospital length of stay or survival [109].

Elevated levels of cardiac troponins are also found in patients with end-stage renal disease in the absence of unstable heart disease. Even using more specific second-generation troponin T assays, up to 53% of asymptomatic patients with end-stage renal disease remain positive for cardiac troponin T [110–112]. An elevated concentration identifies patients at greater risk of all-cause mortality [110,113]. Given the lower frequency of abnormal troponin I in asymptomatic patients with end-stage renal disease, it has been suggested that this may be a more specific marker of cardiac ischaemia than troponin T for this group of patients [113,114]. Several factors are likely to explain the discrepancy between troponins I and T. Free cytosolic proteins are released earlier when cells are damaged, estimated to be 7% for troponin T as compared to 3.5% for troponin I [115]. There is roughly twice as much troponin T as troponin I per gram of myocardium [116]. Moreover, uraemia increases the free serum concentration and the clearance of protein-bound factors. As troponin I is released from the myocardium only as a complex and troponin T is released as a complex as well as free troponin T, it is possible that uraemia may affect the detection, release or clearance of different troponin subunits. Since free and bound troponin T are large molecules (37 and 77 kDa, respectively), it is unlikely that the kidney is responsible for clearance. Indeed, the half-life and clearance of troponin I after an AMI appear similar between patients with normal renal function and end-stage renal disease [117].

A number of studies investigated the prognostic role of serum troponins in patients with renal failure using the newer cardiac troponin assays. The largest of these trials enrolled a total of 733 patients with end-stage renal disease [118]. Troponin T was more commonly elevated than troponin I, and both an increased troponin T and an increased troponin I were predictive of increased mortality. In the setting of an ACS, a recent analysis of over 7000 patients from the GUSTO (Global Use of Strategies To Open occluded coronary arteries) IV trial found that troponin T is an important predictor for adverse outcome in both patients with and without renal failure [119]. In summary, serum cardiac troponin concentrations are frequently increased in asymptomatic patients with renal failure. This is likely to represent multifactorial pathology potentially including cardiac dysfunction, left ventricular hypertrophy, as well as subclinical myocardial infarction and is associated with an increased risk of morbidity and mortality in those patients.

Markers of inflammation

Of the numerous inflammatory markers that have been investigated over the past decade, CRP is the most widely studied. The exact source of elevated CRP levels among patients with unstable coronary syndromes remains unclear. Given that myocardial damage is also a major inflammatory stimulus, it is important to note that in a combined analysis of FRISC-II and GUSTO-IV, CRP elevation over a period of up to 120 hours was only found in patients with elevated troponin levels [120]. Similarly, in the CAPTURE (c7E3 Anti Platelet Therapy in Unstable REfractory angina) study, CRP levels were significantly higher in troponin-positive patients [94]. This suggests that an acute inflammatory process induced by myocardial damage is superimposed on a chronic inflammatory condition, both of which might influence long-term outcome in ACS. It is also important to note, however, that pro-inflammatory cytokines are also released from adipose tissue, tissue macrophages and injured myocardium.

There is robust evidence that, even among patients with troponin-negative ACS, elevated levels of CRP are predictive of future risk [94,125,126]. In the CAPTURE trial, only troponin T was predictive for the initial 72-hour period, but both CRP and troponin T were independent predictors of risk at 6 months [94]. The FRISC study confirmed that mortality is associated with elevated CRP levels at the time of the index event and continues to increase for several years [127]. In all studies the predictive value of CRP was independent of, and additive to, troponin. Most importantly, CRP has prognostic value among patients without evidence of myocyte necrosis; specifically, even among patients negative for troponin, an elevated CRP is predictive of future adverse events [94,126,127]. Recently, however, it was reported from the Reykjavik prospective cohort study, based on a large number of patients over a 20-year follow-up, that the predictive value of a single baseline measurement of CRP for the 20-year incidence of cardiovascular events was much less strong than previously estimated [128–131]. CRP added little to the predictive value provided by the assessment of traditional risk factors, including LDL-cholesterol. Accordingly, more research or more specific markers are necessary to clarify the use of CRP as a marker of cardiovascular risk in clinical practice.

Type 2 secretory phospholipase A_2 ($sPLA_2$) is also an acute-phase reactant, which accumulates in atherosclerotic arterial walls, elicits several effects on monocytes, and provides a link between inflammation and lipid accumulation in atherosclerotic plaques. It is present in the media of normal as well as diseased arteries, hydrolyses phospholipids, and contributes to the production of oxidized LDL-cholesterol which is taken up by macrophages resulting in enhanced transformation into foam cells. The $sPLA_2$ exhibits similar features to CRP as a marker of plaque inflammation as well as endothelial dysfunction [121,122] and may predict coronary events independently of other risk factors in patients with unstable angina [123]. Similarly, elevated levels of the lipoprotein-associated PLA_2 ($Lp\text{-}PLA_2$), using a different approach to determine PA_2 activation, have been shown to predict future coronary events in apparently healthy middle-aged men with moderately elevated total cholesterol, independent of CRP [124].

Current research activities focus on the identification of more upstream markers of the inflammatory cascade which may be more representative of vascular inflammation as opposed to systemic inflammation. These novel inflammatory markers include pregnancy-associated plasma protein A (PAPP-A). This zinc-binding metalloproteinase enzyme is a specific activator of insulin-like growth factor I, an important mediator of atherosclerosis. Among patients who died suddenly from cardiac causes, PAPP-A was abundantly expressed in ruptured and eroded unstable plaques, but was absent or minimally expressed in stable plaques [132]. In plaques with large lipid cores and cap rupture, staining for PAPP-A revealed that the enzyme occurred mostly in the inflammatory shoulder region. A clinical study suggests that measurement of plasma PAPP-A is an independent predictor of ischaemic cardiac events and the need of revascularization in patients who present with suspected myocardial infarction but remain troponin negative [133]. These data require validation in larger cohorts before they can enter routine use.

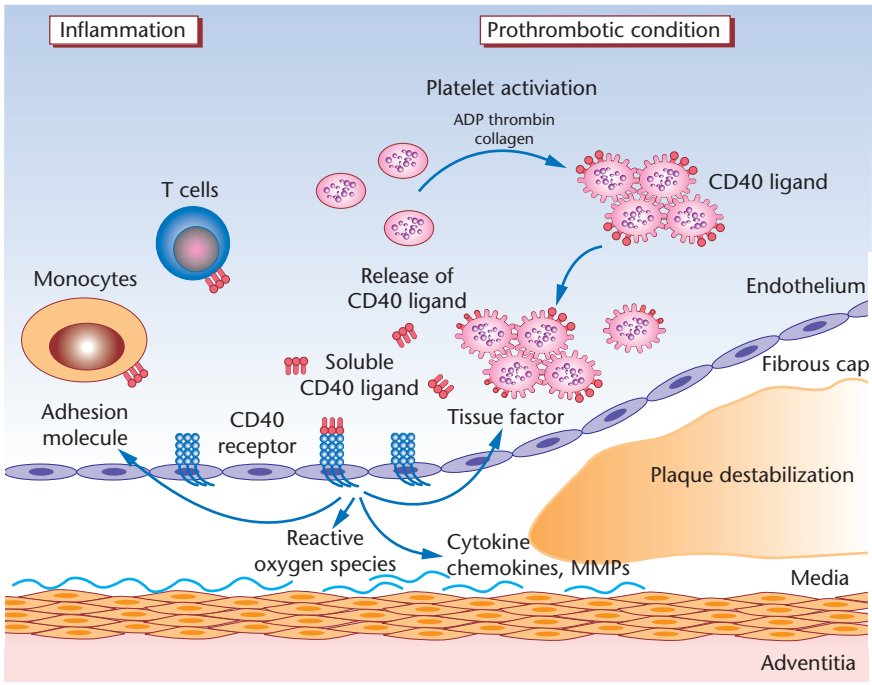

Figure 12.16 The pathophysiological role of soluble CD40 ligand in patients with acute coronary syndromes.

Biochemical markers of platelet activation

It has been shown that soluble CD40 ligand is a powerful biochemical marker of thrombotic inflammatory activation (Fig. 12.16) in patients with ACS, supporting the close relationship between inflammation and thrombotic activation in ACS [134,135]. Furthermore, studies have demonstrated that combining this marker with classical markers of necrosis (troponins) can help us to identify patients at the highest risk for subsequent cardiovascular events. Plaque rupture induces platelet activation through liberation of collagen, thrombin and ADP. The platelet activation results in an increased surface expression of CD40 ligand which subsequently is cleaved from the membrane surface. The released soluble CD40 ligand can activate CD40 on endothelial cells and, thereby, induce a pro-inflammatory cascade in the vessel wall. Moreover, soluble CD40 ligand can activate CD40 which is also expressed on inflammatory cells such as monocytes and T cells. The subsequent activation of these inflammatory cells and their invasion of the ruptured or eroded plaque results in a further inflammatory perturbation of the vessel wall. Importantly, blockade of the glycoprotein IIb/IIIa receptor on platelets inhibits the release of soluble CD40 ligand through inhibition of platelet aggregation via fibrinogen. It has been shown that levels of soluble CD40 ligand do not only identify patients with ACS that are at highest risk for ischaemic events but also predict which patient will derive major benefit from antiplatelet treatment with the glycoprotein IIb/IIIa receptor antagonist abciximab [135].

Inflammatory balance in patients with acute coronary syndromes

Several studies indicate an important role of inflammatory balance in patients with an ACS [136,137]. Interleukin-10 (IL-10) is secreted by activated monocytes/macrophages and lymphocytes [138]. It has multifaceted anti-inflammatory properties including inhibition of the prototypic pro-inflammatory transcription factor NF-κB leading to suppressed cytokine production, inhibition of matrix-degrading metalloproteinases, reduction of tissue factor expression, inhibition of apoptosis of macrophages and monocytes following infection, and promotion of the phenotypic switch of lymphocytes into the T helper type 2 phenotype [137]. All these inflammatory mechanisms have been shown to play a pivotal role for atherosclerotic lesion development and progression, suggesting a potential regulatory role of IL-10. Numerous recent experimental studies have shown that either systemic or local IL-10 gene transfer not only attenuates atherogenesis [138,139], but also affects processes associated with lesion progression [140]. Consistently, in the CAPTURE trial, elevated serum levels of the anti-inflammatory cytokine IL-10 were linked to patients with ACS having a significantly improved outcome [137]. The predictive value of IL-10 serum levels was independent of elevated troponin levels, which reflect the acute risk secondary to thrombotic complications during ACS. Thus, reduced IL-10 serum levels are not only a marker of plaque instability favouring the development of ACS, but—more importantly—are indicative of a poor prognosis even

after the occurrence of an acute ischaemic event caused by plaque instability. In addition, the beneficial effect of elevated serum levels of IL-10 was restricted to patients with elevated CRP serum levels indicative of an enhanced systemic inflammatory response. These data further support the concept that the balance between pro- and anti-inflammatory cytokines is a major determinant of patients' outcome in ACS.

Oxidative stress in acute coronary syndromes

There is growing evidence that myocardial cell injury is not only related to platelet activation but also preceded by recruitment and activation of leucocytes, most notably polymorphonuclear neutrophils [141]. Polymorphonuclear neutrophils have been shown to increasingly undergo degranulation within the coronary circulation in ACS [39]. One of the principal mediators secreted upon degranulation of polymorphonuclear neutrophils is myeloperoxidase, a haemoprotein traditionally viewed as a microbicidal enzyme [142]. There is accumulating evidence that myeloperoxidase displays potent pro-atherogenic properties. For example, myeloperoxidase can oxidize LDL-cholesterol, thereby propagating uptake by macrophages and perpetuating foam cell formation [143]. Furthermore, myeloperoxidase has been shown to activate metalloproteinases and promote destabilization and rupture of the atherosclerotic plaque surface [144]. Also, myeloperoxidase catalytically consumes endothelium-derived nitric oxide, thereby reducing nitric oxide bioavailability and impairing its vasodilatory and anti-inflammatory functions [145,146]. Two studies have revealed that myeloperoxidase is a powerful predictor of adverse outcome in patients with ACS [147,148]. Particularly in individuals with low troponin levels, myeloperoxidase identified patients at increased risk for early cardiovascular events that occur within days after the onset of symptoms [147]. This suggests that myeloperoxidase unmasks states of acute inflammation in the coronary circulation indicative of increased neutrophil activation, which ultimately precedes myocardial injury. While future prospective studies are warranted to confirm these results, the current findings support the rationale to further evaluate myeloperoxidase for risk stratification in patients with ACS and encourage the development of pharmacological strategies to modulate the catalytic activity of this enzyme.

Biochemical markers of neurohumoral activation

Neurohumoral activation of the heart can be monitored by measuring systemic levels of natriuretic peptides secreted from the heart. Atrial natriuretic peptides (ANP) are primarily produced in the cardiac atria, whereas brain (B-type) natriuretic peptides (BNP) are mainly synthesized in the ventricular myocardium [149]. Both peptides are generated as pro-hormones (proANP and proBNP), that upon secretion are cleaved into biologically active peptides (ANP and BNP) and N-terminal pro-hormone fragments (NTproANP and NTproBNP). Natriuretic peptides are released mainly in response to increased stretch or wall tension and are involved in the regulation of blood pressure, blood volume and sodium balance via modulation of natriuresis, vasodilatation and inhibition of the renin–angiotensin–aldosterone system as well as the sympathetic nervous system. In disease states, BNP and NTproBNP have a greater proportional rise than ANP and NTproANP, and have received most of the interest for a clinical application. Both natriuretic peptides are highly sensitive and fairly specific markers for the detection of left ventricular dysfunction. Therefore, investigators originally focused on the predictive value of natriuretic peptides in patients with congestive heart failure but more recently this focus has expanded to include ACS patients with unstable angina and NSTEMI. Patients with ACS and elevated NTproBNP or BNP levels, respectively, have a three- to fivefold increased mortality compared to those with lower levels of NTproBNP or BNP. More importantly, the level of NTproBNP was strongly associated with mortality even when adjusted for age, Killip class and left ventricular ejection fraction determined by echocardiography [150,151]. Moreover, in patients with stable coronary heart disease elevated levels of BNP are independently associated with inducible ischaemia and therefore provide the rationale for the hypothesis that NTproBNP levels in patients with ACS may also reflect ischaemia-induced left ventricular dysfunction even in the absence of myocardial necrosis [152].

Point-of-care testing

If patients with ACS without ST-segment elevations stabilize clinically, minor time delays may not be as critical as in STEMI. However, point-of-care assays are available for the determination of CK-MB, myoglobin and troponins [93,102–104,153–155]. These hand-held, disposable assays use small quantities of anticoagulated blood to determine the presence or absence of abnormal concentrations of cardiac proteins within 15 to 20 minutes. Based on immunochromatic methods these assays allow qualitative determination of myocardial proteins by utilization of mono- or polyclonal antibodies directed against the target protein. Application of a defined amount of whole blood or plasma onto the test strip initiates the assay process. From whole blood samples cellular blood components are separated by a permeable membrane. If abnormal concentrations of cardiac markers are present,

colour-labelled antibodies will bind to the proteins. By means of solid-phase technology the antibody–protein complex adheres to an immobilized ligand as part of the test kit and the process of antibody binding and migration finally results in an identifiable colour development at a specified region of the test kit.

Reading of point-of-care tests is performed visually and therefore is observer dependent. A further major limitation is that visual assessment only allows a yes or no statement without definitive information regarding the concentration of the marker in the blood. In general, a darker or earlier developing signal line indicates a higher concentration of the marker in the sample but remains subjective. Careful reading exactly at the assay-specific indicated time under good illumination is essential to avoid observer misinterpretation especially in cases of marginal antibody binding. Even the faintest colouring should be read as a positive test result. No special skill or prolonged training is required to read the result of these assays. Accordingly, these tests can be performed by a variety of members of the health-care team [156]. Numerous studies have shown that point-of-care test systems are reliable, provided the above precautions were taken into consideration [92,157]. Time to signal appearance (< 10 min) has been shown to identify a subgroup of patients that is at particular risk [158]. For troponin T an optical reading system is offered which also provides a printout of the quantitative result [104,159].

Multimarker approach in clinical practice

Since ACS is a complex event, several markers reflecting the respective pathophysiological pathways may be advantageous for risk stratification. Markers for the acute risk of myocardial infarction and for long-term mortality can be distinguished. The combined use of markers for myocardial necrosis, inflammation and neurohumoral activation may significantly add to our ability to correctly identify patients who are at high risk for future cardiovascular events (Fig. 12.17). Several studies have demonstrated clearly that a multimarker approach improves risk stratification [14,160]. The predictive value of CRP is strongly related to myocardial injury as evidenced by troponin elevation and is more related to the long-term outcome of these patients. Novel inflammatory markers such as myeloperoxidase and PAPP-A appear to be more closely related to the short-term risk of patients with ACS. These individuals with evidence for inflamed and unstable atherosclerotic plaque formation may benefit most from an aggressive medical treatment and the benefits of an early invasive strategy may also be greatest among those with elevated levels of inflammatory biomarkers.

Many of the above markers are not yet available for routine use to translate the complete potential of biochemistry to daily practice. Currently, it is advised to use troponins for the acute risk stratification on arrival of the patient in the hospital. During the subsequent days, BNP or NTproBNP allows estimation of the area that was at risk during the acute event and the impact on long-term outcome. For the detection of the underlying inflammatory activity responsible for the long-term mortality of the patients, currently only CRP is available on a routine basis and should be measured at the time of discharge.

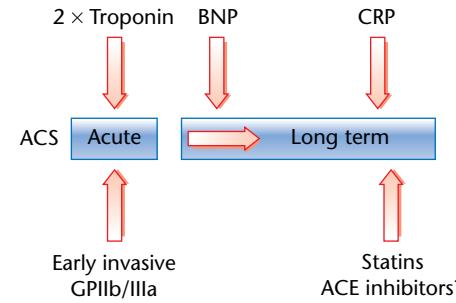

Figure 12.17 Multimarker testing in ACS during hospitalization.

Risk scores in acute coronary syndrome

The integration of underlying risks of coronary artery disease and risks of thrombosis is potentially challenging at the bedside. Accordingly, there is a need for simplified and widely applicable risk stratification tools facilitating the triage and management of patients with ACS.

Age, systolic blood pressure and heart rate

The simplest risk scoring systems have demonstrated that, in population analyses, a simple composite of age, systolic blood pressure and heart rate provides valuable prognostic information for patient groups. However, this information is less accurate and predictive for individual patients [161].

TIMI risk score

Based upon data from clinical trials, the TIMI risk score was derived and tested in STEMI populations [162]. This score allocates points on the basis of age, history of diabetes, hypertension or angina and examination features including blood pressure, heart rate, Killip class and weight. It also includes ST-segment elevation or left bundle branch block on the ECG and time to reperfusion of > 4 hours. Application of the data to the NRMI Registry demonstrates that the registry patients have a higher risk of death than the overall trial populations and the risk score showed strong prognostic capability (C index 0.74 overall). Among patients not receiving reperfusion therapy

the risk score underestimated death rates and offered lower discriminatory capacity (C index 0.65). Nevertheless, this score provides a simple and practical bedside tool for the triage of patients into high-risk, moderate-risk, or low-risk categories. In NSTEMI, the TIMI risk score was less accurate in predicting death (C index 0.61) [163]. The PREDICT score includes assessment of left ventricular function on discharge, with improved predictive accuracy [163].

GRACE risk score

Based upon a large unselected registry population of the full spectrum of ACS, eight variables were derived with independent predictive power for in-hospital death and for post-discharge death or myocardial infarction at 6 months post-discharge. The data were tested prospectively and against an external dataset (GUSTO-IIB). The eight variables contain more than 90% of the predictive capacity of the full multivariable model and the C statistic for in-hospital death was 0.84 and for post-discharge death or myocardial infarction was 0.71. The score can be used to provide a numerical risk of in-hospital death or post-discharge death or MI based upon a score card or using software running on palm devices or personal computers [164,165]. Thus, although the contributions of individual risk factors are difficult to estimate at the bedside for each individual patient, newly established risk-score tools provide simple methods to estimate the risk of death and MI, and hence guide in-hospital and post-discharge management.

Imaging modalities in ACS

Imaging modalities are secondary tools in the diagnosis of ACS. They usually only confirm or exclude the working diagnosis based on biochemical markers and the ECG.

Coronary angiography

This is the gold standard to prove or exclude coronary artery disease. In approximately 10–15% of patients presenting with chest pain no high-grade lesion can be identified, or coronary artery disease is excluded. The extent and location of lesions is useful for risk assessment and decision-making concerning revascularization by means of angioplasty or surgery. The culprit lesions that are responsible for the clinical symptoms frequently show filling defects, indicating intracoronary thrombus formation.

Echocardiography

Left ventricular systolic function is an important prognostic variable in patients with ischaemic heart disease and can easily and accurately be assessed by echocardiography. Two-dimensional echocardiography in experienced hands is a useful bedside technique in the triage of patients with acute chest pain. Regional wall-motion abnormalities occur within seconds after coronary occlusion well before necrosis. However, these are not specific for acute events and may be the result of old infarctions. Transient localized hypokinesia or akinesia in segments of the left ventricle wall may be detected during ischaemia, with normal wall motion on resolution of ischaemia. The absence of wall-motion abnormalities excludes major myocardial infarction. Echocardiography is of additional value for the diagnosis of other causes of chest pain such as acute aortic dissection, pericardial effusion, or massive pulmonary embolism.

Myocardial perfusion scintigraphy

This technology is usually not readily available and is therefore only infrequently used for the triage of patients presenting with acute chest pain. A normal resting technetium-99 myocardial perfusion scintigram effectively excludes major myocardial infarction. An abnormal acute scintigram is not diagnostic of acute infarction unless it is known previously to have been normal, but it does indicate the presence of coronary artery disease and the need for further evaluation.

Cardiac magnetic resonance imaging

This new technology is available in an increasing number of centres on an emergency basis. The multimodality characteristic of cardiac magnetic resonance imaging provides a comprehensive examination, combining regional contractile function, myocardial perfusion and viability. This allows identification of patients with ACS and differentiation of patients with myocardial infarction. In addition, cardiac magnetic resonance imaging can rule out other potential reasons for acute chest pain, such as myocarditis, pericarditis, aortic dissection and pulmonary embolism (Fig. 12.18) [80].

Risk stratification according to guidelines in ACS without persistent ST elevation

The Task Force Report of the European Society of Cardiology distinguishes between short-term and long-term risk in patients presenting with ACS. The short-term risk is related to the acute thrombotic event, whereas the long-term risk is determined by the progression of the underlying disease [101].

The algorithm for the work-up of patients presenting with chest pain to the emergency room is depicted in Fig. 12.19. At presentation patients can be assigned

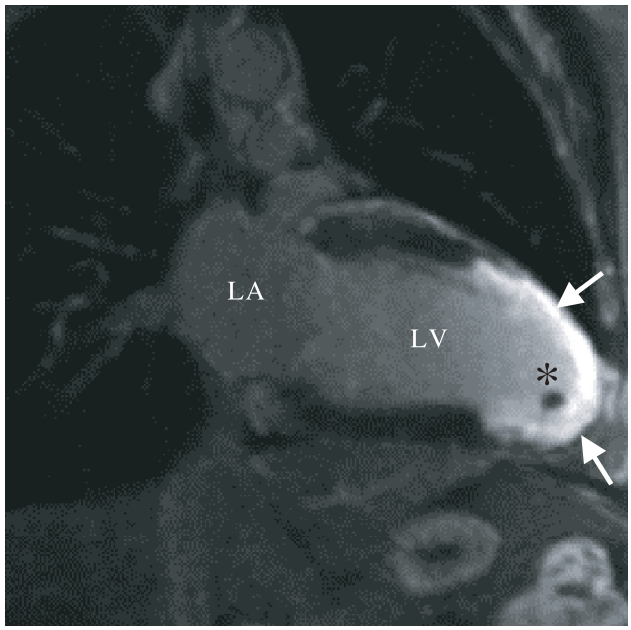

Figure 12.18 Vertical long axis of the left ventricle (LV) using an inversion recovery T_1-weighted gradient echo sequence 10 min after injection of gadolinium DTPA showing a large region of hyperenhancement in the anterior wall and the apex (i.e. late enhancement) representing a transmural infarction (arrow). An apical thrombus shows no contrast uptake (*). LA, left atrium.

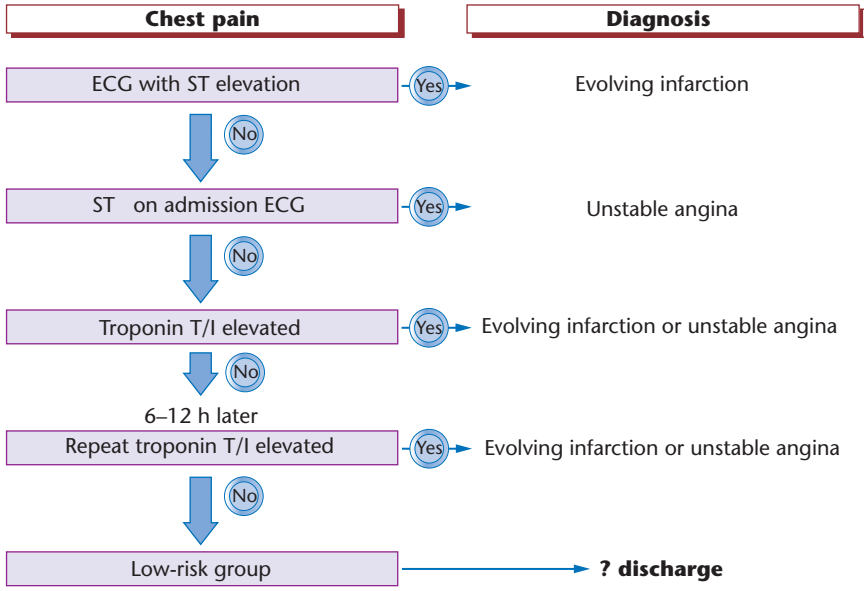

Figure 12.19 Algorithm of work-up of patients with chest pain.

to the high-risk or low-risk group according to several features that have been derived from large studies (Table 12.8). The therapeutic management is to be based on the risk assessment. Troponin elevations play the central role for the acute risk. In addition, dynamic ST-segment depression, critical arrhythmias (ventricular tachycardia, ventricular fibrillation), or haemodynamic instability (symptoms of shock) are linked to increased risk. Furthermore, the presence of diabetes is linked to a high likelihood of significant coronary artery disease and this alone places the patient in the high-risk group.

The long-term risk of mortality is related to well-established parameters. These include age and the established risk factors. From imaging modalities the extent of coronary artery disease (main stem lesion) and reduced left ventricular function are predictors of future outcome. Biochemical markers of inflammation (CRP) and of renal insufficiency (creatinine clearance) are further strongly associated with increased mortality.

Table 12.8 Parameters of high acute risk

Recurrent ischaemia/chest pain
Dynamic ST-segment changes
Elevated biomarkers: troponin, BNP or NTproBNP
Haemodynamic instability
Major arrhythmias (VF, VT)
Diabetes

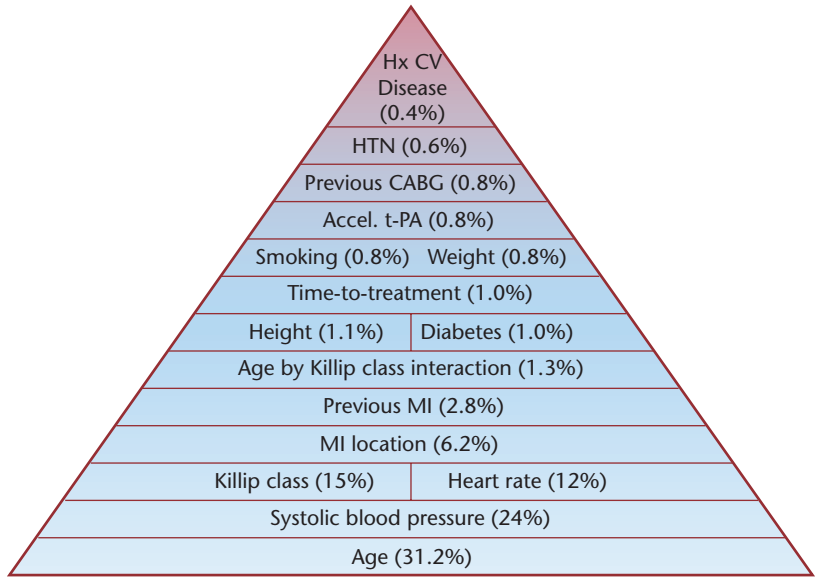

Figure 12.20 Multivariate model of 30-day mortality according to GUSTO I trial. Adapted from Lee *et al*. [166]. Hx, history.

Risk stratification in ST-segment elevation myocardial infarction

Whereas risk factors for the development of atherothrombosis provide insights into disease mechanisms and the opportunity for primary and secondary prevention therapy, analysis of the risk for adverse outcome after presentation with ST-segment elevations is critically important in guiding management and therapeutic decisions. Analysis usually uses a combination of clinical, ECG and biochemical parameters. Five rather simple baseline parameters can be used to predict more than 90% of the 30-day mortality: age, systolic blood pressure, Killip class, heart rate and infarct localization (Fig. 12.20) [166].

Killip class

The haemodynamic impact of the evolving myocardial infarction is clinically evident by the symptoms of shock. The Killip classification is widely used and linked to outcome. Killip class IV ('cardiogenic shock') is found in about 5% of AMI patients and is associated with extremely high mortality.

Infarct location

The prognosis of myocardial infarction is related to the extent of myocardium at risk and, related to this, to the site of coronary occlusion. The ECG reflects the infarct location (Table 12.5). Patients with main stem occlusion only rarely reach the hospital for reperfusion therapy. Occlusion of the proximal left anterior descending coronary artery proximal to the first septal branch is associated with high early and late mortality ('widow-maker'). Large inferior myocardial infarctions as a result of occlusion of a dominant right coronary artery are also a high risk, particularly when the right ventricle is involved. Other locations, such as apical (distal left anterior descending), lateral (diagonal branch), or small inferior infarctions (distal right or circumflex), show ST-segment elevations in only a few leads and have a better outcome. Strictly posterior myocardial infarctions (marginal branch of left circumflex) may escape routine ECG leads or only be evident through ST depression in V1 to V4, but usually have a good outcome.

ECG criteria

The ECG allows the rough location of the infarct artery and identification of the extent of the territory at risk. The development of a bundle branch block or atrioventricular block in anterior myocardial infarctions suggests involvement of a proximal septal artery and is associated with increased mortality. Atrioventricular blocks in inferior myocardial infarctions are frequent and mostly transient.

Biomarkers on presentation

Blood sampling for serum markers must be routinely performed in the acute phase, but one should not wait for the results to initiate reperfusion treatment. The finding of elevated markers of necrosis may sometimes be helpful in deciding to give reperfusion therapy (e.g. in patients with left bundle branch block), but should retard decision-making. Elevation of markers of necrosis (troponin) on arrival in hospital is associated with adverse outcome [167].

Personal perspective

The prevalence of coronary artery disease and consecutively the prevalence of ACS are continuously increasing as a result of growing life expectancy and increasing rates of obesity and diabetes. A further increase is expected not only in highly industrialized countries but also, and most pronounced, in the rapidly developing, densely populated regions of the world. It is already conceivable that diagnosis and risk assessment of individual patients in the near future will be guided by sophisticated biochemical markers that capture earlier stages of pathophysiology long before fatal events have occurred. Further contributions to the early detection of patients at risk are expected from improved non-invasive imaging techniques. There is little room for improvement in the outcome of ongoing ST-segment elevation myocardial infarctions with modern invasive management techniques, but health-education programmes directed towards better early identification may contribute most effectively to reducing fatal outcomes.

13 Management of Acute Coronary Syndromes

Eric Boersma, Frans Van de Werf and Felix Zijlstra

Summary

Optimal treatment of patients presenting with an acute coronary syndrome aims at immediate relief of ischaemia and the prevention of serious adverse events, including death, myocardial (re)infarction and life-threatening arrhythmias. Guidelines recommend that patients with suspected acute coronary syndrome be admitted to an in-patient unit with careful observation for recurrent ischaemia, continuous ECG monitoring, and frequent assessment of vital signs. Once the diagnosis has been established, patient management may include antiplatelet therapy, antithrombin therapy, fibrinolytic therapy, coronary angioplasty, or cardiac surgery.

In patients presenting without persistent ST-segment elevation, aspirin treatment is associated with a 53% (95% CI 39–63%) reduction in the incidence of death or non-fatal myocardial infarction, whereas heparin treatment is associated with a 34% (95% CI 1–56%) reduction in this composite end-point. The use of glycoprotein IIb/IIIa inhibitors in patients undergoing early percutaneous coronary intervention results in a 41% (95% CI 19–56%) reduction in periprocedural thrombotic complications. However, the optimal timing of coronary revascularization is still the subject of debate. The strategy of early invasive treatment was associated with a 15% (95% CI 3–26%) reduction in the composite end-point of death or myocardial infarction after a 1-year follow-up compared with conservative treatment, but the event reduction might be underestimated because of the large number of patients who crossed over to invasive treatment, and the restrictive use of stents and glycoprotein IIb/IIIa inhibitors.

In patients presenting with ST-segment elevation, fibrinolytic therapy is associated with an 18% (95% CI 4–23%) mortality reduction. In patients receiving fibrinolysis within 1 hour of symptom onset, a 48% event reduction can be obtained. A primary percutaneous coronary intervention results in an additional 30% (95% CI 16–42%) mortality reduction compared to fibrinolysis. Ongoing trials will reveal whether a strategy of planned, immediate angioplasty after an initial pharmacological regimen (so-called 'facilitated' angioplasty) will result in even further mortality reduction.

Introduction

Patients presenting with acute chest pain represent a broad clinical spectrum, ranging from atypical and non-cardiac diseases to a class of syndromes including unstable angina pectoris, myocardial infarction and sudden death, otherwise known as acute ischaemic heart diseases or acute coronary syndromes (ACS). In the latter, the chronic process of coronary atherosclerosis has suddenly progressed, with subsequent activation of the coagulation system. Coronary plaque vulnerability and destabilization have multifactorial aetiologies, with inflammation, cap matrix and necrotic lipid core remodelling, and intraplaque haemorrhage being important associated pathophysiological processes [1].

Diagnosis and medical decision-making in acute chest pain patients rest on two important pillars: the electrocardiogram (ECG) and biochemical testing (Fig. 13.1).

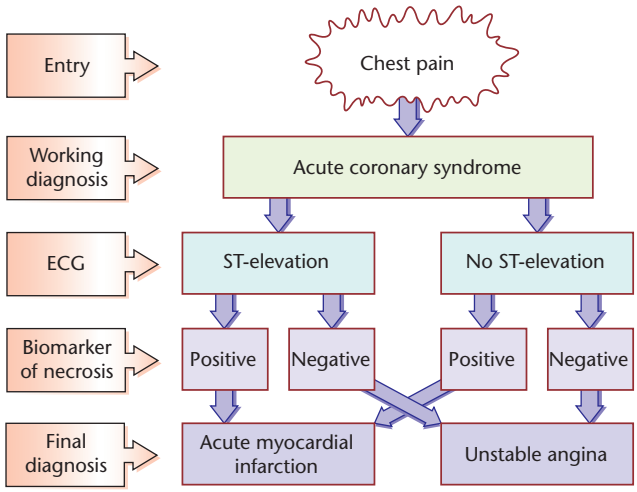

Figure 13.1 Terminology used in acute coronary syndromes. Reproduced with permission from Hamm *et al. Lancet* 2001; **358**: 1533–1538 [151].

Patients presenting with persistent ST-segment elevation (STE) or new onset left bundle branch block with subsequent elevation of serum levels of markers of myocardial necrosis usually have a totally occluded epicardial coronary artery. The therapeutic objective is rapid, complete and sustained reperfusion by fibrinolytic therapy or percutaneous coronary intervention (PCI). Patients with acute chest pain who present without persistent STE, but with ST-segment depression or T-wave abnormalities, are diagnosed as having either myocardial infarction or unstable angina pectoris, depending on the presence or absence of elevated serum levels of markers of myocardial necrosis. ACS patients without persistent STE are candidates for aggressive medical management, possibly followed by PCI.

This chapter presents a concise overview of the treatment options available for ACS patients. For the greater part, this review is limited to in-hospital treatment that has proven clinical benefits, based on evidence gained in randomized controlled clinical trials. Even then, a large number of pharmacological and mechanical interventions has to be discussed. For reasons of readability, with regard to medical therapies, we therefore mainly describe class (efficacy) effects, whereas details on applied dosages are omitted. Still, it should be emphasized that findings of clinical studies should be interpreted in relation to the pharmacological properties of the applied agents, and in relation to evidence that exists from other investigations. Clinicians should preferably use agents that have been proven effective in specific indications. Detailed advice for the treatment of ACS patients can be found in guidelines of the European Society of Cardiology (ESC) and the American College of Cardiology (ACC)/American Heart Association (AHA), in the remainder of this chapter referred to as 'guidelines' [2–5].

Methods

A computerized MEDLINE search identified 19 063 reports that were published in English between January 1980 and June 2004, with 'acute coronary syndromes', 'unstable angina pectoris', or 'myocardial infarction' as major topics, and 'therapy' as a secondary topic. Out of these, we reviewed the abstracts of reports labelled as 'clinical trial' (n = 3944), 'meta-analysis' (n = 134), 'review' (n = 2958), or 'practice guidelines' (n = 55). Relevant papers were selected, and their content was examined, whereas the corresponding bibliographies were manually searched. In addition, a search was performed of the scientific sessions abstracts published between January 2000 and June 2004 in *Circulation*, the *Journal of the American College of Cardiology* and the *European Heart Journal*.

Clinical trial results are summarized by figures that present the number of patients randomized, the absolute incidence of an important efficacy end-point, the relative risk reduction by experimental therapy compared with control therapy, and the absolute risk reduction. The relative risk reduction is expressed as an odds ratio together with the corresponding 95% confidence interval (CI). The pooled odds ratios of trials evaluating similar treatment strategies are determined by the method of Cochrane–Mantel–Haenszel, whereas the Breslow–Day test was applied to examine the statistical evidence of heterogeneity between the trial-specific odds ratios [6,7]. In the figures, individual trial odds ratios are indicated by solid black squares, whereas the stratified overview of the results of all trials is indicated by an open square. Within each figure, the area of these squares is proportional to the amount of statistical information contributed by the trial (i.e. approximately proportional to the number of events).

General care in acute coronary syndromes

Optimal treatment of patients presenting with an acute coronary syndrome aims for immediate relief of ischaemia, and the prevention of serious adverse events, including death, myocardial (re)infarction and life-threatening arrhythmias. The severity of symptoms dictates some of the general care that should be given during the initial treatment. In general, guidelines recommend that patients

with suspected acute coronary syndrome be admitted to an in-patient unit with careful observation for recurrent ischaemia, continuous ECG monitoring, and frequent assessment of vital signs. Once the diagnosis has been established, patient management may include anti-ischaemic therapy, antiplatelet therapy, antithrombin therapy, fibrinolytic therapy, coronary angioplasty or cardiac surgery.

Relief of pain is of paramount importance, not only for humane reasons, but also because the pain is associated with sympathetic activation, which causes vasoconstriction and increases the workload of the heart. Intravenous opioids (morphine or diamorphine) are the analgesics most commonly used in this context. Guidelines recommend the administration of oxygen (by mask or nasal prongs), especially to patients with cyanosis, respiratory distress, and those who have features of heart failure or shock.

Anxiety is a natural response to the pain and the circumstances surrounding an acute coronary syndrome. Reassurance of the patient and his relatives is of great importance. If the patient becomes excessively disturbed, administration of a tranquillizer may be considered, but opioids are frequently all that is required.

Treatment of non-ST-elevation acute coronary syndromes

Anti-ischaemic therapy

Beta-blockers

In non-ST-segment elevation acute coronary syndromes (NSTE-ACS), the primary benefits of beta-blockers are the result of their effects on 1-adrenergic receptors that cause a decrease in cardiac work and myocardial oxygen demand. Slowing of the heart rate also has a favourable effect, acting not only to reduce oxygen demand but also to increase the duration of diastole and diastolic pressure-time, a determinant of coronary flow and collateral flow.

Initial studies of beta-blocker benefits in NSTE-ACS were small and uncontrolled. A meta-analysis of the randomized controlled trials that are conducted in patients with 'threatened myocardial infarction' (i.e. characteristic chest pain but normal ECG, or only ST-segment depression) suggests that initial treatment with intravenous beta-blockers followed by oral treatment for a week leads to a 13% reduction in the risk of myocardial infarction compared with control therapy [8]. Although the trials in patients presenting with NSTE-ACS lack the power to assess reliably the effects of beta-blockers on mortality, randomized trials in patients presenting with stable angina, recent myocardial infarction and STE-ACS have all shown a statistically significant mortality reduction by these agents [9,10]. Guidelines therefore recommend beta-blockers as a routine part of care in acute coronary syndromes.

Nitrates

The therapeutic benefits of nitrates are related to their effects on the peripheral and coronary circulation. The major therapeutic benefit is related to the venodilatory effects, which lead to a decrease in myocardial preload and left ventricular end-diastolic volume, resulting in a decrease in myocardial oxygen consumption. In addition, nitrates dilate normal and atherosclerotic coronary arteries and increase coronary collateral flow.

Most studies of nitrate treatment in NSTE-ACS have been small and uncontrolled [11,12]. In fact, there are no randomized controlled trials that address the clinical efficacy of these agents. Thus, the rationale for the use of nitrates in NSTE-ACS is extrapolated from pathophysiological principles and clinical observations.

Calcium-channel blockers

Calcium-channel blockers are vasodilating drugs. In addition, some agents of this class have significant direct effects on atrioventricular conduction and heart rate. There are three subclasses, which are chemically distinct and have different pharmacological effects: the dihydropyridines (e.g. nifedipine), the benzothiazepines (e.g. diltiazem) and the phenylalkylamines (e.g. verapamil). The agents in each subclass vary in the degree to which they produce vasodilatation, decreased myocardial contractility and delayed atrioventricular conduction. Atrioventricular block may be induced by phenylalkylamines. Nifedipine and amlodipine produce the most marked peripheral arterial vasodilatation. Diltiazem has the least vasodilatory effect. All subclasses cause similar coronary vasodilatation.

There are several small randomized trials that evaluated the clinical effectiveness of calcium-channel blockers in NSTE-ACS. Generally, they demonstrated efficacy in relieving symptoms that appears equivalent to that of beta-blockers [13,14]. However, calcium-channel blockers were not associated with a reduction in mortality or morbidity in these patients. For dihydropyridines, randomized trial data provide evidence for an increased mortality risk when they are administered early as a rapid-release, short-acting preparation without a beta-blocker

[15]. In view of these data, guidelines recommend calcium-channel blockers for symptom relief in patients who do not respond to beta-blockers and nitrates.

Antiplatelet therapy

The primary role of platelets is to maintain vascular integrity through haemostasis. However, in patients with atherosclerosis, this normal process may become excessive and result in thrombosis. The role of platelets in the pathophysiology of atherothrombotic diseases has been confirmed as central. While atherosclerosis is the major underlying chronic pathology, platelet-dependent thrombosis initiated by acute plaque rupture is mainly responsible for the acute clinical event. Platelet adhesion and aggregation are the key processes. Platelets do not adhere to normal endothelium, but do adhere to disrupted endothelial surfaces. Following adhesion, platelets undergo shape changes, secrete the contents of their alpha and dense granules, transform endogenous arachidonic acid into thromboxane A_2, and undergo conformational changes in glycoprotein (GP) IIb/IIIa receptors that effect platelet-to-platelet aggregation. The central role of platelet activation and aggregation in the pathophysiology of ACS makes it an ideal therapeutic target.

Aspirin

Acetylsalicylic acid (aspirin) was the first effective platelet inhibitor to be identified. Aspirin results in an irreversible modification of the enzyme cyclo-oxygenase, rendering it incapable of converting arachidonic acid into thromboxane A_2. Between 1983 and 1990 four randomized trials were conducted that studied the effectiveness of aspirin compared with control therapy in 3096 patients with NSTE-ACS (Fig. 13.2) [16–19]. The daily dose of aspirin varied from 324 to 1300 mg, whereas the treatment period varied from < 1 to 24 months. At the completion of study medication, the composite end-point of death or myocardial infarction was observed in 6.2% of the patients randomized to aspirin and in 12.2% of controls. Thus, aspirin was associated with a 53% relative risk reduction (odds ratio 0.47 and 95% CI 0.37–0.61). In a meta-analysis of 142 randomized trials (73 247 patients) involving a wide range of patients considered to be at high risk of vascular events, prolonged antiplatelet therapy, including aspirin, was associated with a 25% relative risk reduction in the composite end-point of vascular death, myocardial infarction or stroke compared with control therapy (6.9% vs. 9.2% events; odds ratio 0.75 and 95% CI 0.72–0.78) [20]. Aspirin doses in the range 75 to 150 mg were as effective as higher doses. Accordingly, guidelines recommend starting low-dose aspirin (with a loading dose of at least 300 mg) in patients with NSTE-ACS during the acute phase, and continuing medication during long-term follow-up.

Glycoprotein IIb/IIIa inhibitors

Aspirin is a relatively weak antiplatelet agent because it inhibits only one of several pathways that result in platelet aggregation. Blockade of the cyclo-oxygenase pathway by aspirin can be overcome by activation of other agonist pathways. The final common pathway in the process of platelet aggregation is the activation of the GP-IIb/IIIa receptor. Activated GP-IIb/IIIa receptors connect with fibrinogen to form bridges between activated platelets, leading to the formation of platelet thrombi. Thus, inhibitors of platelet GP-IIb/IIIa are more potent agents than aspirin. Four intravenous GP-IIb/IIIa inhibitors (abciximab, eptifibatide, tirofiban and lamifiban) have been evaluated in clinical trials.

Between 1991 and 1997 GP-IIb/IIIa inhibitors were first evaluated in patients undergoing PCI for various indications, to confront the challenge of platelet aggregation caused by culprit plaque disruption. A meta-analysis of 10 randomized trials (13 166 patients) in this environment demonstrated a 36% reduction in the 30-day incidence of death or myocardial infarction by GP-IIb/IIIa inhibitors compared with control therapy [21]. The

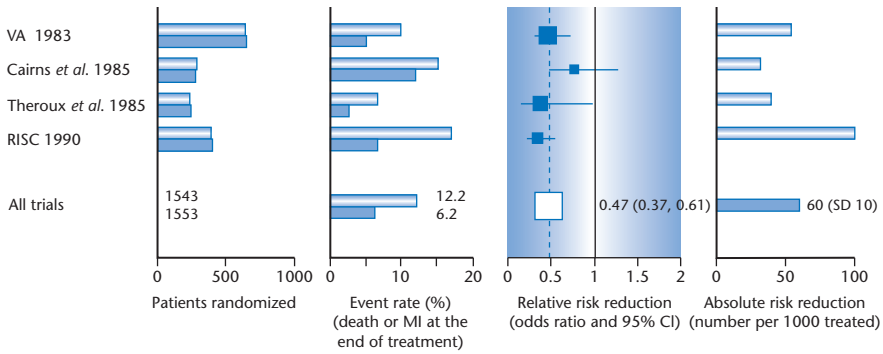

Figure 13.2 Death or myocardial infarction at the completion of study medication in randomized trials of aspirin (dark blue bars) versus control (light blue bars) in patients with non-ST-elevation acute coronary syndrome. Note the variable duration of study medication.

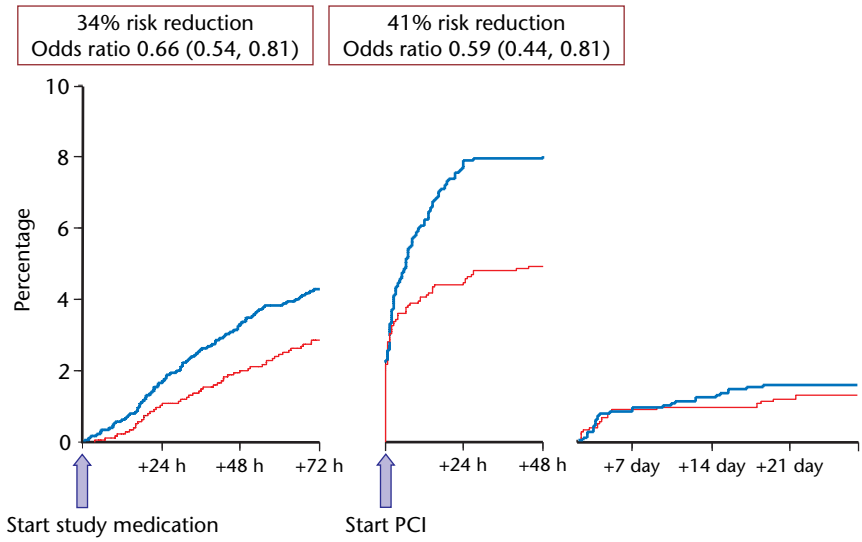

Figure 13.3 Cumulative incidence of death or non-fatal myocardial (re)infarction in patients with non-ST-elevation acute coronary syndrome randomly assigned to GP-IIb/IIIa inhibition (red lines) or placebo. Data were derived from CAPTURE, PURSUIT and PRISM-PLUS. Left panel: event rates during initial period of pharmacological treatment until moment of a PCI or coronary bypass grafting, if any. Middle panel: event rates among PCI patients during 48-hour period after procedure. During and shortly after PCI, all patients were on study medication. Right panel: event rates in period starting 48 hours after PCI, during which all patients were off study medication. At beginning of each period, event rates were (re)set at 0%. Any patient still alive contributes to event estimates in each period. Reproduced with permission from Boersma *et al.*, *Circulation* 1999; **100**: 2045–2048 [25].

CAPTURE trial, which was published in 1997, evaluated the effectiveness of GP-IIb/IIIa inhibitors (abciximab) in 1265 NSTE-ACS patients scheduled for early PCI [22]. The PRISM-PLUS (48-hour treatment with tirofiban; 1915 patients; published in 1998) and PURSUIT (72-hour treatment with eptifibatide; 10 948 patients; published in 1998) trials evaluated the effectiveness of GP-IIb/IIIa inhibitors in NSTE-ACS patients not scheduled for early PCI [23,24]. Still, a substantial number of patients underwent PCI during study medication. A meta-analysis that combined the CAPTURE, PRISM-PLUS and PURSUIT data demonstrated a 41% reduction in the periprocedural incidence of death or myocardial infarction in patients randomized to GP-IIb/IIIa-inhibitors compared with control therapy (4.9% vs. 8.0% events; odds ratio 0.59 and 95% CI 0.44–0.81; Fig. 13.3) [25]. A significant risk reduction was also observed in the short-term period before the intervention.

Several phase II trials have suggested that blockade of the platelet GP-IIb/IIIa receptor may also be useful in the treatment of NSTE-ACS patients not scheduled for early PCI. In this context, between 1994 and 2000 six phase III randomized trials (31 402 patients) were undertaken in aspirin-treated patients in whom early coronary revascularization was not recommended during study drug infusion (Fig. 13.4) [23,24,26–29]. Altogether 12 different treatment regimens were investigated, with a treatment duration that varied from 48 to 120 hours. In a meta-analysis of these trials, GP-IIb/IIIa inhibitors were associated with a modest, but statistically significant, 9% reduction in the 30-day incidence of death or myocardial infarction compared with control therapy (10.8% versus 11.8% events; odds ratio 0.91 and 95% CI 0.85–0.98) [30]. In patients with elevated cardiac troponins GP-IIb/IIIa inhibitors were associated with a 15% event reduction (10.3% versus 12.0% events; odds ratio 0.85 and 95% CI 0.71–1.0), whereas no risk reduction was seen in patients with negative troponins. This observation is in agreement with the notion that such elevated cardiac troponin levels reflect minimal myocardial damage resulting from platelet emboli. These patients seem to have active ongoing intracoronary thrombosis, which can be effectively reduced by powerful antiplatelet therapy.

In view of these data, guidelines recommend treatment with a GP-IIb/IIIa inhibitor in all NSTE-ACS patients scheduled for PCI. Treatment with a GP-IIb/IIIa inhibitor might also be considered early after admission in patients at high risk for thrombotic complications who are not routinely scheduled for early intervention, including those with elevated troponins or ST-segment depression, and diabetic patients. Treatment should then be continued until a decision to perform coronary intervention has been made. It should be noted that lamifiban is not registered for use in NSTE-ACS patients. In Europe,

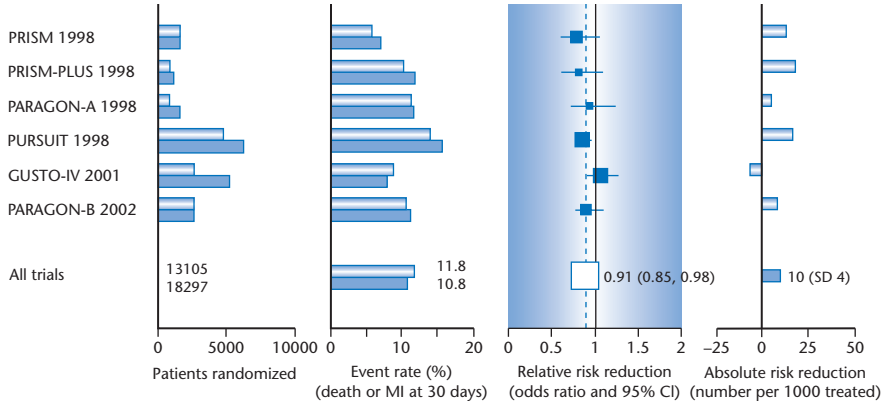

Figure 13.4 Death or myocardial infarction at 30-day follow-up in randomized trials of glycoprotein IIb/IIIa inhibitors (dark blue bars) vs. control (light blue bars) in patients with non-ST-elevation acute coronary syndrome who are not scheduled for early coronary intervention.

eptifibatide is not registered for use in patients undergoing PCI.

Four trials (33 404 patients; published in 2000) addressed prolonged treatment with oral GP-IIb/IIIa inhibitors in NSTE-ACS patients after coronary intervention [31]. Such prolonged treatment showed no evidence of benefit. In fact, a modest, but statistically significant increase in mortality was apparent in patients receiving oral GP-IIb/IIIa inhibitors [31].

Adenosine diphosphate receptor inhibitors

The thienopyridine derivatives, ticlopidine and clopidogrel, are agents that inhibit the platelet aggregation induced by adenosine diphosphate. Combining one of these agents with aspirin may therefore have an additive effect to reduce ischaemic events. Ticlopidine has been evaluated in NSTE-ACS patients by Balsano and colleagues [32]. In their randomized trial (652 patients; published in 1990) ticlopidine was associated with a significant reduction in the composite end-point of vascular death or myocardial infarction at 6 months compared with control therapy (7.3% versus 13.6% events; odds ratio 0.54 and 95% CI 0.30–0.85). However, intolerance of this drug is relatively frequent because of gastrointestinal disorders, or allergic reactions. In addition, neutropenia or thrombocytopenia may occur. Ticlopidine has been superseded by clopidogrel.

The CURE trial (12 562 patients), which was published in 2001, studied aspirin-treated NSTE-ACS patients, who were randomly allocated to treatment with clopidogrel (300 mg loading dose, followed by 75 mg daily) or placebo [33]. Study medication started in the acute phase, and was continued during a median follow-up of 9 months. In CURE, treatment with clopidogrel was associated with a 20% reduction in the incidence of cardiovascular death, myocardial infarction or stroke at the end of study-drug administration compared with control therapy (9.3% versus 11.4% events; hazard ratio 0.80 and 95% CI 0.72–0.90). The event reduction was already present at the 30-day follow-up, and little additional effect was seen beyond 30 days. Major bleeding complications were more common in patients randomized to treatment with clopidogrel than in controls (3.7% vs. 2.7% events; hazard ratio 1.4 and 95% CI 1.1–1.7) but no excess risk in life-threatening bleeding complications was observed. The risk of bleeding complications was relatively low in patients using aspirin doses below 100 mg (2.5% vs. 2.0% events). The clinical benefits of dual oral antiplatelet therapy with aspirin and clopidogrel were confirmed by the CREDO trial (published in 2002), which enrolled 2116 patients who were to undergo elective PCI or were deemed at high likelihood of undergoing PCI (approximately 50% of patients had NSTE-ACS) [34]. Therefore, guidelines recommend that clopidogrel be used in conjunction with a low maintenance dose of aspirin.

Antithrombin therapy

Exposure of blood to tissue factor in the necrotic core of the plaque activates the coagulation cascade and leads to the generation of thrombin. Thrombin is one of the most potent platelet agonists, and recruits additional platelets to the site of vascular injury. In addition to converting fibrinogen to fibrin, thrombin activates factor XIII, which stabilizes the fibrin clot. Thrombin also promotes its own formation via activation of factors V and VIII. Depending on the extent of activation of coagulation and the degree of stasis in the affected artery, a thrombus that is rich in fibrin and erythrocytes may develop and extend upstream and downstream from the ruptured plaque. Thus, unregulated thrombin generation may be an important trigger of (recurrent) ischaemic events.

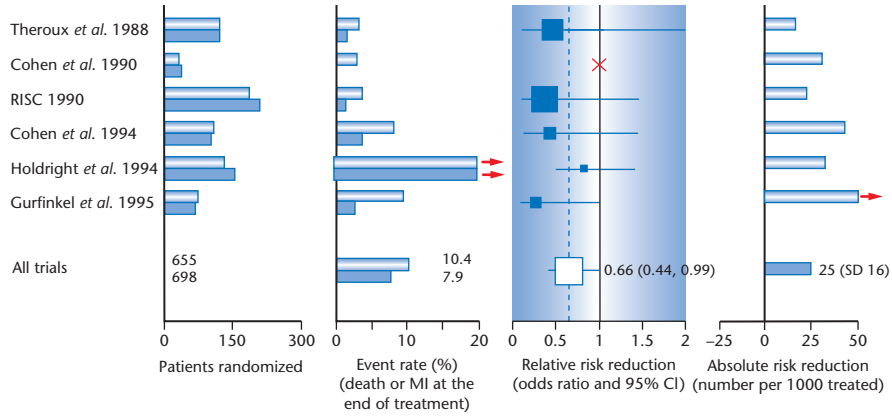

Figure 13.5 Death or myocardial infarction at the completion of study medication in randomized trials of unfractionated heparin (dark blue bars) vs. control (light blue bars) in patients with non-ST-elevation acute coronary syndrome.

Unfractionated heparin and low-molecular-weight heparin

Heparin binds to anti-thrombin III and induces a conformational change that results in rapid inhibition of thrombin, which may prevent propagation of an established thrombus and allows time for endogenous fibrinolysis to occur. In clinical practice, maintenance of therapeutic anti-thrombin control is hampered by unpredictable levels of heparin binding to plasma proteins. In addition, heparin has limited effectiveness against platelet-rich and clot-bound thrombin. Low-molecular-weight heparin (LMWH), which consists of fragments of the heparin molecule, has potential advantages over heparin as it has a greater activity against factor Xa, it produces a more predictable anticoagulant response, and it has a longer plasma half-life. [Note that heparin is also called 'unfractionated' heparin (UFH) to distinguish it from its low-molecular-weight fragments. We will use the term UFH in the remainder of this chapter.] LMWH can be administered subcutaneously based on a weight-adjusted dose and do not require laboratory monitoring. Different LMWH appear to have similar activities in prevention and treatment of venous thrombosis, despite some differences in pharmacology and half-life.

Between 1988 and 1996, six randomized trials (1353 patients) were conducted that compared UFH with control therapy and two trials (1639 patients) compared LMWH (dalteparin, nadroparin) with control in NSTE-ACS patients treated with aspirin (Fig. 13.5) [18,19,35–39]. Treatment duration varied from 2 to 7 days. In these trials, UFH was associated with a 34% reduction in the incidence of death or myocardial infarction at the completion of study medication compared with control therapy (7.9% vs. 10.4% events; odds ratio 0.67 and 95% CI 0.44–0.99). LMWH was associated with a 61% event reduction compared with control therapy (2.1% vs. 5.2% events; odds ratio 0.39 and 95% CI 0.22–0.86).

Between 1995 and 2004, nine randomized trials (27 034 patients) were conducted in NSTE-ACS that compared LMWH (dalteparin, enoxaparin, nadroparin) with UFH (Fig. 13.6) [40–48]. These trials together showed

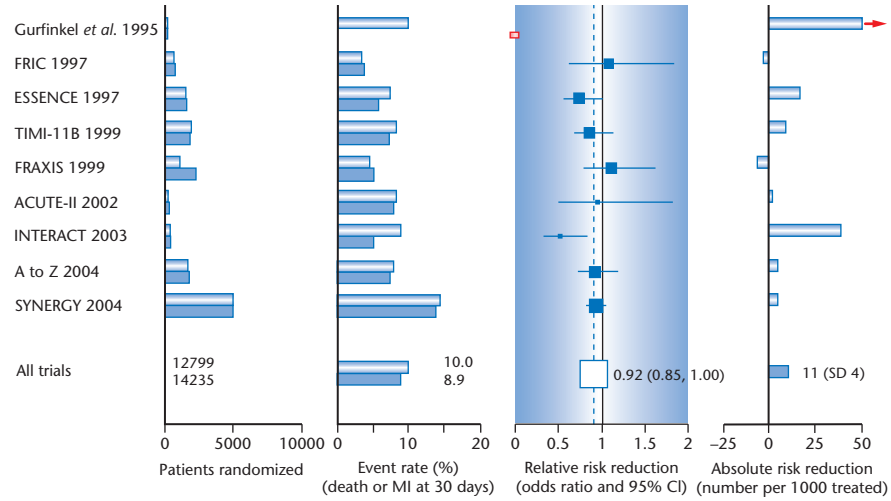

Figure 13.6 Death or myocardial infarction at 30-day follow-up in randomized trials of low-molecular-weight heparin (dark blue bars) vs. unfractionated heparin (light blue bars) in patients with non-ST-elevation acute coronary syndrome. Divergent follow-up duration in Gurfinkel *et al*. [38] was to hospital discharge; in FRIC was 6 days; in FRAXIS was 14 days.

that LMWH was associated with a modest, statistically non-significant, 8% reduction in the incidence of death or myocardial infarction at 30 days compared with UFH (8.9% vs. 10.0% events; odds ratio 0.92 and 95% CI 0.85–1.0). There was statistical evidence of heterogeneity ($P = 0.07$) between the separate trial results. The six enoxaparin trials, which enrolled 21 946 patients [41,42, 44–47], showed more homogeneous results (P-value for heterogeneity 0.3). Enoxaparin was associated with a 9% event reduction compared with UFH, which was just statistically significant (10.1% vs. 11.0% events; odds ratio 0.91 and 95% CI 0.83–0.99) [48]. The incidence of major bleeding complications was slightly higher in patients receiving enoxaparin, but no difference in blood transfusion was noted.

Between 1996 and 1997 five randomized trials (12 099 patients) evaluated the effectiveness and safety of long-term treatment with a LMWH (dalteparin, enoxaparin, nadroparin) in NSTE-ACS patients [49]. Taken together, these trials offer no evidence of a reduction in the incidence of death or myocardial infarction with the use of LMWH compared with control therapy (4.2% vs. 3.9% events; odds ratio 0.98 and 95% CI 0.81–1.2). However, long-term LMWH was associated with a significant increase in the risk of major bleeding.

In view of these data, guidelines recommend short-term antithrombin therapy with either UFH or LMWH as an adjunct to aspirin in NSTE-ACS patients. There is some evidence that enoxaparin is more effective than UFH in preventing death or myocardial infarction, at the cost of a slight excess in major bleeding complications. LMWHs offer significant practical advantages with simplicity of administration, more consistent antithrombin effects, and no need for monitoring. Observational studies have suggested that LMWHs can safely be used in combination with GP-IIb/IIIa inhibitors [50]. In this context, the INTERACT study (746 patients; published in 2003) suggested that efficacy and safety of enoxaparin were better than those of UFH in eptifibatide-treated patients [46].

Direct thrombin inhibitors

When bound to fibrin, fibrin degradation products, or subendothelial matrix, thrombin is resistant to inactivation by the heparin–antithrombin complex. Bound thrombin, which remains enzymatically active, triggers thrombus growth by factors V, VIII and XI, thereby amplifying thrombin generation. Bound thrombin also activates platelets, via thromboxane A_2-independent pathways that are not blocked by aspirin. In contrast to UFH and LMWH, which catalyse the inactivation of thrombin by antithrombin, direct thrombin inhibitors bind to the enzyme and block its interaction with its substrates.

Twelve randomized clinical trials (53 313 patients) were conducted from 1995 to 1998 that evaluated the efficacy and safety of the direct thrombin inhibitors compared with UFH [51–62]. Five trials enrolled patients with NSTE-ACS [51–55], five trials enrolled patients with STE-ACS [56–60], and two trials enrolled patients undergoing PCI [61,62]. The direct thrombin inhibitors under investigation included argatroban, bivalirudin (also known as hirulog), efegatran, hirudin and inogatran, whereas treatment duration varied from 48 to 168 hours. Taking the results of the ACS trials together, treatment with a direct thrombin inhibitor was associated with a modest, but statistically significant, 8% reduction in the incidence of death or myocardial infarction at 30 days (9.7% versus 10.6% events; odds ratio 0.92 and 95% CI 0.87–0.98; Fig. 13.7). There was no evidence of a differential treat-

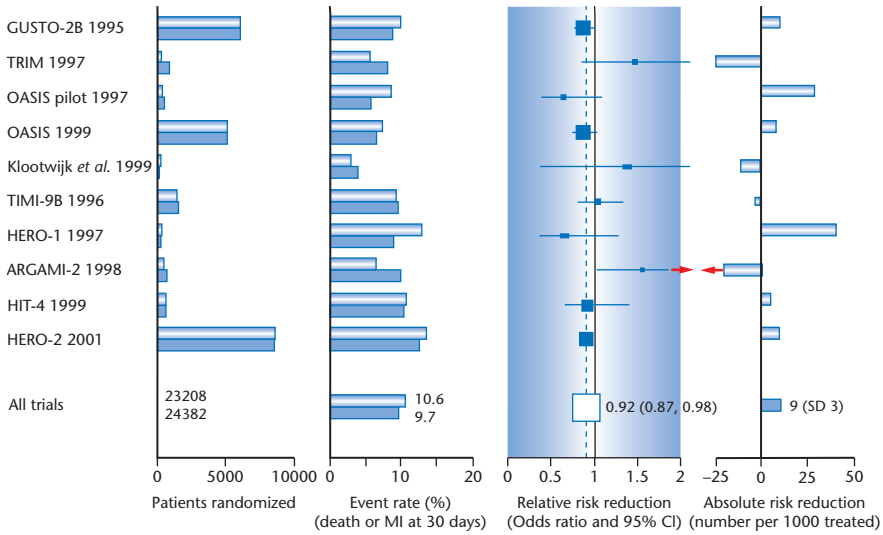

Figure 13.7 Death or myocardial infarction at 30-day follow-up in randomized trials of direct thrombin inhibitors (dark blue) vs. unfractionated heparin (light blue) in patients with acute coronary syndrome. GUSTO-2B, TRIM, OASIS pilot, OASIS and Klootwijk *et al.* [55] enrolled patients without ST-elevation; TIMI-9B, HERO-1, ARGAMI-2, HIT-4 and HERO-2 enrolled patients with ST-elevation.

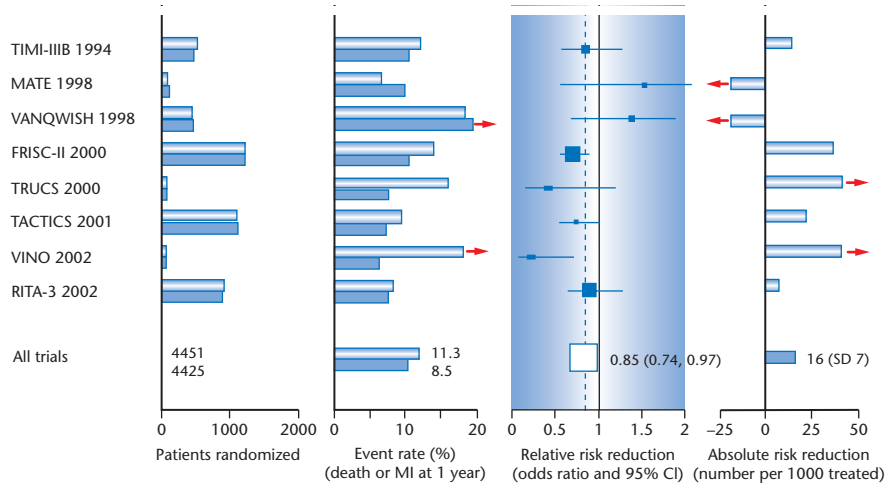

Figure 13.8 Death or myocardial infarction at 1-year follow-up in randomized trials of early invasive (dark blue bars) vs. conservative treatment (light blue bars) in patients with non-ST-elevation acute coronary syndrome. Data are derived from Fox *et al.*, *Lancet* 2002; **360**: 743–751 [73].

ment effect between the separate trials. Mortality as a single end-point was not reduced. Compared with UFH, direct thrombin inhibitors were associated with a lower risk of major bleeding overall. However, there was strong evidence of heterogeneity for major bleeding, which is consistent with the results of individual trials suggesting an increased bleeding risk associated with hirudin, but a risk reduction with bivalirudin [63].

In summary, direct thrombin inhibitors provide a modest clinical benefit over UFH. These agents are not registered for use in ACS patients in Europe.

Early invasive or conservative therapy?

Revascularization, including PCI or coronary artery bypass grafting (CABG), in NSTE-ACS patients is performed to treat ongoing myocardial ischaemia and to prevent recurrent ischaemia and progression to myocardial infarction or death. The indications for myocardial revascularization and the preferred approach depend on clinical characteristics, and the extent and angiographic characteristics of the lesions identified by coronary angiography. Guidelines recommend an early invasive strategy for patients at high risk, including patients with elevated cardiac troponins, patients with diabetes mellitus and those who develop haemodynamic instability during the observation period. For the remaining group of patients early invasive and conservative strategies are both judged appropriate. In clinical practice, however, early revascularization is only applied to a minority of patients. In large-scale international registries of NSTE-ACS patients only 20–25% underwent PCI or CABG during the initial hospitalization [64,65]. Apparently, the most appropriate revascularization strategy in patients presenting with NSTE-ACS is still the subject of debate.

Between 1994 and 2002 eight clinical trials (8876 patients) were undertaken that randomly allocated NSTE-ACS patients to an early invasive strategy or to conservative treatment (Fig. 13.8) [66–73]. Patients randomized to the early invasive strategy underwent cardiac catheterization during the first days after hospital admission (in the majority of patients cardiac catheterization was performed within 72 hours), and, if judged necessary, revascularization as soon as possible thereafter. Treatment decisions in patients randomized to the conservative treatment strategy were left to the discretion of the treating physician, and were mainly based on symptoms. Taking all trials together, early invasive treatment was associated with a 15% reduction in the composite end-point of death or myocardial infarction after a 1-year follow-up compared with conservative treatment (10.4% vs. 12.0% events; odds ratio 0.85 and 95% CI 0.74–0.97). There was, however, evidence of a differential treatment effect between the separate trials. In particular, divergent results were observed in the VANQWISH trial (920 patients; published in 1998), as patients randomized to early invasive treatment had significantly higher 1-year event rates (24.0% vs. 18.6% events; odds ratio 1.4 and 95% CI 1.0–1.9) [68]. The VANQWISH results have been challenged by several investigators, who emphasized the fact that a large proportion of patients allocated to the conservative strategy actually underwent coronary revascularization within 30 days after enrolment (33% compared with 44% in the early invasive arm). Also, in the earlier trials, of which VANQWISH was one, neither intracoronary stents nor GP-IIb/IIIa inhibitors were available for patients undergoing PCI [66–68]. Finally, in VANQWISH, an exceptionally high perioperative mortality was observed in the invasive arm (11.6% vs. 3.4% events; odds ratio 3.7 and 95% CI 1.0–13.6).

A meta-analysis of the five recent trials revealed a 27% event reduction by the early invasive strategy (8.5% vs. 11.3% deaths or myocardial infarction at 1 year; odds ratio 0.73 and 95% CI 0.62–0.86) [74].

Management of ST-elevation acute coronary syndromes

Pharmacological therapy

Fibrinolysis

Since it became clear that a myocardial infarction is caused by an acute intracoronary thrombotic occlusion, treatment strategies have been introduced that aim for rapid, complete and lasting restoration of the coronary blood flow. GISSI-1 (11 806 patients; published in 1986) and ISIS-2 (17 187 patients; published in 1988) are the major landmark studies of fibrinolytic therapy, by demonstrating a 23% reduction in 30-day mortality among patients randomized to streptokinase compared with control therapy (9.8% vs. 12.4% events; odds ratio 0.77 and 95% CI 0.72–0.83) [75,76]. Between 1986 and 1993 nine phase III trials were conducted that randomized at least 1000 STE-ACS patients (within 24 hours of symptom onset) to treatment with a fibrinolytic agent [alteplase, 100 mg over 3 hours; anisoylated purified streptokinase activator complex (APSAC), 30 U in 5 minutes; streptokinase, 1.5 MU over 1 hour; urokinase, two boluses of 1 MU each, 1 hour apart] or control therapy (Fig. 13.9) [75–83]. Taken together, these trials (56 462 patients) showed that fibrinolytic therapy was associated with an 18% reduction in the incidence of death at 30–35 days follow-up (9.3% vs. 11.1% events; odds ratio 0.82 and 95% CI 0.77–0.86) [84]. Fibrinolysis was also associated with a small, but significant excess risk of intracranial haemorrhage (0.4% vs. 0.1% events).

Streptokinase is the most frequently used fibrinolytic agent world-wide. However, because the GUSTO-1 trial demonstrated a further 15% mortality reduction by 'accelerated' or 'front-loaded' alteplase (100 mg infusion over 90 minutes, with over half of the dose within 30 minutes) over streptokinase (6.3% vs. 7.3% events; odds ratio 0.85 and 95% CI 0.78–0.94), front-loaded alteplase became the standard for pharmacological reperfusion therapy [85]. The disadvantage of this development is that front-loaded alteplase increased the risk of intracranial haemorrhage (0.7% vs. 0.5% events) when compared with streptokinase.

During the 1990s several wild-type alteplase mutants were developed with a longer half-life, so that these agents could be administered via bolus injection. Promising results were observed with these agents in phase II trials but subsequent phase III trials, which were published between 1997 and 2000, failed to show superiority of the new agents over front-loaded alteplase with regard to 30-day mortality [86–89]. In a combined analysis of the GUSTO-3 (15 059 patients; reteplase), COBALT (7169 patients; double bolus alteplase), ASSENT-2 (16 949 patients; tenecteplase) and InTIME-2 (15 060 patients; lanoteplase) trials, 7.0% of patients randomized to bolus fibrinolytic agents died within 30 days compared with 6.8% of patients randomized to front-loaded alteplase (odds ratio 1.0 and 95% CI 0.96–1.1). In ASSENT-2, tenecteplase was associated with a significant reduction in the risk of major non-cerebral bleeding complications

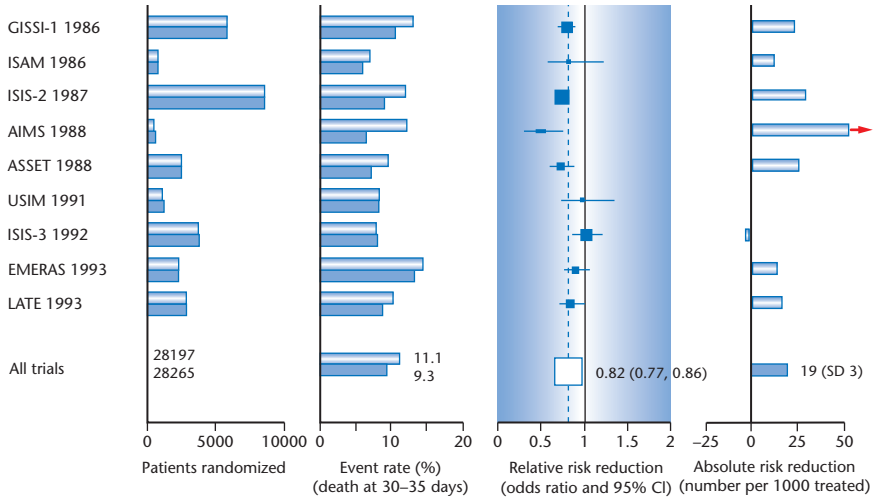

Figure 13.9 Death at 30-day follow-up in randomized trials of fibrinolytic therapy (dark blue bars) vs. control (light blue bars) in patients with ST-elevation acute coronary syndrome.

(26.4% vs. 29.0%), as well as in the need for blood transfusion (4.3% vs. 5.5%; odds ratio 0.76 and 95% CI 0.67–0.87). Some investigators argue that the use of bolus fibrinolytic agents was associated with an increased incidence of intracranial haemorrhage [90]. However, this increased risk was not evident in the group of patients treated with tenecteplase or reteplase. Furthermore, the intensity of adjunctive antithrombin therapy seems to be a confounding factor. In summary, the bolus fibrinolytic agents have a similar effectiveness to, and a slightly more favourable (tenecteplase) safety profile than, front-loaded alteplase.

Adjunctive antiplatelet therapy

Adequate vessel patency does not guarantee perfusion at the myocardial tissue level. There are three important caveats with fibrinolytic therapy in this respect. First, as a result of treatment, the occluding thrombus may fall apart into smaller fragments, causing distal microembolization. Second, treatment with a fibrinolytic agent only resolves the fibrin-rich part of the thrombus, whereas the platelet-rich part remains largely untouched. Finally, fibrinolysis generates elevated levels of free thrombin, and thus activates platelet aggregation, which may cause a further worsening of the microcirculation. To overcome these caveats, pharmacological reperfusion strategies were developed to combine fibrinolytic therapy with aggressive antiplatelet therapy.

The ISIS-2 trial provided undeniable evidence of the benefits of early aspirin therapy in patients presenting with STE-ACS [76]. In that trial, patients randomized to aspirin had a 23% reduced risk of 35-day mortality compared with controls (9.4% vs. 11.8% events; odds ratio 0.77 and 95% CI 0.70–0.85). ISIS-2 also demonstrated that the benefits of fibrinolysis (streptokinase) and aspirin were additive.

Phase II trials in STE-ACS that evaluated combined treatment with reduced-dose fibrinolytic therapy and GP-IIb/IIIa inhibitors provided indirect evidence of a more complete reperfusion with that strategy than with fibrinolytic therapy alone. In this respect, favourable results were observed in terms of ST-segment resolution, thrombosis in myocardial infarction (TIMI) frame count and myocardial blush. Additionally, shorter time periods to ST-segment resolution were observed, indicating improved early reperfusion. On account of these promising observations, two large phase III trials were undertaken to evaluate the clinical efficacy and safety of such combination therapy. In GUSTO-5 (16 588 patients; reported in 2001), combined treatment with reduced-dose reteplase and abciximab was not associated with a lower 30-day mortality compared with full-dose reteplase alone (5.6% vs. 5.9% events; odds ratio 0.95 and 95% CI 0.83–1.1) [91]. It is true that a significant reduction in myocardial re-infarction was observed at 30-day follow-up (2.3% vs. 3.5% events; odds ratio 0.65 and 95% CI 0.54–0.78) but this did not translate into a reduction in mortality during long-term follow-up [92]. Combination therapy was associated with an increased incidence of major bleeding complications (4.6% vs. 2.4% events; odds ratio 2.1 and 95% CI 1.7–2.4), particularly in elderly patients. The results of the ASSENT-3 trial (6095 patients; reported in 2001), which compared half-dose tenecteplase plus abciximab with full-dose tenecteplase alone (in a third arm, patients received tenecteplase plus enoxaparin) were similar to those of GUSTO-5: no effect on mortality, a significant reduction in the incidence of myocardial re-infarction at 30 days, and an increased risk of major bleeding complications [93]. In view of these data, guidelines for STE-ACS do not recommend the routine use of a reduced dose fibrinolytic in combination with a GP-IIb/IIIa inhibitor.

Adjunctive antithrombin therapy

The release of thrombin from the thrombus, as a result of fibrinolysis, contributes to a procoagulant state. Thus, it seems appropriate to combine fibrinolytic and antiplatelet therapy with antithrombin therapy. However, in the large GISSI-2 (20 891 patients; reported in 1990) and ISIS-3 (41 299 patients; reported in 1992) trials, combination therapy with a fibrinolytic agent, aspirin and UFH was not associated with a significant reduction in mortality during a 35-day follow-up, nor with a significant reduction in myocardial re-infarction, compared with combination therapy with fibrinolysis and aspirin [81,94,95]. In contrast, the incidence of major bleeding complications was increased. In the GUSTO-1 trial, no major differences were observed between subcutaneous and intravenous heparin among patients given streptokinase [85]. In view of these data, one could conclude that neither subcutaneous nor intravenous heparin adds much to the outcome in patients treated with streptokinase and aspirin. This opinion, however, is not commonly shared [96], and unfractionated heparin is often used in myocardial infarction patients treated with streptokinase. Apart from that, intravenous heparin as a component of the GUSTO-1 front-loaded alteplase regimen is widely accepted, although front-loaded alteplase without intravenous heparin has not been extensively studied.

As far as LMWHs are concerned, several phase II trials indicated a trend toward a better angiographic patency, improved ST-segment resolution, and lower reocclusion rates associated with enoxaparin compared with UFH, as an adjunct to streptokinase or front-loaded alteplase. In

the ASSENT-3 trial, in which tenecteplase was applied, patients randomized to enoxaparin had a significantly lower incidence of the composite end-point of 30-day death, myocardial re-infarction or refractory ischaemia compared with UFH (11.4% vs. 15.4% events; odds ratio 0.71 and 95% CI 0.59–0.85), without a significant increase in the risk of bleeding complications [93]. However, in the ASSENT-3 PLUS trial (1639 patients; published in 2003) pre-hospital administration of the same dose of enoxaparin resulted in a significant increase in intracranial haemorrhage compared with UFH [97]. Therefore, additional (and larger) studies are needed before reliable conclusions can be drawn on the use of enoxaparin or other LMWHs in combination with fibrinolytic agents.

A total of five randomized trials studied the efficacy and safety of direct thrombin inhibitors as an alternative for UFH in patients presenting with STE-ACS [56–60]. As has been demonstrated above, in patients presenting with ACS, direct thrombin inhibitors are associated with a modest 8% reduction in 30-day death or myocardial re-infarction compared with UFH, but mortality is not affected. In patients presenting with STE-ACS direct thrombin inhibitors were not associated with an increased risk of intracranial bleeding complications compared with UFH [60,63].

Percutaneous coronary interventions

Primary percutaneous coronary interventions

Recent studies have shown that fibrinolytic treatment is not capable of restoring coronary arterial patency in 20–45% of cases, depending on the fibrinolytic agent used [98]. In addition, 5–10% of patients experience an early reocclusion, whereas a late occlusion occurs in 30% of patients [99,100]. Mechanical reperfusion therapy by means of coronary angioplasty is associated with a significantly higher success rate. Furthermore, mechanical reperfusion is not associated with an increased risk of life-threatening intracranial bleeding complications. However, the major challenge of this approach is the treatment delay involved in mobilizing the interventional team and preparing the interventional facility. Under optimal circumstances, this will lead to a 30-minute treatment delay compared with in-hospital initiation of fibrinolytic therapy [101]. When compared with pre-hospital treatment, this delay may range from 60 to 90 minutes.

In light of these factors, the comparative effectiveness of 'primary' PCI (angioplasty without prior or concomitant fibrinolytic therapy) and fibrinolysis has been debated over the last decade. Twenty-two randomized trials (7437 patients), which were conducted between 1990 and 2003, addressed this issue (Fig. 13.10). In these trials, primary PCI was associated with a significant 30% reduction in 30-day mortality compared with fibrinolysis (5.3% vs. 7.4% events; odds ratio 0.70 and 95% CI 0.58–0.84) [102]. When compared with front-loaded alteplase, primary PCI was associated with a 19% mortality reduction (5.5% vs. 6.8% events; odds ratio 0.81 and 95% CI 0.64–1.0). Primary PCI was also associated with a significantly lower incidence of myocardial reinfarction, stroke and intracranial haemorrhage. The initial benefit of primary PCI over fibrinolysis is maintained during long-term follow-up, but no further enhancement of the treatment benefit was observed beyond the 30-day period [103,104]. The best results of primary angioplasty were predominantly achieved by experienced operators (> 75 cases per year), in high volume centres (> 200 cases per year) with door-to-balloon times of less than 90 minutes [104]. Additionally, three studies (2622 patients; published between 2000 and 2003) have confirmed the

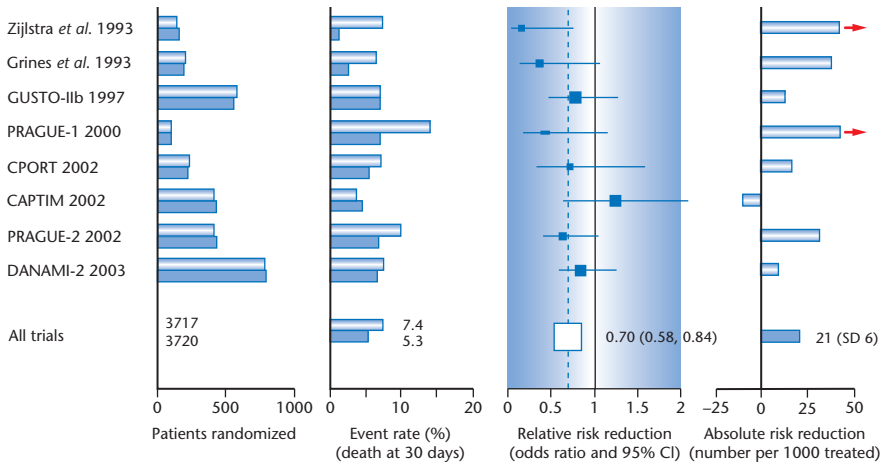

Figure 13.10 Death at 30-day follow-up in randomized trials of primary PCI (dark blue bars) vs. fibrinolytic therapy (light blue bars) in patients with ST-elevation acute coronary syndrome. Results are shown from selected trials that randomized at least 200 patients. Overall results are based on all 22 trials that were conducted between 1990 and 2003 (see text).

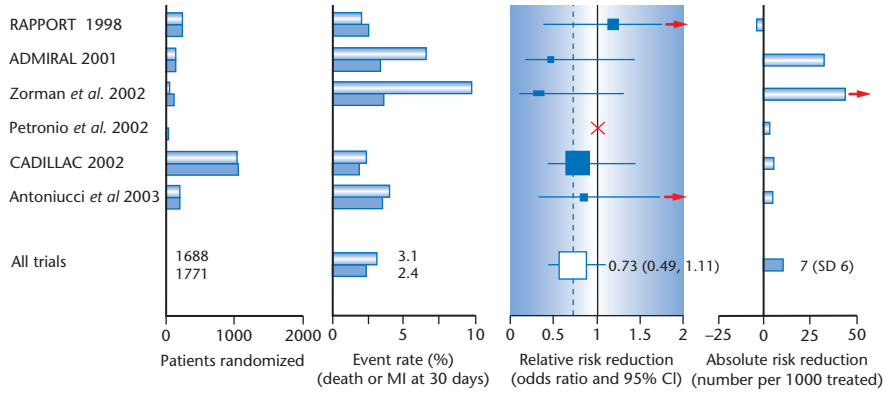

Figure 13.11 Death or myocardial infarction at 30-day follow-up in randomized trials of glycoprotein IIb/IIIa inhibitors (dark blue bars) vs. control (light blue bars) in patients with ST-elevation acute coronary syndrome undergoing primary PCI.

benefit of a transfer for primary PCI strategy over fibrinolytic therapy in acute myocardial infarction [105–107]. It remains unclear whether these excellent results could be applied and translated into daily practice. Still, guidelines consider primary PCI as the preferred therapeutic option when it can be initiated within 90 minutes of the first medical contact.

Rescue percutaneous coronary intervention

'Rescue PCI' is defined as PCI performed on a coronary artery which remains occluded despite fibrinolytic therapy. Limited experience from two randomized trials suggests a trend towards clinical benefit if the infarct-related vessel can be recanalized at angioplasty [108,109]. Although angioplasty success rates are high, an unsolved problem is the lack of reliable non-invasive methods for assessing patency of the infarct-related coronary artery. Coronary intervention in patients who received full-dose fibrinolytics and a GP-IIb/IIIa antagonist may lead to excessive bleeding complications.

Balloon or stent?

No statistically significant difference in mortality was observed between primary coronary stenting or balloon angioplasty. However, primary stenting was associated with a non-significant trend for reduction in the incidence of myocardial re-infarction and a significant reduction in target vessel revascularization [110]. Thus, coronary stenting has emerged as a safe alternative that appears to augment the angiographic and clinical results of primary balloon angioplasty.

Glycoprotein IIb/IIIa inhibitors

The use of GP-IIb/IIIa inhibitors in STE-ACS patients undergoing percutaneous intervention inhibits platelet aggregation at the site of plaque rupture and procedure-induced injury, potentially improving the clinical outcome. Between 1998 and 2003, six randomized trials (3459 patients) of abciximab versus control therapy in patients undergoing primary PCI (with or without stenting) examined this hypothesis (Fig. 13.11) [111–116]. In these trials, abciximab was associated with a non-significant trend for reduction in mortality and myocardial reinfarction at the 30-day follow-up compared with control therapy (2.4% vs. 3.1% events; odds ratio 0.73 and 95% CI 0.49–1.1), which is compatible with the benefit of GP-IIb/IIIa inhibitors as observed in other PCI studies [21]. In the RAPPORT trial (483 patients; published in 1998) [111] haemorrhagic complications were significantly increased in patients receiving abciximab, probably as a result of relatively high heparin doses. Therefore, guidelines recommend the use of abciximab in primary angioplasty only in combination with low-dose heparin.

Facilitated percutaneous coronary interventions

Facilitated PCI refers to a strategy of planned immediate PCI after an initial pharmacological regimen. PCI performed as a matter of policy immediately after fibrinolytic therapy, to enhance reperfusion or reduce the risk of reocclusion, has proved disappointing in a number of earlier trials all showing a tendency to an increased risk of complications and death. However, increased experience and the availability of stents have made PCI following pharmacological intervention safer. In the randomized trials that have been conducted so far, pretreatment with a fibrinolytic agent or with a GP-IIb/IIIa inhibitor resulted in improved pre-procedural coronary patency, whereas there was no evidence of an excess bleeding risk [117–120]. However, these trials did not demonstrate any benefit in reducing infarct size or improving outcomes. Several randomized trials of facilitated PCI are in progress [121].

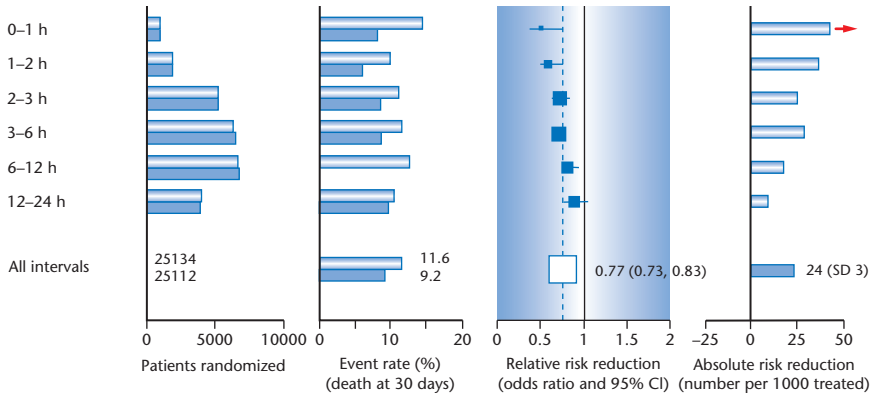

Figure 13.12 Death at 30-day follow-up in randomized trials of fibrinolytic therapy (dark blue bars) vs. control (light blue bars) in patients with ST-elevation acute coronary syndrome, in subgroups according to time from symptom onset to treatment.

Time to treatment and outcome

Time to treatment and outcome after fibrinolysis

Time from symptom onset to treatment is one of the most important determinants of the success of pharmacological reperfusion therapy. A detailed analysis of the relation between treatment delay and treatment effect in placebo-controlled trials indicated that the mortality reduction by fibrinolytic therapy is greatest in patients presenting within 1 hour of symptom onset (Fig. 13.12) [84,122]. The relative mortality reduction in this group was as high as 48% (8.2% vs. 14.7% events; odds ratio 0.52 and 95% CI 0.39–0.69), whereas the absolute mortality reduction was estimated at 65 per 1000 patients treated. Fibrinolytic treatment that was initiated within 2 hours resulted in a significantly higher mortality reduction (45% reduction; odds ratio 0.56 and 95% CI 0.47–0.68) than later treatment (20% reduction; odds ratio 0.80 and 95% CI 0.75–0.85), indicating that most benefit of fibrinolysis can be obtained during the ongoing process of myocardial cell death. Thus, to realize the full life-saving potential of fibrinolysis, treatment should be initiated as soon as possible after symptom onset, preferably within the first 1–2 hours.

Time to treatment and outcome after primary angioplasty

Primary angioplasty is unavoidably associated with an increased treatment delay compared with fibrinolytic therapy, but it is as yet unclear how much the angioplasty-related treatment delay nullifies its benefits. Data from randomized trials indicate that primary angioplasty and fibrinolytic therapy yield equivalent mortality reductions if the angioplasty is delayed by 50 minutes [123]. In other investigations, however, primary angioplasty was associated with a significant reduction in major cardiac end-points over fibrinolysis even after prolonged treatment delays [107]. In a large observational study of 27 080 patients treated by primary angioplasty, increased mortality rates were observed after door-to-balloon times exceeding 2 hours [124]. It should be realized that analyses are hampered by the fact that only a minority of patients undergoing primary angioplasty are treated within 2 hours from onset of symptoms.

Pre-hospital diagnosis and triage

The time that expires between the onset of chest pain and the initiation of reperfusion therapy has three main components. First, the patient needs time to recognize the cardiac nature and severity of the problems, and to seek appropriate medical aid. Unfortunately, most patients fail to react rapidly to symptoms. Several registries indicate that 50% of patients who are eligible for reperfusion therapy do not report their symptoms within 3 hours [65,125]. The time needed for transportation to the hospital is the second component of total treatment delay. Depending on the local infrastructure, the distance to the nearest hospital, and the hour of the day, transport delay may vary from 15 to 90 minutes [126–128]. The third component of treatment delay is the time that is needed inside the hospital for initial evaluation by an emergency room physician, ECG recording and interpretation, laboratory testing, further evaluation by an experienced staff cardiologist, and transport from the emergency room to the coronary care unit or catheterization laboratory where therapy is subsequently initiated. Data from a broad spectrum of European clinical practices demonstrate that the in-hospital delay is considerable: only 25% of patients receiving fibrinolysis are treated within the recommended 20 minutes after arrival at the emergency room, whereas only 50% of patients undergoing primary PCI receive this therapy within the recommended 90-minute time window [65].

These results can be improved by a treatment strategy that aims at diagnosis and triage prior to hospital admission, using 12-lead ECG [129]. In such a system, after myocardial infarction is confirmed, immediate, pre-hospital fibrinolytic therapy can be installed, or the patient can be directly transported to a catheterization laboratory, which will have been prepared before the arrival of the patient. Several investigations indicated that this approach may result in a reduction of the total ischaemic time by approximately 1 hour, regardless of the mode of reperfusion therapy [126–128,130].

Pre-hospital fibrinolysis versus in-hospital fibrinolysis

A meta-analysis of the 10 randomized trials (6607 patients) comparing pre-hospital versus in-hospital fibrinolysis demonstrated a significant 18% mortality reduction at 30 days by the pre-hospital treatment strategy (9.0% versus 10.7% events; odds ratio 0.82 and 95% CI 0.69–0.96; Fig. 13.13) [131]. Additionally, early, pre-hospital fibrinolysis is associated with a higher proportion of aborted infarctions than in-hospital treatment [132,133].

The safety of pre-hospital fibrinolysis is strongly dependent on the possibility of a correct diagnosis in the pre-hospital setting. To confirm ongoing myocardial infarction, a standard 12-lead ECG is required, which can either be transmitted via a telephone connection for interpretation by experienced cardiologists, or interpreted on-site by specifically designed computer programs. Both approaches are associated with similarly low false-positive rates.

Pre-hospital fibrinolysis versus primary percutaneous coronary interventions

The CAPTIM trial (reported in 2002) enrolled 840 patients with STE-ACS, who were randomly allocated to primary PCI or the strategy of pre-hospital fibrinolysis (front-loaded alteplase regimen) with subsequent transport to a centre with interventional facilities [134]. In this trial, primary PCI was associated with a lower incidence in the composite end-point of death, myocardial re-infarction or disabling stroke at 30-day follow-up, but statistical significance was not reached (6.2% vs. 8.2% events; odds ratio 0.75 and 95% CI 0.44–1.3). Interestingly, in CAPTIM, in patients randomized within the first 2 hours after symptom onset, primary PCI seemed to be associated with an increased mortality risk (5.7% vs. 2.2% events), whereas in patients randomized after 2 hours primary PCI seemed to be associated with reduced mortality (3.7% vs. 5.9% events) [135]. The interpretation of the CAPTIM results (especially the results observed in posterior defined subgroups) is complicated by the fact that the study had to be terminated prematurely because of lack of funding (initially, a sample size of 1200 patients was chosen). Also, the vast majority of patients randomized to pre-hospital fibrinolysis underwent coronary angiography (85%) and subsequent angioplasty (70%) within 30 days.

Prophylactic therapies

Beta-blockers

There is overwhelming evidence for the benefits of early beta-blockade in patients with STE-ACS. Benefits have been demonstrated for patients with and without concomitant fibrinolytic therapy, both early and late after symptom onset. Randomized trials revealed a 13% mortality reduction at 7 days by beta-blocker therapy compared with control (3.7% vs. 4.3% events; odds ratio 0.87 and 95% CI 0.78–0.99) [9]. Several observational

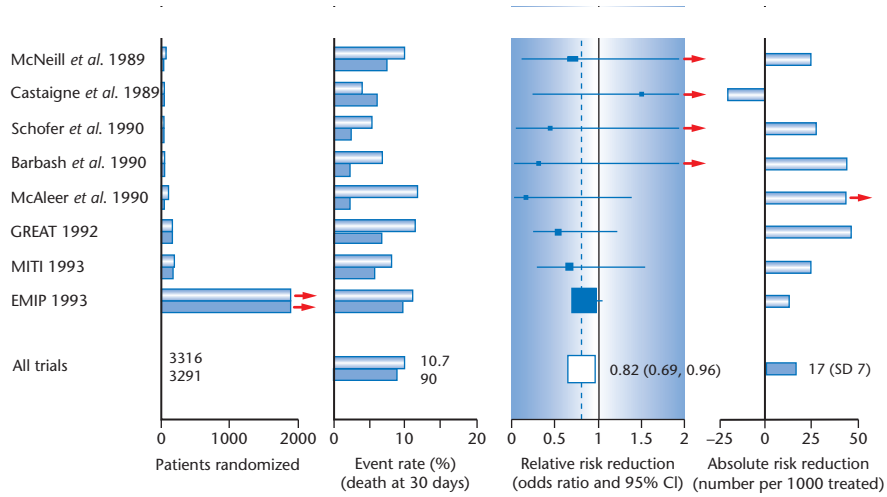

Figure 13.13 Death at 30-day follow-up in randomized trials of pre-hospital (dark blue bars) vs. in-hospital (light blue bars) fibrinolytic therapy in patients with ST-elevation acute coronary syndrome.

studies indicate that early beta-blocker therapy also improves the prognosis of STE-ACS patients undergoing primary PCI [136,137]. Thus, guidelines recommend that beta-blockers should be initiated early in the course of STE-ACS, and continued unless adverse effects have been observed.

Angiotensin-converting enzyme inhibitors

The GISSI-3 (19 394 patients; reported 1994), ISIS-4 (58 050 patients; reported 1995) and Chinese Study (13 634 patients; reported 1995) have shown that angiotensin-converting enzyme (ACE) inhibitors started on the first day reduce mortality in the succeeding 4–6 weeks by a small but significant amount [138–140]. The CONSENSUS II study (6090 patients; reported 1992) with intravenous enalapril, however, failed to show a benefit [141]. This may have been through chance, or because the treatment was initiated early with an intravenous formulation. A systematic overview of trials of ACE inhibition early in acute myocardial infarction indicated that this therapy is safe, well-tolerated and associated with a modest, but statistically significant, 6% reduction in 30-day mortality compared with control therapy (7.3% vs. 7.7% events; odds ratio 0.94 and 95% CI 0.89–0.98) [139]. There is now general agreement on starting ACE inhibitors in the first 24 hours if no contraindications are present. Opinions still differ as to whether to give ACE inhibitors to all patients or to high-risk patients only. In patients who do not tolerate an ACE inhibitor, the angiotensin receptor blocker valsartan is an equally effective alternative [142].

Nitrates

A meta-analysis of 10 trials of early intravenous nitrate therapy conducted in 2041 STE-ACS patients showed a significant mortality reduction compared to control therapy [143]. However, each of the trials was small and the results, although highly significant, had wide confidence limits. In the larger GISSI-3, ISIS-4 and ESPRIM (4017 patients; published in 1994) trials [138,139,144], no significant reduction in mortality was observed by the routine administration of nitrates. Thus, guidelines do not recommend the use of nitrates for the improvement in prognosis of STE-ACS patients.

Calcium-channel blockers

A meta-analysis of trials involving calcium antagonists early in the course of acute myocardial infarction showed a non-significant adverse trend [145]. There is no case for using calcium antagonists for prophylactic purposes in the acute phase of myocardial infarction.

Specific issues

Arrhythmias and conduction disturbances

Arrhythmias and conduction disturbances are extremely common during the early hours after presentation with STE-ACS. In some cases, such as ventricular tachycardia, ventricular fibrillation and total atrioventricular block, these are life-threatening and require immediate correction. Often arrhythmias are a manifestation of a serious underlying disorder, such as continuing ischaemia, pump failure, altered autonomic tone, hypoxia, and electrolyte and acid–base disturbances, that requires attention and corrective measures. Guidelines indicate that the necessity for treatment and its urgency depend mainly upon the haemodynamic consequences of the rhythm disorder.

Diabetic patients

Up to one-quarter of all patients with STE-ACS have diabetes and this figure is expected to increase [146]. Importantly, diabetic patients may present with atypical symptoms and heart failure is a common complication. Diabetic patients who sustain a myocardial infarction still have a doubled mortality risk compared with non-diabetic patients. There are indications that patients with diabetes do not receive the same extensive treatment as non-diabetic patients, presumably because the physician fears treatment complications. Diabetes is not a contraindication for fibrinolytic therapy, even in the presence of retinopathy. Furthermore, treatment with beta-blockers and ACE inhibitors seems to be even more effective than in non-diabetic patients and the risk for complications is negligible. The acute phase is often characterized by deterioration of the metabolic control and hyperglycaemia is an independent predictor of mortality. Strict attention to the glycaemic control by use of intravenous insulin infusion followed by multiple-dose subcutaneous insulin treatment has been shown to reduce long-term mortality [147,148].

There is experimental and limited clinical evidence that routine administration of glucose–insulin–potassium may favourably influence metabolism in the ischaemic myocardium and therefore confer a clinical benefit. Meta-analysis of the available data in 1928 patients suggests a 28% reduction in hospital mortality (16.1% vs. 21.1% events; odds ratio 0.72 and 95% CI 0.57–0.91) [149]. Additional mortality trials are currently being conducted.

Concluding remarks

During the last decades major progress has been made in the treatment of ACS, and this has been reflected in a decreased mortality and in a better quality of life. Ongoing and future research with anti-Xa agents (pentasaccharides), glucose–insulin–potassium infusion, adenosine, supersaturated aqueous oxygen (to reduce reperfusion injury in STE-ACS) and moderate systemic hypothermia may improve the patient's prognosis even further. However, such future treatment refinements will probably not lead to changes as dramatic as those of the past. On the other hand, treatment strategies proven to be effective are still largely underused. This was evident in two recent surveys of clinical practice. In GRACE up to one-third of eligible STE-ACS patients did not receive reperfusion therapy [64]. Similarly, in the Euro Heart Survey of ACS, only half of the patients enrolled with ST-segment elevation received reperfusion therapy [65]. Finally, despite compelling evidence on the importance of very early reperfusion therapy, the time from symptom onset to treatment of 2.7 hours as observed in clinical trials in the beginning of the 1990s has remained unchanged [150]. Therefore, our first aim should be to implement and expand the delivery of effective (acute) treatment in a timely fashion for all eligible ACS patients. In view of the imminent epidemic of cardiovascular disease, with ACS as its most prominent manifestation, adopting these measures from a global perspective will be a great accomplishment that will lead to a better life for patients with this disabling condition.

Personal perspective

During the last decades, major improvements have been achieved in the management and outcome of patients with acute coronary syndromes. The introduction of coronary care units in the 1960s, pharmacological reperfusion therapy in the 1980s, and the widespread application of catheter-based interventions—in combination with aggressive anti-platelet and anti-thrombin therapy—in the 1990s have contributed to a dramatic fall in in-hospital mortality rates in patients presenting with and without ST-elevation. Additionally, chronic treatment with aspirin, beta-blockers, angiotensin-converting enzyme inhibitors, and statins have contributed to an improved long-term prognosis in survivors of the acute phase. Despite these promising developments, acute coronary syndromes will remain a major health issue during the decades ahead, for several reasons. Acute cardiac events will continue to occur at early ages in individuals with a genetic predisposition, and in those with an unhealthy life-style. Furthermore, survivors of an acute coronary syndrome constitute a population with chronic cardiac conditions, who remain at increased risk of future fatal and non-fatal cardiac events. Finally, it should be realized that the Western world is ageing, and (heart) diseases come with age. It is true that ongoing and future research may result in modern treatment options that may help to improve the patient's prognosis even further. However, such frontline research should not distract our attention from what is already known. Data are emerging that treatment strategies proven to be effective are still largely underused. Therefore, the first aim as of today should be to implement and expand the delivery of effective (acute) treatment in a timely fashion for all eligible patients. In view of the imminent epidemic of cardiovascular disease, with acute coronary syndrome as its most prominent manifestation, adopting these measures from a global perspective will be a great accomplishment that will lead to a better life for patients with this disabling condition.

14 Chronic Ischaemic Heart Disease

Filippo Crea, Paolo G. Camici, Raffaele De Caterina and Gaetano A. Lanza

Summary

The coronary circulation serves the purpose of matching myocardial oxygen supply and consumption. A transient mismatch results in myocardial ischaemia, followed by left ventricular dysfunction and ECG changes, with or without angina. Four major clinical syndromes can be identified among patients presenting with chronic ischaemic heart disease. *Stable angina* is caused by critical epicardial coronary artery stenoses, responsible for stress-induced ischaemia. The exercise stress test remains the first-line test for diagnosis; when it cannot be performed or is not interpretable imaging stress tests are necessary. Prognosis is good, annual mortality being < 2%. Risk of major cardiac events is higher in patients with low workload myocardial ischaemia, reduced effort tolerance and multivessel coronary artery disease, in particular if left ventricular function is impaired. *Variant angina* is caused by coronary artery spasm and is characterized by angina at rest, with preserved effort tolerance. Diagnosis requires documentation of transient episodes of ST-segment elevation or of coronary artery spasm at angiography. Risk of major cardiac events is higher in patients with refractory spasm and/or with ischaemia-induced ventricular tachyarrhythmias or bradyarrhythmias. *Cardiac syndrome X* is characterized by anginal pain, predominantly during exercise but also at rest, despite a normal coronary angiogram. Diagnosis requires demonstration of angina and ST-segment depression during stress test, in the absence of wall motion abnormalities. Prognosis is good, but symptoms can be invalidating. *Ischaemic cardiomyopathy* is dominated by symptoms and signs of left ventricular dysfunction. Prognosis is mainly determined by the degree of left ventricular dysfunction.

The coronary circulation

The coronary circulation is composed of three vascular systems arranged in series: (1) the arterial system conveys blood from the aorta to the site of metabolite and gas exchanges with myocardial cells, and controls most of the resistance to flow; (2) the capillary system controls the regional microdistribution of blood flow and blood–tissue exchanges; and (3) the venous system controls intramyocardial blood volume at the end of diastole, thus influencing end-diastolic myocardial fibre length.

Although all the components of the coronary circulation are essential for its correct functioning, evidence accrued over the past few decades has proved that a number of different abnormalities in the arterial system are involved in the pathogenesis of many cardiac diseases and this is why this chapter focuses on this section of the coronary circulation.

Coronary arterial system

The coronary arterial system is composed of three compartments with different functions, although their precise borders cannot be clearly defined anatomically or histologically (Fig. 14.1) [1].

- The proximal compartment is represented by the large epicardial coronary arteries which have a capacitance function and offer little resistance to coronary blood flow. During systole, epicardial coronary arteries accumulate elastic energy as they increase their blood content up to about 25%. This elastic energy is transformed into blood kinetic energy at the

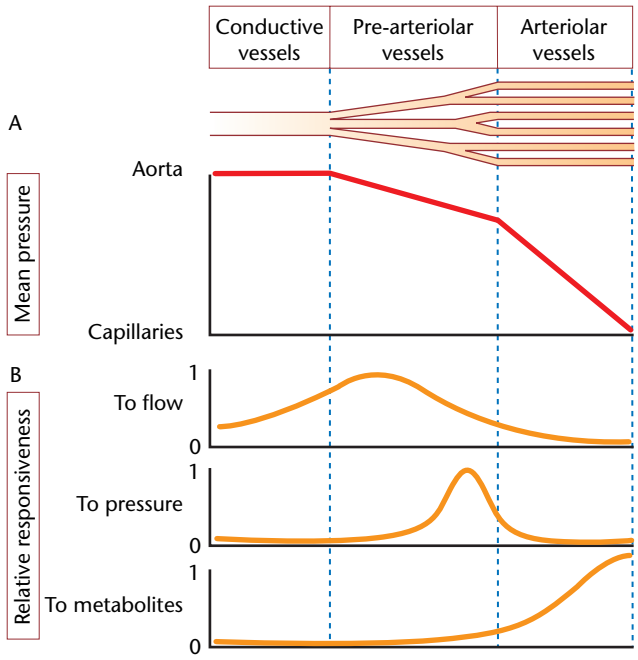

Figure 14.1 (A) Schematic representation of the functional subdivision of the coronary arterial system in conductive vessels, pre-arterioles and arterioles. The pressure drop along conductive vessels is negligible, that through pre-arterioles is appreciable and that through the arterioles is the largest. Pre-arterioles, by definition, are not exposed to myocardial dilator metabolites because of their extramyocardial position or their wall thickness. (B) Conductance vessels and, to an even greater extent, proximal pre-arterioles are more responsive to flow-dependent dilatation. Distal pre-arterioles are more responsive to changes in intravascular pressure and are mainly responsible for autoregulation of coronary blood flow. Arterioles are more responsive to changes in the intramyocardial concentration of metabolites and are mainly responsible for the metabolic regulation of coronary blood flow. Adapted from Maseri *et al.* [1].

beginning of diastole and contributes to the prompt reopening of intramyocardial vessels that are squeezed closed by systole.

- The intermediate compartment is represented by pre-arterioles. They are characterized by a measurable pressure drop along their length. They are not under direct vasomotor control by diffusible myocardial metabolites because of their extramyocardial position or arterial wall thickness. Proximal pre-arterioles are more responsive to changes in flow, while distal pre-arterioles are more responsive to changes in pressure. Their specific function is to maintain pressure at the origin of the arterioles within a narrow range when coronary perfusion pressure and/or flow change.
- The distal compartment is represented by arterioles. They are characterized by a considerable pressure drop along their length and represent the site of the metabolic regulation of myocardial blood flow, as their tone is influenced by substances produced during myocardial metabolism. Their specific function is the matching of myocardial blood supply and myocardial oxygen demand.

Large epicardial arteries have a diameter ranging from a few millimetres to ~500 μm and are visible at coronary angiography. Pre-arterioles (diameter from ~500 to ~100 μm) and arterioles (diameter < 100 μm) are below the resolution of current angiographic systems and hence are not visible at angiography. Notably, each compartment is governed by distinct regulatory mechanisms.

Distribution of coronary vascular resistance in series

The vascular resistance is distributed in series along the coronary vascular bed, but it also varies in parallel vascular segments in different layers of the ventricular wall.

The individual contribution of successive coronary vascular segments to total resistance can be inferred from the progressive drop in mean pressure from the aorta to the coronary sinus. About 10% of the pressure drop occurs in epicardial coronary arteries, 30% in pre-arterioles, 40% in arterioles and 20% from capillaries to large veins (Fig. 14.2) [2]. Notably, such an inference is an approximation as the vascular cross-section varies considerably during the cardiac cycle. Indeed, because the left ventricular wall compresses intramyocardial vessels during systole, most of the coronary blood flow to the left ventricle occurs during diastole. Thus, the contracting heart obstructs its own blood supply. At peak systole there is even backflow in the coronary arteries, particularly in the intramural and small epicardial vessels. During diastole the driving pressure is the pressure gradient between the coronary arteries and either the right atrium or the left ventricle (for veins that drain directly into the ventricle). If perfusion pressure is progressively lowered, diastolic blood flow ceases when the coronary driving pressure reaches 40–50 mmHg, the so-called *pressure at zero flow*, which is largely determined by diastolic compressive forces.

Distribution of coronary vascular resistance in parallel

The distribution of coronary resistance in parallel vascular segments in different layers of the ventricular wall can be studied by pressure/flow curves which provide information on the differences in vascular resistance between subendocardial and subepicardial layers of the ventricular

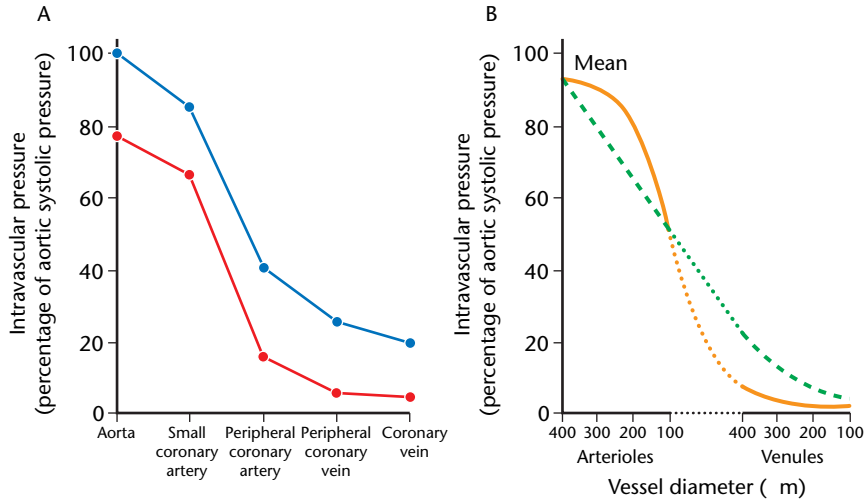

Figure 14.2 (A) Systolic (blue line) and diastolic (red line) pressures in a distal epicardial coronary artery, in a coronary arteriole, in a small coronary vein and in a large coronary vein of anaesthetized dogs, expressed as percentages of aortic pressure. The greatest pressure drop occurs through small coronary arteries. (B) Mean coronary pressure drop from the aorta to small coronary arteries and veins in a rabbit heart, measured on the surface of the epicardium (orange line). The greatest pressure drop occurs at the level of arterioles less than 100 μm in diameter. During intravenous dipyridamole infusion (green line) the pressure drop across pre-arteriolar vessels increases, indicating insufficient flow-mediated dilatation. Adapted from Klassen *et al*. [2] and Chilian *et al*. [33].

wall. In non-beating hearts, maximal conductance is higher in the subendocardial than the subepicardial layers. Conversely, in beating hearts, maximal conductance is lower in the subendocardial layers because of greater extravascular compressive forces during both systole and diastole. The extravascular systolic compressive forces have two components. The first is the intracavitary left ventricular pressure, which is transmitted fully to the subendocardium, but falls off to almost zero at the epicardial surface. The second is the vascular narrowing caused by compression and bending of vessels coursing through the ventricular wall from subepicardium to subendocardium (intramyocardial pressure). Hence, during ventricular contraction, subendocardial arterioles become more narrowed relative to those in the subepicardium and, at the onset of diastole, they present a higher resistance to flow, needing a longer time to resume their full diastolic calibre.

Tachycardia impairs the subendocardial blood flow, particularly in the presence of myocardial hypertrophy. In fact, the time constant of diastolic filling of intramyocardial vessels does not shorten with heart rate and becomes a limiting factor for the perfusion of subendocardial layers. Nevertheless, in conscious dogs, under normal resting conditions, the subendocardial flow is higher than the subepicardial flow (with a ratio of about 1.25:1), because of a greater conductance in the subendocardial arterioles. The latter finding is consistent with the higher subendocardial oxygen demand which is secondary to the greater wall stress in the subendocardial than in the subepicardial layers [3]. Thus, given a sufficiently high perfusion pressure, a sufficiently long diastole and an adequate systolic expansion of conductive arteries, the subendocardium is adequately perfused. However, when perfusion pressure at the origin of arteriolar vessels isreduced compared to that of the aorta (e.g. due to epicardial coronary stenosis or aortic stenosis) perfusion becomes jeopardized earlier in the inner compared to the outer layers of the left ventricle. The inner layers then become even more susceptible to underperfusion if diastolic time is short and in the presence of myocardial hypertrophy. Of note, selective constriction of subepicardial vessels can influence perfusion pressure in subendocardial vessels and hence subendocardial flow. Overperfusion of the subepicardial layers, in particular during exercise, when subendocardial perfusion is hampered by the shortening of diastolic time, might be prevented by sympathetic-system-mediated selective constriction of the subepicardial vessels, as proposed by Feigl [4]. Accordingly, potent constrictors, such as endothelin and α-adrenergic agonists, or adenosine antagonists, such as theophylline [5], cause selective subepicardial constriction which secondarily improves subendocardial perfusion.

Response of the coronary circulation to changes in flow

The shear stress, the tractive force that acts on the vascular wall, is proportional to the shear rate or velocity and to viscosity. Arteries exhibit an intrinsic tendency to maintain a constant shear stress, despite changes in shear rate or in viscosity. Indeed, very high or very low shear stress may jeopardize the interaction between blood elements and the endothelium. In the absence of changes in distending pressure, variations of flow in epicardial

coronary arteries can be achieved by intracoronary injection of arteriolar vasodilators such as adenosine. Angiographic studies in man have shown that epicardial coronary arteries dilate in response to an increase in coronary blood flow and that the increase in coronary diameter is proportional to the increase in flow, thus maintaining shear stress constant [6].

Flow-mediated dilatation occurs also in proximal pre-arterioles during the dilatation of distal pre-arterioles in response to a reduction in perfusion pressure and during arteriolar dilatation in response to an increased myocardial oxygen consumption or following myocardial ischaemia. In this setting, flow-mediated dilatation serves mainly to minimize any fall in pressure along the course of proximal pre-arterioles during dilatation of more distal vessels [7].

Mechanisms of flow-mediated dilatation

Flow-mediated dilatation is determined by vasodilators released by endothelial cells in response to an increase in shear stress, in particular nitric oxide (NO), endothelium-derived hyperpolarizing factor (EDHF) and prostacyclin. NO induces relaxation of smooth muscle cells by activating the formation of cyclic guanosine monophosphate from guanosine triphosphate. EDHF causes hyperpolarization and relaxation of smooth muscle cells by opening K^+ channels, whereas prostacyclin causes relaxation by activating adenylate cyclase, which leads to the formation of cyclic adenosine monophosphate.

NO appears to play a key role in flow-mediated relaxation of the large epicardial vessels, as the latter is prevented by N^g-monomethyl-L-arginine, a specific inhibitor of NO synthesis [8]. The contribution of EDHF to endothelium-dependent relaxation varies as a function of the size of the artery; indeed, it is more pronounced in resistance vessels and might play an important role in pre-arteriolar flow-mediated dilatation [9]. In contrast, the contribution of prostacyclin to flow-mediated relaxation appears to be modest. Yet, prostacyclin-mediated relaxation might be important in the presence of endothelial dysfunction with reduced bioavailability of NO, when it may provide a useful compensatory mechanism [10].

Response of the coronary circulation to changes in perfusion pressure: autoregulation

When metabolic requirements do not vary, the coronary circulation exhibits an intrinsic tendency to maintain blood flow at a constant rate despite changes in perfusion pressure, a mechanism known as autoregulation.

Variations of coronary perfusion pressure in the beating heart, in the presence of unaltered myocardial metabolic requirements, can be achieved by perfusing the coronary circulation independently from the aorta, so that aortic pressure (a determinant of myocardial oxygen consumption) remains constant when coronary arterial pressure is varied. In this setting, pressure/flow curves show that when perfusion pressure is varied, flow remains almost constant over a wide range of pressures, i.e. from 60 to 120 mmHg (Fig. 14.3). The level at which flow remains constant is determined by the level of myocardial oxygen consumption; when this is low the plateau of flow is low, when oxygen consumption is high the plateau is high [11]. Notably, for decreasing perfusion pressures, autoregulation is better maintained in the subepicardium than in the subendocardium, which, therefore, is more susceptible to the detrimental effects of very low perfusion pressures.

Mechanisms of autoregulation

The mechanism responsible for autoregulation is probably a myogenic response of distal pre-arteriolar vessels: they dilate in response to a reduction of perfusion pressure and constrict in response to an increase of perfusion

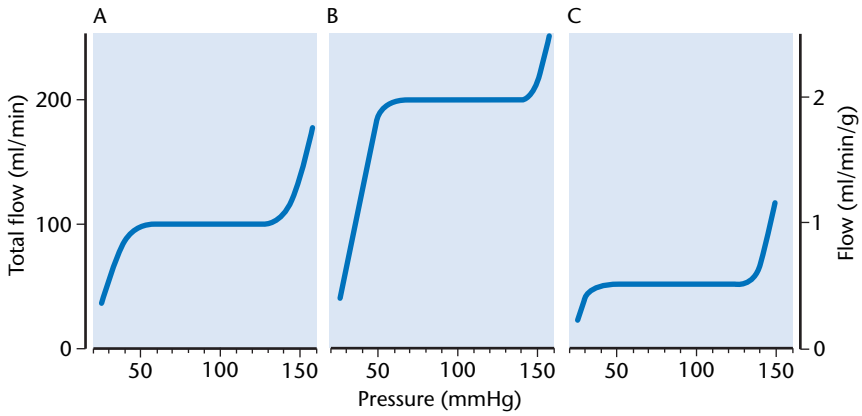

Figure 14.3 Autoregulation of coronary blood flow in anaesthetized dogs in the presence of normal (A), high (B), or low (C) oxygen consumption. In the presence of autoregulation, coronary flow is determined by the level of myocardial oxygen consumption, by the oxygen saturation of arterial blood and by neurohumoral modulation of coronary vasomotor tone. Autoregulation fails when perfusion pressure either decreases or increases beyond the range of pressures within which autoregulation acts. Adapted from Bache *et al.* [11].

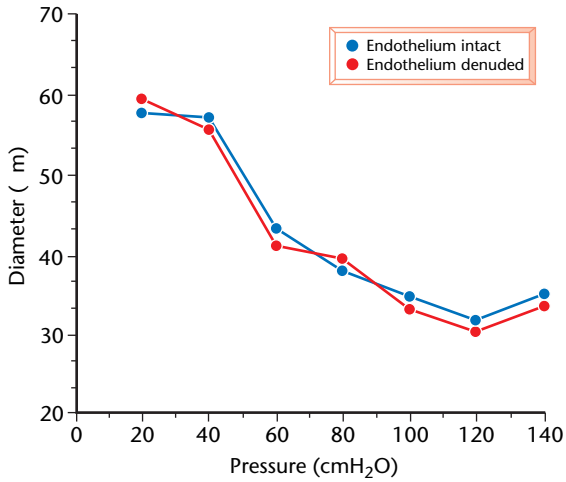

Figure 14.4 Effects of increasing pressures in a dog arteriole. Arteriolar dilatation and constriction were observed at lower and higher pressures, respectively. After mechanical denudation of the endothelium, spontaneous tone and myogenic responses were preserved. Thus, endothelium-independent pressure-induced myogenic constriction in arterioles is the main determinant of coronary autoregulation. Adapted from Kuo *et al*. [12].

pressure (Fig. 14.4) [12]. Myogenic responsiveness in the coronary microcirculation, independent of the endothelium, has been directly demonstrated *in vivo* in vessels that contribute to coronary microvascular resistance, and it is more pronounced in subepicardial than in subendocardial pre-arterioles. The mechanisms of the myogenic constriction in response to an increase in distending pressure are not well understood. They probably involve activation of a non-selective cation channel and subsequent influx of Na^+, K^+ and Ca^{2+} ions. The consequent membrane depolarization enables the recruitment of voltage-dependent calcium channels, which contributes to the increased calcium inflow. Furthermore, stretch initiates hydrolysis of membrane phospholipids, a process which contributes to increased intracellular calcium release. Myogenic contraction is ultimately caused by activation of myosin light chain kinase [13].

Response of the coronary circulation to changes in myocardial oxygen consumption: functional hyperaemia

The coronary circulation supplies the myocardium with blood for its widely and rapidly changing needs. It can supply oxygen in amounts up to five times the baseline consumption, and carries substrates and removes metabolic waste products, all to ensure optimal working conditions for myocardial cells. This demanding function takes place in an organ that generates its own perfusion pressure.

Under basal resting conditions the tone of coronary resistive vessels is high and coronary blood flow is at its lowest level. This intrinsically high resting tone provides the coronary circulation with the ability to increase flow by reducing vasomotor tone when myocardial oxygen consumption increases, a mechanism known as functional hyperaemia. This metabolic control of coronary blood flow is very precise and is fundamental for adequate myocardial oxygen supply. Indeed, in normal humans myocardial oxygen extraction is already considerably raised under resting conditions and does not change appreciably during increased cardiac work up to submaximal levels [14].

For any level of myocardial oxygen consumption, average coronary vascular resistance, and hence flow, can be modulated by a wide variety of neurotransmitters, by autacoids produced by the vessel wall, blood-borne substances, and drugs acting on different segments of resistive vessels. Neurotransmitters are released at nerve endings. Autacoids are generated locally by endothelial cells (NO, prostaglandins, EDHF, endothelin) or by adventitial cells (histamine, kinins, leukotrienes) while others are released by circulating platelets (thromboxane A_2, serotonin) or carried in the bloodstream (adrenaline). Notably, when myocardial oxygen consumption remains constant, any change in flow caused by neurohumoral modulation is mirrored by a change in oxygen extraction, so that vasodilatation or constriction are associated, respectively, with a proportional increase or decrease in coronary sinus Po_2 and oxygen saturation [15].

Determinants of myocardial oxygen consumption

The heart is an aerobic organ which relies almost exclusively on the oxidation of substrates for the generation of energy and can develop only a small oxygen debt. The most important determinant of oxygen consumption is cardiac work, as in the non-beating heart oxygen consumption is only 15–20% of that under normal resting conditions. Oxygen consumption, as for other tissues, is also influenced by the type of substrate used; indeed, it is higher when using predominantly fatty acids (which have a respiratory quotient of 0.7) than when using carbohydrates (which have a respiratory quotient of 1.0). Furthermore, myocardial oxygen consumption is about 15–20% higher in the subendocardium than the subepicardium.

Most of the time the factors that influence myocardial metabolic activity vary concurrently. However, when they are artificially separated under experimental conditions in a canine model, they rank in the following order [16].

1 *Heart rate*. Myocardial oxygen consumption approximately doubles during atrial pacing when heart rate is doubled. However, this is probably an underestimate, as during pacing (but not during exercise) the stroke volume decreases, also causing a decrease in ventricular volume and wall tension.
2 *Aortic pressure*. Myocardial oxygen uptake approximately doubles as mean aortic pressure is increased from 75 to 175 mmHg at constant heart rate and stroke volume.
3 *Myocardial inotropic state*. Myocardial oxygen consumption increases by about 30% when d*P*/dt (the first derivative of systolic left ventricular pressure over time) is doubled by extrasystolic potentiation or by noradrenaline administration at constant heart rate, aortic pressure and cardiac output.
4 *Stroke volume*. Myocardial oxygen consumption increases by about 20% when stroke volume is increased by 60% at constant rate–pressure product (i.e. heart rate times systolic blood pressure).

An accurate measurement of myocardial oxygen consumption requires the determination of coronary blood flow and of arterial–venous difference in blood oxygen content (which is generally achieved by sampling blood simultaneously from the aorta and the coronary sinus). As coronary sinus sampling is required, and as the measurement of coronary flow presents considerable methodological problems, a number of indirect indices have been proposed. Of these, the rate–pressure product is the simplest and yet it correlates closely in a wide range of values with measured changes in myocardial oxygen consumption [14].

Mechanisms of metabolic regulation of myocardial blood flow

By acting on coronary arterioles, adenosine is probably the key mediator of metabolic blood flow regulation. Adenosine is formed by degradation of adenine nucleotides under conditions in which adenosine triphosphate (ATP) utilization exceeds the capacity of myocardial cells to re-synthesize high energy compounds (a process dependent on oxidative phosphorylation in mitochondria). This results in the production of adenosine monophosphate, which is converted to adenosine by the enzyme 5′-nucleotidase. Adenosine then diffuses from the myocytes into the interstitial fluid, where it exerts powerful arteriolar dilator effects through the stimulation of A_2 adenosine receptors on smooth muscle cells. Several findings support the critical role of adenosine in the metabolic regulation of myocardial flow. Indeed, its production increases in cases of imbalance in the supply/demand ratio of myocardial oxygen, with the rise in interstitial concentration of adenosine paralleling the increase in coronary blood flow. Inhibition of adenosine, however, does not reduce the magnitude of functional hyperaemia entirely, thus suggesting that other substances can play a critical role [17].

It is worth emphasizing that the response of the coronary circulation to changes in myocardial oxygen consumption triggers a complex and integrated microvascular response. The arterioles dilate in response to the release of myocardial metabolites and this dilatation decreases both resistance in the overall network and pressure in distal pre-arterioles, which in turn induces myogenically sensitive vessels to dilate. Furthermore, dilatation of distal pre-arterioles and arterioles results in an increase in shear stress and triggers flow-dependent dilatation in larger pre-arterioles and in conductance arteries.

Thus, as proposed by Chilian [18], the coronary circulation matches blood flow with oxygen requirements by coordinating the resistances within different microvascular domains, each governed by distinct regulatory mechanisms. Such an integration appears advantageous because the system does not rely on a single mechanism of control. Accordingly, if a pathological process renders a mechanism dysfunctional, other mechanisms, at least to some extent, can compensate for it, although the price to pay is a reduction of regulatory mechanism reserve.

Response of coronary circulation to a brief coronary occlusion: reactive hyperaemia

When a major epicardial coronary artery is occluded for a short period of time, occlusion release is followed by a significant increase in coronary blood flow, a phenomenon known as reactive hyperaemia. The maximum increase in blood flow occurs within the few seconds after the release of the occlusion and the peak flow, which has been shown to reach four or five times the value of pre-ischaemic flow, is dependent on the duration of the ischaemic period for occlusion times up to 15–20 seconds. Although occlusions of longer duration do not modify further the peak of the hyperaemic response, they do affect the duration of the entire hyperaemic process, which increases with the length of the occlusion [19]. Generally, the excess flow that follows the occlusion, known as flow repayment, is larger than the flow debt incurred during the ischaemic period (Fig. 14.5) [20].

From the previous observations it is generally accepted that myocardial ischaemia, even of brief duration, is the most effective stimulus for vasodilatation of coronary resistive vessels and that, under normal circumstances, reactive hyperaemic peak flow represents the maximum flow available at a given coronary perfusion pressure.

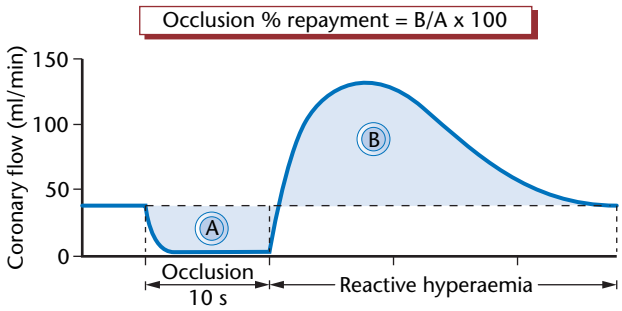

Figure 14.5 Mean coronary blood flow before, during and after coronary occlusion. Area A is the flow debt acquired during occlusion, whereas area B is its repayment following restoration of blood flow (see text for definitions). Typically, the repayment is larger than the flow debt incurred during the ischaemic period.

Values of coronary blood flow comparable to the peak flow of reactive hyperaemia can be achieved using coronary vasodilators such as adenosine or dipyridamole, which induce a 'near maximal' vasodilatation of the coronary microcirculation. This concept, however, has been challenged by studies in experimental animals, as well as in human subjects, that have demonstrated that reactive hyperaemic peak flow may not represent the true ceiling of blood flow achievable at a given perfusion pressure [21,22]. Reactive hyperaemia occurs also in denervated isolated hearts, thus suggesting that flow-mediated, myogenic and metabolic mechanisms (see previous sections) are the main determinants of this phenomenon [23].

Coronary flow reserve

The concept of coronary flow reserve was first introduced by Gould *et al.* in 1974 [24] as an indirect parameter to evaluate the global function of the coronary circulation. Coronary flow reserve is the ratio of coronary blood flow during near maximal coronary vasodilatation to resting flow and is an integrated measure of flow through both the large epicardial coronary arteries and the microcirculation (Fig. 14.6) [25].

Coronary flow reserve must be considered a relative, rather than absolute, value that depends on four main variables:

- resting blood flow
- cross-sectional area of arteriolar vessels per unit volume of myocardium
- extravascular coronary resistance
- arteriolar perfusion pressure.

Since resting blood flow is the denominator in the formula used to compute coronary flow reserve, any increase in resting blood flow (e.g. the increase in resting perfusion seen in patients with arterial hypertension)

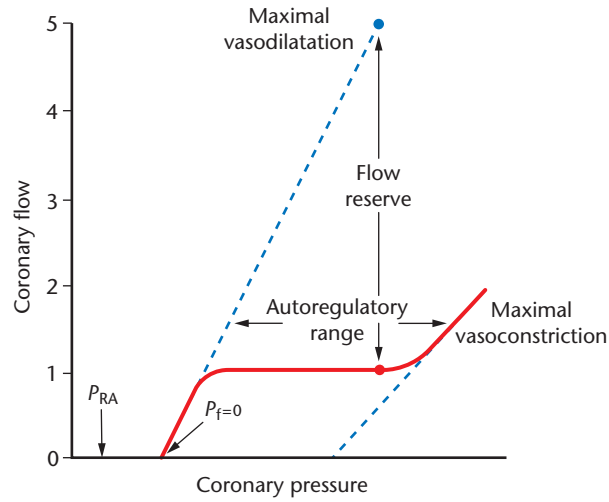

Figure 14.6 Relationship between coronary blood flow and coronary arterial pressure in the left ventricle. At a constant level of myocardial oxygen consumption, coronary blood flow is maintained constant over a wide range of coronary perfusion pressures (red line), included within the boundaries of maximal resistive coronary vessel dilatation or constriction (dashed lines). In the presence of maximal resistive vessel dilatation coronary blood flow and coronary arterial pressure are proportional (dashed line on the left). The red and blue circles represent the basal state and the maximal coronary blood flow, respectively, under normal conditions, giving a coronary flow reserve of 5.0. P_{RA} = right atrial pressure, $P_{f=0}$ = pressure at zero flow.

will lead to a net decrease in the available coronary flow reserve.

The total cross-sectional area of resistive vessels per unit volume of myocardium influences coronary flow conductance and hence the slope of the pressure/flow curve in inner and outer layers of the ventricular wall. The greater the vascular cross-sectional area, the steeper the slope of the pressure/flow curve (the greater the increase in flow per unit increase in pressure). In the presence of maximal vasodilatation the vascular conductance per unit volume of myocardium can be reduced because the total number of resistive vessels per unit volume is decreased or because the lumen of individual vessels is reduced.

Extravascular compressive forces reduce coronary flow reserve mainly in subendocardial layers, in particular during tachycardia and in the presence of elevated diastolic ventricular pressures (Fig. 14.7) [26].

The perfusion pressure that determines flow for any given level of vascular resistance is the pressure at the origin of arteriolar vessels. During maximal coronary dilatation, the slope of the pressure/flow curve is very steep; thus the increase of coronary flow reserve with increasing pressure is substantial. Under physiological conditions

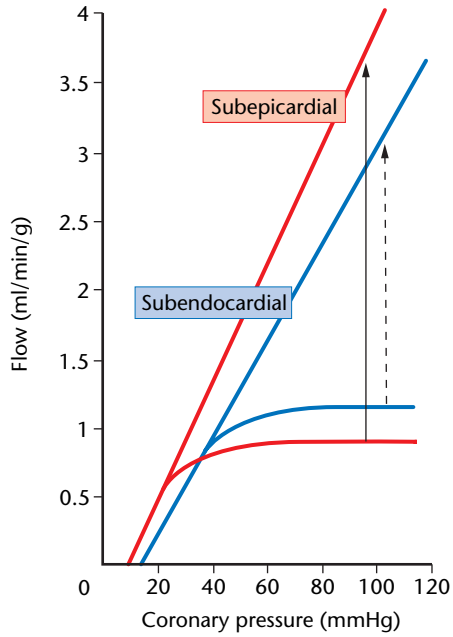

Figure 14.7 Coronary blood flow reserve in subendocardial and subepicardial layers. Under physiological conditions the coronary flow reserve is lower in the subendocardial layers, where there is a higher resting blood flow as a result of a higher oxygen consumption and a lower pressure/flow curve because of higher extravascular compressive forces. This difference between subepicardial and subendocardial layers increases progressively with tachycardia and with elevation of diastolic pressure. Adapted from Bache *et al*. [26].

the coronary perfusion pressure that determines myocardial blood flow corresponds closely to aortic pressure.

In patients, a reduced coronary flow reserve can be the result of a narrowing of epicardial coronary arteries or may reflect a dysfunction of the coronary microcirculation. The latter can be caused by structural (e.g. vascular remodelling with a reduced lumen to wall ratio) or functional (e.g. vasomotor abnormalities) changes, which may involve neurohumoral factors and/or endothelial dysfunction. An abnormal coronary flow reserve may also reflect changes in systemic haemodynamics (e.g. hypotension) as well as changes in extravascular coronary resistance (e.g. increased intramyocardial pressure).

Assessment of coronary flow reserve in man

The assessment of coronary flow reserve in humans implies the measurement of coronary or myocardial blood flow. Several techniques, including Doppler wires and coronary sinus thermodilution, are available for measuring coronary blood flow. These techniques are invasive and affected by serious limitations [27]. While coronary blood flow has units of volume per time (i.e. ml/min), Doppler measurements usually allow assessment of flow velocity (cm/s) and only a few techniques provide volumetric flow [28]. Measurement of inert tracer clearance, the assessment of which can be invasive (based on arterial–venous sampling) or non-invasive (based on external detection of radionuclide wash-out, e.g. ^{133}Xe) provides estimates of regional perfusion, although the mass of tissue subtended by the artery under study is unknown. Single-photon emission computerized tomography (SPECT) allows the non-invasive assessment of directional changes in regional tissue perfusion, but its physical limitations do not permit quantification of myocardial blood flow [29]. Positron emission tomography has been shown to allow non-invasive and accurate quantification of regional myocardial blood flow per gram of tissue, if suitable tracers are used and appropriate mathematical models are applied [30].

Resting and hyperaemic myocardial blood flows are heterogeneous both between and within individuals and exhibit a similar degree of spatial heterogeneity, which appears to be temporally stable. There is a significant linear association between age and resting myocardial blood flow, partly related to changes in external cardiac workload with age whilst hyperaemic myocardial blood flow declines in people over 65 years of age. Hyperaemic myocardial blood flow was found to reach higher values in subjects in whom the standard dose of adenosine (140 µg/kg/min) was used compared to those in whom dipyridamole (0.56 mg/kg infused over 4 min) was used as a hyperaemic stressor [31]. Thus, both age and type of vasodilator used determine the degree of hyperaemia achieved and, thus, are sources of variability. As a result, the inter-individual variability of hyperaemic myocardial blood flow is greater than that observed for resting myocardial blood flow. In normal humans, the range of regional coronary flow reserve is wide, with important clinical implications. Notably, a regional coronary flow reserve of less than 2.5 is often interpreted as abnormal. Yet, many normal left ventricular regions have a coronary flow reserve of less than 2.5 [32].

Myocardial ischaemia

Causes of myocardial ischaemia

Flow limiting stenosis

Under normal circumstances, large epicardial coronary arteries (conduit arteries) offer very little resistance to flow

whilst the pre-arterioles and arterioles, below 500 μm in diameter, are the principal determinants of coronary vascular resistance [33]. Atherosclerotic plaques which determine a reduction of luminal diameter add an extra resistance 'in series', that results in a post-stenotic pressure drop. The latter is compensated for by vasodilatation of resistive vessels and does not have any appreciable effect on coronary flow reserve for reductions of internal luminal diameter up to 50%. Thereafter, however, this compensatory mechanism is progressively exhausted for increasing values of stenosis severity and coronary flow reserve becomes close to unity (i.e. hyperaemic flow = resting flow) for reduction of luminal diameter > 80% (Fig. 14.8) [34]. Functionally, this process progressively limits the ability of the coronary circulation to increase blood flow to meet an increased metabolic demand and is the basis for exercise-induced myocardial ischaemia and angina pectoris in patients with obstructive coronary atherosclerosis.

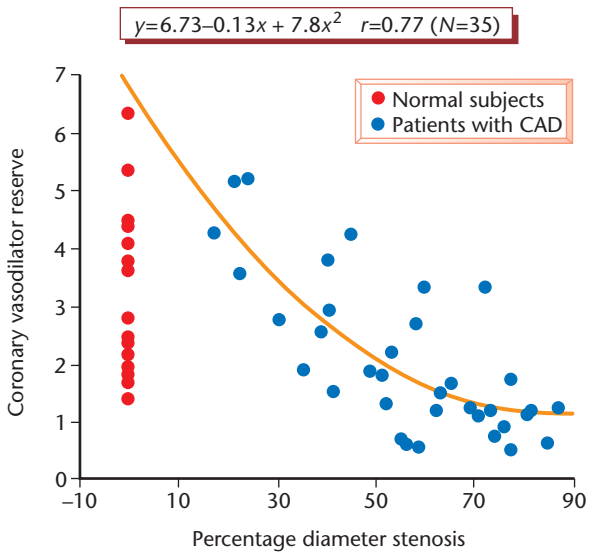

Figure 14.8 Relationship between severity of coronary stenosis (measured by quantitative coronary angiography) and coronary flow reserve (measured non-invasively by positron emission tomography and oxygen-15 labelled water) in patients with coronary artery disease (CAD, blue circles). There is a progressive decline in flow reserve for stenoses with a severity ≥ 50% and the flow reserve approaches unity for stenoses ≥ 80% (i.e. maximum flow, after adenosine, is not different from resting flow). When flow reserve is close to unity, any increase in cardiac workload cannot be met by an adequate increase in blood flow leading to myocardial ischaemia in the region subtended by the stenotic coronary artery. A massive interindividual variability of coronary flow reserve is noted, however, among apparently normal subjects (red circles), thus making the interpretation of coronary flow reserve in the presence of obstructive coronary atherosclerosis rather difficult. Adapted from Uren *et al*. [34].

Occlusive spasm and dynamic stenoses

Coronary artery spasm, consisting of a paroxysmal, intense occlusive vasoconstriction usually involving a segment of an epicardial coronary artery, which results in transmural myocardial ischaemia, is the unique pathogenetic mechanism of variant angina (see below) [35].

Coronary artery spasm may occur at the site of an obstructive coronary atherosclerotic plaque or in angiographically normal or near normal coronary arteries [36]. In some cases it may involve more segments in the same coronary artery branch or even more than one branch. Diffuse coronary spasm may also be observed, in particular in Japanese patients.

The substrate of coronary spasm is a hyperreactivity of smooth muscle cells of the involved coronary segment to vasoconstrictor stimuli [37]. This is likely to be related to alterations in intracellular transduction mechanisms [36], as indicated by the ability of different vasoconstrictor stimuli, acting through different membrane receptors (e.g. sympathetic and parasympathetic activation [38], ergonovine, histamine, dopamine, acetylcholine, serotonin, alkalosis) to precipitate coronary spasm, even in the same patient [37].

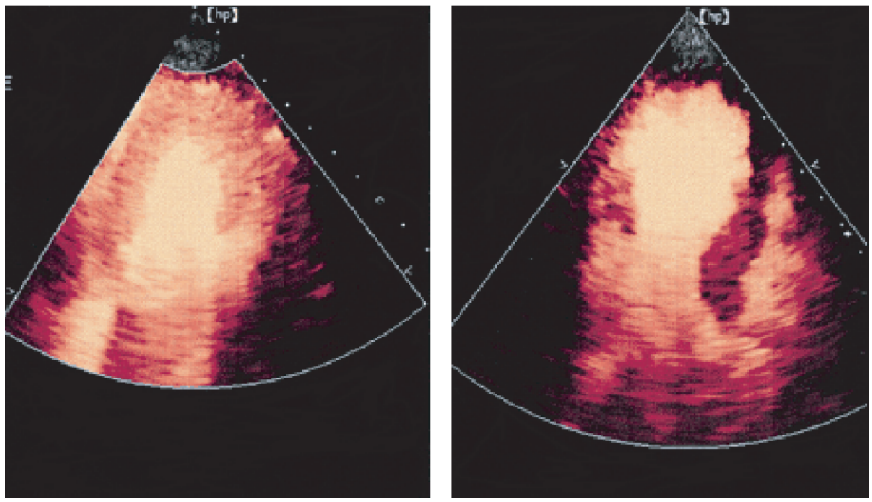
The causes of smooth muscle cell hyperreactivity are unknown, but several possible contributing factors have been suggested, including increased cellular rho-kinase activity [39], abnormalities in ATP-sensitive potassium channels [40] and membrane Na^+–H^+ countertransport [41].

Coronary spasm must be distinguished from dynamic stenoses observed in patients with stable angina. Coronary spasm is caused by hyperreactivity of smooth muscle cells of a localized coronary segment and is occlusive or subocclusive. Dynamic stenoses, instead, are mainly caused by endothelial dysfunction, which facilitates vasoconstriction at the site of pliable critical or subcritical coronary stenoses in response to sympathetic stimuli (such as exercise and mental stress), resulting in a transient worsening of stenosis severity. This may facilitate the occurrence of transient myocardial ischaemia in the presence of an increased myocardial oxygen consumption or even at rest [42].

It is worth noting that, although the main pathogenetic component of acute coronary syndromes is coronary thrombosis [43], abnormal coronary vasomotion of variable severity often plays a contributory role.

Thrombosis

Local thrombosis that occurs at the site of eroded or fissured plaques is central to the initiation of myocardial ischaemia in acute coronary syndromes. Notably, in



Reflow No reflow

Figure 14.9 Assessment of myocardial perfusion by myocardial contrast echocardiography in two patients treated by a primary percutaneous coronary intervention on the left anterior descending coronary artery, 24 hours after the event. Although both patients exhibited TIMI 3 flow in the infarct-related artery and had similar symptom onset to balloon time intervals, one patient exhibited excellent myocardial perfusion (left panel), whereas the other patient displayed 'no reflow' (right panel). The reasons for this different microvascular response to ischaemia–reperfusion are still largely unknown. (Courtesy of Dr Leonarda Galiuto, Cardiology Institute, Catholic University, Rome, Italy.)

about two-thirds of patients thrombus formation occurs at the site of atherosclerotic plaques which reduce lumen diameter by less than 50%, and in 97% of patients at the site of plaques which reduce lumen diameter by less than 70%. In this setting a crucial role is played by local tissue factor expression, and probably also by tissue factor transported by circulating leucocyte-derived microparticles, which interacts with factor VIIa to initiate a cascade of enzymatic reactions resulting in the local generation of thrombin and fibrin deposition. Furthermore, thrombin and collagen exposed by endothelial cell disruption, trigger platelet aggregation, followed by the release of powerful vasoconstrictors.

Microvascular dysfunction

Until quite recently, causes of transient myocardial ischaemia were investigated in conduit coronary arteries. However, recent advances have highlighted the crucial involvement of microcirculation in several clinical manifestations of ischaemic heart disease (IHD). Microvascular dysfunction can be the result of either functional (e.g. endothelial and/or smooth muscle cell dysfunction) or structural (e.g. remodelling of intramural coronary arteries with a reduced lumen to wall ratio) alterations.

A new concept is emerging where 'coronary microvascular disease' is a well-defined condition that often precedes the development of full-blown IHD and may have an independent prognostic value [44]. Indeed, coronary microvascular dysfunction has been documented in asymptomatic subjects with risk factors for IHD, including not only hypertension and diabetes [45], but also hypercholesterolaemia, obesity and smoking [46–48], and can be severe enough to cause angina even in patients with minimal to moderate disease of the epicardial coronary arteries.

Coronary microvascular dysfunction can be observed following percutaneous coronary interventions in patients with stable angina [49] and appears to play an important role also in patients with unstable angina [50]. The 'no reflow phenomenon' is an extreme form of microvascular dysfunction which can occur in the territory of an acute myocardial infarction despite restoration of epicardial blood flow by successful thrombolysis or primary percutaneous coronary interventions, thus negating the potential prognostic advantages of the treatment (Fig. 14.9) [51].

A dysfunction of the coronary microcirculation has also been demonstrated in some cardiac diseases unrelated to coronary artery disease, in particular dilated and hypertrophic cardiomyopathies (Table 14.1) [52,53]. It is worth noting that microvascular dysfunction has been suggested to be a strong predictor of major cardiac events at follow-up in these groups of patients [52,53], whereas it remains unclear whether it may have any prognostic value in other clinical conditions characterized by left ventricular hypertrophy.

Finally, microvascular dysfunction has been suggested to be involved in the pathogenesis of cardiac syndrome X (see below). The hypothesis that angina in cardiac syndrome X is of ischaemic origin was based on the presence of ST-segment depression during spontaneous chest pain episodes and on ECG stress tests, as well as on the evidence of reversible stress-induced myocardial perfusion defects [54], reduced endothelium-dependent and independent coronary vasodilation [55], and metabolic evidence of myocardial ischaemia in some studies [56]. Other

Table 14.1 Clinical conditions associated with evidence of coronary microvascular dysfunction

*The pathogenetic role of microvascular dysfunction is still debated.

studies, however, failed to find evidence of abnormal myocardial blood flow or coronary flow reserve [57], or metabolic evidence of ischaemia during stress tests [58]. Therefore, the pathogenetic mechanisms of chest pain in these patients remain under debate [59]. An ischaemic origin of angina is contradicted also by the lack of transient wall motion abnormalities in the presence of angina and typical transient ST-segment [60]. Maseri *et al*. [1], however, proposed that focal ischaemia in small myocardial regions scattered throughout the myocardium caused by pre-arteriolar dysfunction might explain the paradox of angina and ST-segment depression in the absence of wall motion changes.

Extracoronary cardiac and non-cardiac causes of ischaemia

As described earlier in this chapter, 90% of myocardial blood flow occurs in diastole and this is because of the high extravascular compressive forces during systole. An increase of diastolic ventricular pressure causes an elevation of extravascular compressive force, which can limit myocardial perfusion, thus facilitating effort-induced myocardial ischaemia. An increase of diastolic ventricular pressure is typically observed in hypertrophic cardiomyopathy, in restrictive cardiomyopathy and in hypertensive heart disease. In aortic stenosis both an increase of diastolic left ventricular pressure and a reduction of coronary perfusion pressure contribute to the pathogenesis of effort-induced myocardial ischaemia.

Finally effort-induced myocardial ischaemia can be favoured by a reduction of oxygen content in arterial blood, as observed in anaemia or in patients with severe pulmonary diseases, or by increased metabolic requests, as in hyperthyroidism.

Consequences of myocardial ischaemia

Structural and ultrastructural alterations

Most of our understanding of the early cellular consequences of myocardial ischaemia is derived from experimental studies in animals. It is generally accepted that ischaemia for up to 15–20 minutes is associated with reversible injury, whereas ischaemia of longer duration leads to a progressively more extensive area of irreversible injury. Most of the ultrastructural alterations seen early in ischaemic myocardium, such as cell swelling, glycogen depletion, margination of nuclear chromatin and elongation of myofibrils, become progressively more severe in the irreversible phase. There are, however, two distinctive signs of irreversible damage: amorphous matrix densities in the mitochondria and breaks in the sarcolemma [61].

In the dog, irreversible damage is initially detectable (15–20 minutes after coronary occlusion) in subendocardial layers, which are more susceptible to ischaemia because of the higher myocardial oxygen consumption, and then propagates towards the subepicardial layers (the wavefront of necrosis). Apoptosis appears to be a significant complicating factor of acute myocardial infarction, increasing the magnitude of myocyte cell death associated with coronary artery occlusion, and might play an important role in cardiac remodelling [62].

Metabolic alterations

Under conditions of myocardial ischaemia, oxygen shortage leads to a reduced rate of substrate oxidation (both free fatty acids and glucose) resulting in ATP depletion and accumulation of reduced coenzymes, that are re-oxidized to some extent in the mitochondria by way of the maleate–aspartate cycle. Thus, despite greater glucose availability through both an increased uptake of exogenous glucose and activation of glycogen breakdown, glucose oxidation during ischaemia is negligible. Pyruvate formed through glycolysis cannot be oxidized and, in the presence of increased amounts of reduced nicotinamide adenine dinucleotide (NADH), is converted to lactate by lactate dehydrogenase, thus contributing to tissue acidosis. In addition, a greater amount of alanine, produced via transamination of pyruvate, is released from myocardial fibres. Finally, major changes involve K^+ and Ca^{2+} ions. Loss of intracellular K^+ begins within seconds of the onset of ischaemia and extracellular

concentration markedly increases during the first few minutes. The mechanisms of this loss, which begins before substantial ATP depletion, are still largely unknown. The decrease of transmembrane K^+ gradient is a major cause of abnormalities detectable on surface ECG. The early increase in cytosolic Ca^{2+} results from increased influx and decreased sequestration in the sarcoplasmic reticulum and is thought to be one of the mechanisms of irreversible cell death [63].

After an ischaemic episode, myocardial glucose utilization is higher than in resting conditions despite normalization of the haemodynamic conditions (Fig. 14.10) [64]. This extra glucose is probably used for rebuilding of the glycogen stores that had been depleted during ischaemia.

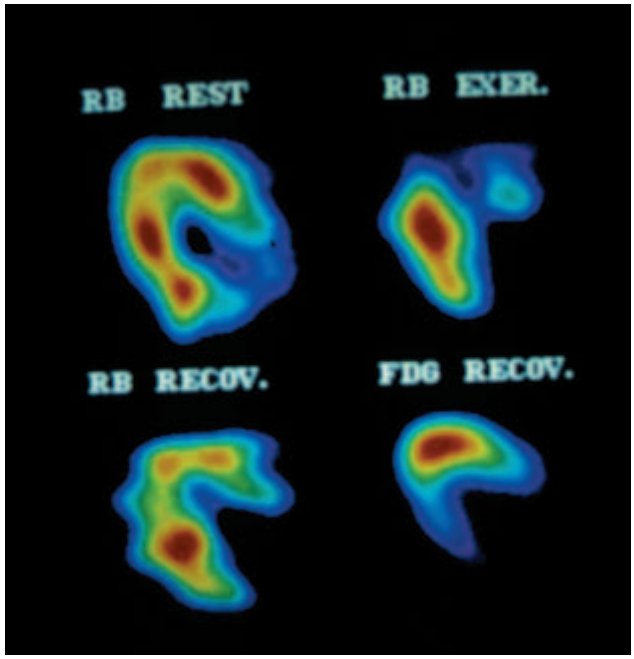

Figure 14.10 Positron emission tomography scans of rubidium-82 (^{82}Rb)- and ^{18}F-labelled deoxyglucose (FDG) uptake in the left ventricle of a patient with left anterior descending coronary artery disease. In each image, the left ventricular free wall is in the 6 o'clock to 10 o'clock position, the anterior wall and septum are in the 10 o'clock to 3 o'clock position, and the remaining open area is in the plane of the mitral valve. The scan at rest (top left) shows a homogeneous cation uptake in all myocardial walls. The ^{82}Rb scan recorded during exercise (top right) shows a severely reduced cation uptake in the anterior left ventricular wall, while the ^{82}Rb scan recorded in the recovery phase (when the patient had neither pain nor ECG changes) shows that perfusion is similar to baseline (bottom left). FDG was injected in the recovery phase after the last ^{82}Rb scan. The FDG scan, recorded 60 minutes after tracer injection, shows a greater FDG uptake in the previously ischaemic area (bottom right). FDG uptake in the anterior wall is 1.55 times higher than that in the non-ischaemic muscle. Adapted from Camici *et al.* [64].

Cardiac function alterations

Over 70 years ago Tennant and Wiggers [65] demonstrated that acute ischaemia rapidly impairs myocardial contractile function. For many years it was believed that relief of ischaemia led to an almost immediate normalization of function, provided that necrosis had not occurred. In 1975, Heyndrickx *et al.* [66] demonstrated, in a conscious dog model, that a 15-minute coronary occlusion (a time period generally not associated with cell death), followed by reperfusion, produced a marked depression in regional contractile function that persisted for at least 6 hours after reperfusion. The term 'myocardial stunning' was coined to describe this viable tissue that exhibited prolonged post-ischaemic ventricular dysfunction. More recently, stunning has been demonstrated to occur in patients with IHD both after exercise-induced and dobutamine-induced ischaemia (Fig. 14.11) [67,68]. Another more persistent form of post-ischaemic left ventricular dysfunction has been demonstrated in patients with chronic IHD: 'hibernated myocardium'. This can be defined as chronically dysfunctional myocardium, subtended by a stenotic coronary artery (with severe limitation of coronary flow reserve), that improves function upon coronary revascularization. The pathophysiology of myocardial hibernation in humans is more complex than initially postulated. The recent evidence that repetitive ischaemia in patients with IHD can be cumulative and leads to more severe and prolonged stunning, further supports the hypothesis that, at least initially, stunning and hibernation are two facets of the same coin [69].

Finally, a consequence of myocardial ischaemia is 'myocardial preconditioning', where a short episode of ischaemia can reduce the morphofunctional effects of a subsequent episode of ischaemia. The term was introduced by Murry *et al.* [70], who found a reduction in myocardial infarct size in dogs, when persistent coronary occlusion was preceded by one or more brief episodes of ischaemia. Preconditioning was subsequently demonstrated in other animal species, and further studies have also shown that a second window of protection can be demonstrated approximately 24 hours after the ischaemic stimulus, lasting for 48–72 hours [71]. In humans, ischaemic preconditioning has also been found to occur as a reduced myocardial suffering during repeated spontaneous or provoked (e.g. by balloon inflation during coronary angioplasty) transient ischaemic episodes [72].

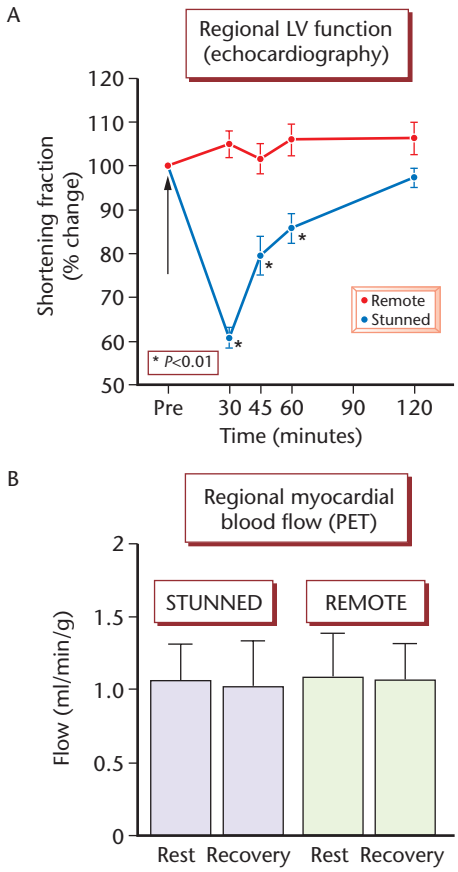

Figure 14.11 Demonstration of stunning in patients with single vessel coronary artery disease and exercise-induced ischaemia. (A) Regional left ventricular wall motion assessed by echocardiography at baseline and at different time points during dobutamine stress test. Shortening fraction in the recovery phase was unchanged in the control territory subtended by a non-diseased coronary artery (red line). By contrast, the shortening fraction was severely reduced in the ischaemic territory (blue line) and returned towards baseline only after 120 minutes from the cessation of dobutamine stress test. (B) In the ischaemic region, myocardial blood flow, as measured by positron emission tomography (PET) and ^{15}oxygen-labelled water, was comparable to blood flow in the non-ischaemic territory, both at baseline and also 30 minutes after dobutamine stress test, when shortening fraction was still severely depressed, thus demonstrating the occurrence of stunning in man. Adapted from Barnes *et al.* [67].

Arrhythmias

Myocardial ischaemia can trigger electrophysiological changes that favour the development of arrhythmias. These are rare during transient episodes of subendocardial ischaemia, whereas they are more common when myocardial ischaemia is transmural and in the setting of acute myocardial infarction. The most common forms of arrhythmia during ischaemia and infarction are ventricular tachyarrhythmias and fibrillation whilst atrioventricular block and asystole occur less frequently. In the canine model, but not in man, life-threatening ventricular arrhythmias are frequently found at the time of post-ischaemic reperfusion.

Reflex sympathetic activation

Ischaemia stimulates the terminal endings of both vagal and sympathetic fibres that innervate the myocardium. Sympathetic activation can further exacerbate myocardial ischaemia by increasing contractility and triggering vasoconstriction and ventricular arrhythmias. Following acute myocardial infarction continued sympathetic activation contributes to ventricular remodelling and hypertrophy and to myocardial β-adrenoceptor down-regulation [73].

Cardiac ischaemic pain

Cardiac ischaemic pain is a late consequence of myocardial ischaemia. Notably, transient myocardial ischaemia and even necrosis can occur in the absence of pain. More than 200 years after the original description of angina pectoris by Heberden [74], the mechanisms that lead to the genesis of cardiac ischaemic pain are still not fully elucidated. However, it now appears that substances released during myocardial ischaemia, that are able to stimulate afferent nerves, trigger the pain signal [75].

An important chemical stimulus is adenosine release by cardiomyocytes during ischaemia [76]. Adenosine plays a major role in the metabolic regulation of myocardial blood flow, because of its powerful vasodilator effect on arterioles. Interestingly, adenosine is also a powerful algogenic substance. Indeed, its intracoronary injection causes angina-like chest pain in the absence of signs of ischaemia. The algogenic effect of adenosine is mediated by A_1 receptors located on the membranes of afferent cardiac nerve fibres, whereas its vasodilator effect is mediated by A_2 receptors on vascular smooth muscle cells. Cardiac ischaemic pain, however, can still be induced after administration of adenosine inhibitors, suggesting that mechanisms other than adenosine are involved in its origin. In particular, bradykinin and substance P have been found to induce or modulate angina pain in man.

Cardiac pain signals are transmitted throughout sympathetic and, in part, vagal nerves to neurones in the dorsal horns of the spinal cord, from here to the thalamus, and from the thalamus to the cortex, where they are processed and decoded as pain [77] (Fig. 14.12).

The central transmission of pain signals generated from the heart is modulated in the central nervous system by both ascending and descending signals. An important

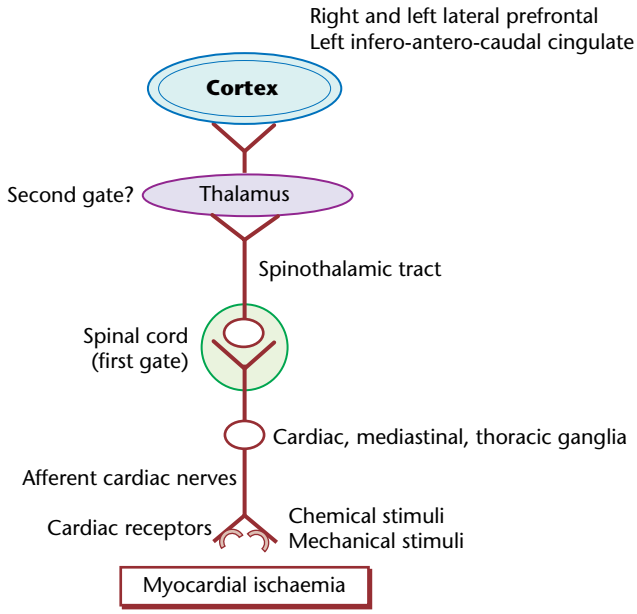

Figure 14.12 Transmission of cardiac ischaemic pain signals to cortical centres. Cardiac ischaemic pain signals generated by chemical stimuli (e.g. adenosine) or mechanical stimuli (e.g. stretching of intramyocardial or periarterial nerve fibres) travel throughout sympathetic and, in part, vagal nerves to neurones in the dorsal horns of the spinal cord. From there pain signals are transmitted to the thalamus and to the cortex where they are processed and decoded as pain. Profound modulation of pain signals occurs both at the spinal and, probably, at the supraspinal level.

modulation is believed to occur in the dorsal horns of the spinal cord, where, according to the gate theory, a group of intermediate neurones may inhibit the transmission of the pain signal [78].

The somatic location of cardiac ischaemic pain does not allow us to predict the site of myocardial ischaemia. Indeed, about 70% of patients who suffer from both anterior and inferior myocardial infarction at different times of their life experience pain in the same body region during the infarctions [79]. Accordingly, separate infusions of adenosine into the right or left coronary artery result in a similar distribution of pain in about 75% of the patients [80]. On the other hand, different locations of angina in the same patient at different times suggest ischaemia originating from different myocardial regions [81].

The ischaemic cascade

The clinical consequences of transmural myocardial ischaemia occur in a rather predictable sequence known as the 'ischaemic cascade' and are characterized by the following events:

- reduction in pH and increase in the concentration of K^+ ions in venous blood draining the ischaemic region;
- regional wall motion abnormalities and signs of global diastolic and systolic left ventricular dysfunction;
- development of ST-segment changes;
- cardiac ischaemic pain.

This sequence of events helps to explain why imaging techniques based on the assessment of regional wall motion are more sensitive than ECG in the detection of myocardial ischaemia.

It has been proposed that severe microvascular dysfunction might be followed by a different 'ischaemic cascade' characterized by the early onset of ECG changes and chest pain in the absence of regional wall motion abnormalities [1].

Coronary collateral circulation

Collaterals develop from pre-existing anastomotic channels (thin-walled structures ranging in diameter from 20 to 200 μm), as a result both of the establishment of a pressure gradient between their origin and termination and of chemical mediators released during tissue hypoxia, a process called arteriogenesis. A pressure gradient of about 10 mmHg has been shown to be sufficient to elicit the development of collateral flow. Intercoronary arterial anastomoses are present in variable numbers in different species: they are so numerous in guinea-pigs that they can prevent infarction following sudden coronary occlusion, whereas, at the other extreme, they are virtually absent in rabbits. In dogs the density of anastomotic channels can deliver 5–10% of preocclusional resting flow. Humans have a slightly worse collateral circulation than dogs, but with a marked interindividual variability [82].

Arteriogenesis occurs in three stages [83]:

- the first stage (first 24 hours) is characterized by passive widening of pre-existing channels and endothelial activation, followed by secretion of proteolytic enzymes which dissolve extracellular matrix;
- the second stage (from 1 day to about 3 weeks) is characterized by migration of monocytes into the vascular wall, followed by secretion of cytokines and growth factors, which trigger proliferation of endothelial and smooth muscle cells and of fibroblasts;

- the third phase (3 weeks to ~3 months) is characterized by thickening of the vascular wall as a result of deposition of extracellular matrix.

In its final stage the mature collateral vessels may reach ~1 mm in luminal diameter. Tissue hypoxia can favour collateral development by acting on the promoter gene of vascular endothelial growth factor (VEGF), but it is not an essential requirement for collateral development. There is no consistent evidence that exercise can favour collateral development. Among risk factors diabetes might impair the ability to develop collateral vessels [84].

Well-developed collateral circulation can be sufficient to prevent myocardial ischaemia in man in the presence of a sudden collateral occlusion, but it rarely provides blood flow adequate to meet myocardial oxygen consumption during maximal physical exercise.

Collateral vessels may also form through angiogenesis, which involves sprouting of new vessels from pre-existing vessels and usually results in the formation of capillary-like structures. This was clearly demonstrated following mammary artery implants in the myocardium of dogs with gradual total occlusion of a major coronary artery. The collateral blood supply provided by such newly formed vessels is rather small compared with that provided by arteriogenesis [85].

Epidemiology of chronic ischaemic heart disease

Population-based studies have shown that the prevalence of angina increases with age, being twice as common in men as it is in women. Indeed, in men angina prevalence increases from 2–5% in the 45- to 54-year-old age group to 11–20% in the age group 65–74 years, whereas in women angina prevalence increases from 0.5–1% to 10–14% for the same age groups. After 75 years angina prevalence is similar in the two sexes. According to these figures, it can be estimated that the prevalence of angina patients in Europe may be as high as 30 000–40 000 per 1 million total population [86].

In the Framingham study [87], among 5127 initially asymptomatic subjects (aged from 30 to 62 years) followed up for 14 years, the mode of first presentation of IHD was predominantly an acute coronary syndrome in men (68%) and predominantly a stable angina in women (56%). The common first presentation of IHD with an acute coronary syndrome is consistent with the observation that acute coronary occlusion usually occurs suddenly at the site of non-flow-limiting stenoses. These observations also suggest a different prevalence of pathogenetic mechanisms of angina in the two sexes.

In the Framingham study [87], among patients who presented with an acute myocardial infarction, 45% of men, but only 15% of women, developed a syndrome of stable angina at follow-up. This figure is probably even lower in the current era of primary coronary interventions.

Population-based studies, however, do not allow us to establish the mechanism of chronic stable angina. Indeed, although in the majority of patients chronic stable angina is associated with obstructive coronary artery disease, it may also be caused by coronary artery spasm or may occur in patients with angiographically normal coronary arteries (cardiac syndrome X).

There have been no systematic studies assessing the epidemiology of variant angina. In two surveys, coronary vasospasm was the presenting mechanism of angina in about 1.5% of patients admitted to hospital because of angina [88].

The prevalence of cardiac syndrome X can be inferred from angiographic studies. Among patients with chest pain that is suggestive of angina pectoris, who undergo coronary angiography, 10–30% are found to have normal or near normal coronary arteries at angiography and no evidence of coronary vasospasm. A sizeable proportion of these patients might present with cardiac syndrome X [89].

Another clinical presentation of chronic IHD is ischaemic cardiomyopathy. The latter can be a complication of myocardial infarction, often after multiple infarctions and in elderly patients, or can be, less frequently, the initial manifestation of IHD. In the GISSI-2 study, signs of cardiac failure at 6 months after a first myocardial infarction were present in 9% of 9860 patients who received thrombolysis [90]. However, the growing survival rate after a first myocardial infarction exposes patients to the natural progressive worsening of the underlying IHD, thus increasing the risk of evolution towards progressive heart failure. Notably, ischaemic cardiomyopathy, either associated or not with stable angina, is the leading cause of heart failure in developed countries, accounting for two-thirds to three-quarters of cases.

Assessment of angina pectoris

Characteristics of angina pectoris

Independent of its causes, the most typical clinical manifestation of myocardial ischaemia is represented by

angina pectoris (*angina*, from the Latin for anguish) [91]. The features of chest pain that should be investigated to diagnose and characterize angina pectoris include type, location, irradiation and duration of pain, modalities of pain onset and offset, and response to nitrate administration. Importantly, a careful assessment of characteristics of chest pain may help to establish the mechanisms responsible for myocardial ischaemia.

In its typical presentation, angina is referred as a constrictive, aching sensation, or pressure or tightness discomfort in the retrosternal area or in the anterior portion of the chest. Typically, the area of pain is indicated by the patient with a clenched fist or an open hand in the middle of the chest. Pain frequently radiates towards the neck, the left shoulder and the medial side of the left arm, and lasts no more than 10–15 minutes. Angina responds promptly to short-acting nitrates.

Several variants, however, exist to this typical presentation. Thus, pain can be represented by a heavy or burning sensation and can radiate towards the epigastrium, the right shoulder or arm, the interscapular area, the jaw and teeth, and, exceptionally, it can also be referred to the upper right abdominal quadrant or to the head [92]. Angina in atypical locations, although rarely, may represent the main or only symptom of IHD.

In most cases it is possible to identify conditions which trigger angina. These are more often represented by physical efforts, but they may consist of stressful or emotional states, exposure to cold, abundant meals or hypertensive episodes. Angina usually subsides by removing the triggering cause, but short-acting nitrates may be necessary to shorten angina duration. Finally, angina can also occur at rest without any apparent triggering cause.

Table 14.2 Differential diagnosis of chest pain

Cardiovascular causes
Ischaemic
Flow-limiting coronary stenosis
Coronary vasospasm
Coronary thrombosis
Microvascular dysfunction*
Non-ischaemic
Coronary arterial wall distension
Dyssynergic myocardial contraction
Aortic dissection
Pericarditis
Pulmonary embolism or hypertension
Non-cardiovascular causes
Gastrointestinal
Oesophageal spasm
Gastro-oesophageal reflux
Gastritis/duodenitis
Peptic ulcer
Cholecystitis
Respiratory
Pleuritis
Mediastinitis
Pneumothorax
Neuromuscular/skeletal
Chest wall pain syndrome
Neuritis/radiculitis
Herpes zoster
Tietze's syndrome
Psychogenic
Anxiety
Depression

*See Table 14.1.

Differential diagnosis of chest pain

Angina pectoris can be simulated by several non-ischaemic cardiac diseases or by extracardiac diseases. Indeed, somatic or visceral pain signals may converge on the same neurones in the spinal dorsal horns which also receive cardiac ischaemic pain signals, thus resulting in a pain sensation similar or indistinguishable, as to type and location, from angina (Table 14.2).

Cardiovascular causes of chest pain

In the absence of obstructive coronary stenoses, spasm or thrombosis, chest pain, usually related to effort or to other conditions of increased myocardial oxygen demand, may occur in patients with severe left ventricular hypertrophy, caused by aortic stenosis, hypertrophic cardiomyopathy, arterial hypertension, or, less frequently, by aortic regurgitation or dilated cardiomyopathy. In these conditions, the increased left ventricular mass is often not matched by a parallel growth of coronary microcirculation; thus, increased oxygen demand cannot be satisfied. Diastolic dysfunction, with increased diastolic pressure, is also present and facilitates subendocardial ischaemia. Finally, coronary microvascular dysfunction can contribute to myocardial ischaemia [53]. Distinction from angina caused by obstructive coronary artery disease may be difficult even after full non-invasive diagnostic investigation and may eventually require coronary angiography.

Notably, angina in the absence of signs of myocardial ischaemia is sometimes experienced by patients who have recently undergone coronary stent implantation [93]. Stretching of the coronary arterial wall at the site of stenting is the likely mechanism in these cases. In very rare cases, angina is triggered by the intermittent appearance of heart rate-dependent left bundle branch block, in the absence of any evidence of myocardial ischaemia [94]. Stretching of afferent nerve fibres caused by dyssynergic

myocardial contraction at the appearance of left bundle branch block is the likely mechanism of pain in these cases.

Aortic dissection must be carefully excluded in patients presenting with chest pain. In this condition chest pain is usually of sudden onset and severe, but in some cases it is subacute and atypical. It often radiates to the back, lasts for hours, is not influenced by breathing or turning and may tend to migrate. A history of hypertension or a marfanoid habitus in young patients should raise suspicions. Differences in peripheral pulses and an enlarged aorta on chest X-ray should also suggest the diagnosis of aortic dissection, which is then confirmed by trans-oesophageal echocardiography, computerized tomography (CT) or cardiac magnetic resonance (CMR).

Chest pain caused by pericarditis is usually easily recognized because of typical changes in breathing and exacerbation by assuming the supine position; pericardial rubs can be present and the ECG usually shows typical diffuse ST-segment elevation.

Chest pain caused by pulmonary embolism is frequently associated with dyspnoea and tachypnoea; the presence of typical predisposing conditions (e.g. recent surgery, prolonged bed rest) should raise suspicions. The ECG, laboratory investigation and imaging techniques usually allow the correct diagnosis.

Finally, pulmonary hypertension, either primary or secondary, may also be associated with chest pain, caused by increased stress on the pulmonary arterial wall or by right ventricular ischaemia. A careful physical examination and appropriate diagnostic tests (e.g. ECG, chest X-ray, echocardiography) usually allow the correct diagnosis of pulmonary hypertension.

Non-cardiovascular causes of chest pain

These include four major groups of clinical syndromes.

Gastro-intestinal disorders are among the most frequent disorders mimicking angina. Oesophageal spasm and reflux, in particular, may cause typical retrosternal or epigastric pain, which can radiate towards the neck, jaw and arms, and can occasionally be relieved by short-acting nitrates. Chest pain caused by gastro-oesophageal reflux usually appears immediately after a meal or at night. Yet, angina can occur under the same circumstances. Furthermore, both reflux and angina can be triggered by exercise. Of note, reflux and oesophageal spasm may coexist with angina, as the latter may be facilitated by autonomic reflexes and pain related to gastro-enteric disorders. The response to anti-acid treatment and endoscopy may help in the differential diagnosis.

Peptic ulcer and gastritis (and/or duodenitis) may sometimes mimic angina. However, the link to meals, the absence of a relation to effort and the response to anti-acid treatment suggest the diagnosis, which can be confirmed by endoscopy.

Acute or chronic cholecystitis can also sometimes simulate atypical angina, but the pain is not relieved by nitrates. Abdominal ultrasound examination is usually sufficient to document the presence of cholecystitis.

Respiratory diseases (pneumothorax, pleuritis, mediastinitis) may cause chest pain, but symptom features and an accurate physical examination usually establish the correct diagnosis, which can subsequently be confirmed by imaging techniques.

Neuromuscular disorders, including chest wall pain syndrome and neuritis, are among the most common causes of chest pain. Neuromuscular chest pain is usually modified by breathing and/or chest movement, and can be induced by pressure on specific points of the chest. Pain is usually long-lasting (hours, days), does not have any relation with effort and is not relieved by nitrates, whereas it is relieved by anti-inflammatory drugs. Tietze's syndrome (swelling and pain of left chondro-sternal joints) is a rare condition that can be easily recognized.

Psychogenic causes should, finally, be taken into account after organic causes of chest pain have all been excluded. Indeed, anxiety and depression are possible causes of chest pain simulating angina pectoris.

Angina equivalents

In some patients myocardial ischaemia is expressed by transient symptoms that are different from angina pectoris, including dyspnoea, arrhythmias and pre-syncope or syncope.

Dyspnoea may occur when transient ischaemia involves a large myocardial mass, thus resulting in severe left ventricular dysfunction and pulmonary congestion/oedema. In this case cardiac auscultation may reveal a third heart sound and basal pulmonary rales might be heard on thorax auscultation. Dyspnoea may also occur when myocardial ischaemia causes left ventricular papillary muscle dysfunction, resulting in severe mitral valve regurgitation. In this case, a new, or worsening of a previous, apical systolic murmur is appreciated on cardiac auscultation during ischaemia.

Arrhythmias induced by myocardial ischaemia can be appreciated by the patient as palpitation (e.g. correlated to effort). Severe tachyarrhythmias (e.g. ventricular tachycardia), but also bradyarrhythymias (e.g. atrioventricular or sino-atrial block) may result in

presyncope or syncope, as a result of a fall in left ventricular output.

Silent ischaemia

A large number of studies using Holter monitoring have consistently shown that most spontaneous episodes of myocardial ischaemia (i.e. 70–80%), regardless of their causes, are silent, as they are not associated with angina, or angina equivalents [95]. Furthermore, silent ischaemia can also be frequently documented during diagnostic stress tests. The proportion of silent ischaemic episodes is similar in the different coronary ischaemic syndromes, being unrelated to the causes of ischaemia. Of note, from a clinical point of view, prognosis of painful and silent myocardial ischaemia is similar, being dictated in both cases by the underlying causes of myocardial ischaemia.

The causes of silent ischaemia are not completely clear, but several mechanisms are likely to contribute to this phenomenon. A relation between extent and severity of myocardial ischaemia and the occurrence of angina has been suggested by some reports. Most studies, however, failed to find differences between patients with painful or painless ischaemia with regard to severity of ST-segment changes, wall motion abnormalities or haemodynamic changes during ischaemic episodes [96]. Thus, on the whole, the association between severity and extent of myocardial ischaemia and occurrence of pain is poor, even in the same patient.

The causes of painless ischaemia can be different in patients who present both painless and painful myocardial ischaemia during the same day, or even in a short period of time, despite similar duration and severity of ischaemia, and in those who predominantly or exclusively present silent ischaemia.

In the former group silent ischaemic episodes are probably the result of a dynamic peripheral and/or central modulation of cardiac pain signals [77,97]. Instead, in patients with predominant, or even only, silent myocardial ischaemia, the failure to develop pain could be because of a generalized defective perception of painful stimuli. Indeed, these patients, compared to those with predominantly painful ischaemia, have a higher threshold and tolerance for pain stimuli, including forearm ischaemia, cold pressor, skin electrical stimulation, intravenous adenosine infusion, and dental pulp stimulation [91]. Increased central release of endogenous opioids, which inhibit nociceptive dorsal horn-convergent neurones, has been proposed as a possible mechanism, but studies comparing plasma levels of endogenous endorphins in patients with predominantly painful or painless ischaemia have given controversial results [91]. Finally, psychological factors may play an important role, as patients exhibiting predominantly silent ischaemia have been found to present lower scores for nervousness, 'excitability' and tendency to complain.

In contrast with current beliefs, there is no definite evidence that silent ischaemia is more prevalent among diabetic patients [98].

Clinical syndromes of chronic ischaemic heart disease

Stable angina

Symptoms and physical examination

Stable angina is characterized by a pattern of angina which has remained stable for at least 2 months. It can be the first manifestation of IHD or can appear in patients who had suffered a previous acute coronary event. Typically, angina is induced by efforts or conditions that increase myocardial oxygen demand (e.g. emotional and psychological stresses, hypertensive episodes). Angina is promptly relieved by interrupting the precipitating event, although short-acting nitrates can accelerate pain relief.

The pathologic substrate of stable angina is the presence of coronary flow-limiting stenoses, which do not allow an adequate increase in coronary blood flow during increased myocardial oxygen demand. Typically, myocardial ischaemia is limited to the subendocardial layers, which is most frequently manifested by ST-segment depression in one or more ECG leads (more often V4–V6).

In stable angina, myocardial ischaemia can occur reproducibly for a given level of exercise or in specific conditions, suggesting fixed stenoses. In most patients, however, the ischaemic threshold is variable, and angina can occasionally occur at rest (mixed angina). This variability can be the result of vasomotion at the site of pliable stenoses, modulating their severity (dynamic stenoses) and/or of vasomotor changes in the coronary microcirculation or collateral vessels [99,100].

The Canadian Cardiovascular Society classification of stable angina is the most widely used to assess the severity of angina pectoris (Table 14.3) [101].

In patients with stable angina general physical examination is often unremarkable, but findings suggesting lipid disorders (i.e. cutaneous xanthomata, xanthelasma, corneal arcus) can be observed on visual inspection. Peripheral pulse examination may reveal bruits and murmurs suggesting arterial stenoses, in particular in the carotid and femoral arteries.

Table 14.3 Canadian Cardiovascular Society classification of angina pectoris*

I	Ordinary physical activity, such as walking and climbing stairs, does not cause angina. Angina results from strenuous or rapid or prolonged exercise at work or recreation
II	Slight limitation of ordinary activity: walking or climbing stairs rapidly, walking uphill, walking or climbing stairs after meals, in cold, in wind, or when under emotional stress, or only during the few hours after awakening. Walking more than two blocks on the level and climbing more than one flight of ordinary stairs at a normal pace and under normal conditions.
III	Marked limitations of ordinary physical activity: walking one or two blocks on the level and climbing more than one flight under normal conditions.
IV	Inability to carry on any physical activity without discomfort. Anginal syndrome may be present at rest.

*Reproduced from [100].

In the absence of left ventricular dysfunction, cardiac examination may be uninformative. However, a rapid pulse may be a clue to thyrotoxicosis or anaemia which can exacerbate angina pectoris. A third and/or fourth heart sound can be heard during angina because of transient cardiac failure. A transient paradoxical splitting of the second heart sound appears in cases sof ischaemia-induced left bundle branch block, whereas a transient systolic murmur may indicate mitral regurgitation following papillary muscle dysfunction, in particular in patients with a dilated left ventricle. Finally, a systolic aortic murmur may suggest that aortic stenosis is a likely cause of angina.

Non-invasive diagnosis

Resting ECG In patients with suspected angina pectoris a resting 12-lead ECG should be recorded, although only occasionally it is of diagnostic value. Indeed, resting ECG is normal in about 50% of cases and, when abnormal, will show abnormalities (e.g. minor ST-segment/T wave changes, atrioventricular or intraventricular conduction disorders, supraventricular or ventricular arrhythmias) that are not sufficiently specific for the diagnosis of IHD because they can be frequently found in several other conditions. However, the detection of pathologic Q/QS waves, even in the absence of any history of previous myocardial infarction, or of typical negative symmetric T waves and/or ST-segment depression, strongly suggests an ischaemic origin of symptoms.

Chest X-ray Although routinely performed in mostpatients, chest X-ray has poor diagnostic value in suspected stable angina. The detection of coronary calcifications, however, is associated with a high probability of obstructive IHD [102].

Exercise stress test (EST) Treadmill or bicycle EST during 12-lead ECG monitoring is the test of choice to diagnose myocardial ischaemia in the majority of patients with suspected stable angina, because of its simplicity and the excellent cost : benefit ratio (Table 14.4) [103].

The main diagnostic ECG abnormality during EST consists of a rectilinear or downsloping ST-segment depression ≥ 0.1 mV, persisting for at least 0.06–0.08 seconds after the J-point, in one or more ECG leads. It is worth noting that in about 15% of patients diagnostic ST-segment changes appear during the recovery phase, rather than during the active phase, of exercise [104].

Table 14.4 Non-invasive tests for diagnosis and prognostic stratification of stable angina

Test	Recommended use	Comments
Exercise ECG	First choice in most patients	Difficult to interpret in presence of abnormal basal ECG
Exercise myocardial perfusion scintigraphy or echocardiography	Patients with non-interpretable ECG Non-conclusive exercise ECG results For accurate location of ischaemia	Imaging techniques more sensitive and specific than ECG Exercise more physiological than pharmacological stressors Echocardiography more informative than nuclear techniques and radiation free, but interpretation more operator-dependent and poor image quality in some patients
Myocardial perfusion scintigraphy or echocardiography during infusion of pharmacological stressors	Patients unable to exercise Preferable if assessment of viable myocardium is also needed	Echocardiography more informative than nuclear techniques and radiation free, but interpretation more operator-dependent and poor image quality in some patients

To obtain maximal diagnostic information from EST, the latter should be symptom/sign limited and performed without the influence of anti-ischaemic drugs. A meta-analysis of the most important studies which investigated the diagnostic value of EST for obstructive IHD reported average sensitivity and specificity of 68% and 75%, respectively [103]. However, a careful analysis of the data, taking into account selection biases of the patient cohorts, suggested that the sensitivity of EST may be lower (about 45%), but that specificity is even higher (about 90%) [105].

The positive predictive value for coronary artery disease of exercise-induced ST-segment depression increases up to 90% if it is accompanied by typical angina pain, if it occurs in the early stages of exercise or persists for more than 5 minutes in the recovery phase, and if it is > 0.2 mV [106,107]. Early appearance, extensive lead involvement and slow normalization after exercise are clues to the presence of multivessel IHD.

When assessing the accuracy of EST, as well as of other non-invasive techniques, for the diagnosis of obstructive IHD, intrinsic bias should be considered, which may account for a proportion of erroneous results. This bias consists of considering the presence or absence of obstructive coronary stenoses at angiography as the gold standard for diagnostic accuracy. Indeed, on the one hand non-invasive stress tests detect myocardial ischaemia, which may be caused by coronary spasm or microvascular dysfunction. On the other hand, obstructive atherosclerosis does not always cause myocardial ischaemia during stress (e.g. for the presence of well-developed collateral circulation).

Several other EST-related variables have been suggested to improve the diagnostic accuracy of EST, including QRS and U wave changes, ST/HR slope or ST/HR index and the ST/HR recovery loop, but their efficacy in improving the predictive value of EST remains doubtful [103].

In clinical practice the interpretation of ST-segment changes during EST should be individualized, particularly considering the pre-test probability for the patient to have obstructive coronary artery disease, which mainly depends on the characteristics of symptoms, but is also influenced by risk factors, in particular age (Table 14.5). Indeed, owing to the suboptimal sensitivity and specificity of EST, pre-test probability influences the predictive value for IHD, according to Bayes theorem (Fig. 14.13) [108]. (Bayes theorem allows the calculation of the probability of a subject to be affected by a disease in the presence of a positive or negative diagnostic test. According to Bayes theorem, the probability of the disease depends not only on the sensitivity and specificity of the test but also on the pre-test probability of the disease in the population of individuals to which the subject belongs [see Fig. 14.13]). According to this theorem, diagnostic tests are particularly useful and maximally informative in patients with an intermediate probability of disease. Indeed, in patients with estimated low pre-test probability of IHD (e.g. a 30-year-old woman with atypical angina), ST-segment depression has low predictive value for IHD, because of a high proportion of false-positive results. As a consequence, the test is not usually recommended for diagnostic purposes in asymptomatic individuals with a good risk factor profile. At the other extreme, in patients with estimated high pre-test probability of IHD (e.g. a 60-year-old diabetic man with typical angina) EST is only confirmatory, whereas a negative test does not allow obstructive coronary artery disease to be excluded. Nevertheless, EST is useful in these patients, providing additional information on the severity of ischaemia, the degree of functional limitation and prognosis [109]. The exact definition of the upper and lower boundaries of intermediate probability is a matter of physician judgement in individual patients, but values of 10% and 90%, respectively, have been suggested [110]. The post-test probability of coronary artery disease, according to characteristics of symptoms, age and magnitude of ST-segment depression induced during exercise stress test, is summarized in Table 14.5.

The exercise ECG stress test has limited value in patients with basal ECG abnormalities, including left bundle branch block, paced rhythm or Wolff–Parkinson–White syndrome, which preclude a correct interpretation of ST-segment changes. False-positive results are also more frequent in patients with resting ST-segment/T wave abnormalities, because of left ventricular hypertrophy, electrolyte imbalance, or drug effects (e.g. digitalis).

An important issue with EST is the diagnosis of obstructive IHD in women, in whom ST-segment depression has been found to have lower specificity (i.e. it is more often a false-positive result) than in men. However, when pre-test probability is accurately determined and patients with normal ECG at rest are selected, EST has the same reliability in women as in men [111].

Scintigraphic stress tests Exercise myocardial perfusion scintigraphy is a robust, non-invasive method of assessing regional myocardial perfusion and allows the diagnosis of myocardial ischaemia by showing a reversible reduction of isotope myocardial uptake at peak exercise, as compared to rest, in myocardial regions supplied by stenotic coronary artery branches (Fig. 14.14).

The three commercially available flow perfusion tracers, ^{201}thallium (^{201}Tl), and ^{99m}technetium-labelled sestamibi or tetrofosmin, have similar accuracies for the detection of IHD.

Table 14.5 Pre-test and post-test exercise stress test likelihood of ischaemic heart disease, according to chest pain features, sex and age

Age (years)		Typical angina		Atypical angina		Non-anginal chest pain

Values represent the percentage of patients found to have significant obstructive coronary atherosclerosis at angiography. Adapted from Isner and Asahara [85].

Published figures of sensitivity and specificity for the diagnosis of coronary disease vary widely and depend upon the characteristics of the population studied (e.g. gender, presenting symptoms, medication, presence of previous infarction, etc.), the imaging technique used (planar or SPECT, qualitative or semi-quantitative analysis) and the experience of the centre. Overall, exercise myocardial scintigraphy is more sensitive than EST for IHD detection, while the specificity of the two tests have been found to be similar. Using SPECT imaging, sensitivity and specificity can be as high as 91% and 89%, respectively [30]. However, the average sensitivity and specificity of exercise ^{201}Tl-SPECT, uncorrected for referral biases, are approximately 89% and 76%, respectively, for qualitative analysis, and 90% and 70%, respectively, for quantitative analysis [105].

Athough scintigraphic exercise stress tests might be considered as an alternative to standard EST to detect ischaemia, they are more expensive and time-consuming, and less cost-effective. Thus, for diagnostic purposes they are only indicated in patients with non-conclusive results of ECG-EST or when ECG is not interpretable (Table 14.4).

Furthermore, scintigraphic studies are more accurate than EST in predicting the presence of multivessel IHD and in detecting the location and extent of myocardial ischaemia [112,113]. Thus, they can be indicated when this information is important.

Pharmacological stressors can be used as an alternative to exercise in patients who are unable to exercise adequately (e.g. elderly patients or patients with peripheral vascular disease or those limited by dyspnoea) [114].

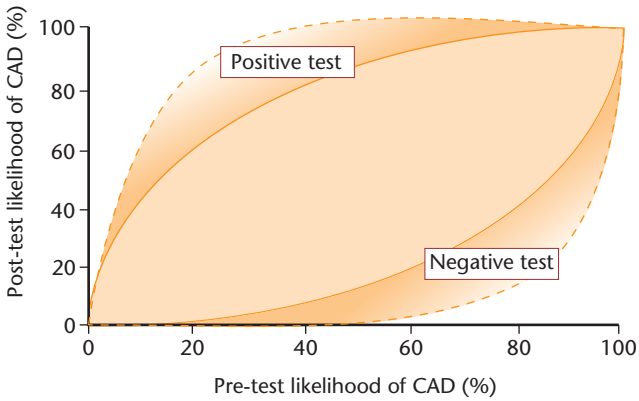

Figure 14.13 The relationship between pre-test probability of obstructive coronary artery disease and the post-test probability of the disease according to the result of a diagnostic non-invasive test with a sensitivity and specificity of 75% (solid lines) and a test with a sensitivity and specificity of 90% (dashed lines). In the former condition, it can be seen that, in the case of a positive test (upper solid line), the probability of disease becomes sufficiently high (50%) only when pre-test probability is at least 20%, and progressively increases with the increase of the pre-test probability. On the other hand, if pre-test probability is elevated, the probability of disease remains high, even in the case of a negative test (bottom solid line). Diagnostic accuracy improves significantly with a test with a very high sensitivity and specificity; indeed, in the case of a pre-test probability of 20%, such a test is associated with a positive predictive value of disease of 85%. However, it can be observed that, in this case also, when pre-test probability is very low (e.g. 5%) a positive test is associated with a presence of disease of only 45% (upper dashed line). At the other extreme, if the pre-test probability is high, post-test probability remains high even in the presence of a negative test (bottom dashed line). Adapted from Epstein [108].

They include the sympathetic agonist dobutamine, which causes an increase of myocardial oxygen consumption simulating physical exercise, and the arteriolar vasodilators dipyridamole and adenosine, which cause subendocardial underperfusion in myocardial regions supplied by stenotic coronary artery branches, because of coronary blood-steal phenomenon.

The diagnostic accuracy with pharmacological stressors has been reported to be similar to that with exercise [115]. The latter, however, is preferable because of the more obvious relation of exercise levels with real-life activities and to the additional diagnostic and prognostic information provided by the results of exercise stress per se.

Radionuclide angiography has been used in previous years to diagnose obstructive IHD, but it has now fallen out of favour because it adds no relevant diagnostic information to that provided by other non-invasive tests.

Echocardiographic stress tests Exercise echocardiography is an alternative to exercise myocardial perfusion scintigraphy as a second-tier test to standard ECG-EST, presenting similar indications and advantages, including a more reliable diagnosis of multivessel disease and location of myocardial ischaemia [116]. Its indications as a real first-step alternative to ECG-EST are similarly doubtful (Table 14.4).

Diagnosis of IHD on echocardiography is based on the detection of stress test-induced reversible regional left ventricular wall motion abnormalities. Compared to scintigraphy, inconveniences include poor image quality in about 15% of patients, higher operator-dependent interpretation, lower sensitivity (in particular for single-

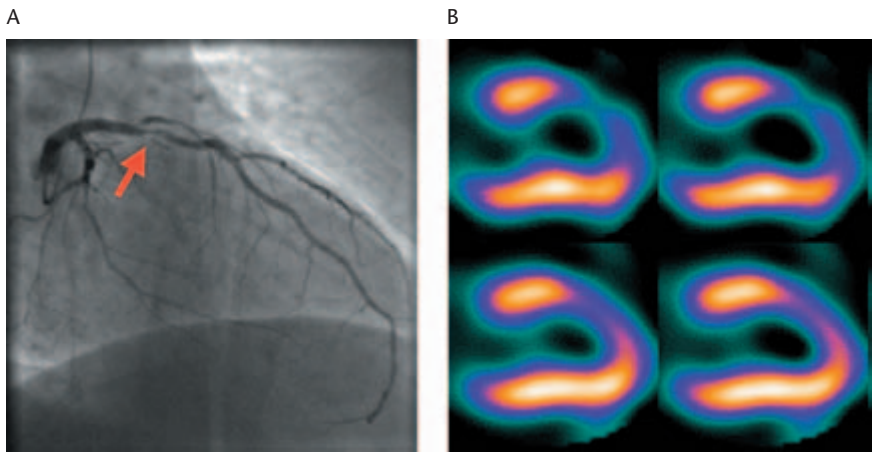

Figure 14.14 (A) severe stenosis is present in the left anterior descending coronary artery (arrow) at coronary angiography. (B) Single positron emission computed tomography (SPECT) identifies the ischaemic area as an exercise stress-induced perfusion defect (upper panels) obtained by either ^{99}technetium-labelled MIBI (left) or ^{201}thallium (right). Images at rest (bottom panels) show partial redistribution of radioisotopes. Taken together, these findings indicate the presence of a previous antero-apical myocardial infarction with inducible myocardial ischaemia in the peri-infarct region. (Courtesy of Dr Paolo Marzullo, Laboratory of Nuclear Cardiology, CNR Institute of Clinical Physiology, Pisa, Italy.)

vessel disease of the left circumflex coronary artery), the need for special training for a correct performance and interpretation, and more difficult assessment of ischaemia in the presence of basal left ventricular wall motion abnormalities. The inability to image at peak exercise is only a minor disadvantage because contractile abnormalities do not usually normalize immediately after peak exercise.

Exercise echocardiography, however, also has some advantages over exercise perfusion scintigraphy, including a slightly higher specificity, the possibility of a more extensive evaluation of cardiac anatomy and function, greater availability, lower cost, and a greater safety (being free of radiation exposure).

Pharmacological stressors are used more frequently than exercise in echocardiography. Indications and stressors for echocardiography are the same as those for pharmacological scintigraphic stress tests. In patients with negative tests, however, atropine is often added, either to dobutamine (especially in patients on beta-blockers) or to dipyridamole, to increase heart rate and the sensitivity of the test.

In a direct comparison of the different stress tests, sensitivity of exercise and dobutamine echocardiography for the diagnosis of obstructive coronary artery disease was similar, whereas sensitivity of dipyridamole echocardiography was lower and specificity did not differ among tests [117].

Ambulatory ECG Holter monitoring Holter monitoring may reveal myocardial ischaemia in up to 10–15% of patients with stable angina who do not develop diagnostic ST-segment depression during exercise testing [118]. This can occur in patients in whom coronary vasoconstriction plays an important role in the pathogenesis of myocardial ischaemia. Accordingly, ECG monitoring may be indicated for diagnostic purposes in a limited number of patients with symptoms suggestive of dynamic stenosis or coronary vasospasm.

Electron beam CT This allows the accurate detection and quantification of coronary artery calcifications, which correlate, through the elaboration of a calcium score, with the severity of coronary artery disease. However, its role in the diagnostic work-up of IHD remains doubtful [119].

Multislice CT angiography CT angiography with peripheral injection of contrast medium is an attractive technique for the non-invasive detection of coronary stenoses. However, its diagnostic accuracy is still uncertain and its routine use cannot be recommended yet [120].

Table 14.6 Indications for coronary angiography

To establish diagnosis
- Typical angina in patients with negative results of non-invasive stress tests
- Unexplained life-threatening ventricular arrhythmias or resuscitated sudden death
- Valvular or congenital heart disease in candidates for cardiac surgery in patients at moderate to high risk of ischaemic heart disease
- Need to establish the diagnosis for clinical or occupational reasons in patients at moderate to high risk of ischaemic heart disease

In candidates for myocardial revascularization
- Severe stable angina (Class 3 or 4 of CCS classification) despite optimal medical therapy
- Mild to moderate stable angina (CCS class 1 to 2) associated with high-risk criteria for adverse outcome on non-invasive testing*
- Mild to moderate angina in patients who are being considered for major non-cardiac surgery, especially vascular surgery (repair of aortic aneurysm, femoral bypass, carotid endarterectomy)
- Recurrence of angina pectoris in patients previously submitted to myocardial revascularization

*See Table 14.7. CCS classification, Canadian Cardiovascular Society Classification.

Invasive diagnosis

By definition, obstructive IHD is ultimately diagnosed by documenting flow-limiting coronary artery stenosis at angiography. Yet, because of the small, but definite, risk of complications and its cost, coronary angiography cannot be recommended as a routine diagnostic procedure to assess chest pain.

Coronary angiography is indicated in the diagnostic work-up in the following situations (Table 14.6):
- typical angina in patients with negative results of non-invasive stress tests;
- unexplained life-threatening ventricular arrhythmias or resuscitated sudden death;
- valvular or congenital heart disease in candidates for cardiac surgery with moderate to high risk of IHD;
- need to establish the diagnosis for clinical or occupational reasons (e.g. activities which would expose the patient himself and/or other people to significant risks in the case of an occurrence of acute ischaemic events) in patients with moderate to high risk of IHD.

Coronary angiography should not be performed in:
- anginal patients who refuse revascularization; and
- anginal patients whose symptoms are well controlled

by treatment and are not candidates for myocardial revascularization, according to prognostic stratification based on non-invasive investigations.

Prognosis and risk stratification

On average, the prognosis of stable angina is reasonably good. Annual mortality is < 2% and occurrence of myocardial infarction is also low [105]. It is possible, however, to identify subsets of patients who are at lower risk and subsets who are at higher risk of major coronary events.

Symptoms, resting ECG and chest X-ray The severity and frequency of chest pain, as expressed by Canadian Cardiovascular Society (CCS) classification, have prognostic implications. Indeed, a low anginal threshold is usually associated with severe coronary flow reserve reduction [121]. Symptoms of acute left ventricular dysfunction during angina, possibly indicating extensive myocardial ischaemia, also predict a worse outcome. However, the relationship between symptoms and IHD severity is less than optimal, thus limiting the value of symptoms for predicting clinical outcome.

The presence of abnormalities on standard 12-lead ECG (i.e. Q waves, persistent ST-T wave abnormalities) and left ventricular enlargement or pulmonary venous congestion on chest X-ray are also associated with a poorer outcome [122].

Non-invasive tests In patients with stable angina, the most important non-invasive prognostic markers include left ventricular function, physical capacity and severity and extent of coronary atherosclerosis. Left ventricular function can be easily assessed by two-dimensional echocardiography (or by radionuclide angiography). Good left ventricular function is usually associated with a good prognosis. Below 40%, further reductions of left ventricular ejection fraction are associated with an exponential increase in mortality [123]. Physical capacity and severity and extent of coronary atherosclerosis can both be assessed by EST. Thus, EST is the key test for risk stratification of patients with stable angina, being also of paramount importance for management decisions. A good effort tolerance in the absence of ischaemia is associated with a good outcome [124]. Indeed, in the Coronary Artery Surgery Study (CASS) registry, completing stage 2 of the Bruce protocol on treadmill EST, in the absence of ischaemia, was associated with a yearly mortality < 1%, even in the absence of treatment with antiplatelet agents and statins. Notably, very low mortality was also observed in patients who went beyond stage 4 of the Bruce protocol, despite three-vessel disease [125].

The occurrence of myocardial ischaemia during exercise, in particular if it appears at low workload and is associated with a low ejection fraction, portends an ominous prognosis [109]. High-risk features of EST are summarized in Table 14.7.

Composite scores, which take into account symptoms, ECG signs of ischaemia and other exercise parameters, have been proposed to improve prognostic stratification of stable angina patients. The Duke Treadmill Score [126], which has been prospectively validated in large cohorts of patients, is based on exercise capacity (as exercise duration), severity of myocardial ischaemia (as maximal ST-segment depression) and appearance of angina, and is calculated from the following formula: exercise duration (Bruce protocol, in min)—(5 × ST-segment depression during exercise test, in mm)—(4 × angina index), where the angina index assumes a value of '0' if there is no angina induced by exercise, '1' if non-limiting angina occurs during exercise, and '2' if angina is the reason for stopping the test. Among patients with suspected IHD, the two-thirds of patients with a Duke score > 5 had a 4-year survival rate of 99% (average annual mortality rate 0.25%), whereas, at the other extreme, the 4% of

Table 14.7 High-risk findings of major non-invasive stress tests

Exercise ECG	ST-segment depression ≥ 1 mm at Bruce stage 1 Slow ST depression recovery (> 5 minutes) after exercise Achievement of workload < 4 METs Abnormal blood pressure response Duke treadmill score ≤ –11
Stress myocardial scintigraphy	Multiple and/or large and/or severe reversible perfusion defects Stress-induced left ventricular dilatation Stress-induced lung thallium-201 uptake
Stress echocardiography	Multiple and/or large and/or severe regional wall motion abnormalities Stress-induced left ventricular dilatation

MET, Metabolic equivalents.

patients, with a score of –11 or less, had a 4-year survival rate of 79% (average annual mortality rate 5%).

In patients who can undergo exercise and exhibit an interpretable ECG, the additional prognostic value of imaging stress tests compared to that of EST is clinically limited [112]. The extent of perfusion defects and/or signs of left ventricular dysfunction on radionuclide scintigraphic tests and the extent of left ventricular wall motion abnormalities on echocardiography, induced by either exercise or pharmacological stressors, have been found to be associated with an adverse clinical outcome in stable IHD patients (Table 14.7) [127,128].

Frequent transient ischaemic episodes during daily life are also associated with a worse prognosis [129], although the information this finding adds to EST is not clear.

Invasive tests It is important to recognize that diagnostic techniques able to identify vulnerable plaques responsible for future acute coronary events are still lacking [130].

Several prognostic indices have been proposed to relate disease severity to the risk of subsequent cardiac events. The simplest and most widely used is the classification into one, two, three, and left main vessel disease. Recently, the extent of coronary atherosclerosis assessed at angiography has been found to be a better predictor of outcome than its severity (i.e. number of coronary artery branches presenting critical stenoses) [131]. Thus the higher mortality rates in patients with multivessel disease, as compared to those with one-vessel disease, are probably the consequence of a higher number of mildly stenotic, or even non-stenotic, plaques that are potential sites for acute coronary events.

The major current focus for risk stratification is on non-invasive techniques, the rationale being the identification of patients in whom revascularization might decrease mortality. Randomized trials of coronary bypass demonstrated that patients randomized to initial surgery had a lower mortality rate than those treated medically only if they were at moderate to high risk for major cardiac events. Accordingly, the use of coronary angiography to identify patients whose prognosis can be improved by revascularization procedures is inappropriate when the estimated annual mortality rate is not higher than 1%; in contrast, it could be appropriate for patients whose mortality risk is greater than 3% [132].

Coronary angiography is indicated for prognostic reasons in patients who are candidates for myocardial revascularization if they present with the following (Table 14.6):

- severe stable angina (CCS class 3 or 4) despite optimal medical treatment;
- mild to moderate stable angina (CCS class 1 to 2) associated with high-risk criteria for adverse outcome on non-invasive testing;
- mild to moderate angina in patients who are candidates for major non-cardiac surgery, especially vascular surgery (repair of aortic aneurysm, femoral bypass, carotid endarterectomy);
- recurrence of angina pectoris after myocardial revascularization.

Vasospastic angina

Prinzmetal's variant angina should be suspected in patients with angina occurring exclusively or predominantly at rest, without any apparent triggering cause. Angina is usually of short duration (2–5 minutes), sometimes recurs in clusters, frequently shows a typical circadian pattern, with a more frequent occurrence in the early morning or in the night hours, and promptly responds to short-acting nitrates. Effort tolerance is often well preserved, but exercise is a trigger of coronary artery spasm in about 25–30% of patients.

The clinical diagnosis is confirmed by the documentation of transient ST-segment elevation (from 1–2 mm up to 20–30 mm) on the ECG during an anginal episode (Fig. 14.15). When it is difficult to record standard ECG during angina, variant angina can usually be diagnosed by ambulatory ECG monitoring over 24–48 hours; this also allows assessment of the total ischaemic burden and the daily distribution of ischaemic episodes [133]. EST can allow the diagnosis of vasospastic angina in a minority of patients by inducing reversible ST-segment elevation during or immediately after the effort. The latter is typically prevented by pre-test assumption of short-acting nitrates.

In some patients a pharmacological provocation test of coronary spasm is necessary to confirm the diagnosis. Provocation tests of spasm can be performed non-invasively, under careful clinical and ECG monitoring, by administration of intravenous ergonovine, which induces typical symptoms and ECG changes. Alternatively, intracoronary administration of ergonovine or acetylcholine can be used to induce spasm during coronary angiography, which allows a direct documentation of coronary spasm (Fig. 14.16). The invasive procedure is warranted in patients in whom the use of systemic provocation tests of coronary spasm are associated with an increased risk of refractory spasm (e.g. prolonged angina, delayed response to short-acting nitrates). Coronary angiography also allows the assessment of coronary vessels. Critical coronary stenoses are found in about half of the patients.

In some patients severe ventricular tachyarrhythmias may develop during ischaemic episodes caused by

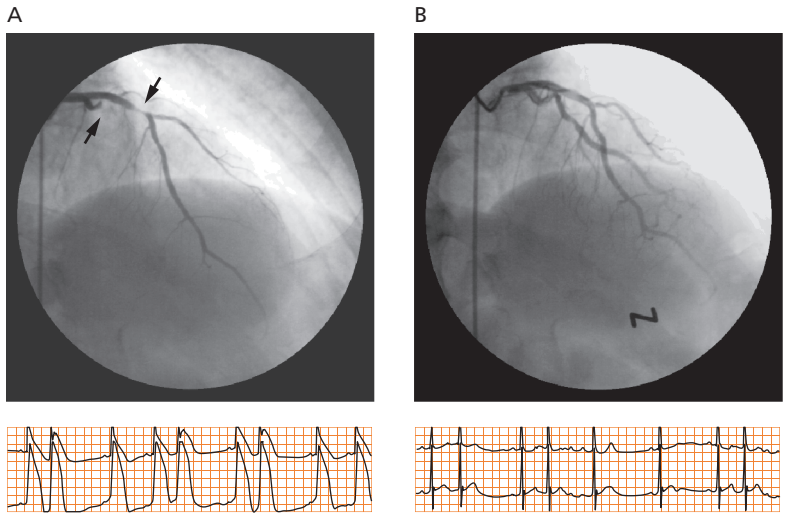

Figure 14.15 Documentation of occlusive coronary artery spasm of both left anterior descending coronary artery and circumflex coronary artery (arrows) following intracoronary administration of 16 μg of ergonovine in a patient with typical variant angina (left upper panel). Coronary spasm promptly resolves after intracoronary administration of 2 mg isosorbide dinitrate (right upper panel). The electrocardiogram shows marked ST-segment elevation up to 20 mm (left bottom panel) which resolves after administration of nitrates (right bottom panel).

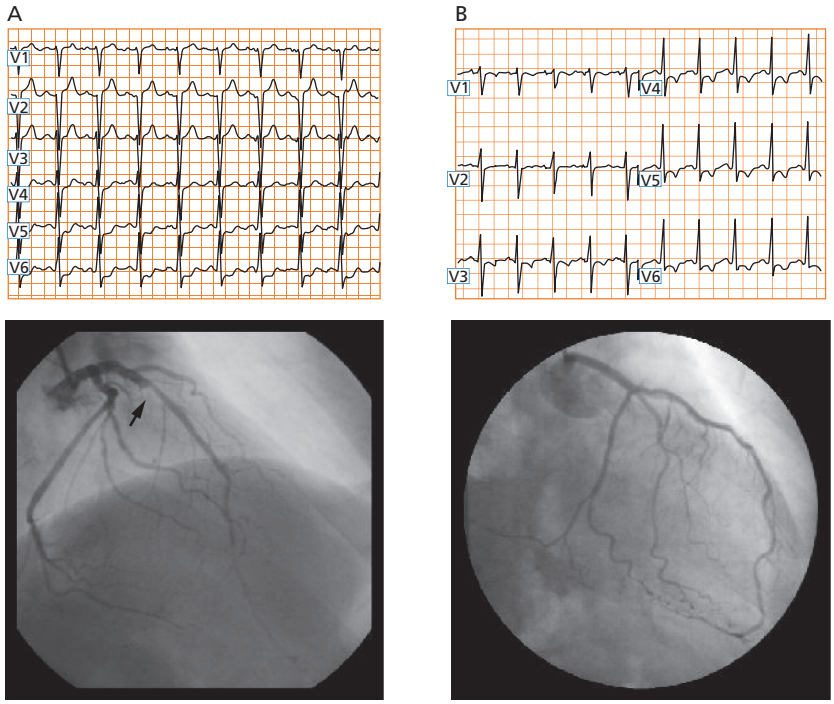

Figure 14.16 'Ischaemic' ST-segment depression (~1.5 mm) in anterior-lateral leads induced by treadmill exercise stress test (Bruce protocol) in two patients with stable effort angina (upper panels). The morphology and severity of ST-segment depression and the workload of exercise (Bruce stage 2) is similar in the two patients. Yet, in patient A (bottom left panel) coronary angiography shows a tight stenosis of proximal left anterior descending coronary artery (arrow), whereas in patient B (bottom right panel) angiography shows angiographically normal coronary arteries (syndrome X patient).

coronary spasm. These patients may present syncope or presyncope associated with angina and are at risk of sudden death [134]. The causes of the individual susceptibility to ventricular tachyarrhythmias are poorly known, but there is no strict relationship with the severity of ischaemic episodes. Severe bradyarrhythmias (sinus arrest, atrioventricular block) may also occur, in particular in patients with inferior transmural ischaemia.

Prognosis of variant angina, in early studies, was found to mainly depend on the presence of multivessel IHD [135]. Subsequent studies, however, showed that sudden death and cardiac arrest, as well as acute myocardial infarction, may occur also in patients with normal or near-normal epicardial arteries [133].

Prognosis of variant angina is strictly dependent on the time of diagnosis. Indeed, most events occur within days or months of symptom onset. Thus a prompt diagnosis is mandatory to initiate drug therapy with vasodilators, in particular with calcium antagonists, which prevent recurrence of spasm in about 90% of patients and have been demonstrated to improve long-term prognosis [136].

High risk factors include multivessel spasm, severe ischaemia-related bradyarrhythmias or tachyarrhythmias, prolonged spasm, in particular those not promptly responding to nitrates, and, finally, spasm that is refractory to high doses of calcium antagonists.

Cardiac syndrome X

Syndrome X is typically characterized by: (1) angina predominantly occurring on effort and typical enough to suggest IHD; (2) 'ischaemia-like' ST-segment depression during angina or provocation tests (Fig. 14.16); (3) normal coronary arteries at angiography; (4) absence of epicardial coronary artery spasm and of known causes of microvascular dysfunction.

There is still debate as to whether microvascular dysfunction is the cause of ischaemia and chest pain in cardiac syndrome X (see above in this chapter). However, there is consensus that enhanced pain perception is present in these patients. It remains controversial, however, whether increased cardiac pain perception is caused by a general nociceptive abnormality related to a cortical defect or rather by a specific peripheral cardiac neural alteration [137,138].

In most cases the features of chest pain do not allow us to distinguish patients with cardiac syndrome X from those with obstructive coronary atherosclerosis. Some features of angina, however, strongly suggest syndrome X, including a prolonged duration of chest pain after interruption of effort and a slow or inconstant response to sublingual nitrates.

Non-invasive diagnosis of syndrome X is not easy. Physical examination is typically unremarkable, whereas EST shows results similar to those observed in patients with obstructive IHD (Fig. 14.16). Exercise myocardial perfusion scintigraphy is positive in about half of the patients [88]. The absence of left ventricular contractile abnormalities during echocardiographic stress test (dipyridamole, dobutamine, or exercise), despite the induction of chest pain and ST-segment depression [139], strongly suggests cardiac syndrome X, as does the lack of improvement of exercise-induced angina and ST-segment changes by short-acting nitrates [140].

Prognosis of syndrome X has consistently been shown to be excellent, as no increase in the risk of major cardiac events has been reported [141]. A significant impairment of left ventricular function at follow-up has been found in the small subset of patients who present with resting or stress-induced left bundle branch block, who, however, are considered to be latent cases of dilated cardiomyopathy. Notably, recent data suggest that evidence of endothelial dysfunction in syndrome X women is associated with the development of clinically silent, but angiographically detectable, coronary artery disease at long-term follow-up [142].

Despite the excellent prognosis, several patients with syndrome X show persistence and even worsening of symptoms over time, with angina attacks becoming more frequent, severe, prolonged and poorly responsive to drug therapy. Symptoms may considerably restrict the patient's daily activities and lead to frequent non-invasive, and even invasive, diagnostic investigations, and to emergency room and hospital admissions. Thus, quality of life in these patients can be severely impaired, making syndrome X a socially and economically relevant cardiac disease [88].

Ischaemic cardiomyopathy

In a number of cases the clinical presentation of chronic stable IHD is dominated by symptoms and signs of left ventricular dysfunction, a condition defined as ischaemic cardiomyopathy [143]. This is the most common form of dilated cardiomyopathy and most often occurs in patients with a history, or evidence, of previous myocardial infarction [144]. Concomitant stable angina can be present in some of these patients.

Ischaemic cardiomyopathy can result from a single large infarction (usually > 20% of myocardial mass) or from multiple smaller infarctions, followed by progressive ventricular dilatation and dysfunction, which may develop over a number of years. The reasons why for a similar extent of myocardial infarction some patients, but not others, develop severe myocardial dysfunction are still largely debated [145].

Notably, some patients may have suffered from one or more silent myocardial infarctions, revealed by pathological Q waves on a routine ECG, developing symptoms of heart failure as the first manifestation of IHD. In other patients there is no clinical and ECG evidence of previous myocardial infarction, suggesting progressive ischaemia-related loss of myocytes, possibly involving apoptosis [62].

Symptoms of left ventricular dysfunction typically include dyspnoea on effort, paroxysmal nocturnal dyspnoea, fatigue, weight gain and reduced urinary output. Physical examination may reveal signs of heart failure, including a reduced first heart sound, presence of a third sound, ankle oedema and pulmonary rales. A systolic murmur can be present when mitral regurgitation occurs as a consequence of left ventricular dilatation or papillary muscle dysfunction.

Echocardiography shows left ventricular dilatation and reduced ejection fraction and, frequently, severe diastolic dysfunction. Coronary angiography usually exhibits multivessel coronary artery disease. In some patients the

Table 14.8 Non-invasive techniques for the assessment of myocardial viability

Test	Advantages	Limitations
SPECT imaging	High sensitivity Possibility of FDG imaging Quantification of left ventricular function Predictive of clinical outcome	Areas of attenuation as non-viability Impossibility to differentiate endocardial and epicardial viability No absolute measure of blood flow Less specific than dobutamine echocardiography and less sensitive than PET
PET imaging	Absolute quantification of myocardial blood flow and glucose utilization In conjunction with euglycaemic clamp allows interindividual and intercentre comparisons of glucose uptake More sensitive than other techniques No attenuation problem Predictive of outcome	Less specific than dobutamine echocardiography and CMR Not ideal to differentiate endocardial and epicardial viability High cost and limited availability
Dobutamine echocardiography	Higher specificity than nuclear techniques Assessment of both viability and ischaemia Assessment of left ventricular function Predictive of outcome Low cost, wide availability	Poor acoustic window in some patients Lower sensitivity than nuclear tests More operator-dependent
Contrast echocardiography	Simultaneous assessment of microvascular integrity and systolic thickening Better examination of extent of viability than echocardiography Possibility to discriminate subendocardial from subepicardial perfusion	Poor acoustic window in some patients Attenuation problems
Contrast CMR	Accurate measurement of wall thickness Assessment of microvascular integrity Assessment of transmural extent of myocardial necrosis Good sensitivity and specificity for viability detection	Need for faster automated techniques Information not in real time Patients with pacemaker or defibrillator* or who are claustrophobic cannot be studied High cost, limited availability

FDG, fluorodeoxyglucose; CMR, cardiac magnetic resonance; PET, positron emission tomography; SPECT, single-photon emission computerized tomography.
*Recent data, however, suggest that patients with electronic devices, including pacemakers, defibrillators and neurostimulators, can be studied by CMR without any significant increase in adverse events [153].

extent and severity of coronary atherosclerosis is much less than predicted by left ventricular dysfunction, thus suggesting that the latter could mainly be caused by a primary myocardial disease, such as myocarditis [146].

In patients with ischaemic cardiomyopathy it is important to establish the presence and extent of hibernated myocardium. Non-invasive imaging methods to assess myocardial metabolic activity, membrane integrity and inotropic reserve are ideally suited for this assessment. Indeed, nuclear techniques allow the identification of viable but dysfunctional myocardial regions, as viable myocardial fibres have intact cell membranes which take up specific labelled tracers like ^{201}Tl (used with SPECT) or ^{18}F-labelled deoxyglucose (used with positron emission tomography), while dobutamine echocardiography identifies regional inotropic reserve and contrast echocardiography allows the assessment of microvascular integrity. Contrast-enhanced CMR is emerging as an important method for viability assessment. The relative merits of nuclear techniques, echocardiography and CMR for myocardial viability assessment are summarized in Table 14.8. Cost, availability and local expertise will always affect, however, the clinical popularity of a given diagnostic approach [147].

The assessment of myocardial viability has relevant therapeutic and prognostic implications, as myocardial revascularization seems to improve symptoms and perhaps prognosis in patients exhibiting viability of several

hibernated myocardial regions, but not in patients without evidence of myocardial hibernation. A word of caution, however, is needed as, in the absence of properly designed randomized prospective trials, these recommendations are merely based on retrospective studies [148].

As already highlighted, ischaemic cardiomyopathy is associated with a poor outcome, compared to stable IHD without severe impairment of left ventricular function. The reasons for the worse clinical outcome include higher risks of (1) life-threatening ventricular arrhythmias, (2) severe left ventricular dysfunction during recurrence of ischaemia or a new myocardial infarction, (3) potentially fatal systemic complications, and (4) iatrogenic complications as a result of the multidrug therapy.

Among IHD patients with ischaemic cardiomyopathy, clinical outcome might be improved by implantation of an automated cardiac defibrillator [149]. However, efforts to identify patients at higher risk of sudden death are warranted because of the high cost of the device. Predictors of sudden death include ventricular arrhythmias, late potentials on signal-averaged ECG, and, finally, depressed heart rate variability [150], heart rate turbulence [151] and baroreflex sensitivity [152], all expressions of an impairment of cardiac sympatho-vagal balance.

Personal perspective

Chronic IHD has three classic clinical presentations, i.e. stable angina, vasospastic angina and ischaemic cardiomyopathy. In addition, a fourth clinical manifestation exists, cardiac syndrome X, which is characterized by typical angina with a normal coronary artery, and the pathophysiology of which remains under debate. Transient myocardial ischaemia results from the complex interplay of different factors including flow-limiting stenoses and abnormal vasomotion of the epicardial coronary arteries as well as dysfunction of the coronary microvasculature. The relevance of pathogenetic components is different in the different clinical syndromes. The anatomic assessment of coronary artery disease still strongly relies on coronary angiography. Improvements which were unthinkable just a few years ago are being made in non-invasive imaging modalities, including multislice computed tomography and cardiac magnetic resonance, which will probably substitute diagnostic angiography in the years to come. Furthermore, functional information provided by these new imaging modalities plays a key role in the assessment of microvascular dysfunction and in the quantification of hibernated myocardium in ischaemic cardiomyopathy. Notably, the quality of life of patients with chronic IHD, who do not need revascularization procedures for prognostic purposes or in whom myocardial revascularization is not feasible, is frequently limited by angina severity. The latter is modulated by central processing of afferent stimuli originating from the heart, resulting in silent ischaemia at one extreme or in enhanced pain perception at the other extreme. A better knowledge of the molecular mechanisms that are responsible for the functional alterations contributing to the determination of the severity of angina in each individual patient is strongly warranted to develop new forms of personalized treatments.

15 Management of Angina Pectoris

Kim Fox, Henry Purcell, John Pepper and William Wijns

Summary

The aims of treatment of chronic stable angina are to minimize or abolish symptoms and also to improve prognosis by preventing myocardial infarction and death. Major advances have been made in antianginal treatment since organic nitrates were first used clinically over a century and a quarter ago. Current drugs may afford prophylaxis as well as relief of symptoms and several agents appear to modify the underlying atherosclerotic disease process and improve prognosis. While much of the decline in ischaemic heart disease (IHD) may be explained by improved treatments, more than half of the decline is attributed to reductions in major risk factors, principally smoking [1]. This chapter reviews life-style, pharmacological and interventional treatments for secondary prevention and for symptomatic treatment of patients with chronic stable angina.

Interventions for secondary prevention

Smoking

Smoking is responsible for 50% of all avoidable deaths and half of these are due to cardiovascular disease [2]. Smoking already kills 1 in 10 adults and is expected to cause 10 million deaths annually world-wide by 2030 [3]. Long-term smoking is associated with impaired endothelium-dependent coronary vasodilatation [4]. Smoking-enhanced platelet aggregation and platelet thrombus formation may be important mechanisms for the increased risk of acute coronary events in smokers [5].

While quitting smoking is difficult, estimates of risk reduction from intervention programmes range from 18 to 65% [6]. Counselling should be available to all smokers on the benefits of smoking cessation in terms of cardiovascular disease (and cancer) prevention. Choice of pharmacotherapy for smoking cessation is dependent on the clinical history of the patient and patient preference. Nicotine replacement therapy (NRT) and sustained-release bupropion (bupropion SR) are first-line treatments for smoking cessation. The cardiovascular effects of nicotine, such as increases in heart rate with small rises in blood pressure, have provoked some concerns about the use of NRT in patients with IHD. However, nicotine patches have been used successfully in heart disease patients without any adverse effects [2]. Similarly, it is suggested that NRT may be initiated as early as 2–3 days after acute myocardial infarction and that it may be used in all patients with angina and cardiac arrhythmias. The growing consensus is that NRT is preferable to continued smoking among patients with stable IHD and that interventions such as NRT should be adopted sooner rather than later. In a randomized multicentre trial [7] of bupropion in smokers with cardiovascular disease, more than twice as many smokers had quit smoking at 1 year with this compound compared with placebo. The safety profile of the drug was similar to that seen in the general smoking population, the commonest adverse effects being insomnia and dry mouth. While further data are required, it is likely that bupropion is a valuable medication for patients with cardiovascular disease. It may be appropriate for heart disease patients to sign a

consent form to agree to undertake smoking cessation therapy following explanation of the immense benefits and the marginal risks involved.

Several novel pharmacological approaches to smoking cessation are currently being investigated including selective blockade of the endocannabinoid system, which is believed to play an important role in energy expenditure and tobacco dependence.

Dyslipidaemia and diet

Dietary modification is an essential part of the management of patients with coronary disease. A diet high in unsaturated and low in saturated fats ('Mediterranean diet') should become part of the life-style of such patients and their families. Patients with coronary disease should aim to bring their total cholesterol to 4.5 mmol/l or less, with low-density lipoprotein cholesterol (LDL-C) 2.5 mmol/l or less; a high-density lipoprotein cholesterol (HDL-C) greater than 25% of total cholesterol should be sought [2]. However, despite an excellent diet, these targets may often not be achieved, in which case pharmacological therapy will be needed.

First-line pharmacological treatment is with a statin, described later; indeed there is a growing consensus that statin treatment should be initiated in all patients irrespective of the level of cholesterol, and treatment titrated to achieve at least the recommendations above.

Other lipid-lowering therapies to consider in patients with angina who have low HDL-C and other features of the metabolic syndrome where LDL-C is below the treatment threshold according to guidelines include fibrates (e.g. bezafibrate, fenofibrate). Fibrates might also be considered when patients are intolerant of statins. Fibrates are especially beneficial in patients with a combination of hypertriglyceridaemia and low HDL-C [8]. Ezetimibe, a cholesterol absorption inhibitor that inhibits passage of cholesterol across the intestinal wall, may also be considered in patients who are intolerant of statins. It may also be co-administered with a lower dose of statin to improve tolerability [9]. A further option is niacin, which has been shown to confer a long-term survival benefit in patients recovering after myocardial infarction [10]; a more modern extended-release niacin preparation appears to be better tolerated than older formulations, which produced a high incidence of adverse effects, e.g. flushing and other cutaneous reactions.

Hypertension and diabetes

Hypertension contributes to all of the major atherosclerotic cardiovascular disease outcomes, increasing risk, on average, two- to three-fold [11]. Coronary disease is the most lethal and common consequence. Hypertension is also the most consistently powerful predictor of stroke. The risk of a recurrent event in patients with IHD is significantly affected by the blood pressure level [12]. Meta-analysis of 61 prospective observational studies has shown that even a 2-mmHg decrease in systolic blood pressure can produce a 7% reduction in risk of IHD mortality and a 10% reduction in risk of stroke mortality [13]. Treatment with any commonly used blood pressure-lowering regimen reduces the risk of total cardiovascular events and larger reductions in blood pressure produce larger reductions in risk [14]. Choice of blood pressure-lowering agent is reviewed in recent guidelines [12].

Diabetes is a cardiovascular disease equivalent and should be managed as such, the assumption being that all patients with type 2 diabetes already have vascular disease [15]. The risk of myocardial infarction in patients with diabetes and no evidence of IHD is similar to that of patients without diabetes who have had a myocardial infarction. Outcomes are worse in diabetic patients for all manifestations of IHD. For patients with known coronary disease and diabetes, rates of death approach 75% over 10 years [16]. Risk of cardiovascular events is further amplified in patients with the metabolic syndrome, where insulin resistance is seen as a key characteristic [17]. Aggressive medical management directed at optimizing glucose and blood pressure control, correcting dyslipidaemia and inhibiting platelet function reduces the likelihood of adverse cardiovascular events.

Other factors

The multifactorial nature of IHD and the multiplicative effect of risk factors, which also include obesity, sedentary life-style, psychosocial stress and so forth, make it important to assess the total cardiovascular risk in an individual patient and to take comprehensive action to address all risk factors.

Physical activity

Physical activity should be promoted for all, but for those with established IHD advice should be based on a preceding formal exercise test. The role of exercise alone in reducing cardiovascular events following myocardial infarction is not known but systematic reviews suggest that cardiac rehabilitation improves coronary risk factors and events in this population [18].

Stress and self-help programmes

Angina patients may also benefit from a self-help angina management programme. One such programme, which

consists of a patient-held 'work book' and audio-taped relaxation programme, has been shown to improve psychological, symptomatic and functional status of patients newly diagnosed with angina [19].

Psychological stress is a well-recognized trigger of myocardial ischaemia [20]. For these reasons stressful driving conditions should be avoided. Occupational stress is also common but pre-retirement patients should be encouraged to return to work and continue their occupation, with appropriate modifications if necessary.

Sexual activity and erectile dysfunction

Sexual intercourse may also become anxiety provoking, particularly for patients recovering after myocardial infarction. Studies have shown that stable, optimally treated angina patients are not at greater relative cardiovascular risk during coitus [21]. Men with cardiovascular disease are more likely to have erectile dysfunction than the general population and may be prescribed agents such as sildenafil (Viagra) or tadalafil (Cialis). One study has shown a lack of any important influence of sildenafil on the development of ischaemia [22], while a further study has shown that sildenafil is well tolerated and produces favourable trends in terms of exercise duration and time to angina on treadmill testing [21]. As dramatic decreases in blood pressure may occur with administration of nitrates within 24 hours of taking sildenafil, their combination is contraindicated.

Hormone replacement therapy

Although oestrogen has antiatherogenic properties, including the potential to improve the lipid profile, hormone replacement therapy is associated with an early increased risk of cardiovascular events. Available evidence suggests that hormone replacement therapy is not indicated for either primary or secondary prevention of IHD, and any potential long-term benefits in lipid profile will be exceeded with statin treatment [23].

Drugs to improve outcomes in angina (secondary prevention)

Antiplatelet agents

Aspirin is the prototypical platelet antagonist and has been available since the end of the nineteenth century. Aspirin was the first drug recognized to have important platelet-inhibitory effects. Its major antithrombotic effect is to irreversibly inhibit platelet thromboxane A2 synthesis, which has pro-aggregatory and vasoconstrictive properties. Aspirin's antiplatelet effects last for the life of the platelet (9–10 days). Aspirin is a mainstay in the treatment and prevention of vascular events. The efficacy of aspirin has been clearly demonstrated in the Antithrombotic Trialists' Collaboration meta-analysis [24]. Its ability to prevent platelet aggregation appears to be its predominant mode of action but a recent study shows that aspirin reduces the incidence and frequency of ischaemic episodes as well as systemic concentrations of haemostatic and inflammatory markers [25]. High-risk patients derive the most benefit from aspirin, with a proportional risk reduction in serious vascular events of 46% in those with unstable angina and 33% among those with stable angina. The benefits were clearly demonstrated in the Swedish Angina Pectoris Trial (SAPAT) [26]. This randomized double-blind trial compared aspirin 75 mg/day and placebo with concomitant treatment of sotalol (mean 160 mg/day) in over 2000 patients with stable angina over a mean period of 50 months. Compared with sotalol and placebo, the aspirin plus sotalol group had a 34% reduction in myocardial infarction and sudden death (P = 0.003). There was also a significant 22–32% reduction in vascular events, vascular death, stroke and total mortality in this latter group.

Daily low doses of aspirin (75–325 mg) seem to be as effective as higher doses for long-term administration, but in an acute setting 150 mg or upwards may be required. Thus aspirin 75 mg daily is the current recommended dose for prevention of serious vascular events in patients with established IHD [24]. There is a two-fold increase in the risk of upper gastrointestinal bleeding associated with aspirin use in the range 75–100 mg daily [27]. Aspirin should not be used in individuals without IHD in whom any potential benefits of therapy are outweighed by the small risk of gastrointestinal bleeding.

Up to one-quarter of individuals may exhibit 'aspirin resistance'. However, no test of platelet function is recommended in order to assess the antiplatelet effect of aspirin in the individual patient [27]. It is difficult to assess the clinical significance of *in vitro* platelet function studies. In patients with contraindications to aspirin or if they are non-responders (aspirin failures) who may experience a cardiac event while taking aspirin, and also in those intolerant of aspirin, clopidogrel 75 mg daily is a suitable alternative. Antiplatelet regimens are needed that are more effective than aspirin alone. Clopidogrel, a thienopyridine, acts by blocking adenosine diphospate (ADP)-dependent activation of platelets. Clopidogrel and ticlopidine are structurally related, although ticlopidine

use has now been eclipsed by clopidogrel as the former has a slower onset of antiplatelet effect and can cause bone marrow toxicity and other adverse effects. Clopidogrel has an established role in acute coronary syndrome (unstable angina and Non ST-segment elevation myocardial infarction (NSTEMI)) and in percutaneous coronary intervention (PCI). It has also recently been approved for use 'as early as possible after symptoms start . . .' in patients with ST segment elevation myocardial infarction (STEMI). The Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management and Avoidance (CHARISMA) study has established that there is no benefit overall of the combination of clopidogrel and aspirin in the long-term in patients with stable vascular disease. Adverse effects with clopidogrel are not dissimilar to aspirin but the frequency of severe rash is higher. Dipyridamole or anticoagulants such as warfarin or thrombin inhibitors are not indicated in stable angina.

Lipid-lowering therapy

Reduction of serum cholesterol is increasingly recognized as essential for the prevention of cardiac events in individuals with IHD. For patients with clinically established cardiovascular disease and diabetes, total plasma cholesterol should be < 4.5 mmol/l (175 mg/dl) and LDL-C < 2.5 mmol/l (100 mg/dl) [2]. Dietary intervention is an important initial treatment in patients with elevated lipids, but only modest reductions (3–5%) in total cholesterol have been achieved in general population studies. However, randomized trials have found that advising people with IHD to adopt a more Mediterranean diet, eating more fish (particularly oily fish), more fruit and vegetables, bread, pasta, olive oil and so forth, may result in a substantial survival benefit [28]. Concentrated fish oil, high in omega-3 fatty acids, reduces high triglyceride levels. One preparation (Omacor) has been shown to reduce sudden cardiac death by 45% when administered as a daily 1-g capsule in survivors of myocardial infarction [29].

There is a considerable body of evidence from randomized clinical trials with 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins, e.g. simvastatin, pravastatin) showing that they significantly improve survival, prevent myocardial infarction and reduce the need for costly hospitalizations and revascularization procedures in IHD patients with a range of cholesterol values. Key trials [30–33] of statins in secondary prevention are summarized in Table 15.1 [34]. Such findings support the view that therapy stabilizes lipid-rich atherosclerotic plaques of mild to moderate severity and therefore makes them less vulnerable to rupture. Intensive lipid lowering with a statin provides greater protection against death and cardiac events than does a standard regimen [35]. Statins appear also to exert anti-inflammatory and antithrombotic effects and may modulate endothelial dysfunction independently of their lipid-lowering effect.

Beta-blockers

Beta-adrenergic receptor antagonists (beta-blockers) reduce myocardial ischaemia, improve exercise tolerance and provide symptomatic relief in angina. Beta-blockers act predominantly by competitive inhibition of β-adrenoceptors, particularly β_1 receptors, which are more prevalent in the heart. Their principal antianginal actions are considered to be slowing of heart rate in response to exercise and emotion, and reducing cardiac output; thus myocardial oxygen demand is reduced and coronary blood flow is increased via increased filling time in diastole. They also reduce blood pressure in response to reductions in heart rate and contractility rather than by reducing peripheral resistance, which also conserves energy expenditure. The so-called cardioselective agents (e.g. atenolol and bisoprolol) bind to β_1 receptors and generally cause less frequent adverse effects such as bronchoconstriction and Raynaud's phenomenon, which are mediated by β_2-receptor blockade. However, β_1 selectivity is only a relative characteristic, and at moderate to high doses β_2-receptor blockade occurs with the cardioselective agents. Beta-blockers are then best avoided in patients with asthma or chronic obstructive airways disease but can be used effectively in patients with diabetes, although they may mask or prolong hypoglycaemia. The recently reported Glycemic Effects in Diabetes Mellitus: Carvedilol–Metoprolol Comparison in Hypertensives (GEMINI) trial [36] showed that carvedilol improved cardiovascular risk factors and stabilized glycaemic control, while worsening of glycaemic control was observed with metoprolol. Such findings highlight potentially important metabolic effects that exist between beta-blockers and which may have important consequences in patients with diabetes.

While they share general β-receptor blocking properties, beta-blockers have pharmacological differences (Table 15.2). For example, drugs that have intrinsic sympathomimetic activity (ISA), also called partial agonist activity (PAA), have less effect on resting heart rate and not only block β-receptors but also stimulate them, depending on the prevailing level of sympathetic activity. These agents cause less bradycardia and may offer advantages to patients who also have peripheral vascular

Table 15.1 Major statin clinical event trials in secondary prevention

disease, although they tend to be less effective in angina prophylaxis. About 15–20% of patients will not tolerate long-term use of beta-blockers. The most common adverse effects include fatigue, dizziness, weakness, depression and, particularly with the lipid-soluble agents, central nervous system problems such as vivid dreams and insomnia. Care must be taken to observe the contraindications to beta-blockade and it should be noted that sudden withdrawal of beta-blockers may occasionally result in rebound angina and an increase in cardiac events.

Meta-analysis of randomized controlled trials after myocardial infarction shows that beta-blockers reduce the odds of death by 23% in long-term trials and by 4% in short-term trials [37]. Most evidence is available for propranolol, timolol and metoprolol, and it cannot be assumed that prognostic benefit will be achieved with other agents; although atenolol is widely used, it has been inadequately evaluated in this setting. A recent meta-analysis of placebo-controlled trials of atenolol in hypertensives [38] suggests no advantage of the beta-blocker over placebo in terms of reducing all-cause cardiovascular mortality or myocardial infarction, and casts doubts about its suitability for hypertensive patients. Beta-blockers have become an important treatment for several supraventricular (e.g. atrial fibrillation) and ventricular (e.g. ventricular tachycardia) arrhythmias. Use of beta-blockers in heart failure is now firmly established but there are no large long-term studies assessing their effect on mortality in patients with angina pectoris [39].

Calcium antagonists

Calcium antagonists are structurally and pharmacologically heterogeneous compounds that share a common property: they inhibit entry of calcium into cells resulting in vasodilatation of vascular smooth muscle and relaxation of myocardial muscle [40]. They have also been shown to be effective in the treatment of coronary artery spasm. Their antianginal effects appear to be mediated through a reduction of myocardial oxygen demand secondary to decreased afterload and myocardial contractility. There are three main classes: verapamil and diltiazem (the non-dihydropyridines) and the dihydropyridines (e.g. nifedipine, amlodipine) (Table 15.3). All these agents and their analogues are effective antianginals. Dihydropyridines may cause reflex tachycardia and are normally prescribed with a beta-blocker. The principal adverse effect is ankle oedema. Diltiazem may cause bradycardia, while constipation and flushing are sometimes seen with verapamil, which can also cause significant depression of myocardial contractility, requiring caution when used with beta-blockade. These latter two agents should not be used in patients with pulmonary congestion/heart failure.

There is evidence that calcium antagonists may retard the atherosclerotic process [41], but more complete clinical data are required to establish whether calcium antagonists have any role other than symptom control in patients with angina. There has been considerable

Table 15.3 Cardiovascular effects of calcium antagonists

controversy about the safety of calcium antagonists. The Angina Prognosis Study in Stockholm (APSIS), which examined the long-term treatment effects of metoprolol and verapamil on the combination of death and non-fatal cardiovascular end-points including myocardial infarction [42], showed no statistically significant difference in treatment effects between both drugs. Similarly, the International Verapamil–Trandolapril Study (INVEST) [43] examined mortality and morbidity outcomes in hypertensives with coronary artery disease by comparing this combined calcium antagonist and angiotensin-converting enzyme (ACE) inhibitor strategy with a non-calcium antagonist treatment strategy (atenolol–hydrochlorothiazide) and showed both strategies to be equally effective. The Incomplete Infarction Trial of European Research Collaborators Evaluating Prognosis post-Thrombolysis (INTERCEPT) showed the safety, and to some degree the benefit, of diltiazem in patients with acute myocardial infarction but without heart failure, who had received thrombolysis [44]. Diltiazem was associated with a relative decrease in the combined event rate for non-fatal myocardial infarction and refractory ischaemia. Although diltiazem has not been studied in an outcome trial in chronic stable angina, the above trial and other supplementary findings [45] suggest that diltiazem has a useful role, potentially improving prognosis, in this population, in the absence of heart failure.

Both verapamil and diltiazem reduce heart rate, unlike the dihydropyridine calcium antagonists such as nifedipine and amlodipine. With the older short-acting formulation of nifedipine, for example, there was a rapid onset of action and pronounced dose-related fluctuations in the vasodilator effect that provoked stimulation of the sympathetic nervous system and reflex tachycardia, causing *increased* risk of cardiac events. A Coronary Disease Trial Investigating Outcome with Nifedipine GITS (ACTION) using a long-acting nifedipine formulation reported recently [46]. This showed that the administration of nifedipine GITS, compared with conventional antianginal treatment (i.e. beta-blockers, nitrates, etc.), had no effect on major cardiovascular event-free survival in patients with stable coronary artery disease. Therefore, although nifedipine GITS does not affect outcomes, it is now shown to be safe in this population.

The Comparison of Amlodipine vs. Enalapril to Limit Occurrences of Thrombosis (CAMELOT) [47] compared the effects of amlodipine or enalapril or placebo in patients with coronary artery disease and normal blood pressure. Results showed that both drugs reduced events including cardiovascular death and non-fatal myocardial infarction (and hospitalization for angina). Results were directionally similar for both drugs but smaller and non-significant treatment effects were seen with enalapril.

Further reviews are available on the use of long-acting calcium antagonists in the management of hypertension and angina [48,49].

ACE inhibitors

ACE inhibitors have been available for over 20 years, initially for hypertension and then for treatment of heart failure. ACE inhibitors act to prevent vasoconstriction by inhibiting the production of the vasoactive octapeptide angiotensin II from the decapeptide angiotensin I. This inhibition results in vasodilatation due to lowering of systemic vascular resistance and natriuresis from inhibition of aldosterone secretion. Inhibition of degradation of bradykinin may also lead to increases in circulating bradykinin, which can contribute to the vasodilator effects. Inhibition of angiotensin II may also reduce sympathetic tone. ACE inhibitors are now recommended for all patients with left ventricular dysfunction (even in the absence of heart failure) following myocardial infarction. These drugs are generally well tolerated. The main adverse effect is to produce a dry cough in up to 20% of individuals. Angio-oedema is one comparatively rare but more serious adverse effect. Subsequent studies suggested that inhibition of the renin–angiotensin system has important effects on improving endothelial dysfunction and other properties that could translate into benefits in IHD [50]. This was confirmed in the Heart Outcomes Prevention Evaluation (HOPE) trial [51], which was conducted

in patients aged 55 years or more, at high risk of cardiovascular complications, characterized by a high prevalence of diabetes, hypertension, stroke and peripheral vascular disease. HOPE showed a significant 22% reduction in the composite end-point of myocardial infarction, stroke or death from cardiovascular disease among the patients assigned to ramipril. This was followed by the European Trial on Reduction of Cardiac Events with Perindopril in Stable Coronary Artery Disease (EUROPA) [52], conducted in a 'broad-risk' population, all with documented stable IHD without left ventricular dysfunction. The majority were on background therapy of aspirin, statins and beta-blockers. Perindopril treatment was associated with a 20% relative risk reduction in cardiovascular death, myocardial infarction or cardiac arrest. Such findings make a compelling indication for use of one or other of these ACE inhibitors in all patients with IHD.

These findings are in contrast to the Prevention of Events with Angiotensin Converting Enzyme Inhibition (PEACE) trial [53]. This compared the effects of the ACE inhibitor trandolapril and placebo added to current standard therapy in patients with stable coronary artery disease and preserved left ventricular function. The incidence of the primary end-point, cardiovascular death, myocardial infarction or coronary revascularization, was almost identical for trandolapril and placebo. The reason why no benefit was demonstrated with the ACE inhibitor is not fully explained. Overall event rates in PEACE were lower than in HOPE or EUROPA, perhaps because of differences in prior medications or revascularization between the different study populations. Similarly, we cannot assume that 'all ACE inhibitors are the same' and important pharmacological differences exist between them; also the dose is likely to be important since both HOPE and EUROPA used higher doses of ramipril and perindopril.

At present we have little information on the effects of angiotensin II receptor antagonists in the treatment of chronic stable angina.

Nicorandil

Adenosine triphosphate (ATP)-sensitive potassium channels are ubiquitous in the heart and blood vessels and are important modulators of cardiovascular function. Nicorandil is a hybrid compound that comprises a potassium channel opener and a nitrate moiety [54]. Nicorandil has a dual mechanism of action on both preload and afterload, producing a dose-related improvement in haemodynamics. Angiographic studies have shown that the drug dilates both stenotic and non-stenotic coronary arteries and it is indicated for prophylaxis and treatment of angina, normally at a dose of 20 mg twice daily. Nicorandil may mimic ischaemic preconditioning, which is a powerful protection against myocardial necrosis. Unlike classical nitrates there appears to be an absence of haemodynamic tolerance to nicorandil. Headache is the problem most commonly encountered, usually occurring early on commencement of treatment and disappearing with chronic dosing. Nicorandil appears to have comparable efficacy to other standard antianginals. Its role in symptomatic treatment is discussed later.

The Impact Of Nicorandil in Angina (IONA) study [55] showed that nicorandil 20 mg twice daily, in addition to standard antianginal therapy, improved outcomes in terms of reducing events related to acute coronary disease and the associated requirement for admission to hospital. The drug may therefore have a useful role in treatment of angina unresponsive to initial medical treatment.

Revascularization

The indications for coronary revascularization and the effects of PCI and coronary artery bypass graft (CABG) surgery on outcomes are discussed later in this chapter.

Drugs for the symptomatic treatment of angina

Nitrates

Both short-acting and long-acting preparations are widely employed. While sublingual tablets are rapidly effective for treating an acute attack, many patients find the nitrate spray more convenient.

Short-acting agents

All patients with angina pectoris should be offered sublingual glyceryl trinitrate (GTN) for symptomatic relief. In patients with minimal symptoms, intermittent use of sublingual GTN may suffice. The precise mechanism of action of nitrates remains to be established but principally involves relaxation of vascular smooth muscle, leading to vasodilatation and unloading of the heart. This is achieved with increased production of nitric oxide, an endogenous vasodilator released by the endothelium. Nitrates reduce both the preload and afterload on the heart. Such combined action results in reduced ventricular filling pressures, cardiac dimensions and

wall tension and, ultimately, reduced energy needs. Nitrates also relax large coronary arteries, can reduce coronary spasm and may also enhance coronary collateral flow, thereby redistributing flow from epicardial to subendocardial ischaemic territory. Although nitrates can cause a reflex increase in heart rate and contractility, such effects are usually not sufficient to negate their beneficial effects.

Long-acting nitrates

Long-acting nitrates are only for symptomatic relief of angina. There are no data showing that long-term treatment with nitrates reduces mortality or the incidence of myocardial infarction in patients with stable angina [56]. Long-term dosing with oral slow-release isosorbide dinitrate does not reduce cardiac events in patients recovering after myocardial infarction [57]. Tolerance to continuous oral or transdermal nitrates develops rapidly [58] and, in order to overcome this, nitrate-free intervals or a modified delivery system designed to provide a low-nitrate period have been recommended. The worry about intermittent nitrate therapy is that rebound exacerbation of symptoms may occur.

The safety of nitrates has been established with long-term use. Adverse effects include headache and occasionally postural hypotension. Only about 10% of patients are non-responders to nitrate therapy and a further 10% experience adverse effects requiring withdrawal of therapy [59].

Also available in certain countries is molsidomine, a vasodilator with an action similar to organic nitrates (i.e. increases levels of nitric oxide) and which has antianginal activity similar to long-acting nitrates without causing tolerance.

Beta-blockers

The mode of action and use of beta-blockers has been described in detail above. Beta-blockers should be considered first-line treatment for the relief of angina. All angina patients who require regular symptomatic treatment should be treated, unless contraindicated, with a beta-blocker [60]. Beta-blockers without ISA/PAA are titrated to achieve resting heart rates of between 55 and 60 b.p.m., although 50 b.p.m. may be required in more severe angina.

Calcium antagonists

There is no evidence suggesting superiority of one calcium antagonist over another in the treatment of angina. The heart rate-lowering effects of diltiazem and verapamil are considered to offer similar advantages to beta-blockers and they may be used as first-line treatment when beta-blockers are inappropriate. Dihydropyridines may be useful in combination with a beta-blocker. The sequence of use of beta-blockers and calcium antagonists is outlined in the treatment algorithm shown in Fig. 15.1.

Metabolic agents

A number of antianginal drugs exert their anti-ischaemic effects primarily by altering myocardial metabolism [61]. Such drugs may be useful in patients with refractory angina who are already receiving 'optimal' medical treatment or who may not be suitable for revascularization.

Trimetazidine, which is available in some European countries, is a metabolic agent that has no haemodynamic effects. It has been shown to preserve energy balance and prevent disturbance of ion haemostasis during ischaemia. Its specific mechanism of action is unknown but its antianginal effects are attributed to modulatory effects on intracellular calcium [62]. Trimetazidine also stimulates glucose oxidation and acts as a partial fatty acid oxidation inhibitor (pFox inhibitor). Antianginal efficacy has been established with immediate-release formulations of trimetazidine three times daily [63] and, more recently, with a modified-release formulation of trimetazidine 35 mg daily. The most commonly reported adverse effects with clinical doses are fatigue/drowsiness.

Ranolazine, a new anti-ischaemic drug, is a selective inhibitor of the late sodium current that has the potential to reduce intracellular sodium-dependent calcium overload and its detrimental effects on cardiomyocyte function. It is currently undergoing the European approval process. Benefits have been shown in the Monotherapy of Ranolazine in Stable Angina (MARISA) trial [64] and the Combination Assessment of Ranolazine in Stable Angina (CARISA) trial [65]. Ranolazine as monotherapy in the dose range 500–1500 mg twice daily and in combination with other antianginals and ranolazine 750–1000 mg sustained release twice daily, increases exercise tolerance and reduces ischaemia and also provides additional symptomatic relief in addition to atenolol, amlodipine or diltiazem at standard doses, without adverse long-term survival consequences over 1–2 years of therapy. The most commonly reported adverse effects with ranolazine are constipation, dizziness, nausea and asthenia.

Other metabolic agents include L-carnitine, dichloroacetate [66], glucose–insulin–potassium (GIK), perhexiline, and etomoxir, an investigational carnitine-palmitoyl transferase 1 inhibitor. While it is early days for some of these compounds, others described above have been available for a number of years and although they are

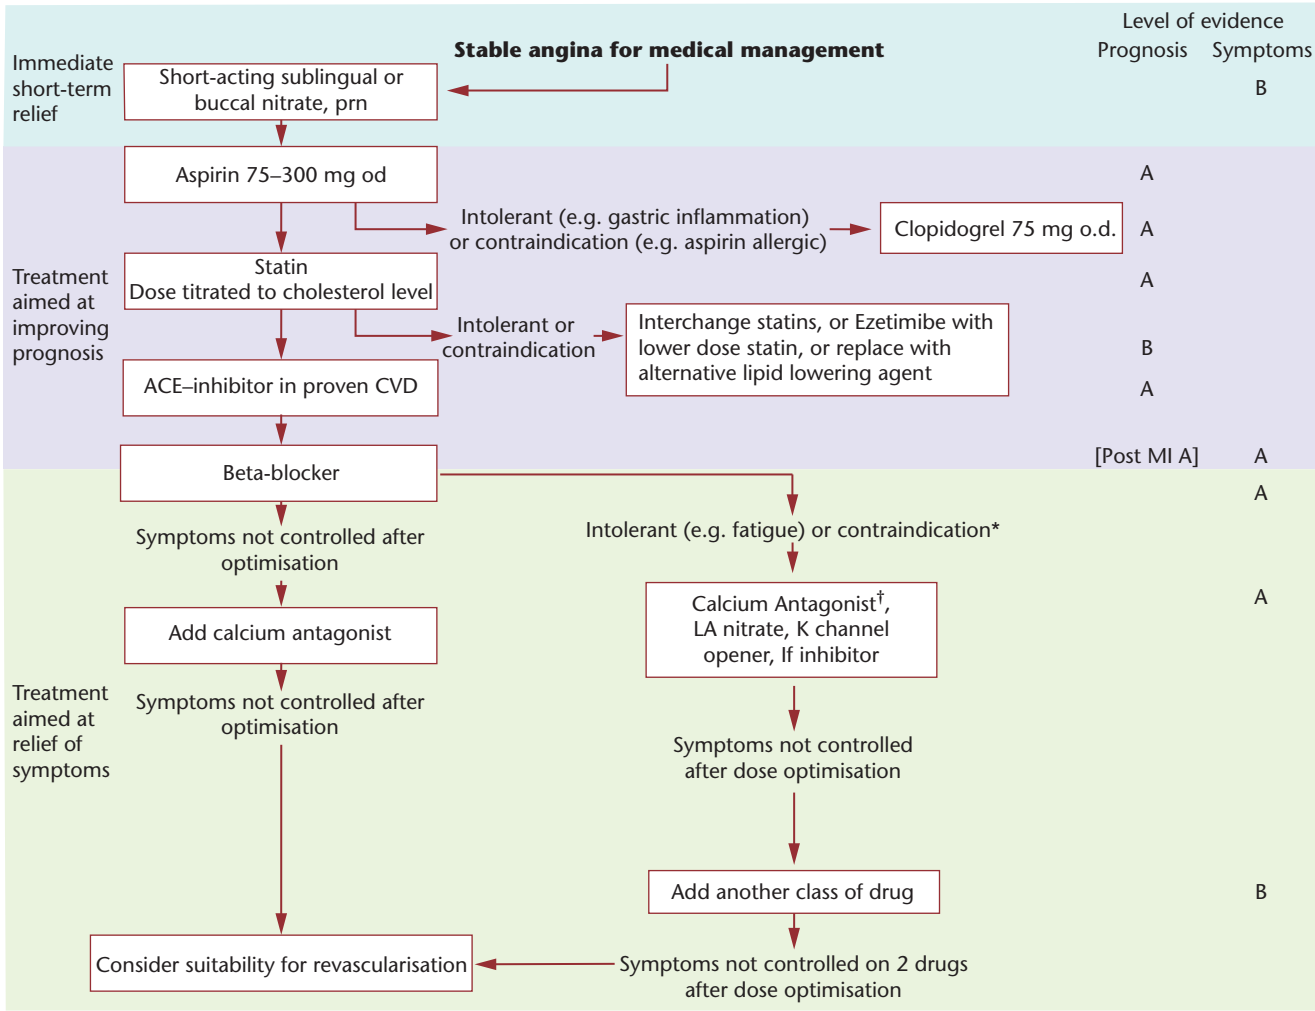

Figure 15.1 Algorithm for medical management of stable angina. High-risk candidates for revascularization on prognostic grounds alone should be identified and referred appropriately. Evidence for prognosis refers to evidence of reduction in CV death or CV death/MI. Evidence for symptoms includes reduction in need for revascularization and hospitalization for chest pain. *Relative contraindications to beta-blockade include asthma, symptomatic peripheral vascular disease and first-degree heart block. †Avoid short-acting dihydropyridine formulations when not combined with a beta-blocker.

promising, longer-term safety and outcome trials are eagerly awaited.

Specific bradycardic agents

A high resting heart rate is associated with an increased risk of IHD [67]. Drugs that lower heart rate, such as beta-blockers, have been shown to reduce the risk of sudden death and re-infarction in patients with IHD. Beta-blockers also play an important role in prevention of anginal attacks as described above. Because beta-blockers have haemodynamic effects other than lowering of heart rate and blood pressure (e.g. they are negatively inotropic), they are not well tolerated by all patients. The question remains whether agents which have a pure bradycardic action without other haemodynamic effects might also have clinical benefits in angina. There are a number of agents that have a direct action on the sinoatrial node [68], including zatebradine, which is no longer being developed because of its propensity to cause QT prolongation and dose-related ocular adverse effects.

Ivabradine specifically inhibits I_f, a primary pacemaker current, and does not induce significant prolongation of repolarization over the dose range 2.5–10 mg twice daily.

A recent randomized controlled trial over a 4-month period [69] showed that ivabradine produces dose-dependent improvements in exercise tolerance and time to ischaemia during exercise. There was an increase in the incidence of mild visual symptoms, mainly with ivabradine 10 mg, which resolved spontaneously or with drug cessation. These may be linked to the presence of retinal ion channels similar to those mediating I_f. There were no 'rebound' phenomenon with ivabradine withdrawal.

Specific heart rate modulating agents may have an important role in the future. Ivabradine has recently received approval for use from the European Agency for the evaluation of medicinal products (EMEA).

Treatment strategies

Figure 15.1 provides an algorithm for the treatment of patients with angina. The strategy involves mainstay drugs for improving prognosis (i.e. aspirin, statin, ACE inhibitor and beta-blocker) and then a tiered system to introduce specific antianginals, calcium antagonists and so forth. The levels of evidence for these drugs are also provided. In patients with minimal symptoms, intermittent sublingual GTN may suffice. No one drug has shown consistently greater efficacy in relieving chest pain or reducing exercise-induced ischaemia. In general, optimal dose regimens of a given class of drug are preferable to routine use of combination therapy. Many patients respond to monotherapy when drugs are used at the appropriate doses; when monotherapy fails it is often advisable to add another class of antianginal. Patients who do not have adequate control of symptoms on maximal doses of two drugs should be referred for cardiological assessment rather than be given a third drug.

A number of other therapies have been proposed for the treatment of angina. These include dietary supplementation with antioxidants, for example. Space does not allow comprehensive review here but, while patients may benefit from these, this issue is still unresolved. We also concur with guidelines in the USA that chelation therapy has no role in the treatment of chronic stable angina.

Conclusions

We have reviewed the evidence for treatments providing symptomatic relief of stable angina and life-style and pharmacological interventions that may be disease modifying. The majority of angina patients will be treated medically. There are very extensive data following long experience with many of the current antianginals. Newer classes have become available and other investigational agents are in the pipeline. It may be that patient treatment will be optimized more readily using a combination of an antianginal that has haemodynamic effects and a compound which has metabolic effects only. The first requirement is to ensure the safety of treatments employed and, secondly, to reduce myocardial ischaemia and improve patient outcome.

Revascularization

All patients thought to have angina should be referred to a cardiologist to identify whether they might benefit from prognostic investigation and treatment [70]. Criteria for access to coronary angiography and revascularization have been developed (Tables 15.4 and 15.5). The criteria stratify patients into four different classes: 1, 2a, 2b and 3. Class 1 includes patients for whom there is very strong evidence of effectiveness. Class 2a includes those with indications for which there is strong evidence of effectiveness and for which most cardiologists would offer treatment. Class 2b includes patients with indications where there is no clear evidence of benefit and class 3 includes patients where there is strong evidence that they should not have angiography or revascularization. Table 15.4 indicates patients who should be referred for a coronary angiogram, ranging from those with chronic disabling angina to those who are at lower risk. Similarly, Table 15.5 outlines those patients who warrant revascularization, ranging from those with significant main-stem disease to those with borderline stenoses but no ischaemia on exercise testing.

Coronary bypass surgery

Coronary artery surgery is the most documented, evaluated and audited operation in the history of medicine. There are two main indications for operation: symptomatic and prognostic. The former involves patients whose angina is not controlled by medical treatment. The latter is the presence of coronary artery disease, which has been shown to have a better prognosis with surgery than with medical treatment. Such disease includes: (1) significant stenosis of the left main stem, (2) significant proximal stenosis of the three major coronary arteries, and (3) significant stenosis of two major coronary arteries, including high-grade stenosis of the proximal left anterior

Table 15.4 Indications for coronary angiography in chronic stable angina

Class 1
A Patients with disabling (CCS class 3–4) chronic stable angina particularly if the symptoms are inadequately responding to medical therapy
B Patients with high-risk criteria on non-invasive testing regardless of angina severity
C Patients who have survived sudden cardiac death or serious ventricular arrhythmia
D Patients with angina and symptoms and signs of congestive cardiac failure
E Patients with clinical characteristics that indicate a high likelihood of severe coronary artery disease, e.g. patients awaiting renal transplantation, those with dilated cardiomyopathy of unknown cause, those with chronic stable angina being considered for major vascular surgery
F Patients previously treated by myocardial revascularization (PCI or CABG) who develop recurrence of moderate or severe angina

Class 2a
A Patients with inadequate prognostic information after non-invasive testing
B Patients with significant left ventricular dysfunction (EF < 45%) or history of myocardial infarction, CCS 1 or 2 angina and demonstrable ischaemia but less than high-risk criteria on non-invasive testing
C Chronic stable angina in patients with bundle branch block if readily induced ischaemia is demonstrable by myocardial perfusion scintigraphy/dobutamine stress echocardiography
D Patients in whom it is essential to establish the diagnosis for clinical or occupational reasons
E Patients with CCS class 1 or 2 angina but intolerance to adequate medical therapy

Class 2b
A Patients with CCS class 1 or 2 angina, preserved left ventricular function and less than high-risk criteria on non-invasive testing who are rendered symptom-free on medical therapy
B Asymptomatic patients awaiting major surgery with a good exercise tolerance and/or less than high-risk criteria on non-invasive testing
C Patients with ventricular ectopics/asymptomatic non-sustained ventricular tachycardia with normal echocardiogram and low-risk non-invasive testing
D Asymptomatic patients with incidental left bundle branch block, normal echocardiogram and low-risk non-invasive testing
E Patients with atrial fibrillation/atrial flutter with normal echocardiogram and low-risk non-invasive testing

Class 3: patients who generally do not need coronary angiography
A Patients with CCS class 1 or 2 angina who respond to medical therapy and who have no evidence of ischaemia on non-invasive testing
B Asymptomatic low-risk patients with no evidence of ischaemia on non-invasive testing
C Patients who prefer to avoid revascularization

descending artery. The presence of impaired left ventricular function increases the prognostic advantage of surgery over medical treatment in all categories. This information comes from two major randomized studies: the European Coronary Artery Study and the North American CASS study. Early reports demonstrated a symptomatic advantage of CABG over medical treatment. As follow-up lengthened, the prognostic advantages began to emerge in a number of subgroups [72].

The overall operative mortality for elective first-time CABG is 2–4% [73]. There are well-developed risk stratification models available for the assessment of risk in individual patients. There is the paradox that the higher the risk of operation, the greater the benefit of surgical over medical treatment. In patients with three-vessel disease, the completeness of revascularization is a significant determinant of the relief of symptoms over a 5-year period [74]. Approximately 80% of patients are angina-free 5 years after surgery and 63% at 10 years, but by 15 years only 15% are free of an ischaemic event [75].

Choice of conduit

The acceleration in adverse events after 10–15 years is due to gradual occlusion of vein grafts in addition to progressive disease in the native coronary vessels. Independent predictors of recurrence of angina are female gender, obesity, preoperative hypertension and lack of use of the left internal mammary artery (LIMA) as a conduit to the left anterior descending artery (LAD) [76]. Over the last

Table 15.5 Indications for coronary revascularization for chronic stable angina

Class 1

A CABG for patients with significant LMS disease

B CABG for patients with three-vessel disease: the survival benefit is greater in patients with abnormal left ventricular function

C CABG for patients with two-vessel disease with significant proximal LAD disease and either left ventricular dysfunction or demonstrable ischaemia on non-invasive testing

D PCI for patients with two- or three-vessel disease with significant proximal LAD coronary artery disease who have anatomy suitable for catheter-based therapy

E PCI or CABG for patients with one- or two-vessel coronary artery disease without significant proximal LAD disease but with a large area of viable myocardium and high-risk criteria on non-invasive testing

F CABG or PCI for patients with one- or two-vessel coronary artery disease without significant proximal LAD disease who have survived sudden cardiac death or sustained ventricular tachycardia

G In patients with prior PCI, CABG or PCI for recurrent stenosis associated with a large area of viable myocardium and high-risk criteria on non-invasive testing

H PCI or CABG for patients who have not been successfully treated by medical therapy and can undergo revascularization with acceptable risk

Class 2a

A Repeat CABG for patients with multiple SVG stenoses, especially when there is significant stenosis of a graft supplying the LAD. It may be appropriate to use PCI for focal SVG stenoses

B Use of PCI or CABG for patients with one- or two-vessel coronary artery disease without significant proximal LAD disease but with a moderate area of viable myocardium and/or demonstrable ischaemia on non-invasive testing

C Use of PCI or CABG for patients with one-vessel coronary artery disease with significant proximal LAD disease

D Use of PCI for patients with symptomatic LMS disease and/or evidence of myocardial ischaemia on non-invasive testing who are not candidates for CABG

Class 3

A Use of PCI or CABG for patients with one- or two-vessel coronary artery disease without significant proximal LAD coronary artery disease, who have no symptoms or mild symptoms that are unlikely to be due to myocardial ischaemia, or who have not received an adequate trial of medical therapy and (a) have only a small area of viable myocardium or (b) have no demonstrable ischaemia on non-invasive testing

B Use of PCI or CABG for patients with borderline coronary stenoses (50–60% diameter in locations other than the LMS) and no demonstrable ischaemia on non-invasive testing

C Use of PCI or CABG for patients with insignificant coronary stenoses (< 50% diameter)

D Use of PCI for patients with significant LMS disease who are candidates for CABG. Those with significant LMS disease have a class 1A indication for CABG

Note: in this context the term 'non-invasive testing' includes exercise stress testing, dobutamine stress echocardiography, myocardial perfusion scanning, positron emission tomography assessment of myocardial blood flow and intravascular ultrasound and assessment of fractional flow reserve.

CABG, coronary artery bypass graft; LAD, left anterior descending; LMS, left main stem; PCI, percutaneous coronary intervention; SVG, saphenous vein graft.

20 years the standard procedure has been to graft the LAD with the LIMA and use saphenous vein for the other bypass grafts. By 10 years, 60% of vein grafts are stenosed or occluded. Since at least 70% of patients are alive 10 years after surgery, the recurrence of symptoms from vein graft disease remains a clinical problem. Large observational studies have shown that the use of the LIMA graft improves survival and reduces the incidence of late myocardial infarction and recurrent angina and the need for further cardiac interventions. There appears to be significant survival benefit when using bilateral internal mammary artery (IMA) grafts irrespective of age, ventricular function and the presence of diabetes [77,78] (Fig. 15.2). Furthermore, the benefit of using bilateral IMAs increased with the duration of follow-up, particularly in terms of the need for repeat surgery, which at 10 years was 40% for single IMA grafting and 8% for bilateral IMA grafting in well-matched patients. Ten years after CABG, 90% of IMA grafts continue to function well. With the use of skeletonized IMA pedicles, the risk of sternal devascularization and subsequent dehiscence is much reduced, even in diabetics. Other arterial grafts include the radial artery and the right gastroepiploic artery. The greatest experience has been with the radial

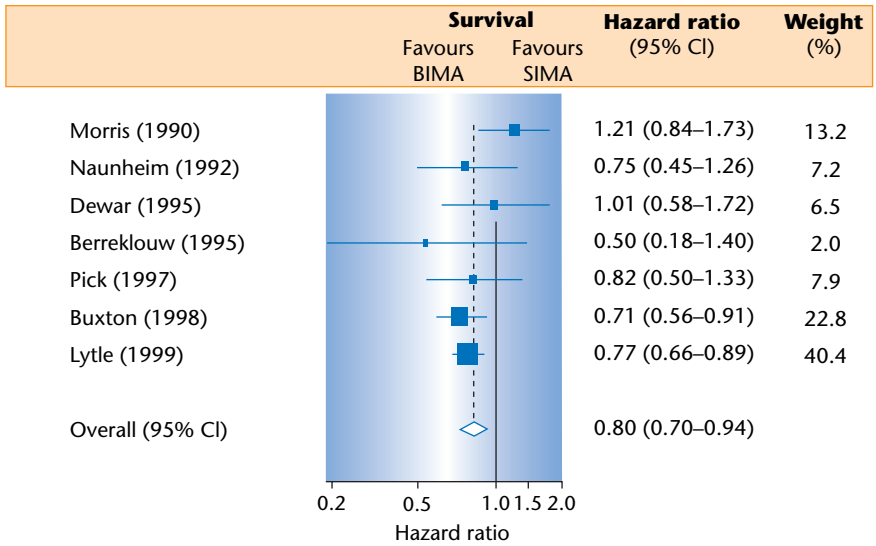

Figure 15.2 Meta-analysis of single internal mammary artery (SIMA) and bilateral internal mammary artery (BIMA) grafts [78].

artery, where reports have indicated patency rates of greater than 90% at 3 years. There is a learning curve with radial artery grafts and it is now clear that they should only be used for coronary vessels with high-grade stenosis or occlusion.

A prospective, randomized, single-centre trial in 438 patients investigated whether angiographic patency of the radial artery was superior to that of the free right internal mammary artery (RIMA) or saphenous vein and whether radial artery grafts have superior outcomes to free RIMA or saphenous vein grafts [79]. No evidence emerged of a greater freedom from untoward events with radial artery use. A recent report in which the post-operative angiograms of 310 symptomatic patients were reviewed showed disappointing results for medium-term patency of the radial artery [80]. At 5 years the patency results were 92% for LIMA, 85% for RIMA, 64% for saphenous vein and 53% for radial artery grafts. There was a gender difference for the radial graft patency, with elderly females faring worse.

Beating heart surgery ('off-pump')

The use of an extracorporeal circulation (cardiopulmonary bypass) for performing coronary artery surgery remains the most commonly used approach. However, there are risks, including a whole-body inflammatory response and the production of microemboli. The need for aortic cannulation and manipulation of the ascending aorta may lead to release of emboli, especially in elderly atheromatous patients, who constitute an increasing proportion of the patient pool accepted for coronary surgery. So-called 'off-pump' surgery may lead to a reduction in perioperative mortality and morbidity. The recent introduction of stabilization devices has enabled surgeons to treat patients with three-vessel disease in this way (Fig. 15.3). Randomized trials comparing off-pump with the standard procedure are now available. Although the use of blood products was reduced in the off-pump group (3% vs. 13%) and the release of creatine kinase (CK)-MB isoenzyme was 41% less in the off-pump group, there were no differences in perioperative complication rates. There was no difference in outcome in the first 1–3 years after surgery between off-pump and standard groups [81,82]. A meta-analysis of six studies including 558 patients randomized to on-pump and 532 to off-pump found no significant difference in the combined end-point of death, stroke or myocardial infarction [83]. More recently, Khan and colleagues [84] in a further

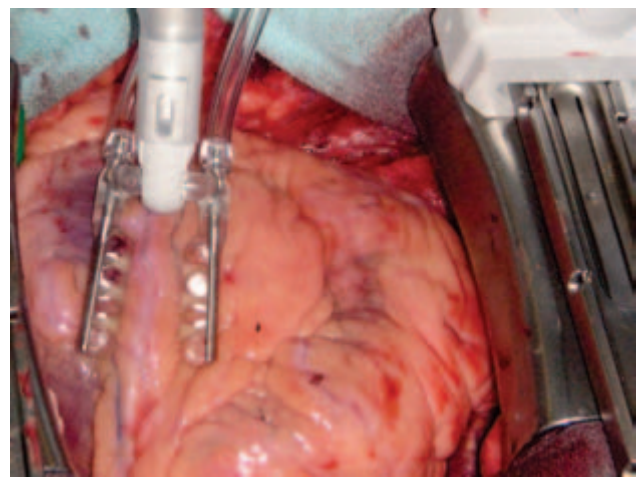

Figure 15.3 Use of a stabilizer to enable anastomosis of left internal mammary artery to left anterior descending artery on the beating heart.

randomized trial with angiographic follow-up at 3–6 months showed a significant reduction in graft patency (90% vs. 98%) in the off-pump group. These studies suggest that the use of off-pump surgery is not a panacea but should be applied cautiously and selectively to patients with good target vessels and significant comorbidity.

In the debates about on-pump and off-pump surgery, on-pump is usually treated as a single commodity. However, cardiopulmonary bypass can be conducted in several distinct ways. Cardioplegic arrest may be employed using a variety of solutions at different temperatures and by different routes, antegrade or retrograde or a combination of the two. Non-cardioplegic methods have a long pedigree and can be very effective. With the use of stabilizers, cardiopulmonary bypass can be employed without the insult of global ischaemia caused by aortic cross-clamping, and used to empty the heart while local stabilization of the target vessel is secured. When the vessel is opened a shunt may be placed, thus minimizing any regional ischaemia. This approach has proved effective in patients with hibernation and dilated hearts, and in repeat coronary surgery.

Repeat coronary artery surgery

The incidence of repeat coronary artery surgery, as a proportion of all coronary artery surgery, is less in Europe (5–10%) than in North America (10–15%). There is a higher morbidity and a two to three times higher mortality [85]. Although the relief of angina is less predictable and less complete than after first-time surgery, the long-term outcome is encouraging, with 73% of patients free of angina at 5 years. The indications for reoperation have not been defined by randomized trials, but the same principles apply as for first-time surgery. Stenosis in a vein graft to the LAD is associated with a reduction in survival [86]. A major improvement in survival after reoperation was especially evident for patients in this category. Among these patients, survival rates were 84% and 74% for the reoperation group at 2 and 4 years compared with 76% and 53% for the medically treated group.

Surgery in the presence of impaired left ventricular function

In the early 1980s, Rahimtoola [87] reviewed the results of coronary bypass surgery trials and identified patients with coronary artery disease and chronic left ventricular dysfunction that improved with revascularization. The results of medical treatment for ischaemic cardiomyopathy have been poor. Coronary revascularization provides superior long-term survival but may be associated with a high operative mortality and significant morbidity for certain patient subgroups with heart failure and very low ejection. At one time heart transplantation provided an attractive alternative, but the severe and worsening shortage of donor organs has made this option largely impractical, as the mortality while waiting for a transplant reduces the overall survival for patients assigned to this form of treatment.

Coronary artery disease is the major cause of heart failure. It accounts for 95% of cases of congestive heart failure in patients aged 25–75 years. More than 50% of patients with congestive heart failure and coronary artery disease have evidence of stress-induced ischaemia or hibernation [88]. The pathophysiology underlying this disease includes myocyte loss with scar formation, chronic dysfunction in viable myocardium associated with stunning and hibernation, and structural changes in remote myocardium. The potential benefits of revascularization are to reduce the ischaemic burden, reduce the arrhythmic potential, reduce maladaptive growth and restore the coordinated movement in dysfunctional segments [89].

Data from the CASS registry for patients with left-ventricular ejection fraction (LVEF) below 35% involved 651 patients [90,91]. The 5-year survival was significantly better in surgical patients (68%) than in the medical group (54%). The contrast became more marked in patients with LVEF less than 26%, whose 5-year survival was 63% with surgery but 43% with medical treatment. This information is the cornerstone of our current approach to patients with coronary artery disease and congestive heart failure.

With recent improvements in anaesthesia and myocardial management, the operative mortality has been reduced to less than 10% in most series [92–94]. Perioperative care has been enhanced by the increased use of balloon counterpulsation and short-term ventricular assist devices. Angina often present in these patients can be successfully ameliorated by surgery [94] as can symptoms of heart failure, particularly if there is careful selection of patients [95–98].

Clearly, revascularization can improve functional status in patients with ischaemic cardiomyopathy, but viability assessment is crucial for the appropriate selection of patients.

Conclusions

Coronary artery surgery remains the gold standard for the alleviation of symptoms in patients with coronary artery disease. In addition there are small subsets in whom surgery will improve prognosis, notably those with left main-stem or proximal anterior descending disease, as well as those with impaired left ventricular function and three-vessel coronary disease. In addition, it is an

important form of treatment for patients with ischaemic cardiomyopathy, including those for whom angina is a minor component of their symptoms. New approaches are likely to reduce the morbidity of the procedure, particularly in respect of stroke in elderly patients.

Percutaneous coronary intervention

Introduction and historical background

Balloon angioplasty is aimed at restoring blood flow through stenotic coronary arteries by mechanical dilatation, i.e. inflation of a balloon catheter steered percutaneously to the narrowed site under fluoroscopic guidance. The procedure was introduced in 1977 by Grüntzig [99] and has gained increasing clinical application since then [100,101]. In Europe, PCI is presently preferred over CABG in a ratio of 3 : 1 [102]. Ease of use and convenience of PCI weighs heavily against the greater durability of the more invasive bypass operation. Also, both the safety and efficacy of PCI have continuously improved further to technological progress and advances in adjunctive pharmacological management. Following the availability of miniature and highly steerable guidewires, which have permitted access to virtually any branch of the epicardial coronary tree, the next decisive improvement resulted from the development and successful application of endovascular metallic scaffolds, called stents [103–105]. Stents are presently used in more than 80% of all PCI procedures [100–102]. The stent implantation technique itself has been optimized by proper stent expansion and apposition against the wall, as learned from intravascular ultrasound imaging [106]. Stented angioplasty is superior to balloon angioplasty for the following reasons.

1 Plaque fracture and dissection caused by balloon inflation often resulted in a pseudo-successful procedure while limited luminal enlargement was actually obtained.
2 The dilated lesion shows greater stability after stenting, while abrupt closure within 48 h following balloon treatment was not uncommon (up to 15% in the presence of severe residual dissection).
3 The angiographic result obtainable after stenting is predictable irrespective of stenosis complexity.
4 Stent implantation results in fewer vessel reocclusions and lower rate of reintervention.

Several randomized clinical trials support the above-mentioned statements, particularly the Benestent family of trials, which represent the foundations of the practice of PCI, at least in Europe [107–110] (Fig. 15.4). For instance, Benestent II tested the hypothesis that use of a heparin-coated stent (plus aspirin and ticlopidine) would result in a better event-free survival than standard balloon angioplasty [108]. After stenting, 87.2 and 84.3% of patients were event-free at 6 and 12 months respectively, as opposed to 80.7 and 77.6% after balloon angioplasty. Despite allocation to balloon treatment, bail-out stenting was unavoidable in 13% of patients. The rates of stent thrombosis were as low as 0.2%. The best outcome (89.3% event-free rate at 6 months) was observed in patients randomized to clinical follow-up, in which repeat angiography was only performed on clinical grounds [109] (Fig. 15.4). Other randomized clinical trials have shown that this benefit was maintained up to 5 years after the initial procedure [110,111]. The results of PCI have thus greatly improved over the last few years due to a number of factors acting in synergy [111]. However, until fairly recently, restenosis after stented angioplasty had remained the Achilles heel of PCI.

Advances in the treatment and prevention of restenosis after PCI

Prior to the stent era, numerous mechanical and pharmacological approaches to the prevention of restenosis were tested and shown to be failures. Although a variety of devices have been developed to crack, break, stretch, scrape, shave or burn the atherosclerotic plaque, the durability of an initially successful procedure has been hindered by an incidence of angiographic restenosis within 6 months as high as 50%. This is because restenosis after balloon angioplasty or any other mechanical intervention except stenting is a complex wound healing process that results in exuberant neo-intimal proliferation as much as in constrictive remodelling of the vessel [112]. Implantation of a metallic stent cage virtually eliminates vessel shrinkage and thereby significantly reduces clinical restenosis, i.e. the need for repeat intervention due to recurrent symptoms. At the same time, implantation of metallic stents exacerbates the neo-intimal proliferative reaction such that there remain a number of lesion subsets associated with poor short-term outcome and angiographic restenosis rates above 30%, specifically small vessels, long lesions, saphenous vein graft disease and ostial lesions [113]. Restenosis inside a previously deployed metallic stent is difficult to treat because of recurrence rates ranging from 19 to 83% after any new intervention, albeit plain balloon angioplasty or a combined procedure involving plaque debulking [114]. This is particularly the case when diffuse or proliferative in-stent restenosis is present. Because in-stent restenosis has been shown to be almost exclusively due to neo-intimal

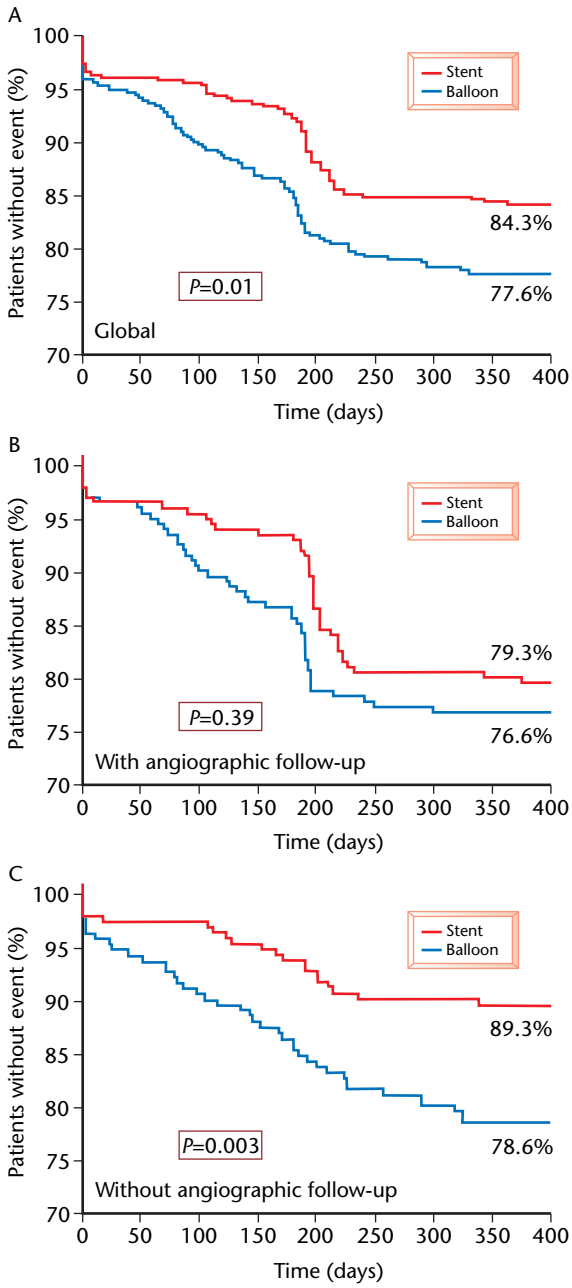

Figure 15.4 Major adverse clinical event (MACE)-free survival in patients randomized to balloon angioplasty vs. implantation of bare metal stenting (Benestent II trial). In the global population (A), most of the events occur at 6 months after randomization. In the subgroup randomized to angiographic follow-up (B), these events represent mostly reinterventions that are triggered at least in part by angiography. In the patient subgroup randomized to clinical follow-up (C), the outcome in both balloon and stent groups is driven by clinical needs. This study design documented for the first time the extent to which systematic repeat angiography interferes with regular patient care.

proliferation, intracoronary irradiation was successfully applied, with either gamma or beta radiation [115]. However, long-term results of brachytherapy have been plagued with exceedingly high rates of stent thrombosis and late vessel occlusion [116–118], presumably due to delayed re-endothelialization. Vascular brachytherapy applied at the time of the initial stented angioplasty, in an attempt to prevent later proliferation of in-stent neointima, has been abandoned as well, due to a number of unexpected problems: subacute and late stent thrombosis, edge failure and geographical miss, acquired stent malapposition against the vessel wall due to vessel expansion and late recurrence [119]. Presently, drug-eluting stents (DES) are replacing metallic stents. These metallic scaffolds are covered with polymers from which less than 0.1 mg of cytotoxic and anti-inflammatory compounds (e.g. paclitaxel, sirolimus, everolimus) are progressively eluted over the first weeks after stent implantation. Both angiographic restenosis rates and the need for repeat intervention due to symptom recurrence have been reduced by over 60%, at least with the use of the currently approved devices (Table 15.6) [120]. Another development is the increasingly frequent use of direct stenting, i.e. stent implantation without balloon pre-dilatation. Animal experiments have suggested that direct stenting reduces endothelial and vessel wall damage and produces less neo-intimal proliferation [121]. When applicable with DES, restenosis rates as low as 2% have been observed [122,123]. Clinical follow-up for up to 4 years after DES seems to indicate durability of this result and additional long-term data are accumulating [124]. In addition to their favourable impact on restenosis and symptom recurrence, the use of DES will likely cause an expansion of the indications for PCI, as indicated by the evaluation of 'real world' practice in centres where DES have already completely replaced metallic stents [125,126]. Registries and surveillance data suggest that results obtainable in 'real life' are indeed comparable to those reported in randomized clinical trials, even in patient and lesion subsets considered at higher risk for poor outcome and which are usually excluded from such trials [125,126].

Indications for PCI in patients with chronic IHD

Mechanical revascularization vs. medical treatment

The obvious goal of revascularization in patients with stable coronary artery disease is to relieve angina, improve quality of life and revert signs of inducible ischaemia [127]. In patients with severe ischaemia, such as those included in the ACIP trial (patients had both stress-inducible ischaemia and at least one episode of silent ischaemia on 48-h Holter monitoring), revascularization

Table 15.6 Meta-analysis of 11 randomized clinical trials on drug-eluting stents combining sirolimus and paclitaxel, polymeric and non-polymeric delivery

	Drug-eluting stents ($n = 2641$)*	Bare metallic stent ($n = 2449$)*	Odds ratio	95% confidence interval
All-cause mortality	0.95 (26)	0.86 (21)	1.11	0.61–2.06
Myocardial infarction	2.69 (71)	2.94 (72)	0.92	0.65–1.25
Target lesion revascularization	4.20 (111)	13.19 (323)	0.26	0.14–0.45
Major adverse cardiac events	7.84 (207)	16.37 (401)	0.42	0.32–0.53
Angiographic restenosis†	8.91 (155)	29.37 (457)	0.18	0.06–0.40

Note: odds ratio < 1.00 favours drug-eluting stent, odds ratio > 1.00 favours bare metallic stent.
*Values are percentages with numbers in parentheses.
†Drug-eluting stent ($n = 1739$) and bare metallic stent ($n = 1556$).
Adapted with permision from Babapulle *et al*. [120].

significantly reduced death and infarction rates at 2 years follow-up compared with medical treatment [128,129]. However, in the vast majority of patients with stable angina, prognosis is excellent and unlikely to be improved by PCI. Instead, the AVERT trial [130], in which patients were randomized to PCI or medical care including high-dose atorvastatin (80 mg daily), strongly challenged the idea that every epicardial stenosis should be 'fixed'. In fact, outcome was better in patients treated medically and at 1.5 years the incidence of any ischaemic event was 13.4% after atorvastatin vs. 20.9% after PCI. Given the incremental benefit of statins [131,132] and ACE inhibitors [133] in patients with chronic IHD undergoing revascularization, the COURAGE trial was initiated in order to reassess the role of aggressive medical therapy alone and in combination with PCI. While the results are awaited, revascularization should be triggered by the symptomatic status and/or the documented evidence of inducible ischaemia, not just by the presence of a seemingly significant stenosis. Unless the stenosis appears critical at coronary angiography, even experienced interventional cardiologists cannot accurately predict the haemodynamic significance of most narrowings based on visual assessment or quantitative coronary angiography [134]. Although non-invasive stress imaging (with a sensitivity of 76–88% and specificity of 80–88%) should ideally be applied prior to cardiac catheterization, a majority of patients in the real world undergo coronary angiography without prior functional testing [135]. When exercise-induced ischaemia has not been documented for any reason, the measurement of pressure-derived fractional flow reserve (FFR) can be applied during the invasive examination. This test is simple, easily obtained and lesion specific, and an FFR below 0.75 is a robust surrogate for inducible ischaemia [136–138]. In the DEFER trial [137,138], PCI was either performed or deferred based on the FFR value. Event-free survival was similar between the deferral and PCI groups (92% vs. 89% at 12 months and 89% vs. 83% at 24 months), indicating that PCI does not improve outcome when performed on stenoses that are non-flow-limiting.

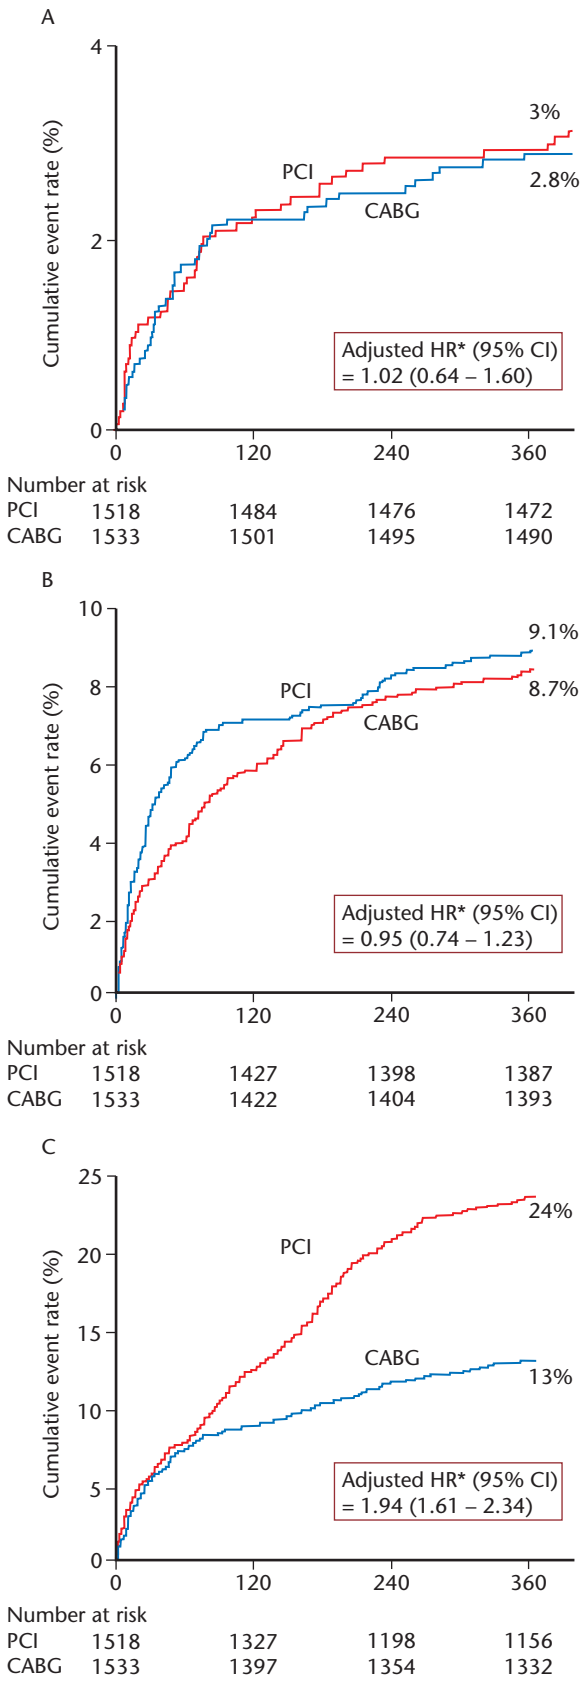
PCI vs. CABG

Meta-analysis of 7964 patients randomized between 1987 and 1999 showed no statistically significant risk difference for irreversible adverse events (death, myocardial infarction and stroke) between the two revascularization strategies at 1, 3 or 8 years [139]. Mortality at 3 years was 5.2% in early trials on balloon angioplasty vs. 3.5% in recent trials on stented angioplasty [139,140]. Symptomatic relief was equivalent at the expense of an increased need for repeat revascularization in patients allocated to PCI. Compared with the balloon era, stented angioplasty using metallic stents has halved the risk difference for repeat revascularization at 1 year [139,140], which however remains at 18% after PCI vs. 4.4% after CABG (95% CI hazard ratio 3.3–5.9) (Fig. 15.5). The value of DES in treating patients with multivessel disease who would otherwise be candidates for bypass surgery was evaluated in the ARTS II registry [141]. At 1 year, clinical outcome was equivalent to the results obtained with bypass surgery in the surgical arm of ARTS I. These results provided the rationale and the design of prospective randomized clinical trials comparing CABG with DES in patients with multivessel disease (FREEDOM, SYNTAX).

PCI in specific patient and lesion subsets

Chronic total occlusion

Chronic total occlusion still represents the anatomical subset where PCI is associated with low technical success and high complication rate, including extensive



dissection, side-branch occlusion, distal embolization and coronary perforation [142]. When the occlusion can be crossed with a guidewire and the distal lumen has been reached, satisfactory results are obtainable with stent implantation albeit at the expense of a high restenosis rate (32–55%) [143]. The use of DES has been shown to improve these results in a significant way [144,145].

PCI in patients with multivessel disease and/or diabetes mellitus

In patients with multivessel IHD and high-risk profile, CABG was associated with better survival than PCI after adjustment for risk profile [146]. Initial differences in cost and quality of life between CABG and PCI were no longer significant at 10–12 years of follow-up [147]. Although a direct comparison of PCI with CABG in diabetics is not yet available, every subgroup or *post hoc* analysis has invariably shown that the outcome for diabetics is worse following PCI [148]. In the ARTS I trial [149], outcome for diabetics was poor in both treatment arms, but even more so following PCI. After 3 years, mortality was 7.1% in the PCI and 4.2% in the CABG group, with a still significant difference in event-free survival of 52.7% in the PCI group and 81.3% in the CABG group [150]. Preliminary data from ARTS II, a prospective registry [141], suggest that the use of DES in patients with multivessel disease and/or diabetes mellitus may change this situation, a possibility that is currently being evaluated in randomized trials.

PCI for unprotected left main disease

The presence of unprotected left main coronary artery stenosis identifies an anatomical subset that benefits from revascularization by CABG. Stenting for unprotected left main disease is considered in the absence of other revascularization options [151]. Initial data on the use of DES seem promising but remain observational [152].

PCI in patients at high surgical risk

The AWESOME trial [153] showed that PCI is a safe and effective alternative to CABG for patients with refractory

Figure 15.5 Meta-analysis of ARTS I, SoS, ERACI-2 and MASS-2 shows no significant difference in total mortality (A) or in combined irreversible events including death, myocardial infarction and stroke (B) between patients with multivessel disease randomized to percutaneous coronary intervention (PCI) or coronary artery bypass graft (CABG). However, the need for repeat revascularization procedures at 1 year following PCI remains nearly twice that after CABG (C).

ischaemia who are at high surgical risk. The 'patient choice registry' revealed that PCI, including PCI of protected left main (i.e. partially bypass protected), is a valuable option for many post-CABG patients, rather than repeat bypass surgery [153]. Other high-risk groups include the elderly [154] and patients with renal failure [155]. Both the SYNTAX and FREEDOM trials will capture the outcome data of these patient subgroups that are usually excluded from randomized clinical trials.

PCI for saphenous vein graft disease

Although stented angioplasty yields better immediate results than balloon angioplasty [156,157], later outcome is affected by further progression of graft atherosclerosis and thrombosis. PCI of *de novo* stenoses in vein grafts is a high-risk procedure due to the high likelihood of distal embolization of thrombotic or atheromatous debris, which is not reduced with the use of glycoprotein IIb/IIIa inhibitors [158]. The no-reflow phenomenon that follows is characterized by inadequate flow at tissue level despite a fully dilated/reopened epicardial conduit. The embolized areas undergo microvascular disruption, endothelial dysfunction, myocardial oedema or inflammation that may cause critical haemodynamic deterioration [159]. Prevention of embolization and no-reflow phenomenon entails the use of distal protection systems, some of which are of proven efficacy [160,161].

Adjunctive pharmacological treatment

Antithrombotic and antiplatelet regimen

The mechanical trauma induced by PCI to the endothelium and deeper layers of the vessel wall is a strong stimulus for platetet activation and clotting, which necessitates careful combined antiplatelet and anticoagulant treatment [162]. An increasingly aggressive pharmacological approach portends the risk of an excess in bleeding and vascular complications. Technical advances such as arterial access through the radial artery, the use of smaller size femoral sheaths and closure devices have permitted the safe use of multiple agents.

Since most PCI procedures are accompanied by stent implantation, all patients should receive aspirin and thienopyridine treatment [163,164]. To ensure full antiplatelet activity, clopidogrel should be initiated at least 6 h prior to the procedure with a loading dose of 300 mg, ideally administered the day before a planned PCI [165–167]. Prolonged treatment with clopidogrel (beyond 1 month) in patients with stable IHD is recommended after use of DES. There is presently no consensus on the optimal duration of dual antiplatelet therapy after DES but many physicians empirically recommend prolonged treatment up to 1 year, particularly after stenting of complex or multiple lesions. The impact of possible resistance to antiplatelet agents requires further investigation [168]. Glycoprotein IIb/IIIa inhibitors, the most potent antiplatelet drugs that block the fibrinogen receptor, were proven beneficial in high-risk PCI, particularly during acute coronary syndromes [169,170]. Given the overall low risk of PCI in stable IHD patients, the potential of glycoprotein IIb/IIIa receptor inhibitors of increasing the risk of bleeding complications and the considerable cost of their systematic use, they are not a part of standard periprocedural medication but should be considered in complex or high-risk procedures [171,172]. Unfractionated heparin is given as an intravenous bolus either under activated clotting time guidance or in a weight-adjusted manner (usually 100 IU/kg or 50 IU/kg if glycoprotein IIb/IIIa receptor inhibitor is given). Continued heparinization after completion of the procedure, either preceding or following arterial sheath removal, is not recommended. Low-molecular-weight heparins are considered to be more predictable anticoagulants than unfractionated heparin but data on their use as sole anticoagulant during PCI in stable IHD patients are limited. Bivalirudin is a direct thrombin inhibitor with short-lasting effect that should be used in patients with heparin-induced thrombocytopenia [173]. Bivalirudin monotherapy and provisional glycoprotein IIb/IIIa blockade provided comparable outcome to heparin plus planned glycoprotein IIb/IIIa inhibition [174–176]. The value of bivalirudin as first-choice anticoagulant during PCI is being assessed (ACUITY trial).

Post-procedural pharmacological treatment

Patients with chronic IHD undergoing PCI should benefit from secondary prevention measures [177] and hospital admission should be taken as an opportunity to implement changes in risk profile and to optimize pharmacological treatment. Surveys indeed indicate that ACE inhibitors and statins are underused in patients undergoing PCI [102].

Special devices and adjunctive technology

Atheroablative and debulking techniques

High-speed (140 000–180 000 rpm) diamond-burr rotablation pulverizes the atheroma. This technology is helpful in fibrotic or heavily calcified lesions that cannot be crossed by a balloon or adequately dilated before planned stenting [178]. Directional coronary atherectomy can remove obstructive plaque but has not proven clinically

beneficial [179,180]. The procedure is technically demanding, potentially associated with increased complication rates and of questionable value in specific lesion subsets (ostial and bifurcation stenoses). Cutting balloons create longitudinal plaque incisions and are marginally useful during the treatment of in-stent restenosis to avoid slippage of balloons at inflation.

Vascular brachytherapy

In-stent restenosis is due to intimal hyperplasia within metallic stents. In several randomized clinical trials, intracoronary brachytherapy showed significant improvement in angiographic and clinical outcome in native coronary arteries and in saphenous venous bypass grafts [115]. However, late thrombosis and late recurrence progressively reduce the initial benefit [116–118]. With the use of DES for both *de novo* stenting and the treatment of restenosis after bare-metal stenting, the indications for the more complex brachytherapy procedure are disappearing.

Intravascular ultrasound

By providing a cross-sectional quantifiable image of the lumen, plaque and vessel wall, intravascular ultrasound is a valuable adjunct to angiography, but its systematic use did not translate into a measurable reduction of major adverse clinical endpoints after PCI [181–183]. New developments include the analysis of the differential radiofrequency signals emitted by the various plaque components, a potentially useful application for plaque characterization [184].

Drug-eluting stents

DES using a wide variety of drugs and polymers have yielded opposing results indicating that not all approaches will uniformly prevent restenosis. Randomized clinical trials have shown positive angiographic and clinical results with the sirolimus- and the paclitaxel-eluting stents, initially in low-risk subjects and favourable lesion subsets (see Table 15.6) [120]. Compared with the use of bare metal stents, DES reduce the rate of major adverse cardiac events by 58% from 16.4 to 7.8%, a difference driven by a 74% reduction in the need for repeat revascularization. As the evidence is accumulating, indications for the use of DES are extended to small vessels, chronic total occlusions, bifurcational and ostial lesions, vein graft disease and in-stent restenosis.

Because stenting with DES now seems to confer durable results from the onset, indications for PCI are expanding to patient and lesion subsets that would otherwise require bypass surgery. Indeed, randomized clinical trials comparing PCI using DES with CABG in patients with unprotected left main stenosis and multivessel disease, particularly in the presence of diabetes, are ongoing. Similar to metallic stents, the major drawback of DES is (sub)acute stent thrombosis, an unpredictable event that is often accompanied by acute ischaemia and myocardial infarction. In pivotal randomized trials the rate of stent thrombosis varies between 0.6 and 1.6%, no different from the rate with bare stent controls [185,186]. Case reports of late (beyond 1 year) thrombosis shortly after interruption of clopidogrel, ticlopidine or aspirin treatment [187,188] suggest that the time window might be longer for DES than for metallic stents. Because of the perceived need for prolonged (3–6 months) prescription of aspirin and clopidogrel in order to avoid stent thrombosis, metallic stents are still preferred in patients scheduled to undergo extracardiac surgery.

Conclusions

PCI can be considered a valuable initial mode of revascularization in all patients with stable IHD and objective ischaemia in the presence of almost every lesion subset, with one exception: chronic total occlusions that cannot be crossed. The use of metallic stents and newer adjunctive medications has improved the procedural outcome after PCI. With DES, greater durability of the initial result is granted, now that the angiographic restenosis rate has declined below 10%. Until the results of proper randomized clinical trials become available, PCI should be used with reservation in diabetics with multivessel disease and in patients with unprotected left main stenosis. Therefore the decision to recommend PCI or CABG will continue to be guided by technical improvements in cardiology or surgery, local expertise and patients' preference [189].

Personal perspective

Angina is a common and disabling condition. We believe that secondary prevention is the way forward. Not only drugs but life-style modification is where the major opportunities lie in terms of preventing cardiovascular events in this patient population. We must also make every endeavour to develop new strategies and treatments to improve outcome, but we must ensure that properly tested measures and treatments are put into clinical practice. Undoubtedly there will be significant technological advances in operative techniques and in the deployment of new devices for percutaneous coronary intervention and cardiac surgery. However, although of considerable importance in improving symptoms and quality of life, these will be unlikely to play a major role in delaying or preventing cardiac events. While gene/stem-cell therapy provides a 'new frontier' and an exciting approach to treatment of atherosclerotic disease, any investment in this research has so far paid few dividends and we believe that it is unlikely to do so for some years to come.

Chapter 15: Management of Angina Pectoris - UPDATES

Since the publication of the book, the following updates have been made to the online version of this chapter.

In the final paragraph under the heading:

Drugs to improve outcomes in angina (secondary prevention)
Antiplatelet agents

The text:

'Clopidogrel has an established role in acute coronary syndrome . . . thrombin inhibitors are not indicated in stable angina.'

has been updated with the following text:

Clopidogrel has an established role in acute coronary syndrome (unstable angina and Non ST-segment elevation myocardial infarction (NSTEMI)) and in percutaneous coronary intervention (PCI). It has also recently been approved for use 'as early as possible after symptoms start . . .' in patients with ST segment elevation myocardial infarction (STEMI). The Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management and Avoidance (CHARISMA) study has established that there is no benefit overall of the combination of clopidogrel and aspirin in the long-term in patients with stable vascular disease. Adverse effects with clopidogrel are not dissimilar to aspirin but the frequency of severe rash is higher. Dipyridamole or anticoagulants such as warfarin or thrombin inhibitors are not indicated in stable angina.

16 Myocardial Disease

Otto M. Hess, William McKenna and Heinz-Peter Schultheiss, with co-authors Roger Hullin, Uwe Kühl, Mathias Pauschinger, Michel Noutsias and Srijita Sen-Chowdhry

Summary

Diseases of the myocardium can be divided into three different forms: primary myocardial disease (the cardiomyopathies), inflammatory myocardial disease (myocarditis) and secondary myocardial diseases. There is a large overlap between the three different forms. Furthermore, primary myocardial diseases are mainly genetically transmitted, whereas inflammatory and secondary myocardial diseases are mostly acquired.

Definition and classification

Primary myocardial diseases are described as cardiomyopathies. These are defined as disease of the myocardium associated with cardiac dysfunction. They are divided into five different groups (Fig. 16.1).

Inflammatory myocardial disease is defined as inflammation of the myocardium and its structures caused by infectious and non-infectious agents. The inflammation may involve the myocytes, interstitium, vessels and/or pericardium. However, inflammation of the endocardium (endocarditis) is a disease on its own and is described in Chapter 22.

Secondary myocardial diseases are defined as disease of the myocardium of known origin. There are seven subgroups:

1 ischaemic cardiomyopathy;
2 hypertensive cardiomyopathy;
3 valvular cardiomyopathy;
4 alcoholic cardiomyopathy;
5 metabolic cardiomyopathy;
6 muscular dystrophy cardiomyopathy;
7 peripartum cardiomyopathy.

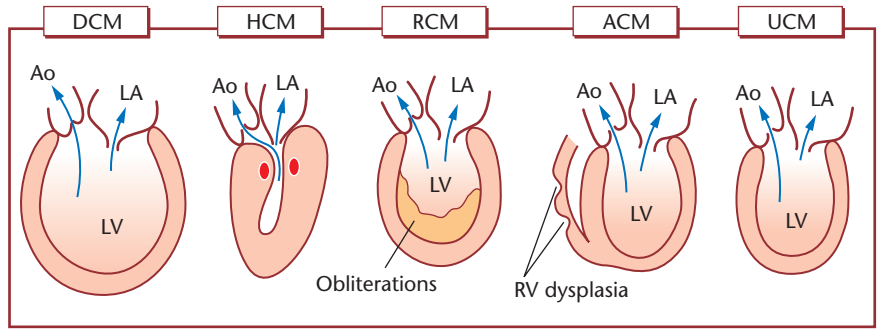

Figure 16.1 Classification of cardiomyopathies based on a report of the World Health Organization and International Society and Federation of Cardiology [38]. DCM, dilated cardiomyopathy; HCM, hypertrophic cardiomyopathy; RCM, restrictive cardiomyopathy; ACM, arrhythmic cardiomyopathy; UCM, unclassified cardiomyopathy.

Primary myocardial disease (cardiomyopathies)

Hypertrophic cardiomyopathy

Definition, aetiology and prevalence

The first account of hypertrophic cardiomyopathy (HCM) dates back to Donald Teare in 1958 who reported a common finding of asymmetric hypertrophy in the hearts of nine victims of sudden death from six families. Histological assessment of the myocardium revealed muscle bundles in different orientations separated by connective tissue. This seminal case series highlighted four cardinal features of the disease: unexplained hypertrophy of the left ventricle, myocyte disarray, familial occurrence and an association with sudden cardiac death (SCD). The pathological description coincided with growing awareness of left ventricular outflow tract obstruction (LVOTO) in young people without aortic valve disease, an entity then termed 'idiopathic hypertrophic subaortic stenosis'. Over the next two decades it became clear that neither the asymmetric distribution nor the presence of obstruction was necessary for a diagnosis of HCM; concentric, apical and eccentric patterns of hypertrophy are well recognized, while LVOTO has both clinical and prognostic importance but is present in less than one-quarter of these patients.

A milestone in the understanding of HCM came with the identification of mutations in the cardiac β-myosin heavy chain gene [1] (see Chapter 7). Later, other sarcomeric proteins were implicated in HCM, including α-tropomyosin, cardiac troponin T, troponin I, myosin-binding protein C, regulatory myosin light chain, essential myosin light chain, cardiac actin, titin, cardiac α-myosin heavy chain and troponin C. This led to the concept that HCM is a disease of the sarcomere, the contractile apparatus of the cell. Analysis of genotype–phenotype correlations demonstrated that hypertrophy is not essential for diagnosis, e.g. mutations in troponin T may be associated with subtle or no hypertrophy but a high incidence of SCD [2]. This established the view of HCM as an inherited heart muscle disorder caused by mutations in sarcomeric proteins, resulting in myocyte disarray, with or without fibrosis, myocardial hypertrophy and small-vessel disease (narrowing of intramural coronary arteries by medial thickening). The most common pattern of inheritance is autosomal dominant. Penetrance is incomplete and age-related: 55% for those aged 10–29 years, 75% for those aged 30–49, and 95% in gene carriers over the age of 50 [3].

Recently, attention has focused on non-sarcomeric variants of HCM, termed 'phenocopies'. The prevalence of HCM in the adult population is estimated at 1 in 500. However, only about 60% of adults with HCM have mutations in sarcomeric genes. A small proportion of the remainder may have unknown defects in components of the sarcomere, but this is unlikely to fully account for the discrepancy. Indeed, the majority of young children with left ventricular hypertrophy (LVH) do not have sarcomeric disease but rather metabolic disorders, mitochondrial cytopathies and syndromes with characteristic extracardiac features, disease states that may exist in adults with apparent HCM. Routine measurement of plasma α-galactosidase A levels among adult male HCM patients demonstrated a 4% prevalence of previously undiagnosed Anderson–Fabry disease [4]. Similarly, Danon's disease, another X-linked lysosomal defect, was identified in 1% of HCM index cases by DNA testing [5].

Timely detection of cardiac phenocopies of HCM is important. First, the cardiac profile is frequently distinct from that of sarcomeric HCM, with an increased incidence of conduction disease and progression to cavity dilation and heart failure. Management of these disorders also requires vigilance for extracardiac complications, such as skeletal myopathy, renal impairment and neurological involvement. Furthermore, specific therapies such as enzyme replacement in Fabry's disease may alter the natural history of the disease. Finally, recognition of recessive, X-linked and mitochondrial patterns of inheritance has major implications for familial assessment.

Towards a unifying hypothesis for the pathogenesis of HCM

The clinical, pathological and genetic diversity of HCM therefore precludes a comprehensive definition. LVH may be subclinical; myocyte disarray is present in Noonan's syndrome and Friedreich's ataxia but otherwise rare among the phenocopies; and a broad spectrum of genetic defects can give rise to HCM (Table 16.1).

That a single unifying mechanism may underlie sarcomeric HCM and the cardiac phenocopies is an attractive concept. One of the first attempts to define the primary dysfunction in HCM was the contractile deficit hypothesis [6]. It was theorized that the various sarcomeric mutations result in diminished contractility of cardiac myocytes. This in turn leads to increased cell stress, which induces production of trophic and mitotic factors that ultimately cause hypertrophy, myocyte disarray and fibrosis. Cytoskeletal function is impaired in dilated cardiomyopathy and after myocardial infarction, but preserved in HCM, accounting for the absence of cavity dilation in the latter. Early supporting evidence

Table 16.1 Disease-causing genes in hypertrophic cardiomyopathy (HCM) and phenocopies

Sarcomeric mutations (?ineffective ATP utilization)

Friedreich's ataxia (deficiency of frataxin, a key activator of mitochondrial energy conversion)
?Interference with ATP transport
Senger's syndrome
Syndromic HCM
Tyrosine phosphatase (Noonan's and LEOPARD syndromes)

LEOPARD, *l*entigines, *e*lectrocardiogram abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormalities of the genitalia, *r*etardation of growth, and *d*eafness; LHON, Leber's hereditary optic neuropathy; MELAS, mitochondrial encephalomyopathy, lactic acidosis, stroke-like episodes; MERRF, myoclonic epilepsy and ragged red fibres.

came primarily from *in vitro* studies demonstrating reduced contractility of cells expressing β-myosin heavy chain and troponin T mutations [7,8]. Conversely, several mutations in β-myosin heavy chain are associated with enhanced enzymatic and mechanical properties [9], troponin T mutants show enhanced thin filament motility [10,11], and mutant α-tropomyosin may allow increased force output at submaximal calcium concentrations [12]. Non-sarcomeric HCM is also less easily explained on the basis of diminished contractile performance.

More recently, Ashrafian *et al*. [13] have postulated a central role for compromised cellular energetics in the development of HCM and related phenotypes. The energy deficit may result from an aberration at any point along the pathway of ATP synthesis, transfer, regulation and expenditure.

- Abnormalities in the handling of glycogen (e.g. phosphorylase B kinase deficiency), glucose or fatty acids (e.g. CD36 and carnitine deficiencies) reduce the substrate available for ATP production.
- The mitochondrial cytopathies and Friedreich's ataxia may interfere with ATP synthesis [14].
- Senger's syndrome, characterized by HCM, congenital cataracts and lactic acidosis, is associated with low activity of mitochondrial adenine nucleotide translocator 1, responsible for ATP transport out of the mitochondria.
- Mutations in AMP-activated protein kinase, the cellular fuel gauge, have been linked to HCM with pre-excitation, conduction system disease and a propensity towards early cavity dilation and systolic impairment [15].
- Emerging data suggest that lysosomal storage of glycosphingolipids in Fabry's disease may cause reduced activity of respiratory chain enzymes [16].
- The sarcomeric mutations have differing effects on contractility, but inefficient ATP utilization is a shared consequence.

Finally, the cellular energy deficit impairs the functioning of the sarcoplasmic reticulum calcium reuptake pump. The prolonged cytosolic calcium transient may serve as the signal that triggers cellular hypertrophy, although the exact pathway remains to be unravelled. Indeed, genetic defects that produce an HCM-like phenotype by an unknown mechanism may turn out to be components of the downstream signalling pathway. An example is tyrosine phosphatase non-receptor-type II protein, which has been implicated in both Noonan's syndrome and LEOPARD syndrome (*l*entigines, *e*lectrocardiogram abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormalities of the genitalia, *r*etardation of growth, and *d*eafness).

The energy depletion hypothesis represents an attempt to reconcile the contrasting effects of the sarcomeric mutations on cellular contractility, and additionally succeeds in accounting for many of the cardiac phenocopies of HCM. Supporting evidence is emerging; magnetic resonance spectroscopy of mutations in β-myosin heavy chain, troponin T and myosin-binding protein C found significant reductions in the cardiac phosphocreatine to ATP ratio, an indicator of myocardial energy status [17]. Energetic abnormalities are also observed in ischaemic heart disease and heart failure, and have been considered

a consequence of hypertrophy rather than the primary defect. However, the presence of the bioenergetic deficit in non-penetrant gene carriers without hypertrophy argues against a secondary phenomenon [18]. Nevertheless, the value of any unifying paradigm is contingent on its relevance in the clinical arena. Grouping the sarcomeric mutations together remains meaningful owing to similarities in clinical presentation, risk stratification and management. Accordingly, validation of the energy depletion hypothesis awaits diagnostic and therapeutic applications. From a clinical standpoint, many disorders associated with unexplained hypertrophy have little in common with sarcomeric HCM, and are more usefully approached as distinct disease entities.

Pathophysiology

The main functional consequences of HCM are as follows.

DIASTOLIC DYSFUNCTION

Both the active and passive phases of diastole are abnormal in HCM. Isovolumetric relaxation in early diastole requires energy-dependent calcium uptake in the sarcoplasmic reticulum and is prolonged in HCM. Myocyte disarray, cellular energy deficit and altered affinity of mutant sarcomeric proteins for Ca^{2+} are all potential factors. Increased pressures are a corollary of ventricular filling prior to completion of active relaxation. Subendocardial ischaemia is both a contributor to diastolic dysfunction and a consequence of it, since the delay in pressure decay may result in diminished endocardial coronary blood flow.

Passive relaxation during ventricular filling in late diastole is determined by compliance. Both hypertrophy and interstitial fibrosis cause increased chamber stiffness in HCM, again resulting in increased filling pressures and reduced coronary blood flow.

Limited exercise capacity is common in HCM. Decreased time for filling at high heart rates, combined with impaired compliance, leads to a reduction in end-diastolic volume. This limits the ability of the left ventricle to augment stroke volume via the Frank–Starling mechanism. Chronotropic incompetence is common in HCM.

ISCHAEMIA

Reduced coronary flow reserve is well recognized in HCM; baseline coronary velocity is elevated compared with normal subjects, while velocities during hyperaemia are similar [18]. Systolic extravascular compression may play a role but does not wholly account for the deficiency, since the diastolic coronary vasodilator reserve is also diminished [19]. Changes in the coronary microcirculation have been implicated: arteriolar lumen area is smaller and capillary density is less, both parameters showing an inverse relationship with LVH [18]. Increased coronary conductance is thought to be related to higher oxygen demands of LVH. However, vascular medial hypertrophy and lack of capillary growth preclude increments in coronary conductance during hyperaemia.

LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION

LVOTO, once the defining feature, is present in around 25% of HCM. Obstruction may also occur at mid-cavity level, or distally in the form of apical obliteration. Subaortic LVOTO, with systolic anterior movement (SAM) of the mitral valve, is the commonest form and the most amenable to treatment.

Mechanism of SAM Current thinking dictates that two conditions facilitate SAM: (1) abnormal valve apparatus with sufficient slack in the leaflets to allow movement; and (2) a haemodynamic force with an anterior component during systole.

Primary structural abnormalities of the mitral valve apparatus have been observed in patients with obstructive HCM, the most important of which is anterior displacement of the papillary muscles (Figure 16.2) [20]. This predisposes to SAM by (1) reducing the posterior tension conferred by the papillary muscles on the mitral valve; (2) increasing the proximity of the leaflets to the

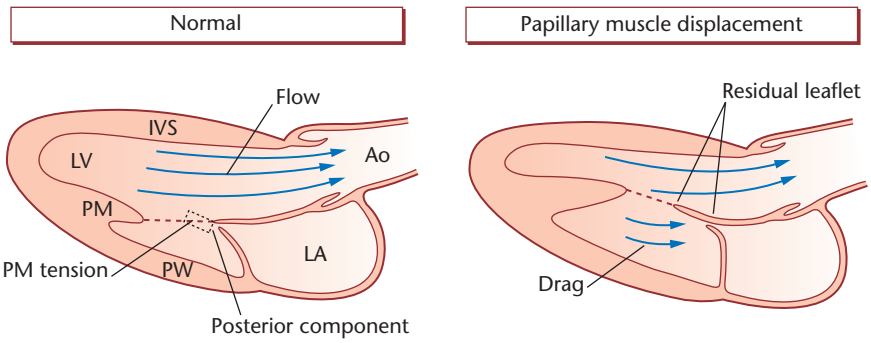

Figure 16.2 Anterior displacement of the papillary muscles in hypertrophic cardiomyopathy. Ao, aorta; IVS, interventricular septum; LA, left atrium; LV, left ventricle; PW, posterior wall. Reproduced with permission from Levine *et al.* [20].

left ventricular outflow stream; and (3) pulling the posterior leaflet upwards so that it meets the anterior leaflet near its mid-portion, thereby leaving a long portion of the distal leaflet unrestrained and susceptible to anterior forces. Incomplete coaptation of the leaflets also results in posteriorly directed mitral regurgitation. A central or anterior mitral regurgitant jet raises suspicion of intrinsic mitral valve disease.

The nature of the haemodynamic force has been subject to much debate [21]. Originally, SAM was thought to be due to the Venturi effect, which refers to the increase in velocity and concomitant decrease in pressure that occurs as fluid flows through a constriction. An object in the path of the fluid is subject to a force perpendicular to the direction of flow that pulls it into the stream. Thus, as blood is ejected into the narrow outflow tract in systole, it accelerates and a reduction in the static pressure occurs. The pressure difference thereby created pulls the mitral valve leaflet towards the septum.

Alternatively, the flow drag effect, i.e. the force exerted by a fluid in the direction of flow, may be involved. Thus, blood ejected into the LVOT pushes the free residual leaflet anteriorly. Doppler echocardiography suggests that SAM begins very early in systole, when the outflow tract velocity is normal [20]. The relatively low velocity is unlikely to generate significant Venturi forces; conversely, there will be increased contact of the flowing blood with the valve, augmenting the drag effect. Flow drag may therefore be the dominant hydrodynamic mechanism for SAM, although Venturi forces may also contribute as blood velocity in the outflow tract increases during systole.

ABNORMAL VASCULAR RESPONSES

In normal subjects, cardiac output rises during exercise. At high heart rates, filling time is reduced and augmentation of left ventricular end-diastolic volume requires increased venous return. This is dependent on constriction in non-exercising venous capacitance beds, which compensates for the vasodilation occurring in exercising muscle. The importance of this mechanism may be greater with HCM and diastolic dysfunction, which precludes adequate ventricular filling at high heart rates. Peripheral vasoconstriction is mediated by increased sympathetic stimulation during exercise, and partially attenuated by a number of vasodilatory influences, including stretch-induced activation of arterial baroreceptors and cardiac mechanosensitive receptors, and release of atrial and brain natriuretic peptides.

Around 30% of patients with HCM fail to increase their systolic blood pressure by ≥ 25 mmHg during exercise, or show a paradoxical fall in blood pressure of ≥ 20 mmHg. The inappropriate vasodilator response has been ascribed to excess stimulation of left ventricular mechanoreceptors by abnormal wall stress, due to myocyte disarray and fibrosis, exaggerated sensitivity of arterial baroreceptors and raised levels of natriuretic peptides [22].

ARRHYTHMIA

Triggers for ventricular arrhythmia in HCM include ischaemia, LVOTO, vascular instability and cellular energy depletion, while myocyte disarray and fibrosis provide the arrhythmogenic substrate. Non-sustained ventricular tachycardia (VT) occurs in around 20%. In contrast, sustained VT is rare and raises suspicion of a left ventricular apical aneurysm, sometimes seen in patients with mid-cavity obstruction.

Atrial fibrillation (AF) is linked with left atrial dilation, which is often associated with mitral regurgitation and LVOTO. As the most common sustained arrhythmia in HCM, chronic or paroxysmal AF is observed in 20–25%; subclinical AF may occur even more frequently. The prevalence of AF increases with advancing age.

WALL THINNING AND CAVITY DILATION

A decrease in left ventricular wall thickness was previously documented in up to 15% over 3 years [23]. Over a longer follow-up period, wall thinning ≥ 5 mm was noted in 60% of patients with severe LVH, accounting for the rarity of marked LVH in the elderly [24]. The mechanisms underlying left ventricular remodelling in HCM remain to be elucidated, although it is likely that ischaemia, compromised energetics and injury from abnormal haemodynamic loading lead to myocyte loss and fibrosis. However, cavity dilation and systolic impairment are infrequent, occurring in less than 5% of patients with HCM.

Clinical presentation

Clinicians should be alert to the possibility of HCM in a variety of circumstances (Table 16.2).

Diagnostic testing

Diagnostic testing should include a 12-lead ECG and echocardiography (Table 16.3). Family members will require assessment. Annual review is recommended from early adolescence, since the clinical manifestations of HCM frequently develop during pubertal growth. Relatives without evidence of disease at physical maturity were traditionally considered to be unaffected. However, growing recognition of late-onset HCM has led to the recommendation that adult relatives are offered continued evaluation on a 5-yearly basis [25]. Children below the age of puberty are usually assessed only if they are

Mode of presentation	Common aetiologies
Chest pain	Ischaemia, LVOTO
Exertional dyspnoea	Diastolic dysfunction
Reduced exercise capacity	LVOTO, systolic impairment, atrial fibrillation with uncontrolled ventricular response rate
Palpitation	Supraventricular arrhythmia (SVT, AF), ventricular arrhythmia (frequent VPBs, NSVT)
Syncope/presyncope	Supraventricular arrhythmia, LVOTO, vasovagal, ventricular tachyarrhythmia, vascular instability
Cardiac arrest	Ventricular tachyarrhythmia, supraventricular arrhythmia (e.g. AF) triggering VF, bradyarrhythmia, electromechanical dissociation
Incidental finding on health screen	
Familial evaluation	

AF, atrial fibrillation; LVOTO, left ventricular outflow tract obstruction; NSVT, non-sustained ventricular tachycardia; SVT, supraventricular tachycardia; VF, ventricular fibrillation; VPB, ventricular premature beat.

Table 16.2 Clinical presentation of hypertrophic cardiomyopathy and underlying mechanisms

Echocardiography

Major criteria

LV wall thickness ≥ 13 mm in the anterior septum or
≥ 15 mm in the posterior septum or free wall
Severe SAM (septum–leaflet contact)

Minor criteria

LV wall thickness of 12 mm in the anterior septum or posterior wall or of 14 mm in the posterior septum or free wall
Moderate SAM (no septum–leaflet contact)
Redundant mitral valve leaflets

Electrocardiography

Major criteria

Left ventricular hypertrophy and repolarization changes
T-wave inversion in leads I and aVL (≥ 3 mm) (with QRS–T wave axis difference ≥ 30°), V3–V6 (≥ 3 mm) or II and III and aVF (≥ 5 mm)
Abnormal Q (> 40 ms or > 25% R wave) in at least two leads from II, III, aVF (in absence of left anterior hemiblock), V1–V4; or I, aVL, V5–V6

Minor criteria

Complete bundle branch block or (minor) interventricular conduction defect (in LV leads)
Minor repolarization changes in LV leads
Deep S V2 (> 25 mm)
Unexplained chest pain, dyspnoea or syncope

Guidelines are applicable only to first-degree relatives of index cases with confirmed hypertrophic cardiomyopathy, all of whom have a 50% probability of carrying the mutation. Diagnosis is established in the presence of 1 major criterion, or 2 minor echocardiographic criteria, or 1 minor echocardiographic plus 2 minor electrocardiographic criteria. Other causes of left ventricular hypertrophy (e.g. athletic training and hypertension) may confound diagnosis.
LV, left ventricular; SAM, systolic anterior motion of the mitral valve.

Table 16.3 Guidelines for the diagnosis of familial hypertrophic cardiomyopathy

Table 16.4 Characteristic ECG findings in hypertrophic cardiomyopathy (HCM)

Left-axis deviation
Left bundle branch block
Pathological Q waves in inferolateral leads
T-wave inversion (commonly in inferolateral leads)
ST-segment changes
Criteria for left atrial enlargement
Giant negative T waves in V3–V5 or V4–V6 (distal HCM)

symptomatic, have a high-risk family history, participate in competitive sports, or when there is heightened parental anxiety.

The other issue pertaining to familial assessment is the need for sensitive diagnostic criteria. Systematic evaluation of patients with known disease-causing mutations has identified a sizeable subset (20–50%) who do not fulfil conventional echocardiographic criteria for HCM, but who nevertheless show discernible abnormalities on ECG and echocardiography. Since autosomal dominant inheritance implies a 50% probability of any first-degree relative carrying the gene, minor abnormalities are more likely to represent disease expression than in the general population (Table 16.3) [26].

Characteristic ECG findings in HCM are summarized in Table 16.4. Voltage criteria for LVH seldom occur in isolation in HCM, but are common in normal adolescents and young adults. Pre-excitation is a recognized feature, particularly in conjunction with mutations in AMP kinase; however, a short PR interval with a slurred QRS upstroke is not infrequently observed in HCM patients without accessory pathways.

Echocardiography is the first-line investigation for assessing wall thickness, cavity dimensions, systolic and diastolic function, and outflow tract obstruction. Exercise echocardiography is of value in patients with chest pain, dyspnoea or presyncope for determining dynamic LVOTO. Tissue Doppler imaging is a useful adjunct for identifying regional abnormalities in systolic and diastolic function and changes in long-axis function, particularly in subclinical forms of the disease. Although the original diagnostic criteria for HCM stipulated left ventricular wall thickness ≥ 15 mm, any degree and distribution of LVH may be present. Considerable attention has been focused on the difficulty in distinguishing morphologically mild HCM (wall thickness 13–14 mm) from hypertrophy in athletes. Diagnosis of HCM is facilitated by the presence of repolarization abnormalities or pathological Q waves on the ECG. Echocardiography may be helpful as the left ventricular cavity is commonly enlarged in athletes but small in HCM; diastolic function is normal or enhanced in athletes but usually impaired in HCM; and left atrial size is normal in athletes but often increased in HCM.

Patients with a confirmed diagnosis of HCM should undergo exercise testing on an annual basis. An abnormal blood pressure response is a risk factor for sudden death, although its prognostic impact appears to be greatest in patients under 40 years of age. Simultaneous metabolic gas exchange measurements are useful for obtaining an objective assessment of exercise capacity. Metabolic exercise testing may be important in differentiating HCM from cardiovascular adaptation to training; athletes frequently demonstrate peak oxygen consumption > 120% of predicted, while over 98% of HCM patients show abnormal indices.

Holter ECG monitoring is recommended annually. Findings include paroxysmal AF, which merits antiarrhythmic therapy for suppression and/or anticoagulation, and non-sustained VT, a risk factor for sudden death. Extended monitoring with an event recorder or implantable loop recorder may be warranted in patients with symptoms suggestive of arrhythmia.

Management

Management of patients with HCM (Fig. 16.3) aims to alleviate symptoms, prevent complications (e.g. AF) and reduce sudden cardiac death.

MEDICAL THERAPY

Asymptomatic patients with mild LVH should not receive drug therapy, whereas asymptomatic patients with severe LVH should be treated with verapamil to improve relaxation and diastolic filling thereby lowering diastolic filling pressure [27–29].

Symptomatic patients should be first treated with verapamil, a calcium channel blocker that improves diastolic filling (positive lusitropic effect; Table 16.5) and reduces systolic outflow tract obstruction (negative inotropic

Table 16.5 Common agents and doses for treating hypertrophic cardiomyopathy

Calcium channel blockers
Verapamil 120 mg two to three times daily
Diltiazem 180 mg once or twice daily
Beta-blockers
Inderal 80 mg two to three times daily
Metoprolol 100–200 mg daily
Bisoprolol 5–10 mg daily
Antiarrhythmic drugs
Amiodarone 100–200 mg five times weekly
Disopyramide 100 mg three times daily or 200 mg twice daily

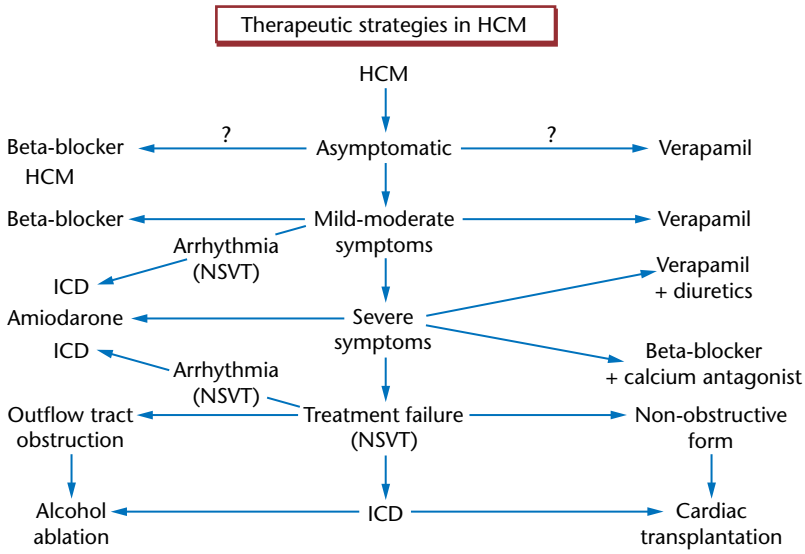

Figure 16.3 Treatment strategy in hypertrophic cardiomyopathy (HCM). ICD, implantable cardioverter-defibrillator; NSVT, non-sustained ventricular tachycardia. Reproduced with permission from Hess and Sigwart [30].

effect). As an alternative diltiazem may be used, although documentation is less extensive. If these drugs fail to improve symptoms, beta-blockers may be used either alone or in combination with a calcium channel blocker. Beta-blockers reduce outflow tract obstruction by their negative chronotropic and inotropic actions. Furthermore, the decrease in heart rate increases left ventricular size, which further reduces outflow tract gradient and increases diastolic filling time. However, these drugs exert no positive lusitropic effect and do not effectively improve diastolic function as do calcium channel blockers. Diuretics may be used in severely symptomatic patients to reduce filling pressure, although caution is recommended because these patients are sensitive to sudden volume changes. Volume sensitivity can be explained by the steep left ventricular pressure–volume curve, when a small drop in filling pressure reduces stroke volume and cardiac output dramatically. Diuretics may be used in combination with a beta-blocker or calcium channel blocker in order to reduce symptoms of pulmonary congestion.

Disopyramide, an antiarrhythmic drug that alters calcium kinetics, has been associated with symptomatic improvement and abolition of systolic pressure gradient. This effect has been attributed to its negative inotropic action and peripheral vasoconstriction. Nevertheless, long-term experience with this drug is limited.

Beta-blockers, calcium antagonists and the conventional antiarrhythmic drugs do not appear to suppress serious ventricular arrhythmias in HCM. However, amiodarone, which prolongs action potential duration and refractoriness of cardiac fibres, is effective in the treatment of both supraventricular and ventricular arrhythmias. Although it is believed that amiodarone improves prognosis and symptoms in HCM, only limited and inconclusive data are available. Amiodarone may be used in patients with supraventricular (AF) and ventricular tachyarrhythmias, although in severe cases implantation of a defibrillator may be mandatory.

Contraindications to medical treatment with calcium channel blockers or beta-blockers may be prolongation of the atrioventricular (AV) interval (risk of second- or third-degree AV block). Treatment with beta-blocking agents may be contraindicated in the presence of asthma bronchiale or chronic obstructive pulmonary disease.

Timing of therapy Treatment is indicated when the patient becomes symptomatic or LVH is severe. Refractoriness to medical therapy usually indicates progression of the disease. At this point more aggressive therapies such as alcohol ablation of the septum [30] or surgical septal myectomy are indicated. Double-chamber pacing for symptomatic relief and reduction of outflow tract obstruction has been used previously but is not recommended at present. However, insertion of an implantable cardioverter-defibrillator (ICD) is strongly advised in high-risk patients with severe LVH and a history of non-sustained or sustained tachyarrhythmias or syncopes [31]. Patients with severe LVH, recurrent syncopes, sustained and non-sustained ventricular tachyarrhythmias, a history of familial sudden cardiac death and a genetic phenotype for an increased risk of premature death should receive an ICD.

SURGICAL TREATMENT

Until recently, septal myectomy has been considered the treatment of choice for therapy-refractory patients with obstructive HCM [32,33]. Long-term follow-up after surgical myectomy has shown excellent results (Fig. 16.4)

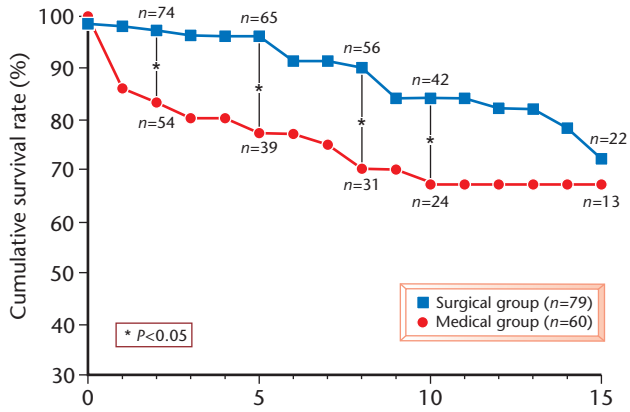

Figure 16.4 Cumulative survival rates of 139 patients with hypertrophic cardiomyopathy. Group 1, medical therapy ($n = 60$); Group 2, surgical therapy ($n = 79$). The average follow-up was 8.9 years for the entire study group, 8.2 years for Group 1 and 9.4 years for Group 2. Group 2 had higher 2-, 5-, 8- and 10-year survival rates than those of Group 1.

but ventricular remodelling with dilatation of the left ventricle may occur in 15–20% of patients. Alcohol ablation has changed this treatment strategy and surgical resection of the septum is reserved for selected cases with combined procedures such as coronary bypass grafting or mitral valve repair.

ALCOHOL ABLATION OF THE SEPTUM

Alcohol ablation of the ventricular septum can be considered to reduce LVOTO [34–36]. Outflow tract gradients of more than 30–50 mmHg at rest and 75–100 mmHg after provocation (extrasystole, isoproterenol infusion or amyl nitrite inhalation) are considered to qualify for septal ablation. With a small over-the-wire balloon catheter, 1–3 ml of pure alcohol are injected over 5 min into the first or second septal branch (Fig. 16.5) after identification of the correct ablation site by contrast echocardiography (Fig. 16.6).

Alcohol injection leads to a small myocardial infarction with a rise in creatine kinase (CK) of 500–1500 U/l. There is alcohol-induced septal hypokinesis, which leads to a reduction in outflow tract gradient (Fig. 16.7). In approximately one-third of patients the pressure gradient disappears immediately and in two-thirds after weeks or months (Fig. 16.8). Ventricular remodelling with a decrease in muscle mass and septal/posterior thickness takes 3–4 months.

Not all patients show a complete loss of outflow tract obstruction. Those who fail can be treated a second time. Complications include transient or permanent third-degree AV block (Fig. 16.9). Therefore, the procedure should not be done without a temporary pacemaker; 3–5% of all patients require definitive pacemaker implantation.

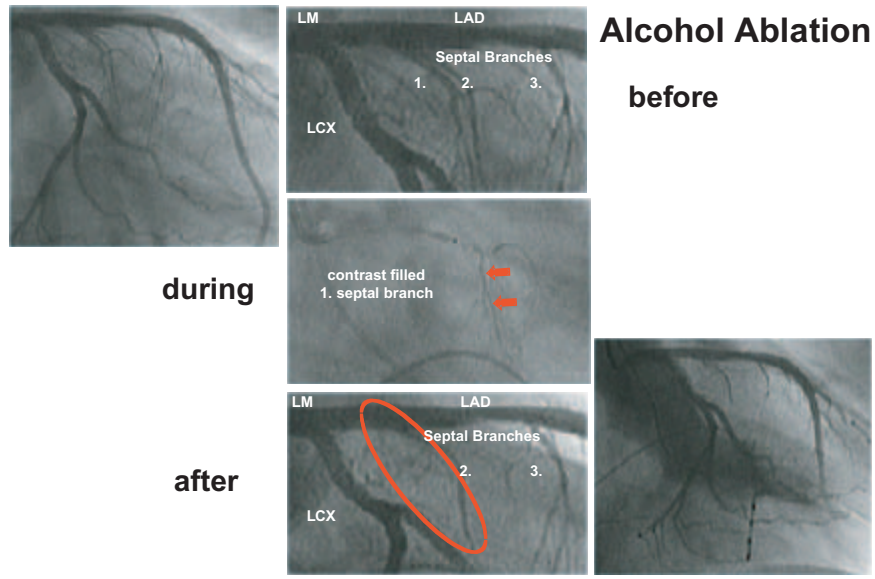

Figure 16.5 Coronary angiogram of the left coronary artery at high magnification. The left anterior descending (LAD) and left circumflex (LCX) coronary arteries can be clearly seen (top left) as well as the first (1), second (2) and third (3) septal branches (top middle). An over-the-wire balloon catheter is introduced into the first septal branch. The balloon is inflated and contrast material is injected (red arrows, middle panel) through the balloon catheter to identify the area at risk. Next, echocontrast (Levovist, Schering SA) is injected through the balloon catheter to identify the myocardial region in the two-dimensional echocardiogram. Pure ethanol is infused over 3–5 min, which leads to reduction or elimination of outflow tract obstruction. The last angiogram (bottom right) shows that the first septal branch has disappeared after alcohol injection (circle). LM, left main stem.

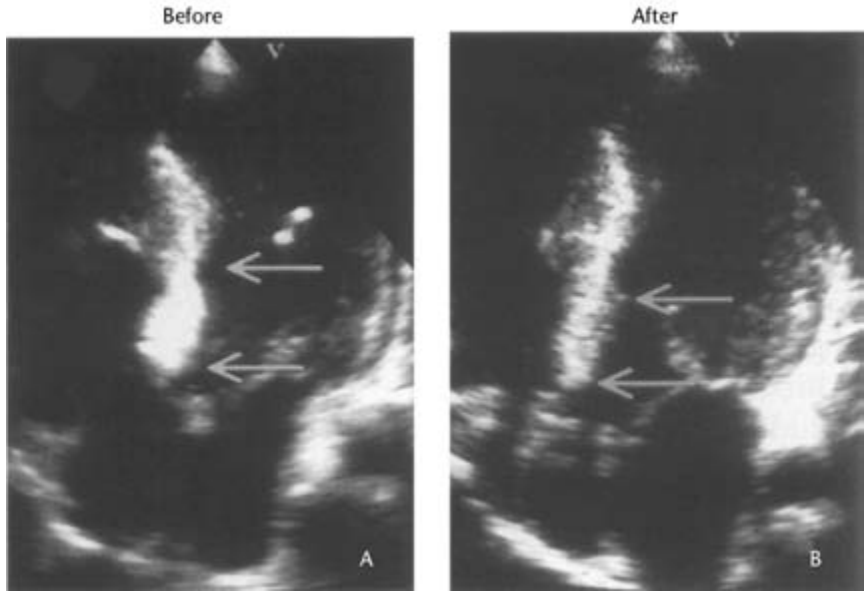

Figure 16.6 Two-dimensional echocardiogram before and after alcohol ablation. (A) Arrows indicate septal hypertrophy after injection of echocontrast medium. (B) Normalization of septal thickness 1 month after the intervention (arrows). Reproduced with permission from Faber *et al.* [36].

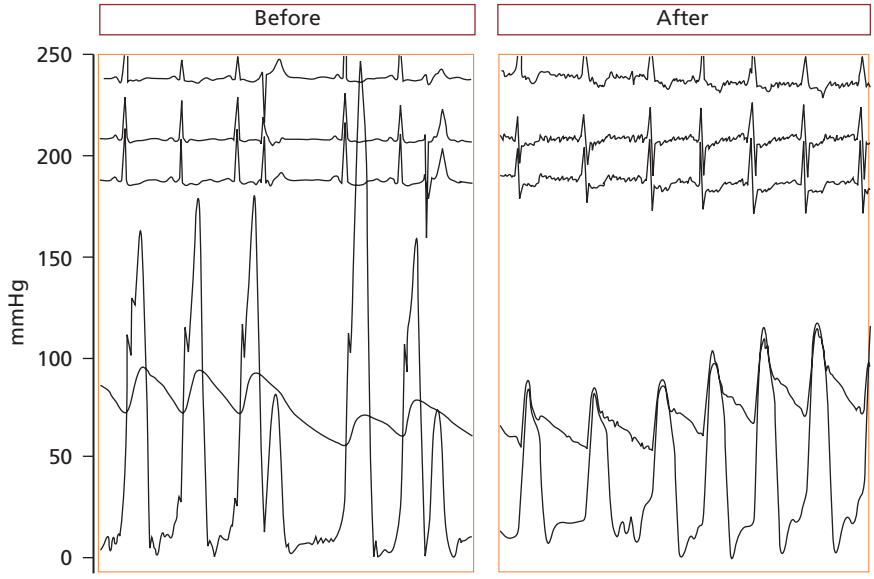

Figure 16.7 Pressure recording in a patient with hypertrophic cardiomyopathy before and after alcohol ablation of the septum. Before the intervention there is a large pressure gradient at rest (75 mmHg) and after post-extrasystolic potentiation (150 mmHg). The systolic pressure gradient disappears completely after alcohol ablation.

Complications

Sudden death is the most important threat for patients with HCM. Approximately 50–60% of those who die do so suddenly. Sudden death is assumed to be due to ventricular tachyarrhythmias, but haemodynamic factors and myocardial ischaemia may contribute. Young age (< 30 years) and a positive family history for cardiac arrest are risk factors for sudden cardiac death [37].

Syncopes may occur as a result of either arrhythmias or a sudden increase in outflow tract obstruction. Rapid changes in body position or strenuous exercise may lead to an increase in outflow tract obstruction because of a decrease in venous return with a decrease in cardiac volumes and an increase in outflow tract obstruction ('ASH-crash') or as a result of an increase in cardiac contractility with hypercontraction of the left ventricle (increase in outflow tract obstruction) and elimination of the left ventricular cavity (drop in cardiac output).

Strenuous exercise or competitive sports should be avoided because of the risk of sudden death. Typically, sudden death occurs during or after strenuous physical exercise.

AF as a cause of diastolic dysfunction, with increased filling pressure and dilatation of the atria, should be pharmacologically or electrically converted because of

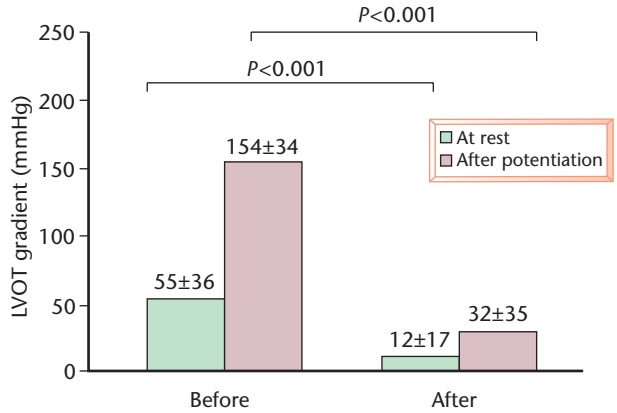

Figure 16.8 Left ventricular pressure gradient before and after alcohol ablation. Maximal pressure gradients are indicated at rest (first bar) and after post-extrasystolic potentiation (second bar). Data are shown at baseline (left bars) as well as 6 months after alcohol ablation (right bars). After the intervention there is a significant decrease in pressure gradients to one-quarter of the initial values.

the haemodynamic consequences of the loss of atrial contraction on cardiac output. If sinus rhythm cannot be reached, oral anticoagulation is mandatory when no contraindications exist.

Infective endocarditis may occur in about 5% of patients with HCM and antibiotic prophylaxis is indicated. Infection typically occurs on the aortic or mitral valve or on the septal contact site of the anterior mitral leaflet.

Prognosis and outcome

The clinical course in HCM is variable and may remain stable over years. However, HCM patients with risk factors such as a familial history of premature death, recurrent syncopes, septal thickness > 30 mm or a genetic phenotype with an increased risk of premature death may show a poor outcome [37]. Annual mortality rates have been reported to range between 2 and 3% but may be higher in children. Clinical deterioration is often slow but clinical symptoms are poorly related to the severity of outflow tract obstruction. Generally, symptoms increase with age. The occurrence of AF is an indicator of diastolic dysfunction with increased filling pressures and dilated atria. Timely conversion of AF is indicated.

Randomized clinical trials have not been undertaken, possibly because of the relatively low prevalence and the variability of the disease as well as the presence of symptomatic and asymptomatic patients. There is an urgent need for such randomized multicentre treatment trials.

Dilated cardiomyopathy

According to the WHO/ISFC Task Force on the Definition and Classification of Cardiomyopathies, the diagnosis of 'idiopathic' dilated cardiomyopathy (DCM) should only be made after exclusion of the specific cardiomyopathies [38]. Clinical evaluation alone does not allow reliable

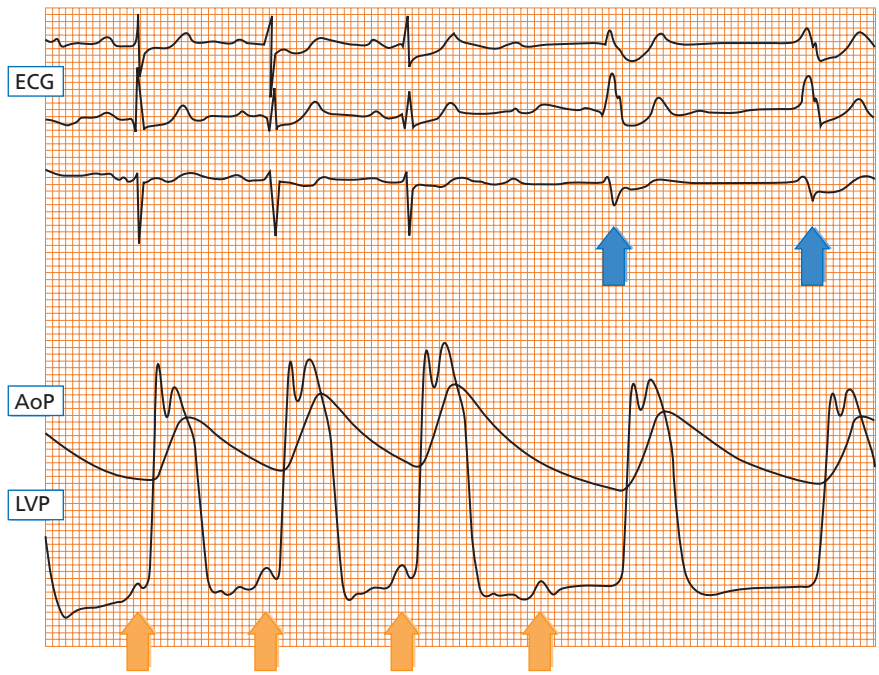

Figure 16.9 Simultaneous ECG and pressure recordings in a patient during alcohol ablation. Arrows indicate atrial contraction in the pressure curve (lower row). Occurrence of third-degree atrioventricular (AV) block can be seen after the fourth atrial beat, with a left ventricular escape rhythm (bundle branch block, dark arrows). Three to four minutes after the occurrence of third-degree AV block, normal sinus rhythm was restored. AoP, aortic pressure; LVP, left ventricular pressure.

segregation of specific cardiomyopathies, i.e. inflammatory, ischaemic and alcoholic cardiomyopathy, or cardiomyopathies associated with metabolic disorders [39–46].

Definition and prevalence

DCM is a chronic heart muscle disease characterized by cavity enlargement and impaired systolic function of the left or both ventricles (Table 16.6). The extent of myocardial dysfunction is not accounted for by abnormal loading conditions such as systemic hypertension or valve disease, previous infarction, ongoing ischaemia or sustained arrhythmia. The age-adjusted prevalence of DCM in the USA is 36 per 100 000 population.

Aetiology

Once considered idiopathic or sporadic, DCM is now recognized to be familial in at least 40–60%. Other factors linked with pathogenesis include anthracycline derivatives such as doxorubicin, and malnutrition, particularly thiamine and protein deficiencies. Many apparently secondary forms of DCM, notably alcoholic cardiomyopathy and peripartum cardiomyopathy, probably arise when incompletely penetrant genetic disease is unmasked by an additional insult to the myocardium (alcohol) or stress upon the cardiovascular system (pregnancy).

Table 16.6 Diagnostic criteria for dilated cardiomyopathy

1 Left ventricular ejection fraction < 0·45 (> 2SD) and/or fractional shortening < 25% (> 2SD), as ascertained by echocardiography, radionuclide scanning or angiography *and*
2 Left ventricular end-diastolic diameter > 117% of the predicted value corrected for age and body surface area, which corresponds to 2SD of the predicted normal limit + 5%
Exclusion criteria, which can lead to phenocopies
Systemic arterial hypertension (> 160/100 mmHg documented and confirmed at repeated measurements and/or evidence of target-organ disease)
Coronary heart disease (obstruction > 50% of the luminal diameter in a major branch)
History of chronic excess alcohol consumption, with remission of heart failure after 6 months of abstinence
Clinical, sustained and rapid supraventricular arrhythmias
Systemic diseases
Pericardial diseases
Congenital heart disease
Cor pulmonale

The prevalence of familial DCM has been underestimated, because disease expression is frequently incomplete in family members. Prospective evaluation of the asymptomatic relatives of DCM patients revealed isolated left ventricular enlargement in 20%, mild contractile impairment in 6% and frank DCM in 3% [47]. Asymptomatic relatives with left ventricular enlargement showed histological and immunohistochemical changes similar to those with established disease, including myocyte pleomorphism, interstitial fibrosis and markers of inappropriate immune activation [41]. A proportion of relatives with minor abnormalities progressed to overt DCM, underscoring their importance as markers of early disease. Thus, relying on the family history alone is not adequate, and clinical screening of relatives is requisite for identification of familial cases.

A further issue is the variability of the phenotype in familial DCM, which may include arrhythmia, stroke, conduction system disease and sudden death in addition to ventricular dilation and dysfunction. Since the most common pattern of inheritance is autosomal dominant, first-degree relatives of DCM index cases have a 50% probability of being genetically affected, and the likelihood that mild unexplained features represent disease expression is high. Specific diagnostic criteria have been proposed for familial DCM [48]. Variable and age-related penetrance is a second impediment to recognition of familial cases. In one Italian series, penetrance was 10% in those less than 20 years old, 34% in those aged 20–30 years, 60% in those aged 30–40 and 90% in those over 40 [48]. This is compounded by the fact that the families seen in clinical practice are often small. Estimation of the true prevalence of familial DCM will therefore necessitate serial assessment of extended families over lengthy follow-up periods.

In those with no family history, DCM has been thought to be due to acute myocarditis. A triphasic model has been proposed, with an initial insult to the myocardium, followed by chronic inflammation, leading to ventricular remodelling and dysfunction [49]. The primary insult is believed to be a viral infection. Enteroviruses and adenoviruses are most commonly implicated. Although acute viral myocarditis is rapidly fatal in a small subset of patients, predominantly children, the majority recover without complications. Some will develop chronic inflammation as a corollary of viral persistence or triggered autoimmunity, with endomyocardial biopsies demonstrating lymphocyte infiltration and histological markers of immune activation. Studies employing polymerase chain reaction (PCR) techniques to detect viral ribonucleic acid in cardiac tissue have reported positive findings in up to 35% of DCM patients [49]. More recently, it was reported that a high proportion of patients with

the acute or healing phase of myocarditis or DCM have immunohistochemical evidence of enterovirus capsid protein VP1 in myocardial tissue, indicating translation of viral epitopes and a role for latent viral infection in pathogenesis [50]. In a small cohort of patients with left ventricular failure and viral persistence, 6-month therapy with β-interferon resulted in elimination of viral genomes and improvement in left ventricular function [44]. However, the demonstration of viral presence in DCM does not amount to a causal link, particularly as enteroviral genome has also been detected in patients with ischaemic heart disease [51].

The autoimmune model of DCM invokes a central role for the immune system in causing continued myocardial injury. During the initial viral infection, an effective immune response is critical in preventing fulminant myocarditis, with clinical markers of immunity such as anti-cardiac IgG correlating with a favourable outcome [49]. Unfortunately, tissue damage during this initial insult may result in the presentation of previously sequestered myocardial peptides to the immune system. Alternatively, molecular mimicry between viral proteins and endogenous myocardial antigens may result in an organ-specific autoimmune response. A third potential mechanism involves viral-induced expression of class II major histocompatibility complex (MHC) molecules in cardiac tissue, leading to presentation of self-peptides to infiltrating T cells and activation of organ-specific immunity. Evidence for inappropriate class II MHC expression has been found in endothelial and endocardial cells from cardiac biopsies of patients with DCM. Lending further support to the autoimmune hypothesis is the presence of circulating heart-reactive antibodies in 25–30% of patients with DCM and symptom-free relatives [52]. Of note, cardiac antibodies were more commonly found among relatives who showed disease progression, but frequently became undetectable during follow-up and in advanced DCM. A possible role as early markers of disease susceptibility is therefore suggested. From a therapeutic standpoint, a 3-month course of steroids and azathioprine for immunosuppression was associated with early and lasting improvement in left ventricular function in DCM patients with evidence of MHC up-regulation on cardiac biopsy [46].

It should be noted that the familial preponderance of DCM is compatible with autoimmune pathogenesis, since susceptible self-antigens may bind more avidly to certain MHC alleles than others. The HLA-DR4 allele, for example, appears to confer a predilection for autoimmune disorders such as rheumatoid arthritis and multiple sclerosis, and does in fact show a weak association with DCM. Similarly, viruses may act as a trigger factor for the development of DCM in subjects with a genetic predisposition. The absence of viral nucleic acids in the hearts of patients with familial DCM [53] argues against this possibility, implying that viral DCM and familial DCM are indeed distinct patient populations. Furthermore, DCM behaves as a single gene disorder in many affected families, and the identification of disease-causing mutations has provided insight into its pathogenesis. Autosomal dominant transmission predominates in adult-onset DCM, although recessive, mitochondrial and X-linked forms are also recognized.

Genetics

Elucidation of the molecular aetiology of DCM has proved challenging because of its exceptional genetic heterogeneity. One of the first major breakthroughs was the identification of dystrophin as the causative gene in X-linked familial DCM [54]. Defects in dystrophin are also responsible for Duchenne and Becker muscular dystrophy [55]. While muscular dystrophy patients frequently develop DCM, skeletal muscle involvement is rare among sufferers with X-linked DCM, although serum CK muscle isoforms are elevated in both [54] (see also Chapter 7).

A 427-kDa rod-shaped protein, dystrophin, localizes to the inner aspect of the myocyte cytoplasmic membrane (sarcolemma). Its large size is thought to predispose to a high rate of spontaneous mutations [56]. Dystrophin binds to actin at its N-terminus and to the transmembrane dystrophin–glycoprotein complex at its C-terminus (Fig. 16.10), thereby providing a link between the cytoskeleton and sarcolemma. Most of the mutations isolated in X-linked DCM affect the N-terminal domain [54].

The first disease-causing gene in autosomal dominant DCM to be discovered was cardiac actin and was localized to chromosome 15q14 [55]. Actin is a sarcomeric thin filament with a dual function in myocytes: it interacts with other components of the sarcomere (β-myosin heavy chain, α-tropomyosin, troponins) and has a key role in force generation within the contracting myocyte. At its other end, actin binds to the anchoring proteins dystrophin and α-actinin (which resides in Z-bands and intercalated discs), thereby facilitating transmission of the contractile force to the sarcolemma and adjacent myocytes. Interestingly, mutations in the sarcomeric end of actin are associated with HCM [57], while defects in its anchoring end cause DCM, presumably via impaired force transmission. A similar mechanism has been invoked for the DCM-related α-tropomyosin mutations, which may cause localized charge reversal at the surface of the tropomyosin protein. This may affect stability of the tropomyosin molecule and disrupt its

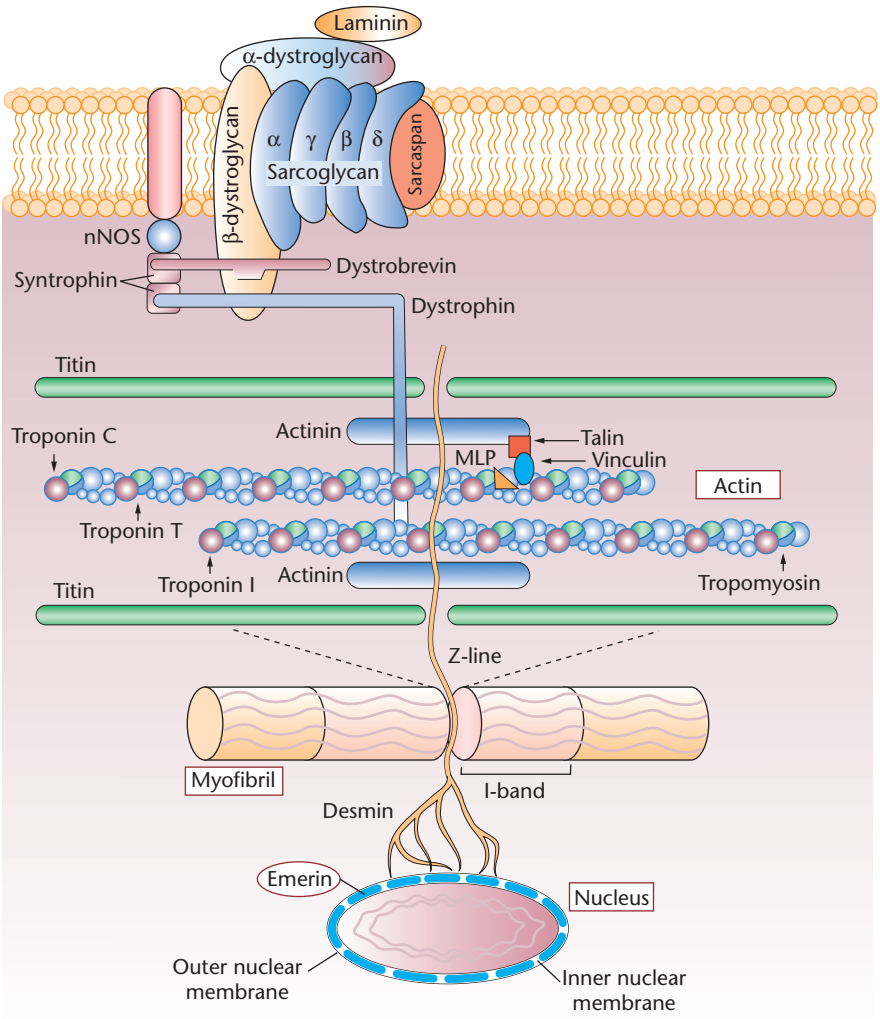

Figure 16.10 Proteins and pathways involved in the development of cardiomyopathy. nNos, neural nitric oxide synthase; MLP, muscle LIM protein. Reproduced with permission from Towbin and Bowles [54].

electrostatic interaction with actin within the thin filament [58]. The role of the thin filament in transmitting force to adjacent sarcomeres will be compromised [54]. In contrast, the tropomyosin mutations isolated in HCM cause an increase in isometric force output; inefficient sarcomeric ATP utilization is the likely consequence.

A missense mutation in the intermediate filament desmin has also been identified in a family with DCM [59]. The association of desmin, actin and dystrophin suggests that disruption of cytoskeletal function might be the final common pathway of disease expression [59]. In line with this, DCM mutations in δ-sarcoglycan [54], β-sarcoglycan [54] (both components of the dystrophin–glycoprotein complex), Cypher/Zasp (a Z-line protein that bridges the sarcomere to the cytoskeleton) [60] and metavinculin [59] (which connects actin filaments to the intercalated disc) have been found. Skeletal myopathy, which varies from subclinical to overt, may be an associated feature of some of these mutations.

Mutations in a number of other sarcomeric genes, including β-myosin heavy chain [61], cardiac troponin T and troponin C [62], may result in DCM. A recessive missense mutation in troponin I has also been isolated in a DCM family [63]. Early-onset disease expression and adverse prognosis have been reported in many families with sarcomeric DCM. The discovery of sarcomeric mutations in DCM raises two important issues. First, the mechanism by which these mutations induce ventricular dilation and impairment merits investigation; their functional effect is not readily explained by impaired transmission of force. Second, an explanation must be sought as to why certain sarcomeric mutations cause DCM, while other defects in the same genes produce the distinct phenotype of HCM. It has been proposed that the mutations associated with DCM may result in a deficit in force generation by the sarcomere. Conversely, the sarcomeric mutations that cause HCM may enhance mechanical function, and induce ventricular remodelling (i.e. hypertrophy) through ineffective utilization of ATP.

Impaired generation and transmission of force are therefore considered the key mechanisms underlying disease expression in DCM. Both may be relevant in the case of titin, a giant sarcomeric protein recently implicated in autosomal dominant DCM [61]. Titin binds to α-actinin, stabilizes the myosin filament and confers elasticity to the sarcomere. The position of the mutation is likely to be the main determinant of the functional effect.

Further gene identification studies have elicited mutations that are less easy to fit into the above model. An example is phospholamban, a transmembrane sarcoplasmic reticulum phosphoprotein that regulates the activity of the calcium reuptake pump. A missense mutation in phospholamban has been isolated in a family with autosomal dominant DCM [64], leading investigators to speculate that abnormal calcium handling, with consequent contractile impairment, may be an additional mechanism for the development of heart failure.

DCM in conjunction with conduction system disease is recognized in several kindreds. The autosomal dominant form is linked to mutations in the *LMNA* gene on chromosome 1q21 [61], which encodes two main isoforms, lamin A and C, by alternative splicing. The lamins are intermediate filament proteins of the inner nuclear membrane that are thought to contribute mechanical strength to the nuclear envelope. A role in transcription regulation is also postulated [65]. The phenotypic spectrum associated with mutations in lamin A/C is broad, encompassing skeletal myopathies, progeria, Charcot–Marie–Tooth disease and familial partial lipodystrophy, as well as progressive AV block and DCM. Disruption of the integrity of the nuclear envelope, resulting in premature cell death, has been suggested as the molecular basis for these diseases. However, the functional effect of specific mutations remains an area of active research. DCM with conduction system disease may also be inherited as an X-linked trait, in which emerin [66], another component of the nuclear membrane, has been implicated.

Despite the remarkable diversity of molecular mechanisms in DCM, the consequences at a cellular level are similar: neuroendocrine activation and local production of cytokines, maladaptive myocyte hypertrophy, apoptosis, fibrosis, and progressive ventricular dilation and impairment. Thus, the premise of a final common pathway may hold true. Recent studies demonstrate disruption of the N-terminus of dystrophin in both DCM and ischaemic heart failure, implying that loss of cytoskeletal integrity may be central to myocyte dysfunction in the failing heart. Of note, dystrophin remodelling was reversible following support with a left ventricular assist device (LVAD), suggesting that reduction of mechanical stress is critical to recovery of cellular and cardiac function [67].

Clinical presentation

CLINICAL COURSE

The natural history of DCM is heterogeneous and most patients are not critically ill. The prognosis of DCM has improved significantly in the last decades as a consequence of optimized treatment with angiotensin-converting enzyme (ACE) inhibitors and beta-blockers and, generally, is not different between sporadic or familial cases of DCM [68,69]. However, patients with DCM can be separated into two groups according to disease progression [68]:

1 patients with a more favourable outcome (group 1);
2 patients with a rapidly progressive downhill course, high mortality and urgent indication for heart transplantation (group 2).

More favourable outcome in DCM is associated with improvement in left ventricular function under medical treatment, a shorter duration of clinical symptoms, younger age, a worse NYHA class and a history of hypertension [70] (Fig. 16.11).

In patients with DCM, medical treatment with ACE inhibitors and/or beta-blockers improves left ventricular pump function in 50% of cases, while normalization occurs in 16%. In the remaining 33%, however, disease progresses long term, even independent of the initial response to treatment [68]. As many as 20% of patients with DCM will die within 1 year after diagnosis [71], most frequently due to sudden death (64%), with terminal

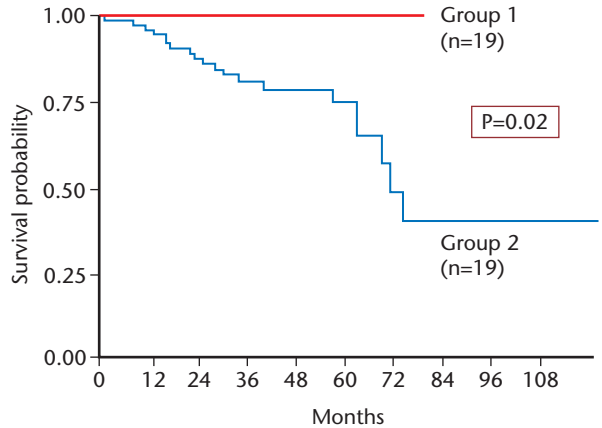

Figure 16.11 Kaplan–Meier survival curves of two groups of patients with dilated cardiomyopathy. Group 1, improvement of left ventricular ejection fraction (LVEF) with medical treatment; group 2, no improvement in LVEF. The survival probability was significantly different ($P = 0.02$).

heart failure accounting for most other cases. The 8-year transplant-free survival is as follows:

- 94% in those with normalized left ventricular ejection fraction (LVEF);
- 83% in those with functional NYHA class I–II and LVEF > 40%;
- 64% in those with NYHA class I–II when combined with LVEF ≤ 40%;
- 31% in those with persisting functional NYHA class III–IV.

CLINICAL SYMPTOMS

Clinical symptoms in patients with DCM are no different to those in patients with heart failure of other aetiology (see Chapter 21). Most often, DCM patients are less symptomatic and present with higher exercise tolerance when compared with other cardiomyopathies. Clinical symptoms in patients with DCM and systolic dysfunction of other aetiology can be grouped into major (specific) and minor (unspecific) criteria according to the Framingham study [72] and occur at different frequencies (Table 16.7).

Information from physical examination and medical history are not only valid and cost-effective for management decisions in heart failure but also relevant with respect to prognosis. Because of effective medical treatment, many patients with systolic pump dysfunction present with no or minor clinical symptoms. Nevertheless, the hepatojugular reflux and the third heart sound provide clinical information on the prognosis of the individual patient even in the context of best modern medical management [73].

Table 16.7 Clinical symptoms in patients with congestive heart failure: percentage occurrence of major and minor criteria

Major criteria	
Pulmonary rales	81%
Cardiomegaly	70%
Elevated jugular pressure	55%
Radiological signs of congestion	48%
Paroxysmal nocturnal dyspnoea	32%
Orthopnoea	31%
Third heart sound	19%
Minor criteria	
Exertional dyspnoea	93%
Peripheral oedema	56%
Depression	46%
Pleural effusion	32%
Hepatomegaly	14%
Nocturnal coughing	12%
Heart rate > 120 b.p.m.	4%
Weight loss < 4.5 kg in 6 months	2%

Pathophysiology

The initial stimuli that induce DCM are diverse: arterial hypertension, familial or genetic factors, myocarditis of viral or toxic origin, tachyarrhythmias, abnormal immune response. The consequent increased wall stress in combination with neurohumoral activation causes maladaptive changes in myocardial structure (remodelling), with complex molecular and cellular modifications. Histologically, remodelling is associated with cellular hypertrophy of cardiomyocytes, together with changes in the quantity and nature of the interstitial matrix. Biochemically, expression of the adult gene programme decreases and re-expression of fetal genes increases. Finally, the number of viable, functionally active cardiomyocytes decreases via programmed cell death (apoptosis) (Fig. 16.12). Several factors known to be present in the failing myocardium have been shown to cause apoptosis of cardiomyocytes *in vitro*:

- catecholamines via β-adrenergic signalling and reactive oxygen species [74];
- wall stress and angiotensin II [75];
- nitric oxide and inflammatory cytokines [76].

Thus it is not surprising that almost all the drugs used in heart failure have an antagonistic action on these pathways. All these drugs reduce and, potentially, reverse

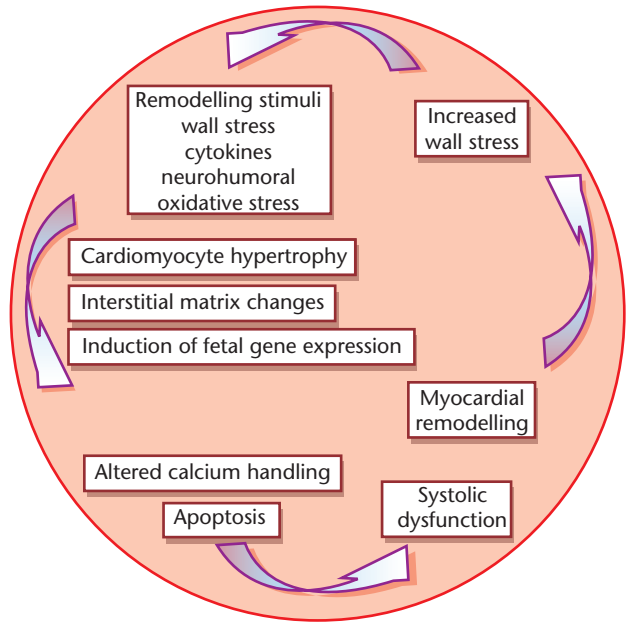

Figure 16.12 Vicious cycle in systolic dysfunction. Different remodelling stimuli induce complex cellular changes, ultimately resulting in systolic and/or diastolic dysfunction and increased wall stress, thereby promoting pathological remodelling.

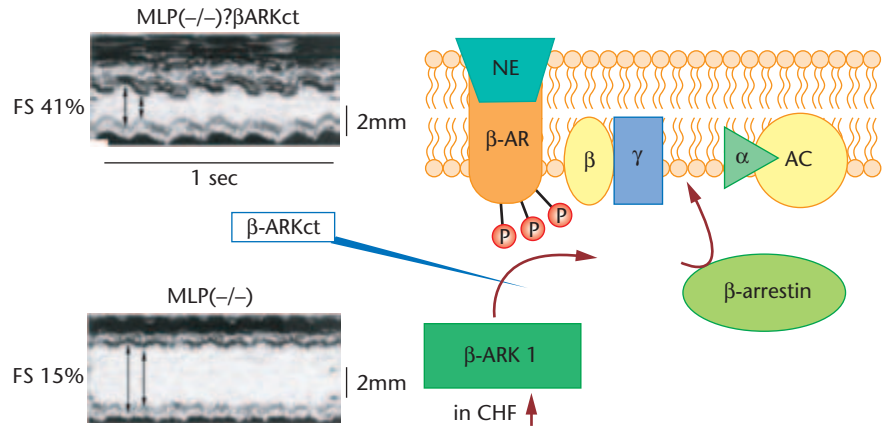

Figure 16.13 Signalling through the β-adrenergic receptor (βAR) in heart failure. βARK1 binds to the βγ-subunit of activated G-proteins, translocates to the sarcolemmal membrane and phosphorylates the agonist-occupied receptor. Phosphorylation allows binding of β-arrestin, uncoupling the receptor from further G-protein stimulation and downstream effectors such as adenylyl cyclase (AC). Both βARK1 and β-arrestin are required for homologous βAR desensitization, a phenomenon that occurs after the persistent agonist (noradrenaline, NE) stimulation characteristic of chronic heart failure. Expression of the C-terminal truncated, ineffective βARK1 in MLP (–/–) rescues myocardial function (see M-mode echocardiogram) and restores β-adrenergic responsiveness.

pathological cardiac remodelling and improve survival by attenuating stress signalling in the heart.

THE β-ADRENERGIC SYSTEM

Prolonged increased sympathetic activity results in both desensitization and down-regulation of sarcolemmal cardiac β-adrenergic receptors. Desensitization of β-adrenergic receptors is promoted by increased β-adrenoreceptor kinase (β-ARK) expression in the failing heart; this enzyme phosphorylates the β-adrenergic receptor [77]. Phosphorylated β-adrenergic receptors are then internalized and sequestered in the failing cardiomyocyte [78]. In the transgenic dominant-negative MLP mouse model of heart failure, cardiac expression of a dominant-negative β-ARK mutant restores β-adrenergic signalling and prevents progression to heart failure in several models of animal heart failure (Fig. 16.13). These results suggest that the loss of β-adrenergic signalling in the failing heart is a key mechanism, although the mechanism responsible for the salutary effects of beta-blockade still remain unclear.

CALCIUM HOMEOSTASIS

Calcium is vital for contractile function, and therefore it is not surprising that abnormalities in calcium handling have been implicated in the systolic dysfunction of DCM. Calcium ions enter the cardiac muscle cell through L-type calcium channels during each heart beat and trigger calcium release through ryanodine receptors. This raises the intracellular calcium concentration about tenfold. Reuptake of calcium into the sarcoplasmic reticulum via the sarcoplasmic reticulum Ca^{2+}-ATPase allows cardiac relaxation. The ability of the Ca^{2+}-ATPase to pump calcium back into the sarcoplasmic reticulum is governed by its interaction with phospholamban, a small modulatory protein within the membrane of the sarcoplasmic reticulum [79] (Fig. 16.14). In the failing heart, calcium release and uptake is diminished owing to a decrease in expression and activity of the Ca^{2+}-ATPase, resulting in diastolic and systolic dysfunction. The notion that aberrant calcium handling contributes to the pathogenesis of systolic dysfunction in DCM is supported by the finding that in mice lacking the cardiac LIM domain (double-zinc finger domain found in Lin1, Isl1 and Mec3 protein MLP, the heart failure phenotype is completely abrogated by homozygous deletion of the gene encoding phospholamban, which allows for enhanced calcium reuptake by the sarcoplasmic reticulum. However, the apparently beneficial effects of phospholamban ablation can be observed only in a subset of mouse models of DCM and heart failure because the phospholamban knockout does not rescue cardiomyopathic hearts resulting from sarcomere abnormalities [80].

NATRIURETIC PEPTIDES

Heart failure in DCM is accompanied by the up-regulation and secretion of atrial and B-type natriuretic peptides by the heart that signal through cell-surface receptors coupled to guanylate cyclase [81]. The resultant activation of protein kinase G by cGMP has been shown

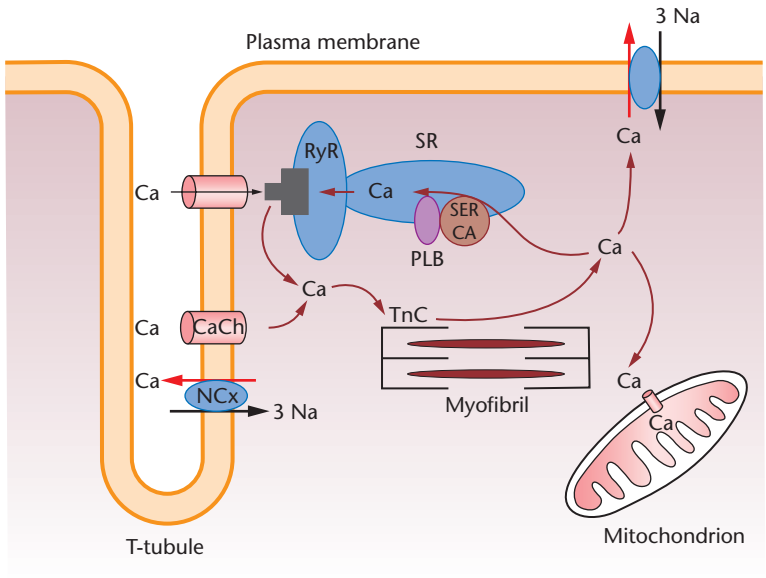

Figure 16.14 Calcium homeostasis. Membrane depolarization opens voltage-activated L-type calcium channels (CaCh), extracellular Ca^{2+} ions enter the cardiomyocyte and induce Ca^{2+} release by ryanodine receptors (RyR). Cytosolic Ca^{2+} concentration rises and intiates contraction. ATP-driven reuptake of Ca^{2+} ions into the sarcoplasmic reticulum (SR) by the sarcoplasmic Ca^{2+}-ATPase (SERCA) or extrusion of Ca^{2+} via the sodium–calcium exchanger (NCx) lowers cytosolic Ca^{2+} concentration and terminates contraction.

to suppress fetal gene activation through mechanisms that are only beginning to be unveiled. Nevertheless, the observation that gender influences the severity of cardiomyopathic phenotypes [82] suggests the presence of other underlying but not yet identified pathogenetic mechanisms.

Diagnostic testing

Clinical examination in patients with DCM is frequently of limited value in the assessment of haemodynamics and prognosis. Therefore, plasma biomarkers and physical examinations such as echocardiography, QTc interval or maximal exercise testing are often used to obtain additional objective information.

NEUROHORMONES

B-type natriuretic peptide, which is released in response to myocyte stretch [83], has become an established biomarker for guiding medical treatment [84]; furthermore, plasma concentrations approximately twice above normal are predictive of increased long-term mortality in patients with heart failure.

The plasma concentration of interleukin 6 correlates with the severity of symptoms and is an identified predictor of cardiovascular mortality in stable severe chronic heart failure [85]. Plasma concentrations of noradrenaline (norepinephrine) are predictive of cardiovascular morbidity and mortality.

ELECTROCARDIOGRAPHY

Electrocardiography provides no specific diagnosis in DCM. However, AF is associated with increased mortality or heart failure progression in all types of cardiomyopathy with chronic heart failure. In DCM, a decrease in heart rate variability due to chronic excessive sympathetic stimulation is related to an adverse prognosis [86], and prolonged QTc intervals predict mortality [87]. In addition, complex ventricular arrhythmias and decreased heart rate variability during 24-h Holter monitoring, when associated with low ejection fraction, place DCM patients at higher risk of death. Left bundle branch block with QRS duration of 130–150 ms reflects high intra-left ventricular dyssynchrony and has been proposed as a criterion for selecting patients for resynchronization therapy.

ECHOCARDIOGRAPHY

In DCM, LVEF < 30%, left ventricular end-diastolic pressure (LVEDP) ≥ 15 mmHg, and onset or worsening of mitral regurgitation are associated with increased cardiac mortality [87]. Furthermore, the size and shape of the left ventricle and the Doppler findings predict the development and severity of heart failure symptoms. A restrictive physiology with high atrial filling pressures is associated with a higher mortality rate. However, if the abnormal filling is reversed into one of pseudo-normal or impaired relaxation, the survival of DCM patients with this pattern is much better, whereas persistence of restrictive filling after 3 months despite optimal medical treatment is associated with a high mortality. Mitral valve insufficiency in DCM is associated with adverse prognosis; however, surgical mitral valve repair by undersized annuloplasty in combination with coaptation of the

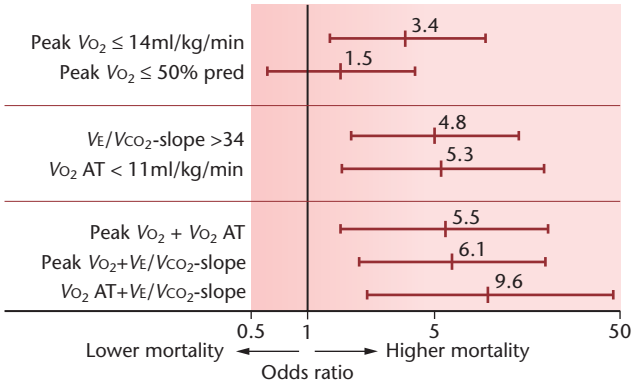

Figure 16.15 Cardiopulmonary exercise testing: predictors of death within 6 months in patients with ischaemic or dilated cardiomyopathy given as odds ratios (univariate analysis). Bars are 95% confidence intervals. Reproduced with permission from Gitt *et al*. [90].

Table 16.8 Survival in patients with ischaemic or dilated cardiomyopathy depends on the percentage achieved of predicted peak oxygen uptake

Percentage Vo_2max	1-year survival	2-year survival
≤ 50%	74%	43%
> 50%	98%	90%

mitral valve leaflets has a favourable outcome [88]. Thus, transoesophageal echocardiography plays an important role with respect to treatment of the mitral valve insufficiency in DCM.

CARDIOPULMONARY EXERCISE TESTING

Cardiopulmonary exercise testing measures the adequacy of the cardiac response to strenuous exertion and is an established predictor of risk in DCM [89] (Fig. 16.15 and Table 16.8). In addition, Vo_2 of anaerobic threshold (when < 11 ml/kg/min) and ventilatory efficiency (slope of VE vs. VCO_2) > 34 in combination are reliable predictors for 6-month mortality [90]. Prediction of prognosis is no different between ischaemic or dilated cardiomyopathy, although patients differ with respect to their neurohumoral profile.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) has become a new standard for the assessment of ventricular volumes, ejection fraction, myocardial mass and regional wall motion (Fig. 16.16). Paramagnetic contrast detects regional abnormalities in myocardial contraction [91]. In addition, late

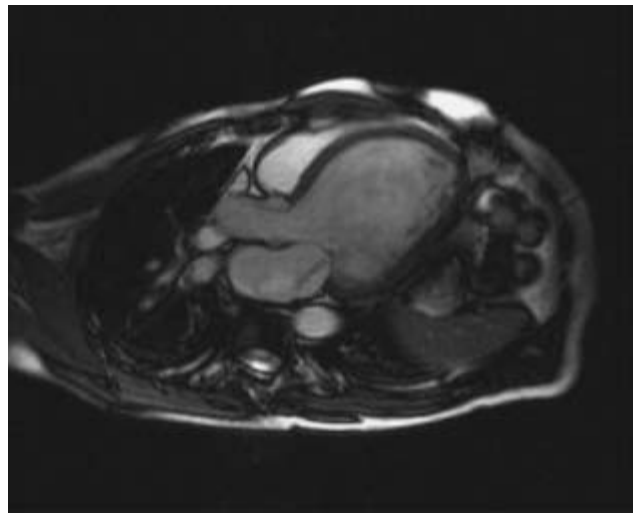

Figure 16.16 Cardiac magnetic resonance image in a patient with dilated cardiomyopathy. Horizontal transection of the dilated left ventricle with mitral jet due to mitral regurgitation.

enhancement marks areas of non-viable myocardium with higher sensitivity when compared with thallium scintigraphy [92].

LEFT AND RIGHT HEART CATHETERIZATION

Coronary angiography is required to exclude coronary atherosclerosis when the diagnosis of idiopathic DCM is considered. Additional information regarding cardiac output, wall stress, distensibility, compliance and pulmonary artery pressure can be obtained, and pulmonary wedge pressure or pulmonary resistance may add to risk stratification. Cardiac catheterization should not be considered when instituting chronic therapy.

ENDOMYOCARDIAL BIOPSY

Frequently, the histology of endomyocardial specimens is non-specific, with cardiomyocyte hypertrophy, enlarged nuclei and increased interstitial fibrosis. However, most asymptomatic relatives of patients with DCM with left ventricular enlargement have histopathological and immunopathological findings similar to those of patients with established disease [41]. In addition, *in situ* hybridization allows detection of persisting viral genome in endomyocardial biopsy (EMB) and thus the diagnosis of chronic myocarditis, even when microscopic examination does not demonstrate lymphocytic infiltration.

Management

Independent of the aetiology and possible specific

therapeutic options (e.g. anti-inflammatory, antiviral or immunomodulatory agents), the general guidelines for the treatment of heart failure apply equally to DCM, i.e. ACE inhibitors, angiotensin (AT)II receptor blockers, beta-blockers, diuretics, aldosterone antagonists, digitalis and cardiac transplantation [93,94]. Potentially cardiotoxic agents (i.e. alcohol, anthracyclines) should be discontinued [95]. In addition, exercise training can contribute to alleviation of heart failure symptoms and improve prognosis [96]. Similarly, in DCM with left bundle branch block and QRS duration > 120 ms and NYHA III–IV, cardiac resynchronization therapy may be considered [97–99] (see Chapter 21).

Cardiac transplantation remains the ultimate treatment option in patients with DCM with terminal heart failure refractory to conventional treatment [100]. LVADs may improve left ventricular function until cardiac transplantation ('bridge to transplantation') or until sustained improvement of left ventricular function occurs ('bridge to recovery') [101–103]. The value of partial ventriculectomy is limited [104].

Risk assessment and primary prevention of SCD is a challenge in DCM, especially since programmed ventricular stimulation has no predictive value as opposed to its use in ischaemic heart disease [105]. Aborted SCD is an indication for ICD (secondary prevention). Syncope is a strong predictor of SCD in DCM [106]. The combination of left ventricular end-diastolic diameter > 70 mm and non-sustained VT on Holter monitoring, and the combination of LVEF < 30% and non-sustained VT on Holter monitoring may identify patients at higher risk for SCD [107,108]. Conventional heart failure treatment also reduces mortality due to prevention of SCD (see Chapter 24) [109,110]. Microvolt T-wave alternans constitutes a promising method for the prediction of arrhythmic events [111]. ICD appears superior in the primary prevention of SCD compared with amiodarone: whereas the AMIOVIRT study showed no significant difference between amiodarone or ICD [112], the COMPANION trial [99] and the SCD-Heft trial demonstrated the superiority of ICD [113]. Rate control and/or rhythm control should be achieved in DCM patients with AF.

Anticoagulation is indicated in DCM patients with AF [114]. In light of the thromboembolic complications in DCM patients with substantially impaired left ventricular function [115–117], anticoagulation should be prescribed. However, evidence from the ongoing randomized WATCH trial on the benefit of anticoagulation in DCM patients with sinus rhythm must be awaited [118].

Genetic counselling is advisable in patients with familial DCM and their first-degree relatives. Since a high proportion of affected relatives are asymptomatic despite left ventricular enlargement, screening (ECG, echocardiography) should be performed in first-degree relatives [119].

Prognosis and outcome

The 5-year survival of DCM patients averages between 36% [120] and 30% [121]. After the initial diagnosis of DCM, clinical courses are highly heterogeneous. Identification of modifiable prognostic factors and elaboration of effective interventions is important for the outcome of DCM patients. Detailed prospective investigations have been elucidated by the Heart Muscle Disease Study Group. A subgroup characterized by a rapidly progressive course with high mortality rates, need for inotropic and/or LVAD support and urgent transplantation can be distinguished from the subgroup with more favourable outcome responding to concurrent heart failure medication (about 50% of patients). Less frequently (about 16%), healing courses can be observed [68], especially in the setting of acute DCM/fulminant myocarditis [122–124]. Transplant-free survival, as well as SCD, in

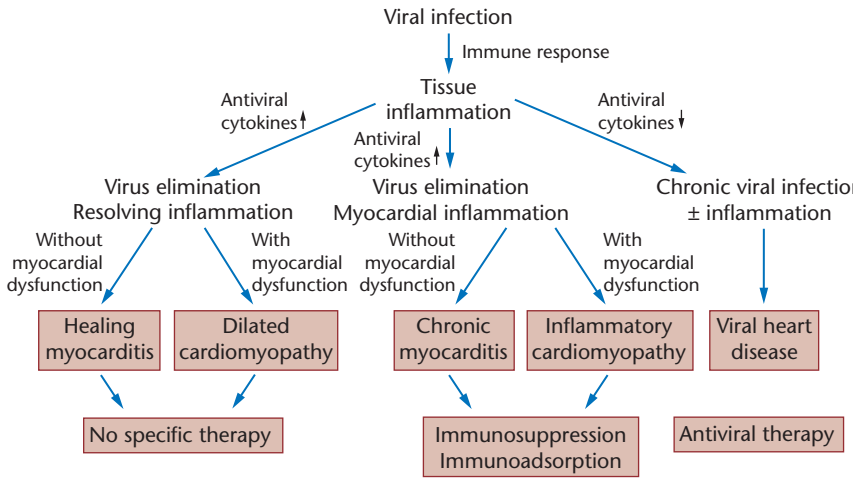

Figure 16.17 Pathophysiology of inflammatory cardiomyopathy and specific treatment options.

DCM patients is significantly associated with the course of NYHA/LVEF improvement under optimized heart failure medication [68].

Evidence emerging confirms the decrease in mortality and hospitalization of DCM patients undergoing heart failure treatment [68,125]. However, this treatment does not specifically target the cause of the disease, and some DCM patients do not respond (Fig. 16.17). Pathogenic substrates of DCM, namely inflammation and especially cardiotropic viral persistence/viral replication, are associated with adverse outcome [126–129], whereas histological morphometric analyses have no predictive value [130,131]. There is an emerging role for gene mutations, which are associated with a worse prognosis in DCM [132].

Several immunomodulatory trials have demonstrated sustained beneficial effects in DCM patients with chronic progressive courses despite full-scale heart failure medication [44–46]. However, results from ongoing multicentre trials must be awaited.

Restrictive cardiomyopathy

Definition and classification

Restrictive cardiomyopathy is characterized by abnormal diastolic function with either thickened or rigid ventricular walls leading to elevated filling pressures of the left- or right-sided cardiac chambers. In contrast to constrictive pericarditis, left- and right-sided diastolic filling pressures are discordant in restrictive cardiomyopathy but concordant in constrictive pericarditis. 'Discordant' describes the haemodynamic phenomenon of dissociation between left and right ventricular diastolic filling pressures during respiration, whereas 'concordant' describes parallel changes in both left and right ventricular diastolic pressures during respiration (Fig. 16.18).

The classification of restrictive cardiomyopathy is based on aetiological and clinical findings.

1 Primary forms
- (a) Löffler's endocarditis
- (b) Endomyocardial fibrosis

2 Secondary forms
- (a) Infiltrative diseases
- (b) Storage diseases
- (c) Post-radiation disease

Primary forms are associated with inflammation and hypereosinophilia and are due to chronic inflammatory processes, i.e. parasite infections, autoimmune diseases or eosinophilic leukaemia. Primary forms are rare in Western industrialized countries but may be endemic in some African or South American countries [133–137]. Secondary forms are caused by a variety of systemic diseases which are associated with thickening of the myocardial wall by infiltration, storage or excessive fibrosis.

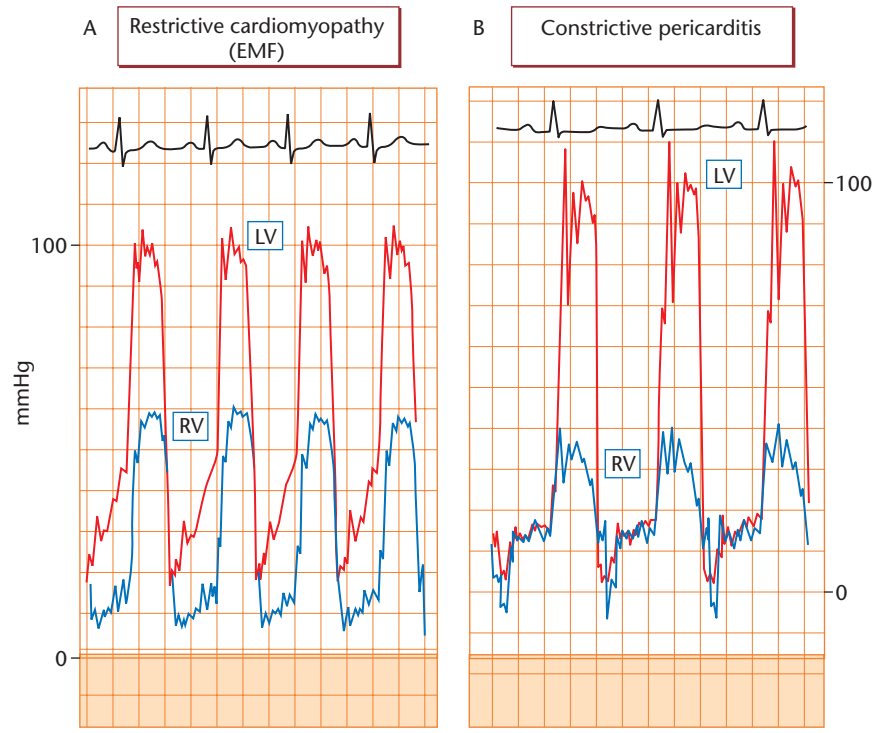

Figure 16.18 Simultaneous pressure recordings of the left ventricle (LV) and right ventricle (RV) in restrictive cardiomyopathy (A) and constrictive pericarditis (B). Diastolic pressures are discordant in (A) but concordant in (B).

Secondary forms are classified by the specific type of material deposition, i.e. infiltration, storage or replacement. Depending on the degree of infiltration or storage, clinical course in restrictive cardiomyopathy is often mitigated [137–140].

Primary forms

There are two primary forms of restrictive cardiomyopathy: the acute form, which is called Löffler's endocarditis, and the chronic form, which is termed endomyocardial fibrosis.

Löffler's endocarditis

The acute form of primary restrictive cardiomyopathy was described for the first time by Wilhelm Löffler in Zurich in 1936 [141]. He observed two patients who died from endocarditis, with extensive fibrosis of the endocardium and thrombotic thickening with severe blood eosinophilia. The fibrotic process is usually located at the apex of one or both ventricles and extends into the inflow tract, frequently involving the chordae tendineae [142–146]. These obliterations cause mitral and/or tricuspid regurgitation. Histological examination shows acute eosinophilic myocarditis involving both the endocardium and myocardium, with mural thrombosis often containing eosinophils and fibrotic thickening.

PATHOPHYSIOLOGY

The pathophysiological mechanism is not clear but eosinophils are thought to play a major role. Any process associated with hypereosinophilia for several weeks or months may lead to eosinophilic myocarditis [139,140]. Patients may die ultimately from cardiogenic shock, thromboemboli, or renal or respiratory dysfunction. Hypereosinophilia may be due to autoimmune disease, rheumatoid arthritis, parasite infections or eosinophilic leukaemia [147]. The patient shown in Fig. 16.19 suffered from eosinophilic leukaemia that was stabilized by medical therapy. Because of severe congestive heart failure, the patient underwent left ventricular decortication, which was associated with a dramatic clinical improvement. One year after the operation, the patient died from recurrence of eosinophilic leukaemia.

CLINICAL MANIFESTATIONS

The typical clinical symptoms include weight loss, fever, cough, rash and congestive heart failure. Although early cardiac involvement may be asymptomatic, cardiac dysfunction can be found in more than 50% of all patients. Cardiomegaly may be present on the chest radiograph, with lung congestion. Mitral or tricuspid regurgitation is common in most patients. Systemic embolism is frequent and often associated with neurological and renal dysfunction. Death is usually due to congestive heart failure.

DIAGNOSIS

Chest radiography may show cardiomegaly and pulmonary congestion, with dilatation of one or both atria. The ECG usually shows non-specific ST-segment and T-wave abnormalities. Arrhythmias are often present, especially AF [138]. The most important tool for diagnosis is echocardiography, which shows localized thickening of one or both ventricles at the apex (Fig. 16.19) with involvement of the chordae tendineae. Typically the atria are enlarged, associated with mitral and/or tricuspid regurgitation. Systolic function is usually preserved, with a typical restrictive mitral inflow pattern [143]. Cardiac catheterization shows markedly elevated ventricular filling pressures in the presence of a small ventricle with typical obliterations of the apex. Most patients have mild to moderate tricuspid or mitral regurgitation. The diagnosis may be confirmed by right or left ventricular EMB.

MANAGEMENT

Cardiac therapy is based on treatment of restrictive cardiomyopathy, including diuretics and after-load reduction with ACE inhibitors or AT1 receptor blockers. Beta-blockers may be used for reducing heart rate, or digitalis in the case of AF. Because of the risk of cardiac embolization, low-molecular-weight heparin or oral anticoagulation is mandatory.

Medical therapy depends on the aetiology of the hypereosinophilic syndrome: autoimmune disease may be treated with corticosteroids or immunosuppressive agents, rheumatoid arthritis with anti-tumour necrosis factor α, or eosinophilic leukaemia with antiproliferative agents [144].

Surgical therapy may be considered in patients who remain symptomatic but have been stabilized medically (Fig. 16.19). Endocardial decortication of one or both ventricles may be performed and may improve cardiac symptoms and reduce cardiac mortality.

PROGNOSIS

The classic syndrome of Löffler's endocarditis is associated with a poor prognosis and most patients die within 6–12 months. Since the cause of hypereo-sinophilia remains unknown in most patients, clinical outcome is often poor, although corticosteroids may suppress hypereosinophilia. Those patients with a known aetiology for hypereosinophilia may do better [145].

DIFFERENTIAL DIAGNOSIS

In a subacute phase, Löffler's endocarditis may mimic

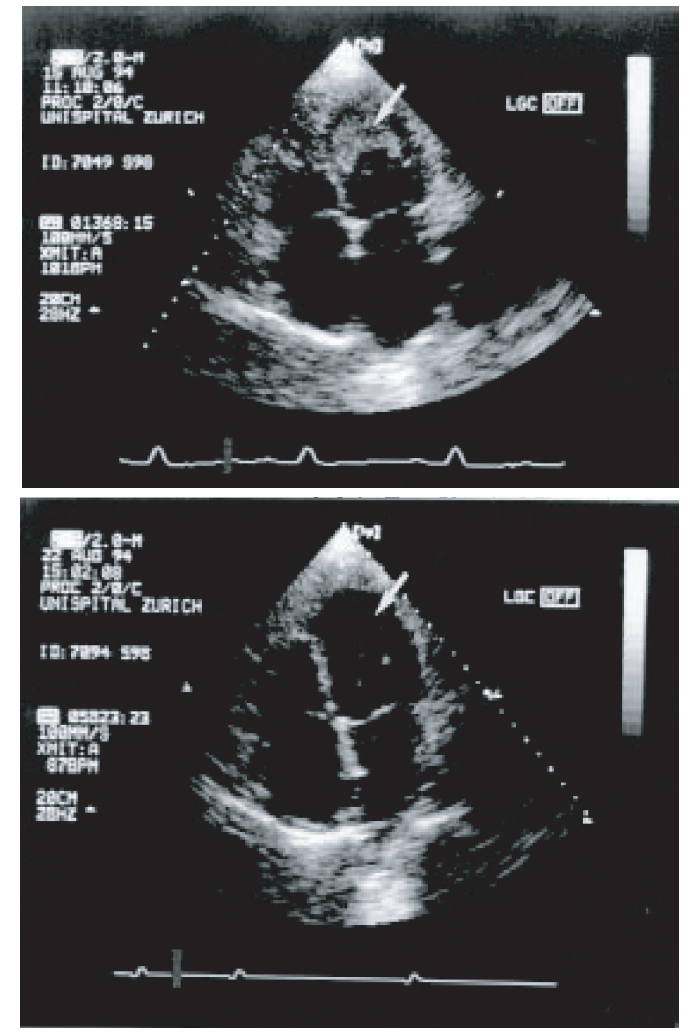

Figure 16.19 (A) Preoperative and (B) postoperative two-dimensional echocardiograms (four-chamber view) of a patient with eosinophilic leukaemia and Löffler's endocarditis of the left ventricle. Preoperatively, the left ventricle is globular and small but regains normal size with a clear decrease in left atrial chamber volume after surgical decortication.

chronic endomyocardial fibrosis. However, the clinical picture of acute illness, fever, cough, congestive heart failure and hypereosinophilia is so typical that correct diagnosis should not be missed.

Endomyocardial fibrosis

Endomyocardial fibrosis was first described in 1936. Since then, the endemic or equatorial African and the sporadic European form have been characterized. Endomyocardial fibrosis is marked by intense endocardial thickening of the apex and subvalvular apparatus of one or both ventricles [137,138]. The fibrotic thickening of the apex leads to obliteration of one or both ventricles, with obstruction to filling producing restrictive and, in some biventricular forms, constrictive physiology.

Three types of endomyocardial fibrosis have been described: right ventricular (10%), left ventricular (40%) and biventricular (50%) (Fig. 16.20). The African form is associated with a mean age of approximately 30–40 years and a male-to-female ratio of 2 : 1. The European form is associated with a mean age of 30–50 years and a male-to-female ratio of 1 : 2.

AETIOLOGY

The term 'primary restrictive cardiomyopathy' suggests idiopathic pathophysiology without a clear infective agent or autoimmune disease. In fact, aetiology appears to be multiple, such as parasite infections in equatorial Africa (filariasis) or autoimmune diseases associated with glomerulonephritis or rheumatoid arthritis.

The common pathophysiological pathway for both Löffler's endocarditis and endomyocardial fibrosis is probably excessive blood eosinophilia [139,145]. Hypereosinophilia of any cause (parasite infection, autoimmune disease, eosinophilic leukaemia, etc.) may also be responsible for the occurrence of endomyocardial fibrosis. It is believed that eosinophils are mechanically

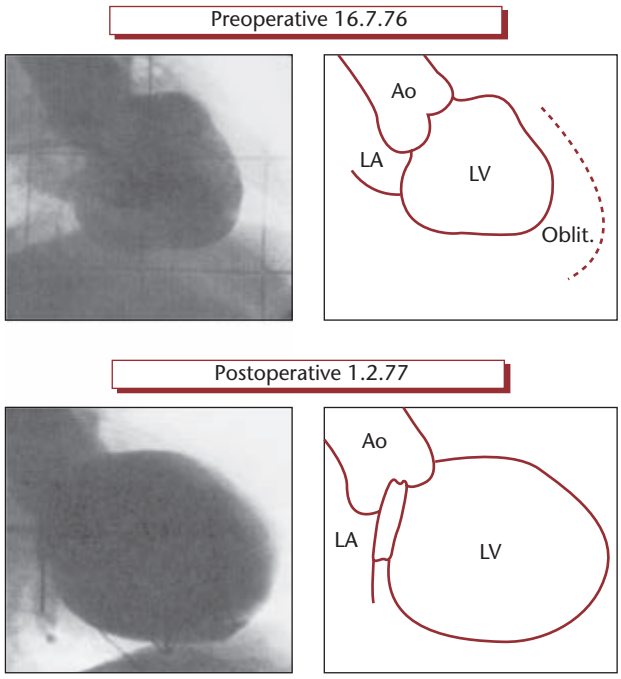

Figure 16.20 Preoperative (top) and postoperative (bottom) angiograms in a patient with biventricular endomyocardial fibrosis. The left ventricle (LV) is of globular shape with severe regurgitation into the left atrium (LA). After surgical decortication, the ventricle is significantly larger and mitral regurgitation is no longer present due to prosthetic valve replacement. Ao, ascending aorta. Reproduced with permission from Hess [137].

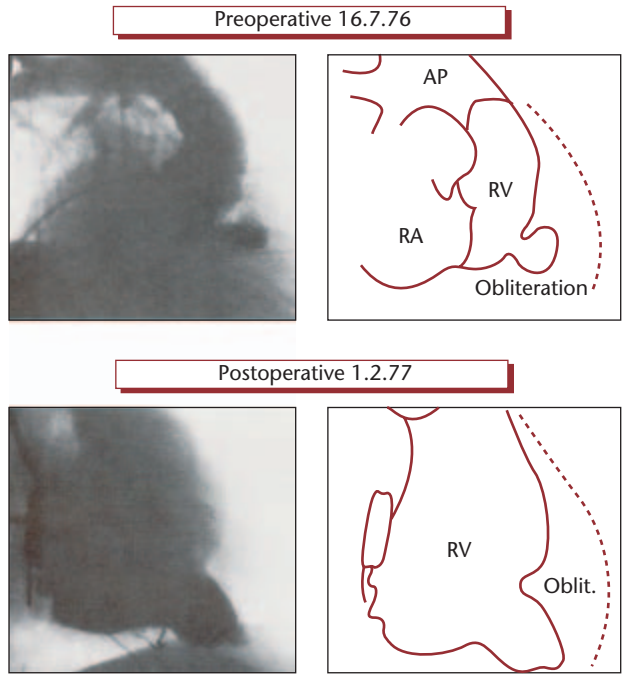

Figure 16.21 Preoperative (top) and postoperative (bottom) right ventricular angiograms in a patient with biventricular endomyocardial fibrosis (same patient as in Fig. 16.20). A characteristic, almost pathognomonic finding is obliteration of the right ventricular apex with a residual bay-like formation. After decortication, the right ventricle becomes larger but the bay-like formation persists. Prosthetic valve replacement has been performed because of severe tricuspid regurgitation. AP, arteria pulmonalis; RA, right atrium; RV, right ventricle. Reproduced with permission from Hess [137].

destroyed in the ventricles, which release fibroblast-stimulating factors that cause the typical lesions in the inflow tract and apex. The obliteration leads to a reduction in chamber volume (Figs 16.20 and 16.21, top panels), typically associated with mitral or tricuspid regurgitation because the chordae tendineae are often involved. Haemodynamically, the obliterations are associated with diastolic dysfunction and increased filling pressures, leading to lung congestion and right-sided heart failure. Typically the chambers are small but systolic contractions are maintained [137]. The clinical course is chronic and may be stable for several years or decades. However, progression to severe heart failure may be fast. The only treatment is surgical decortication [137].

DIAGNOSIS

The most important tool for diagnosis is two-dimensional Doppler echocardiography. The typical obliterations of the left ventricular apex can be seen (Fig. 16.19), with normal contractions of the basal regions. The haemodynamic consequence of diastolic dysfunction is atrial dilation, and AF may occur [143,144].

Chest radiography may not be very helpful but mild to moderate enlargement of the cardiac silhouette with signs of pulmonary congestion may be present. Pleural effusion may be seen. In patients with slow progression, diffuse calcifications of the endocardium may be found.

Laboratory findings are usually unspectacular but there may be increased C-reactive protein, electrolyte imbalance due to diuretic treatment and haematological changes according to the underlying disease.

MANAGEMENT

Heart failure treatment for diastolic dysfunction is appropriate in patients with mild to moderate restriction. Diuretics and ACE inhibitors may be helpful. Digitalis can be used in patients with atrial flutter or fibrillation. Beta-blockers are appropriate in patients with tachycardia but bradycardia is not well tolerated in these patients with small ventricles and high filling pressures.

Endocardial decortication has to be considered in advanced disease. Typically one or both ventricles are decorticated, with mitral or tricuspid valve replacement

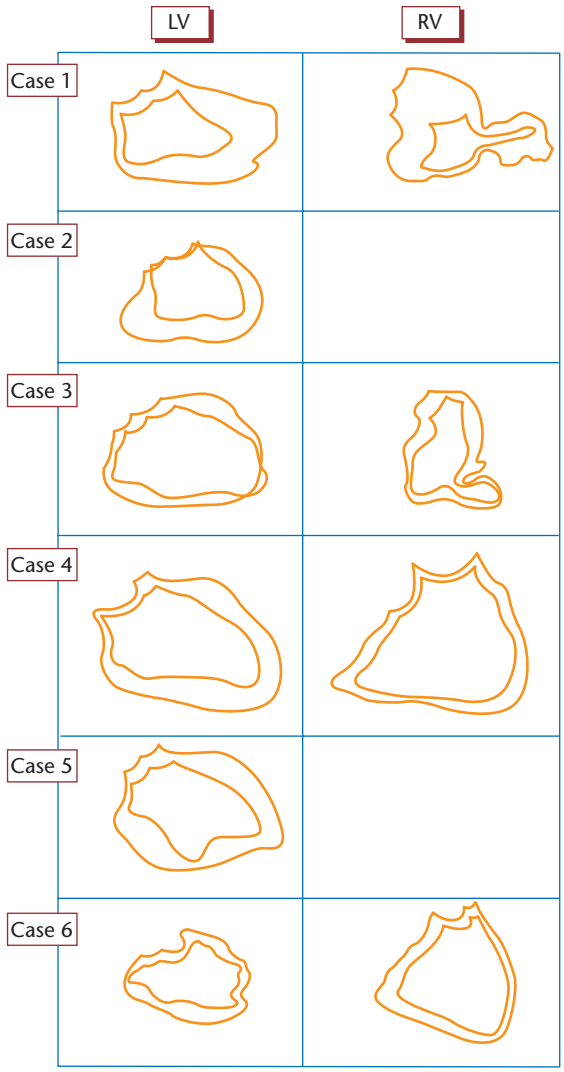

Figure 16.22 Typical angiographic findings (end-diastolic and end-systolic silhouettes) in six patients with endomyocardial fibrosis. LV silhouettes are shown on the left, RV silhouettes on the right. Please note the irregular shapes of the left and right ventricles with bay-like formations of the RV in cases 1 and 3.

because of involvement of chordae tendineae and papillary muscles. Good to excellent surgical results have been reported by several groups but slow progression to systolic heart failure may become a problem [148–156]. After decortication most patients show an increase in cardiac volumes (Figs 16.20 and 16.21), with a decrease in LVEDP (Fig. 16.22).

PROGNOSIS

Clinical course may be stable over years. When restriction becomes clinically apparent, a downhill course begins with a decrease in quality of life. After surgical decortication the clinical course may remain stable when the remaining myocardium is not severely fibrotic and

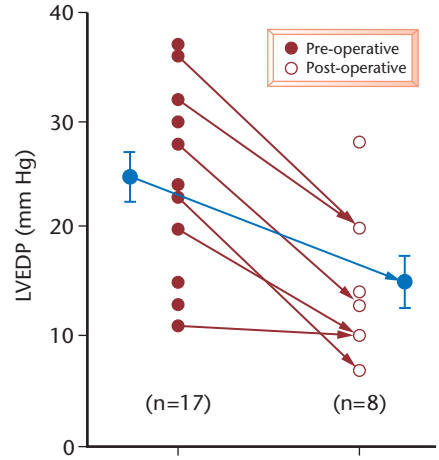

Figure 16.23 Left ventricular end-diastolic pressure (LVEDP) in 17 patients with endomyocardial fibrosis before (left) and 6–12 months after (right) successful decortication of the left ventricle ($n = 8$). LVEDP decreases from 25 to 15 mmHg as a consequence of improved diastolic function. Reproduced with permission from Hess *et al.* [155] and Schneider *et al.* [156].

dysfunctional. In rare cases recurrence of an acute Löffler's endocarditis may occur. At our institution a female patient developed Löffler's endocarditis, with marked blood eosinophilia and fibrotic thickening of the endocardium, 1 year after successful biventricular decortication [155]. The patient died a few days later in cardiogenic shock. Cardiac transplantation may be considered in patients with severe biventricular endomyocardial fibrosis but secondary pulmonary hypertension may be a limiting factor.

DIFFERENTIAL DIAGNOSIS

Primary restrictive cardiomyopathy can be difficult to differentiate from post-viral constrictive pericarditis, carcinoid syndrome of the right ventricle and amyloidosis [155,156]. There is a triad of key features of endomyocardial fibrosis.

1 Apical obliterations of one or both ventricles (echocardiogram or angiocardiogram).
2 Mild cardiomegaly with severe pulmonary congestion.
3 Mitral and/or tricuspid regurgitation; diastolic heart failure.

Secondary forms

Infiltrative diseases

In infiltrative diseases, a product of metabolism, inflammation or carcinomatosis pervades the cardiac interstitium and increases stiffness of the myocardium, thereby restricting ventricular relaxation, increasing filling pressures and reducing stroke volume.

Site of amyloid deposition	Clinical manifestations
Myocardium	Myocardium becomes firm, thickened and poorly compliant Diastolic dysfunction predominates early in disease course Systolic impairment occurs with disease progression
Valves and papillary muscles	Focal thickening of valves may be seen Valvular dysfunction rare but recognized
Conduction system	Conduction abnormalities (e.g. atrioventricular block) Atrial arrhythmia Ventricular arrhythmia Sudden arrhythmic death
Coronary arteries and other vessels	Deposits occur in media and adventitia, rarely in lumen Ischaemia, infarction, sudden death

Table 16.9 Clinical consequences of amyloid deposition in the cardiovascular system

AMYLOIDOSIS

Amyloidosis refers to a large group of disorders in which soluble extracellular proteins are misfolded and deposited as insoluble fibrils in the tissues, leading to disruption of tissue architecture and organ dysfunction. The disease may be acquired or hereditary, and is classified according to the nature of the fibril precursor protein and clinical features.

Acquired amyloidosis In primary (or AL) amyloidosis, the fibrillar protein is composed of κ and λ immunoglobulin light chains, produced by a proliferating clone of plasma cells. A systemic disease that tends to follow a rapidly progressive course, primary amyloidosis is often seen in conjunction with plasma cell dyscrasias such as multiple myeloma or the monoclonal gammopathies.

Secondary (or AA) amyloidosis occurs in association with chronic inflammatory disorders such as rheumatoid arthritis, ankylosing spondylitis and familial Mediterranean fever. Nephrotic syndrome and renal failure are common at presentation. The amyloid fibrils are composed of protein A.

β_2-Microglobulin amyloidosis is a complication of long-term haemodialysis that usually occurs in localized peri-articular form but is occasionally systemic.

Senile systemic amyloidosis is seen in patients over the age of 60 years. The fibril precursor is normal wild-type transthyretin. Congestive heart failure, heart block, AF and ventricular arrhythmia are recognized manifestations. Progression is slow and prognosis better than that of other acquired forms.

Hereditary amyloidosis Hereditary amyloidosis is the result of a mutation in one of a number of fibril precursor proteins, including transthyretin, apolipoprotein AI or AII, lysozyme, fibrinogen Aα chain, gelsolin and cystatin C. The phenotype varies according to the protein affected. Autosomal dominant inheritance is typical.

Cardiovascular involvement Amyloidosis frequently affects the heart. The propensity for cardiovascular involvement is greatest in primary, senile systemic and certain hereditary forms of the disease. Cardiac disease is relatively less common in AA amyloidosis but is a marker of unfavourable prognosis when present [157]. Amyloid fibrils may be deposited in the myocardium, papillary muscles, valves, conduction system and/or vessels, with consequent clinical manifestations (Table 16.9).

Clinical presentation of cardiac amyloidosis Clinical suspicion of cardiac amyloidosis arises in the following circumstances:

1. cardiac disease in the setting of established AL amyloidosis and/or plasma cell dyscrasia;
2. ventricular dysfunction or arrhythmia and long-standing connective tissue disease or other chronic inflammatory disorder;
3. any patient with restrictive cardiomyopathy of unknown aetiology;
4. LVH on echocardiography but a low-voltage ECG;
5. congestive heart failure of unknown cause refractory to standard medical therapy.

Diagnosis of cardiac amyloidosis The preliminary work-up for a patient with suspected cardiac amyloidosis includes a 12-lead ECG and two-dimensional echocardiography, with or without Holter monitoring. Characteristic findings are summarized in Table 16.10 [158]. A low-voltage ECG with increased septal and posterior left ventricular wall thickness on echocardiography is specific for

Table 16.10 Clinical investigations in cardiac amyloidosis

12-lead ECG
Low voltage*
Interventricular conduction delay/bundle branch block
Varying degrees of atrioventricular block
Poor R-wave progression ('pseudo-infarct pattern')*
Left-axis deviation

Holter
Atrial fibrillation
Other tachyarrhythmia or bradyarrhythmia

Two-dimensional echocardiography
Concentric or asymmetric thickening of the left ventricular wall
Occasional thickening of the right ventricle
Sparkling/granular appearance of myocardium*
Thickened interatrial septum*
Thickened valves and/or papillary muscles
Left atrial or biatrial dilation
Pericardial effusion
Diastolic dysfunction in early disease (E/A reversal)
Restrictive physiology (E >> A)
Systolic impairment with normal end-diastolic volume

Histology
Apple-green birefringence under polarized light microscope after staining with Congo red*
Immunoperoxidase stains to differentiate light chains/transthyretin/protein A, etc.

Cardiac catheterization
Raised filling pressures

Serum and urine electrophoresis for presence of monoclonal protein in patients with suspected AL amyloidosis

Genetic testing
Commercially available to detect common mutations

*Features considered relatively more specific for amyloidosis.

cardiac amyloidosis on non-invasive testing [158]. Other investigations that are of value include protein electrophoresis and genetic testing. EMB is often diagnostic, although multiple specimens may have to be obtained to avoid sampling errors.

Management and outcome Treatment is directed at both the underlying disease process and the cardiac complications. Systemic therapy is type-specific, underscoring the importance of determining the precise aetiology of amyloidosis. Prognosis of AL amyloidosis is poor; however, in subgroups of patients, combined treatment with high-dose melphalan and autologous stem cell transplantation has resulted in haematological remission, improved 5-year survival and reversal of amyloid-related disease [159]. In contrast, senile systemic amyloidosis is characterized by slow progression not requiring alkylating agents [160]. Reactive AA amyloidosis may respond to anti-inflammatory and immunosuppressive drugs that reduce production of acute-phase reactant serum amyloid A protein.

Ventricular dysfunction secondary to amyloidosis may be difficult to treat. Diuretics and vasodilators are used judiciously owing to the risk of hypotension with excessive falls in preload. Digoxin is contraindicated because it binds to amyloid fibrils and toxicity may develop at ordinary therapeutic doses. Complex ventricular arrhythmia has been documented in patients with cardiac amyloidosis and may be a predictor of SCD. Beta-blockers are administered with caution as they may promote AV block and their negative inotropism is often poorly tolerated. Implantation of a permanent pacemaker is indicated in patients with symptomatic bradyarrhythmias or complete AV block.

SARCOIDOSIS

Sarcoidosis is a multisystem disease characterized by non-caseating granulomas. Familial aggregation [161] suggests that genetic factors are involved. The lungs and lymphatic system are frequently affected. Cardiac involvement is uncommon; myocardial granulomas were detected in 27% of patients in one study [162]. It should be noted that microscopic granulomas within the heart may be overlooked at autopsy, resulting in underestimation of their prevalence. Indeed, cardiac disease has been reported in 58% of patients with sarcoidosis [163]. The most common sites of sarcoid granulomas are the left ventricular free wall (96%), septum (73%), right ventricle (46%), right atrium (11%) and left atrium (7%) [164].

Early treatment with corticosteriods and, if required, additional immunosuppressive agents improves outcome. Timely diagnosis is critical. Unfortunately, the perception that cardiac involvement is rare may lead to a delay in detection and therapy; in one study an ante-mortem diagnosis was made in only 65% of subjects [162]. Left ventricular diastolic dysfunction was present in 14% of patients with biopsy-proven pulmonary sarcoidosis but no other clinical features of cardiac disease [165], suggesting that subclinical sarcoid cardiomyopathy may be under-recognized.

Cardiovascular manifestations The cardiac complications of sarcoidosis and probable underlying mechanisms are summarized in Table 16.11.

Clinical presentation of cardiac sarcoidosis cardiac involvement should be considered in any sarcoidosis with symptoms of arrhythmia (i.e. palpitation, presyncope or syncope). Also worth investigating are patients with

Table 16.11 Cardiovascular manifestations of sarcoidosis

Abnormality	Manifestations	Proposed mechanism(s)
Conduction defects (common)	Primary AV block Bundle branch block Complete AV block Sudden death	Granulomatous or fibrous involvement of the basal interventricular septum and conduction system
Ventricular arrhythmia (common)	Frequent PVCs Non-sustained VT Sustained VT Sudden death	Associated with involvement of the LV free wall and aneurysm formation Granulomas and scarring create substrate for re-entry VT is frequently inducible by PVCs
Restrictive cardiomyopathy	Diastolic dysfunction	Myocardial infiltration by granulomas results in poor compliance
Dilated cardiomyopathy	Systolic impairment	Fibrogranulomatous replacement of the myocardium
Isolated right heart failure	RV hypertrophy RV dysfunction	Extensive fibrotic pulmonary sarcoidosis with secondary pulmonary hypertension
Myocardial hypertrophy	Asymmetric septal LVH Localized septal LVH Apical LVH	Inflammation in the septum or at the LV apex
Valvular dysfunction	Mitral regurgitation	Papillary muscle involvement
Atrial arrhythmia	SVT or AF	Atrial dilation secondary to LV dysfunction or cor pulmonale Granulomatous involvement of the atria
Pericarditis	Pericardial effusion	Fibrogranulomatous infiltration of pericardium
Coronary artery disease	Stenosis	Granulomatous vasculitis

AF, atrial fibrillation; AV, atrioventricular; LV, left ventricle; LVH, left ventricular hypertrophy; PVC, premature ventricular contraction; RV, right ventricle; SVT, supraventricular tachycardia; VT, ventricular tachycardia.

dyspnoea out of proportion to pulmonary disease, particularly if physical signs of heart failure are present. Since sudden death may be the first manifestation of cardiac sarcoidosis, periodic screening with 12-lead ECG and echocardiography, with or without Holter monitoring, may be indicated.

Isolated cardiac sarcoidosis is rare and usually followed by systemic involvement. Alternatively, cardiac manifestations may develop after pulmonary sarcoidosis has resolved. In many cases, medical attention is not sought for mild respiratory complaints, or cough and dyspnoea are misattributed to infection or allergy. Thus, cardiac complications may be the presenting feature of the sarcoidosis. In patients without a diagnosis, the following cardiac abnormalities should raise suspicion:

1 the young patient with conduction system disease;
2 DCM with AV block, abnormal wall thickness, regional wall motion abnormalities, or perfusion defects in anteroseptal and apical regions that improve with stress [166];
3 sustained re-entrant VT [167], non-specific ECG abnormalities and echocardiogram, and angiographically normal coronary arteries;
4 restrictive cardiomyopathy of unknown aetiology;
5 presumed arrhythmogenic right ventricular cardiomyopathy and AV block, or signs and symptoms of chronic respiratory disease [168].

Diagnosis of cardiac sarcoidosis The minimum work-up for any patient with suspected cardiac sarcoidosis comprises a 12-lead ECG, echocardiography and Holter monitoring (Table 16.12).

Management and outcome Corticosteroids are first-line therapy for cardiac sarcoidosis. Prevention of disease progression necessitates early treatment, preferably at the time of diagnosis. Improvement or resolution of arrhythmia, conduction defects or perfusion abnormalities is well documented [169]. Left ventricular systolic impairment may respond, although steroids should ideally be commenced prior to the development of heart failure. The combination of pacemaker implantation for bradyarrhythmia and steroid therapy may improve prognosis and reduce mortality from SCD. Heart failure is now the main cause of death from cardiac sarcoidosis [170]. Once established, systolic heart failure may be

Table 16.12 Clinical investigations in cardiac sarcoidosis

12-lead ECG
Non-specific depolarization or repolarization abnormalities
Poor R-wave progression ('pseudo-infarct pattern')
Varying degrees of atrioventricular block
Arrhythmia

Two-dimensional echocardiography
Mild thickening of the left ventricular wall, concentric or asymmetric
Thinning of the myocardium with or without aneurysms in later stage, resulting from fibrosis
Right ventricular hypertrophy, dilation, and/or dysfunction
Increased pulmonary artery pressure
Mitral regurgitation secondary to papillary muscle dysfunction
Pericardial effusion
Systolic and/or diastolic dysfunction
Biatrial enlargement with restrictive physiology

Holter monitoring
Frequent PVCs, sustained or non-sustained VT
Bradyarrhythmias or conduction system disease

Myocardial perfusion scan
Perfusion defects affecting the anteroseptal and apical regions that improve with stress on thallium scanning
Gallium uptake in areas of inflammation

Magnetic resonance imaging
Structural and functional changes described above
Focal enhancement following administration of gadolinium, indicating fibrosis

Chest radiography/computed tomography
Detects pulmonary features of sarcoidosis in patients with cardiac presentation

Cardiac catheterization
Angiographically normal coronary arteries in presence of perfusion defect
Coronary artery stenosis secondary to vasculitis
Increased pulmonary artery pressure

Endomyocardial biopsy
High specificity but low sensitivity because of patchy disease involvement and likelihood of sampling errors

PVC, premature ventricular contraction; VT, ventricular tachycardia.

treated with ACE inhibitors and/or AT2 receptor antagonists and beta-blockers. The use of beta-blockers in patients with early conduction system disease warrants careful monitoring.

Antiarrhythmic therapy for recurrent VT remains largely empirical. Placement of an ICD should be considered for all sarcoidosis patients with ventricular tachyarrhythmia. Besides offering optimal protection against sudden death, the ICD may enable control of refractory VT by antitachycardia pacing. VT storm that is resistant to drug therapy may require catheter ablation as a last resort.

Table 16.13 Systemic manifestations of haemochromatosis

Cutaneous hyperpigmentation
Diabetes mellitus

Hypogonadotropic hypogonadism
Arthropathy

Storage diseases

The storage disorders are inborn errors of metabolism that result in the accumulation of the substrate or byproduct of the affected pathway. The intracellular location of the metabolite distinguishes storage disease from infiltrative disorders, in which deposition is confined to the interstitium. Accretion of the abnormal metabolite in the heart is toxic to myocytes and induces either concentric (HCM-like phenotype) or eccentric (DCM-like phenotype) hypertrophy.

HAEMOCHROMATOSIS

Haemochromatosis refers to genetically determined disorders of iron metabolism that result in iron overload and deposition. Organ dysfunction is due to the toxic effects of redox-active iron. Most commonly affected are the liver, pancreas, joints and heart (Table 16.13). The adult-onset form of haemochromatosis has been linked to mutations in the *HFE* gene on the short arm of chromosome 6 and, less commonly, the gene encoding transferrin receptor 2 (*TfR2*) [171]. Autosomal recessive inheritance with variable penetrance is typical. Heterozygosity is present in 8–10% of people of European descent, while 5 in 1000 are homozygous. Overt disease expression is rare in women of child-bearing age owing to protective blood loss during menstruation.

Three stages are recognized in the natural history of adult-onset haemochromatosis. In the initial biochemical phase, iron overload is confined to the plasma compartment, with increased transferrin saturation. More than 50% of *HFE* homozygotes with the most common disease-causing mutation (C282Y) will progress to the second deposition phase, in which iron accumulates in parenchymal tissues, with concomitant elevation of serum ferritin levels. Few patients progress to the final stage, with impairment of target organ function.

This pattern of gradual iron loading is in marked contrast to juvenile hereditary haemochromatosis, in which organ dysfunction ensues by the age of 30, with hypogonadism and glucose intolerance. Cardiac complications are also common and may result in premature death from

intractable heart failure. Mutations have been identified in the genes encoding hepcidin (*HAMP*) and hemojuvelin (*HJV*) [171].

Cardiovascular involvement Although haemochromatosis seldom affects the heart in isolation, cardiac complications are occasionally the presenting feature of the disease. The site and quantity of iron deposition within the heart determines the type and extent of cardiac dysfunction. The ventricles are commonly involved, leading in most cases to DCM, although a restrictive picture may be present. Subclinical cardiac disease can be identified by echocardiography.

On histology stainable iron is localized to the sarcoplasm but is generally absent from the interstitium. Cardiac haemochromatosis is therefore a storage disorder rather than infiltration, as evidenced by the normal ventricular wall thickness [172]. Ultrastructural studies reveal the presence of iron in the cytoplasm, nucleus and mitochondria; at least part of the toxicity of iron is ascribed to oxidative damage to the mitochondrial genome, with progressive mitochondrial dysfunction [173]. Consistent with this hypothesis is the predilection of haemochromatosis for organs with high mitochondrial activity: liver, pancreas and heart.

Of note, degenerative changes and fibrosis are minimal within the myocardium, probable accounting for the infrequency of ventricular tachyarrhythmia. Nevertheless, heart failure is often accompanied by ventricular extrasystoles or even VT, which may be difficult to treat [174]. In some patients, intravenous lidocaine (lignocaine), procainamide and propafenone fail to terminate sustained VT, as might DC cardioversion. Amiodarone may be successful in restoring sinus rhythm [175]. In a case of haemochromatosis presenting with recurrent syncope, both spontaneous and inducible polymorphic VT was present but there was no evidence of impaired ventricular function or diabetes, although liver function tests were mildly elevated. Marked signal loss in the liver was detected on MRI, a technique also useful for monitoring myocardial iron overload [176].

Commonly observed in cardiac haemochromatosis are atrial flutter or fibrillation and supraventricular tachycardia, possibly due to iron deposition in the atrium or related to increased pressures from ventricular dysfunction. Involvement of the conduction system may manifest as varying degrees of AV block or sick sinus syndrome.

Management and outcome Regular phlebotomy is the mainstay of treatment for cardiac haemochromatosis, and may effect partial or complete reversal of ventricular dysfunction and suppression of arrhythmia. Depletion of myocardial iron has been documented by serial EMB. Cardiac MRI offers a non-invasive means of assessing the response to therapy. Blood count, serum ferritin and transferrin saturations should also be monitored; excessively rapid mobilization of iron is thought to carry a risk of aggravating end-organ damage. Standard medical therapy is indicated for heart failure and arrhythmia.

Unfortunately, the correlation between cardiac iron load and function may decline in advanced disease [177]. It has been suggested that there is a threshold beyond which the toxic effects of iron accumulation in the myocardium result in permanent ultrastructural or metabolic derangements. Reduction in myocardial iron deposits at this stage do not result in improvement of cardiac function. Thus early diagnosis and initiation of prophylaxis or venesection remain critical. Screening of first-degree relatives for the disease is imperative and may be facilitated by increased availability of genetic testing.

GLYCOGEN STORAGE DISEASE

Glycogen storage disease (GSD) is a group of inherited metabolic disorders characterized by abnormalities in the enzymes that regulate the synthesis or degradation of glycogen. Glycogen storage occurs in the liver, heart, skeletal muscle and/or central nervous system. The heart is affected in types II, III and IV [178]. Cardiac manifestations often include severe LVH, which may mimic HCM or demonstrate a restrictive pattern. Cavity dilation and systolic impairment develop in advanced stages, producing a DCM-like phenotype. Conduction system disease is also described.

Glycogen storage disease type II Type II GSD, or Pompe's disease, is caused by deficiency of acid α-glucosidase (acid maltase) [179], which cleaves α-1,4 and α-1,6 glycosidic linkages of glycogen. The mode of inheritance is autosomal recessive. Genetic counselling and family screening are paramount once the diagnosis has been established.

The infantile form of type II GSD usually presents in the first months of life with failure to thrive, generalized hypotonia and weakness. Macroglossia and moderate hepatomegaly are associated features. Cardiomegaly is evident on chest radiography and may raise suspicion of the disease. Plasma CK levels are markedly elevated. The diagnosis is confirmed by enzyme assay of muscle or skin fibroblasts; acid α-glucosidase activity is virtually undetectable.

ECG findings in type II GSD include left-axis deviation, short PR interval, high-voltage QRS complexes and repolarization abnormalities. Echocardiography confirms severe concentric biventricular hypertrophy [180], which initially resembles HCM and may be associated with LVOTO. Systolic function is normal or hyperdynamic in

the initial stages, but deteriorates with disease progression as the ventricles dilate. Weakness of the diaphragm and intercostal muscles may necessitate mechanical ventilation, but high airway pressures may reduce ventricular filling and are poorly tolerated [181]. Death usually results from cardiorespiratory failure.

At post-mortem, the heart may be three times normal size. Fibroelastic thickening of the endocardium is often present. Histology reveals glycogen accumulation in cardiomyocytes, contained within membrane-bound vacuoles and free in the cytoplasm. Skeletal muscle shows a similar appearance.

In the past, infantile-onset Pompe's disease was almost uniformly fatal by 1 year of age. However, enzyme replacement therapy is promising and emphasizes the importance of early recognition, since the therapeutic window is short. In limited clinical trials of recombinant human acid α-glucosidase, treated infants showed decreased cardiomegaly, motor improvement and prolonged survival [181,182].

Late-onset type II GSD, in which disease develops after the age of 12 months, is associated with residual acid α-glucosidase activity (≤ 10% of normal in toddlers and children, and up to 40% in adults). Presentation in the elderly has been documented [183]. Interestingly, the clinical picture is dominated by proximal myopathy and respiratory insufficiency. Cardiac involvement is rare, suggesting that partial enzyme activity may be sufficient to protect the heart.

Glycogen storage disease type III Type III GSD, also known as Cori's or Forbe's disease, is caused by deficiency of the enzyme amylo-1,6-glucosidase, which is involved in 'debranching' the glycogen molecule during catabolism. This results in arrest of glycogen breakdown when the outermost branch points are reached. Phosphorylase limit dextrin, an abnormal form of glycogen, accumulates in affected tissue [184].

Type III GSD is also transmitted in autosomal recessive fashion. The clinical heterogeneity is explained at least in part by the variety of mutations identified. Fasting hypoglycaemia and hepatomegaly predominate. While liver dysfunction usually resolves during adolescence, worsening dysfunction and cirrhosis are also described. Cardiac involvement generally takes the form of LVH resembling HCM, which may be accompanied by SAM and LVOTO [185]. Many patients with echocardiographic abnormalities are asymptomatic. However, biventricular dilation, recurrent sustained VT and sudden death have also been reported. Late gadolinium enhancement has been observed on cardiac MRI, suggesting that progressive fibrosis may be the substrate for cavity dilation and re-entrant VT.

Glycogen storage disease type IV Type IV GSD is an autosomal recessive disorder linked to deficiency of the 'branching' enzyme amylo-1,4-1,6 transglucosidase [186]. The accumulation of polyglucosan bodies (an abnormal form of glycogen) in the liver may cause cirrhosis and hepatic failure in early childhood. However, non-progressive forms have also been documented [187]. Skeletal myopathy may occur and cardiac involvement characteristically manifests as congestive heart failure. A late-onset variant of type IV GSD is also described, with complete deficiency of branching enzyme and presentation in adolescence with DCM [188].

Fabry's disease

Anderson–Fabry disease is a metabolic storage disease in which deficiency of the enzyme α-galactosidase (α-Gal A) results in progressive tissue deposition of glycosphingolipids. Glycosphingolipids are components of the cytoplasmic membrane that consist of an outer saccharide component attached to a lipid called ceramide; the B blood group antigen is an example. Their ultimate breakdown inside lysosomes requires the action of a number of hydrolytic enzymes. α-Gal A is a lysosomal hydrolase responsible for the degradation of glycolipids with a terminal α-galactosamine residue. This substrate accumulates within cells owing to lack of α-Gal A activity in Fabry's disease.

The α-Gal A gene is located in the Xq22 region of the X chromosome. X-linked inheritance accounts for the male predominance, with incidence estimated at 1 in 40 000 to 1 in 60 000. Varying degrees of disease expression may nevertheless occur in female carriers as a result of random X-chromosome inactivation [189,190].

Fabry's disease predominantly affects the skin, endothelium, kidneys, liver, pancreas and nervous system (Table 16.14). Cardiac involvement is also common. In the classic phenotype, clinical manifestations begin in childhood or adolescence, on average at 10 years of age. Unfortunately, the non-specific symptoms may be misattributed to 'growing pains' or rheumatological diseases. Relentless progression is usual; neurological, cardiac and renal complications develop from late adolescence to adulthood. The average lifespan of 40 years improved by about a decade following introduction of renal dialysis. However, a major advance in Fabry's disease has been enzyme replacement therapy, which underscores the importance of early recognition. Clinical trials of gene-activated and recombinant human α-Gal A showed marked and rapid reduction in plasma and tissue levels of globotriaosylceramide, diminished pain and improved renal function [189].

Atypical variants of Fabry's disease may manifest after the age of 40. The phenotype is milder and may be

Table 16.14 Systemic manifestations of Fabry's disease

Pain
Chronic burning tingling pain in hands and feet
Fabry's crisis (acute severe pain precipitated by stress, exertion, concurrent illness/fever)

Skin
Angiokeratomas, lymphoedema

Eyes
Corneal opacity

Gastrointestinal
Diarrhoea, abdominal discomfort, vomiting

Neurological
Tinnitus, vertigo, headache, transient ischaemic attacks, cerebrovascular accidents

Pulmonary
Obstructive airways disease

Renal
Proteinuria, lipiduria, uraemia, hypertension, end-stage renal failure

Other
Reduced saliva and tear production; exercise and heat intolerance

confined to one organ system; isolated cardiac or renal manifestations are recognized. Residual enzyme activity is present in these patients, whereas α-Gal A levels are virtually undetectable in the classic form.

Cardiovascular involvement Intracellular accumulation of glycosphingolipids has been observed in the myocardium, conduction system, valves and vascular endothelium. Myocardial involvement typically manifests as LVH resembling HCM. Concentric hypertrophy is the most frequent distribution (37%), followed by asymmetric septal hypertrophy (10%). Eccentric and distal patterns of hypertrophy occur less frequently [4,191, 192]. The degree of hypertrophy shows a positive correlation with age and an inverse relationship with the level of α-Gal A activity; blood pressure does not appear to be a major determining factor. SAM and LVOTO may be present. As in HCM, systolic function is generally preserved, but mild to moderate diastolic impairment is common. A restrictive picture is rare. The deposits account for only around 1% of the increase in left ventricular mass, suggesting that the metabolic derangement induces compensatory hypertrophy by a mechanism that is still to be elucidated (see p. 483).

Thickening of the papillary muscles and mitral valve leaflets, with mild accompanying regurgitation, occurs in over half of patients with Fabry's disease. Mitral valve prolapse appears less common. Minor structural abnormalities of the aortic valve were observed in a smaller subset [191].

AF and non-sustained VT may occur in Fabry's disease, although the exact prevalence is uncertain. Varying degrees of AV block are a corollary of conduction system involvement.

Preferential storage of glycosphingolipids in the endothelium of cerebral vessels is associated with premature strokes. The vertebrobasilar circulation is predominantly affected. Endothelial dysfunction of coronary capillaries contributes to subendocardial ischaemia. Hypertension and dyslipidaemia related to chronic renal failure may also predispose patients with Fabry's disease to coronary artery disease. A relatively high prevalence of cigarette smokers has been reported among the Fabry population; it has been suggested that smoking may alleviate the neuropathic pain associated with the disorder.

Clinical management Patients with Fabry's disease experience the same cardiac symptoms as those with sarcomeric HCM, including anginal chest pain, exertional dyspnoea, palpitation, syncope and presyncope. In the isolated cardiac form of Fabry's disease, systemic manifestations are absent and diagnosis is dependent on enzyme assay and/or EMB. Affected males have reduced or undetectable levels of α-Gal A in plasma and peripheral leucocytes. Assessment of α-Gal A activity in 79 consecutive patients with late-onset HCM revealed a 6% prevalence of Fabry's disease [4]. X-linked inheritance will raise suspicion. Routine screening for Fabry's disease has therefore been advocated in male patients with HCM.

Female heterozygotes, in contrast, may have relatively high residual α-Gal A activity, limiting the value of enzyme assay in establishing the diagnosis. Confirmation of Fabry's disease in a male relative is strongly suggestive. Where this is not possible, EMB may elicit the diagnosis. Among 34 consecutive women with late-onset HCM, histology and/or electron microscopy showed features consistent with Fabry's disease in 12% [192]. Genetic testing may facilitate familial evaluation. Most affected families have private mutations, accounting in part for the variability in disease expression and prognosis. *De novo* mutations are uncommon.

Enzyme replacement is now the mainstay of disease-specific treatment. The cardiac manifestations of Fabry's disease respond to standard management strategies.

Post-radiation disease

Radiation may cause damage to any structure, including the pericardium, myocardium, valves, conduction system and coronary arteries. Much of our knowledge of radiotherapy-induced cardiovascular disease arose from

experience with survivors of Hodgkin's disease, many of whom are young and may develop sequelae. Chest irradiation is also used to treat breast cancer, lung cancer and seminomas [193]. The clinical impact of post-radiation cardiovascular disease will become more significant as long-term survival from cancer improves.

Myocardial involvement At least two mechanisms are thought to underlie myocardial injury from irradiation: microcirculatory damage and free-radical toxicity. Work with experimental animals suggests that the former is a three-stage process. The first acute phase occurs shortly after exposure to radiation and is characterized by acute inflammation of small and medium-sized arteries. In the latent phase that follows, damage to capillary endothelial cells causes thrombotic occlusion and ischaemia. Progressive myocyte death and fibrosis occurs over time. Experimentally, the end-result is extensive fibrosis and death. Fortunately, myocardial disease is generally milder in patients who have received radiotherapy, most of whom remain asymptomatic. Clinically overt cardiomyopathy is uncommon and generally shows a restrictive pattern. A DCM-like phenotype may occur with anthracycline derivatives, the cardiotoxicity of which is increased by radiation.

Pericarditis Pericardial disease may occasionally present during irradiation, although delayed onset is far more common. Early acute pericarditis is usually associated with radiation-induced necrosis of a large tumour adjacent to the heart. Radiotherapy is continued and long-term sequelae are rare (see also Chapter 15).

Delayed pericardial disease may present months to years after radiation exposure in two overlapping forms: (1) an acute pericarditis that evolves, in around 20% of patients, into chronic constrictive pericarditis; and (2) chronic pericardial effusion, which often resolves spontaneously over years. Patients with symptoms and/or evidence of haemodynamic compromise may benefit from total parietal pericardiectomy, which is associated with a more favourable outcome than pericardiocentesis alone.

Arrhythmia/conduction system disease The prevalence of conduction defects after radiotherapy is unknown, and delayed onset may preclude corroboration of a causal link. However, sick sinus syndrome and varying degrees of AV block have been reported. The level of the block is commonly infranodal rather than within the AV node. Supraventricular and ventricular arrhythmia have also been documented.

Valvular disease Among 294 asymptomatic patients previously treated with mediastinal irradiation for Hodgkin's disease, 29% had valve disease of sufficient clinical importance to justify antibiotic prophylaxis. The aortic valve was more commonly affected than the mitral and tricupsid valves, owing perhaps to its proximity to the radiation field. Both regurgitation and stenosis have been reported, although their relative frequency is unresolved. The prevalence of valve dysfunction increased with the time elapsed from radiotherapy.

Coronary artery disease Increased risk of coronary artery disease has been reported in patients previously treated with mediastinal irradiation. The left anterior descending and right coronary arteries fall within the typical radiation mantle field and are frequently affected. Proximal narrowing involving the ostia is typical [194]. Coronary artery disease generally occurs in patients with at least one other recognized risk factor besides exposure to radiation.

Clinical management Patients with radiation-induced cardiovascular disease may present with symptoms characteristic of the particular complication. Thus, acute pericarditis is accompanied by pleuritic chest pain and fever, while myocardial disease may manifest as chronic progressive dyspnoea. However, many radiotherapy recipients are asymptomatic. Subclinical myocardial dysfunction, pericardial effusion and valvular abnormalities are far more common than overt disease. Possibly silent myocardial infarction occurs more commonly in this subgroup than in the general population, owing to damage to cardiac nerve endings by irradiation.

Periodic cardiovascular evaluation of radiotherapy recipients has been advocated in order to identify clinically occult abnormalities [195]. A non-invasive work-up should include 12-lead ECG, echocardiography, exercise testing, Holter monitoring and a fasting blood lipid profile. Cardiac MRI may also be useful (see Chapter 3). Risk factors for coronary artery disease should be monitored and primary prevention measures instituted where necessary. Patients with valvular dysfunction may need endocarditis prophylaxis. Pregnancy is associated with increased cardiovascular demand and women should be encouraged to undergo cardiac assessment during antenatal care.

Contemporary radiotherapy techniques that involve lower total radiation doses and which minimize cardiac exposure by subcarinal shielding may diminish the risk of most types of cardiac disease. The antioxidant and iron chelator dexrazoxane confers protection against the cardiotoxic effects of anthracyclines, while amifostine reduces radiation-induced toxicity. Concurrent administration of cardiotoxic chemotherapeutic agents during radiotherapy should be avoided if at all possible. Aggressive treatment of hypertension and hyperlipidaemia

in this population may also reduce the likelihood of coronary artery disease developing in later life.

Arrhythmogenic cardiomyopathy

Definition

The 1996 WHO classification of cardiomyopathies defines arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C) as a group of heart muscle diseases characterized by structural and functional abnormalities of the right ventricle due to localized or diffuse atrophy with replacement of the myocardium by fatty and fibrous tissue [38]. Preferred areas include the outflow tract, the apex and the subtricuspid area of the free wall. Usually, the ventricular septum is spared [196]. Generally, men aged 15–35 years are affected [197]. Clinically, these morphological alterations are associated with regional or global right ventricular dysfunction and life-threatening arrhythmias of right ventricular origin (e.g. premature ventricular beats, sustained VT or ventricular fibrillation), occasionally causing SCD in young patients with apparently normal hearts [196,198]. Since its first description by Fontaine *et al*. in 1977, considerable progress has been made in understanding its pathogenesis, morbid anatomy and clinical presentation [199–204]. Genetic background, natural history, exact clinical diagnosis including risk stratification, and treatment of high-risk patients are still poorly defined.

Aetiology and prevalence

Progressive loss and fibrofatty replacement of right ventricular myocardium in ARVD/C may be due to apoptosis of cardiomyocytes [205], myocardial inflammation [196,202,206], genetically determined myocardial atrophy [202] and possibly viral involvement [207]. Furthermore, regional clustering in Greece or northern Italy and familial history suggests an inherited disease usually with autosomal dominant inheritance and variable penetrance and phenotypes [197,208–210]. Because the disease is difficult to diagnose and because many patients may be asymptomatic until their first presentation with sudden death, the true incidence and prevalence of ARVD/C are unknown [211].

Genetics

Familial background has been demonstrated in 30–50% of ARVD/C cases [197]. Sporadic development or familial disease with incomplete penetrance and variable phenotypic expression may constitute for the remaining cases. Both males and females can carry the disease and transmit it. At present, 10 chromosomal loci on seven chromosomes have been identified (Table 16.15) [212]. Three involved gene products have been identified. In a rare inherited disease with a recessive form of transmission and 90% penetrance, mapped to chromosome 17, a defect in the gene encoding the cytoskeletal protein plakoglobin has been identified [213]. Genetic analysis of a similar disease with keratoderma and woolly hair at infancy and development of heart failure during adolescence revealed a mutation on chromosome 6p23–p24 encoding for desmoplakin, a protein important for attachment of intermediate filaments to the desmosome [214]. Mutations in the cardiac ryanodine receptor gene (chromosome 1q23–q24) may impair intracellular calcium release and trigger electrical instability and VT.

Table 16.15 Genetics of arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C)

Chromosome	Gene	Reference

Pathophysiology

Acquired replacement of the right ventricular anterolateral free wall myocardium by fatty or fibrofatty tissue extending from the epicardium towards the endocardium in a wave-like manner is characteristic. Fatty replacement of the myocardium may be diffuse (80%) or segmental (20%). Transmural infiltration is often associated with increased wall thickness. Saccular aneurysms of the apex, infundibulum or postero-inferior wall are detected in 50% in the fibrofatty variant. Histomorphological findings with atrophic myocardium and focal myocyte necrosis in association with infiltrating lymphocytes resemble chronic myocarditis. Myocardial inflammation [206,215], viral infections [207] and genet-

ically determined dystrophy may be involved in the apoptotic loss of cardiac myocytes [205,216]. Islands of surviving myocardium interspersed with fatty or fibrofatty tissue may predispose to re-entrant tachycardia.

Clinical presentation

Exercise-triggered symptomatic VT of right ventricular origin (left bundle branch block configuration) is the most common clinical presentation. Palpitations and syncope are not uncommon due to sustained or non-sustained VT. With respect to VT morphology, it may be difficult to differentiate ARVD/C from benign and non-familial idiopathic right ventricular outflow tract tachycardia or pre-excitated AV re-entry tachycardia. In untreated patients, prolonged VT may degenerate into ventricular fibrillation. Because many patients are asymptomatic until their first presentation with sudden death, the true incidence and prevalence of VT-derived ventricular fibrillation leading to sudden cardiac arrest remains unknown. Patients presenting with congestive heart failure with or without ventricular arrhythmias are often misdiagnosed as having DCM.

Diagnostic testing

Clinical history may provide diagnostic and prognostic information if clinical events including palpitations, dizziness, presyncope, syncope and arrhythmias or a positive familial history are present.

ECG abnormalities are detected in up to 90%. Most commonly, right ventricular involvement is associated with T-wave inversion in V1–V3 without right bundle branch block. Repolarization abnormalities in leads beyond V3 may suggest left ventricular involvement [200]. Right bundle branch block, prolongation of QRS duration in V1–V3, and epsilon wave caused by ventricular postexcitation (in about 30%) reflect delayed right ventricular activation and are distinct ECG markers of the disease. Epsilon waves may be atypical and look like a smooth potential forming an atypical prolonged R' wave in leads V1–V3 if increased numbers of myocardial fibres are activated with delay. Therefore, any QRS duration in V1–V3 that exceeds QRS duration in V6 by more than 25 ms should be considered an epsilon wave [200].

Right ventricular angiography, which reveals right ventricular dilatation and regional or segmental wall movement abnormalities or dyskinesia typically detected in the infundibular, apical and subtricuspid region (bulgings and aneurysms), is the gold standard for the diagnosis of ARVD/C. These features, which have a diagnostic specificity of 90%, may also be detected non-invasively by MRI and echocardiography. MRI allows accurate characterization of right ventricular function and anatomy. Limitations of MRI in the detection of characteristic structural changes include exact determination of right ventricular free wall thickness and estimation of the amount of fatty tissue in comparison with the normally present epicardial and pericardial fat tissue. Differential diagnostic exclusion of other heart diseases, quantification of left and right ventricular function and structural abnormalities, non-invasive serial examinations of disease progression and screening of family members constitute the enormous potential of echocardiography as the preferential first-line diagnostic procedure. In minor forms of ARVD/C, localized abnormalities of the right heart cavities are difficult to detect. Subtle lesions may be missed by all imaging techniques.

The *in vivo* documentation of the typical histological changes of ARVD/C by EMB may be of diagnostic value but is limited by low sensitivity, especially in mild forms. EMB cannot prove transmural replacement of the myocardium by fatty or fibrofatty tissue. Moreover, the focal or segmental nature of lesions, the lack of involvement of the ventricular septum and the natural content of fatty tissue in older healthy patients may contribute to the low sensitivity of biopsy-derived diagnosis. The increased content of fatty and fibrotic tissue in older individuals or other cardiomyopathic conditions also interferes with the diagnostic accuracy of MRI.

Based on clinical and morphological findings, diagnostic criteria have been established for ARVD/C (Table 16.16) [217]. The diagnosis is based on two major criteria, one major plus two minor criteria, or four minor criteria, respectively, encompassing histological, electrocardiographic and arrhythmic factors [218].

Risk stratification

Prevention of fatal arrhythmic events and SCD is the main goal of management of ARVD/C. The development of often stress-induced ventricular fibrillation or haemodynamically intolerable VT is difficult to predict, especially in asymptomatic young subjects and athletes. Guidelines for prophylactic treatment of identified patients with minor symptoms or minor morphological changes are not available. Asymptomatic patients at high risk of sudden death are characterized by familial background and complex ventricular arrhythmias at young age or during competitive sport activities, syncope, or left ventricular involvement. In spite of ECG, Holter monitoring, exercise stress testing and signal-averaged ECG analysis, the predictive value of these non-invasive diagnostic tools for fatal events remains insufficient. Symptomatic patients should undergo a more detailed invasive analysis including left ventricular angiography, programmed ventricular stimulation and EMB.

Table 16.16 Major and minor criteria of arrhythmogenic right ventricular dysplasia/cardiomyopathy

Major criteria
Familial disease confirmed at necropsy or surgery
Epsilon wave or QRS duration > 110 ms in V1–V3
Severe RV dilatation and systolic dysfunction with no/mild LV involvement
Localized RV aneurysms (akinetic/dyskinetic areas with diastolic bulgings)
Severe segmental RV dilatation
Fibrofatty replacement of myocardium (endomyocardial biopsy)
Minor criteria
Family history of premature sudden death (< 35 years)
Family history based on clinical diagnostic criteria
Late potentials (signal-averaged ECG)
Inverted T waves in V2 and V3, no RBBB, in patients > 12 years
LBBB-type tachycardia (sustained or non-sustained) on ECG, Holter monitoring or during exercise testing
Ventricular extrasystoles (> 1000 in 24 h) on Holter monitoring
Mild global reduced RV dilatation and/or RV dysfunction with preserved LV function
Mild segmental RV dilatation
Regional right heart hypokinesia

LBBB, left bundle branch block; LV, left ventricle; RBBB, right bundle branch block; RV, right ventricle.

Management of heart failure

Treatment of severe right ventricular or biventricular systolic dysfunction consists of current heart failure therapy, including ACE inhibitors or AT1 receptor antagonists, beta-blockers, diuretics, digitalis, spironolactone and anticoagulants. Heart transplantation may be considered in patients with refractory congestive heart failure.

Management of arrhythmias

Since the risk of sudden death in patients with ARVD/C is still poorly defined, pharmacological and non-pharmacological therapy is individualized. In patients with preserved systolic ventricular function, treatment of well-tolerated and non-life-threatening ventricular arrhythmias empirically includes amiodarone, beta-blockers, sotalol or propafenone. In patients with left ventricular dysfunction, pharmacological treatment is limited to amiodarone, possibly in combination with class I antiarrhythmics or beta-blocking agents.

The insertion of an automatic ICD is the treatment of choice in patients with syncope, cardiac arrest, documented VT or ventricular fibrillation, or positive familial history of SCD. The use of an ICD is limited by the progressive morphological changes within the right ventricular myocardium with low endocardial signals and increased pacing threshold.

Since new arrhythmic foci may develop over time due to the progressive nature of the disease, VT recurrences are reported in over 50% after catheter ablation. Nevertheless, monomorphic VT may be terminated by radiofrequency ablation in unstable patients with otherwise not effectively controlled arrhythmias. Sustained VT with ineffective drug control despite ICD may require heart transplantation.

Prognosis and outcome

Biventricular dysplastic involvement resulting in substantial left ventricular dysfunction mimicking DCM is rare. Progressive right ventricular failure may be a serious problem in a minority of patients, as may ventricular arrhythmias. Untreated sustained or non-sustained VT may be well tolerated by the majority of patients over a number of years but may degenerate to ventricular fibrillation and to sudden death (incidence of 1–2% per year) [196,204].

Unclassified cardiomyopathy: left ventricular non-compaction

Left ventricular non-compaction (LVNC) is a myocardial disease with a genetic basis that may result in heart failure, arrhythmia, thromboembolism and sudden death. It has only recently been recognized as a distinct cardiomyopathy and is defined by the presence of the following structural abnormalities.
