Infection by *Fasciola hepatica*, the sheep liver fluke, results from ingestion of encysted metacercariae on watercress or other aquatic vegetables. Infection is prevalent in sheep-raising areas in many countries, especially parts of South America, the Middle East, and southern Europe. *Fasciola gigantica* has a more restricted distribution in Asia and Africa and causes similar findings. Eggs are passed from host feces into fresh water, leading to infection of snails, and then deposition of metacercariae on vegetation. In humans, metacercariae excyst, penetrate into the peritoneum, migrate through the liver, and mature in the bile ducts, where they cause local necrosis and abscess formation.

Two clinical syndromes are seen, related to acute migration of worms and chronic infection of the biliary tract. Symptoms related to migration of larvae present 6–12 weeks after ingestion. Typical findings are abdominal pain, fever, malaise, weight loss, urticaria, eosinophilia, and leukocytosis. Tender hepatomegaly and elevated liver function tests may be seen. Rarely, migration to other organs may lead to localized disease. The symptoms of worm migration subside after 2–4 months, followed by asymptomatic infection by adult worms or intermittent symptoms of biliary obstruction, with biliary colic and, at times, findings of cholangitis. Early diagnosis is difficult, as eggs are not found in the feces during the acute migratory phase of infection. Clinical suspicion should be based on clinical findings and marked eosinophilia in at risk individuals. CT and other imaging studies show hypodense migratory lesions of the liver. Serologic assays may be positive about 1 month before eggs are seen in stool, but specificities of available tests are not ideal. Definitive diagnosis is made by the identification of characteristic eggs in stool. Repeated examinations may be necessary. In chronic infection, imaging studies show masses obstructing the extrahepatic biliary tract.

Fascioliasis is unusual among fluke infections, in that it does not respond well to treatment with praziquantel. The

treatment of choice is triclabendazole, which is also used in veterinary medicine, but is not available in the United States. Standard dosing of 10 mg/kg orally in a single dose or two doses over 12 hours achieves a cure rate of about 80%, but repeat dosing is indicated if abnormal radiologic findings or eosinophilia do not resolve. The second-line drug for fascioliasis is bithionol (30–50 mg/kg/d orally in three divided doses on alternate days for 10–15 days); this drug is no longer available in the United States. Treatment with either drug can be accompanied by abdominal pain and other gastrointestinal symptoms. Prevention of fascioliasis involves avoidance of ingestion of raw aquatic plants.

CLONORCHIASIS & OPISTHORCHIASIS

Infection by *Clonorchis sinensis*, the Chinese liver fluke, is endemic in areas of Japan, Korea, China, Taiwan, Southeast Asia, and the far eastern part of Russia. Millions of people are affected and, in some communities, prevalence can reach over 80%. Opisthorchiasis is principally caused by *Opisthorchis felineus* (regions of the former Soviet Union) or *Opisthorchis viverrini* (Thailand, Laos, Vietnam). Clonorchiasis and opisthorchiasis are clinically indistinguishable. Parasite eggs are shed into water in human or animal feces, where they infect snails, which release cercariae, which infect fish. Human infection follows ingestion of raw, undercooked, or pickled freshwater fish containing metacercariae. These parasites excyst in the duodenum and ascend into the biliary tract, where they mature and remain for many years, shedding eggs in the bile.

Most patients harbor few parasites and are asymptomatic. An acute illness can occur 2–3 weeks after initial infection, with fever, abdominal pain, tender hepatomegaly, urticaria, and eosinophilia. The acute syndrome is difficult to diagnose, since ova may not appear in the feces until 3–4 weeks after onset of symptoms. In chronic heavy infections, findings include abdominal pain, anorexia, weight loss, and tender hepatomegaly. More serious findings can include recurrent bacterial cholangitis and sepsis, cholecystitis, liver abscess, and pancreatitis. An increased risk of cholangiocarcinoma has been documented.

Early diagnosis is presumptive, based on clinical findings and epidemiology. Subsequent diagnosis is made by finding characteristic eggs in stool or duodenal or biliary contents. Repeated concentration tests of stool may be necessary. Imaging studies show characteristic biliary tract dilatations with filling defects due to flukes. Serologic tests can be helpful but are limited by suboptimal specificity.

The drug of choice is praziquantel, 25 mg/kg orally three times daily for 2 days, which provides cure rates over 95%. One day of treatment may be sufficient. Re-treatment may be required, especially in some areas with known decreased praziquantel efficacy. The second-line drug is albendazole (400 mg orally twice daily for 7 days), which appears to be somewhat less effective.

PARAGONIMIASIS

Eight species of *Paragonimus* lung flukes cause human disease. The most important is *Paragonimus westermani*.

Paragonimus species are endemic in East Asia, Oceania, West Africa, and South America, where millions of persons are infected. Eggs are released into fresh water, where parasites infect snails, and then cercariae infect crabs and crayfish. Human infection follows consumption of raw, undercooked, or pickled freshwater shellfish. Metacercariae then excyst, penetrate into the peritoneum, and pass into the lungs, where they mature into adult worms over about 2 months.

Most persons have moderate worm burdens and are asymptomatic. In symptomatic cases, abdominal pain and diarrhea develop 2 days to 2 weeks after infection, followed by fever, cough, chest pain, urticaria, and eosinophilia. Acute symptoms may last for several weeks. Chronic infection can cause cough productive of brown sputum, hemoptysis, dyspnea, and chest pain, with progression to chronic bronchitis, bronchiectasis, bronchopneumonia, lung abscess, and pleural disease. Ectopic infections can cause disease in other organs, most commonly the CNS, where disease can present with seizures, headaches, and focal neurologic findings due to parasite meningitis and to intracerebral lesions.

The diagnosis of paragonimiasis is made by identifying characteristic eggs in sputum or stool or identifying worms in biopsied tissue. Multiple examinations and concentration techniques may be needed. Serologic tests may be helpful; an ELISA available from the CDC has sensitivity and specificity > 95%. Chest radiographs may show varied abnormalities of the lungs or pleura, including infiltrates, nodules, cavities, and fibrosis, and the findings can be confused with those of tuberculosis. With CNS disease, skull radiographs can show clusters of calcified cysts, and CT or MRI can show clusters of ring-enhancing lesions.

Treatment is with praziquantel (25 mg/kg orally three times daily for 2 days), which provides efficacy of at least 90%. Alternative therapies are bithionol and triclabendazole. As with cysticercosis, for cerebral paragonimiasis, praziquantel should generally be used with corticosteroids. Chronic infection may lead to permanent lung dysfunction and pleural disease requiring drainage procedures.

INTESTINAL FLUKES

The large intestinal fluke, *Fasciolopsis buski*, is a common parasite of pigs and humans in eastern and southern Asia. Eggs shed in stools hatch in fresh water, followed by infection of snails, and release of cercariae that encyst on aquatic plants. Humans are infected by eating uncooked plants, including water chestnuts, bamboo shoots, and watercress. Adult flukes mature in about 3 months and live in the small intestine attached to the mucosa, leading to local inflammation and ulceration. Other intestinal flukes that cause similar syndromes include *Heterophyes* (North Africa and Turkey) and *Metagonimus* (East Asia) species; these species are transmitted by undercooked freshwater fish.

Infections with intestinal flukes are often asymptomatic, although eosinophilia may be marked. In symptomatic cases, after an incubation period of 1–2 months,

manifestations include epigastric pain and diarrhea. Other gastrointestinal symptoms, ileus, edema, and ascites may be seen uncommonly. Diagnosis is based on identification of characteristic eggs or adult flukes in the stool. In contrast to other fluke infections, illness more than 6 months after travel in an endemic area is unlikely. The drug of choice is praziquantel, 25 mg/kg orally as a single dose. Alternative therapies are triclabendazole and niclosamide (for most species).

CESTODE INFECTIONS

NONINVASIVE CESTODE INFECTIONS

The four major tapeworms that cause noninvasive infections in humans are the beef tapeworm *Taenia saginata*, the pork tapeworm *Taenia solium*, the fish tapeworm *Diphyllobothrium latum*, each of which can reach many meters in length, and the dwarf tapeworm *Hymenolepis nana*. *Taenia* and *Hymenolepis* species are broadly distributed, especially in the tropics; *D latum* is most prevalent in temperate regions. Other tapeworms that can cause noninvasive human disease include the rodent tapeworm *Hymenolepis diminuta*, the dog tapeworm *Dipylidium caninum*, and other *Taenia* and *Diphyllobothrium* species. Invasive tapeworm infections, including *T solium* (when infective eggs, rather than cysticerci are ingested) and *Echinococcus* species, will be discussed separately.

1. Beef Tapeworm

Infection is most common in cattle breeding areas. Humans are the definitive host. Gravid segments of *T saginata* are passed in human feces to soil, where they are ingested by grazing animals, especially cattle. The eggs then hatch to release embryos that encyst in muscle as cysticerci. Humans are infected by eating raw or undercooked infected beef. Most individuals infected with *T saginata* are asymptomatic, but abdominal pain and other gastrointestinal symptoms may be present. Eosinophilia is common. The most common presenting finding is the passage of proglottids in the stool.

2. Pork Tapeworm

T solium is transmitted to pigs that ingest human feces. Humans can be either the definitive host (after consuming undercooked pork, leading to tapeworm infection) or the intermediate host (after consuming food contaminated with human feces containing *T solium* eggs, leading to cysticercosis, which is discussed under invasive tapeworm

infections). As with the beef tapeworm, infection with *T solium* adult worms is generally asymptomatic, but gastrointestinal symptoms may occur. Infection is generally recognized after passage of proglottids. Autoinfection with eggs can progress to cysticercosis.

3. Fish Tapeworm

Infection with *D latum* follows ingestion of undercooked freshwater fish, most commonly in temperate regions. Eggs from human feces are taken up by crustaceans, these are eaten by fish, which are then infectious to humans. Infection with multiple worms over many years can occur. Infections are most commonly asymptomatic, but nonspecific gastrointestinal symptoms, including diarrhea, may occur. Diagnosis usually follows passage of proglottids. Prolonged heavy infection can lead to megaloblastic anemia and neuropathy from vitamin B₁₂ deficiency, which is due to infection-induced dissociation of the vitamin from intrinsic factor and to utilization of the vitamin by worms.

4. Dwarf Tapeworm

H nana is the only tapeworm that can be transmitted between humans. Infections are common in warm areas, especially with poor hygiene and institutionalized populations. Infection follows ingestion of food contaminated with human feces. Eggs hatch in the intestines, where oncospheres penetrate the mucosa, encyst as cysticercoid larvae, and then rupture after about 4 days to release adult worms. Autoinfection can lead to amplification of infection. Infection with *H nana*, the related rodent tapeworm *H diminuta*, or the dog tapeworm *D caninum* can also follow accidental ingestion of infected insects. *H nana* are dwarf in size relative to other tapeworms but can reach 5 cm in length. Heavy infection is common, especially in children, and can be accompanied by abdominal discomfort, anorexia, and diarrhea.

▶ Laboratory Findings

Diagnosis is usually made based on the identification of characteristic eggs or proglottids in stool. Egg release may be irregular, so examination of multiple specimens or concentration techniques may be needed.

▶ Treatment

The treatment of choice for noninvasive tapeworm infections is praziquantel. A single dose of praziquantel (5–10 mg/kg orally) is highly effective, except for *H nana*, for which the dosage is 25 mg/kg. Treatment of *H nana* is more difficult, as the drug is not effective against maturing cysts. Therefore, with heavy infections with this parasite a repeat treatment after 1 week, and screening after therapy to document cure are appropriate. Therapy can be accompanied by headache, malaise, dizziness, abdominal pain, and nausea.

The alternative therapy for these infections is niclosamide. A single dose of niclosamide (2 g chewed) is effective against *D latum*, *Taenia*, and *D caninum* infections. For *H nana*, therapy is continued daily for 1 week. Niclosamide may cause nausea, malaise, and abdominal pain.

Craig P et al. Intestinal cestodes. *Curr Opin Infect Dis.* 2007 Oct; 20(5):524–32. [PMID: 17762788]

INVASIVE CESTODE INFECTIONS

1. Cysticercosis

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to *T solium* through fecal contamination of food.
- ▶ Seizures, headache, and other findings of a focal CNS lesion.
- ▶ Brain imaging shows cysts; positive serologic tests.

▶ General Considerations

Cysticercosis is due to tissue infection with cysts of *T solium* that develop after humans ingest food contaminated with eggs from human feces, thus acting as an intermediate host for the parasite. Prevalence is high where the parasite is endemic, in particular Mexico, Central and South America, the Philippines, and Southeast Asia. An estimated 20 million persons are infected with cysticercosis yearly, leading to about 400,000 persons with neurologic symptoms and 50,000 deaths. Antibody prevalence rates up to 10% are recognized in some endemic areas, and the infection is one of the most important causes of seizures in the developing world and in immigrants to the United States from endemic countries.

▶ Clinical Findings

A. Symptoms and Signs

Neurocysticercosis can cause intracerebral, subarachnoid, and spinal cord lesions and intraventricular cysts. Single or multiple lesions may be present. Lesions may persist for years before symptoms develop, generally due to local inflammation or ventricular obstruction. Presenting symptoms include seizures, focal neurologic deficits, altered cognition, and psychiatric disease. Symptoms develop more quickly with intraventricular cysts, with findings of hydrocephalus and meningeal irritation, including severe headache, vomiting, papilledema, and visual loss. A particularly aggressive form of the disease, racemose cysticercosis, involves proliferation of cysts at the base of the brain, leading to alterations of consciousness and death. Spinal cord lesions can present with progressive focal findings.

Cysticercosis of other organ systems is usually clinically benign. Involvement of muscles can uncommonly cause discomfort and is identified by radiographs of muscle showing multiple calcified lesions. Subcutaneous involvement presents with multiple painless palpable skin lesions. Involvement of the eyes can present with ptosis due to extraocular muscle involvement or intraocular abnormalities.

B. Laboratory Findings

CSF examination may show lymphocytic or eosinophilic pleocytosis, decreased glucose, and elevated protein. Serology plays an important role in diagnosis. ELISAs with sensitivity and specificity over 90% are available.

C. Imaging

The diagnosis of neurocysticercosis can be difficult. With neuroimaging by CT or MRI, multiple parenchymal cysts are most typically seen. Parenchymal calcification is also common. Ventricular cysts may be difficult to visualize, with MRI offering better sensitivity than CT.

▶ Treatment

The medical management of neurocysticercosis is controversial, as the benefits of cyst clearance must be weighed against potential harm of an inflammatory response to dying worms. Anthelmintic therapy hastens radiologic improvement in parenchymal cysticercosis. However, some randomized trials have shown that corticosteroids alone are as effective as specific therapy plus corticosteroids for controlling seizures, and some reports have shown exacerbation of disease after anthelmintic therapy. Active lesions with a high likelihood of progression, such as intraventricular cysts, may benefit from therapy. At the other end of the spectrum, inactive calcified lesions probably do not benefit from therapy. Overall, it remains difficult to determine when treatment is indicated. When treatment is deemed appropriate, standard therapy consists of albendazole (10–15 mg/kg/d orally for 8 days) or praziquantel (50 mg/kg/d orally for 15–30 days). Albendazole is probably preferred, since it has shown better efficacy in some comparisons and since corticosteroids appear to lower circulating praziquantel levels but increase albendazole levels. Increasing the dosage of albendazole to 30 mg/kg/d orally may improve outcomes. Corticosteroids are usually administered concurrently, but dosing is not standardized. Patients should be observed for evidence of localized inflammatory responses. Anticonvulsant therapy is provided if needed, and shunting is performed if required for elevated intracranial pressure. Surgical removal of cysts may be helpful for some difficult cases of neurocysticercosis and for symptomatic non-neurologic disease.

Sinha S et al. Neurocysticercosis: a review of current status and management. *J Clin Neurosci.* 2009 Jul;16(7):867–76. [PMID: 19394828]

2. Echinococcosis

ESSENTIALS OF DIAGNOSIS

- ▶ History of exposure to dogs or wild canines in an endemic area.
- ▶ Large cystic lesions, most commonly of the liver or lung.
- ▶ Positive serologic tests.

▶ General Considerations

Echinococcosis occurs when humans are intermediate hosts for canine tapeworms. Infection is acquired by ingesting food contaminated with canine feces containing parasite eggs. The principal species that infect humans are *Echinococcus granulosus*, which causes cystic hydatid disease, and *Echinococcus multilocularis*, which causes alveolar hydatid disease. *E granulosus* is transmitted by domestic dogs in areas with livestock (sheep, goats, camels, and horses) as intermediate hosts, including Africa, the Middle East, southern Europe, South America, Central Asia, Australia, New Zealand, and the southwestern United States. *E multilocularis*, which much less commonly causes human disease, is transmitted by wild canines, and endemic in northern forest areas of the northern hemisphere, including central Europe, Siberia, northern Japan, northwestern Canada, and western Alaska. An increase in the fox population in Europe has been associated with an increase in human cases. The disease range has also extended southward in Central Asia and China. Other species that cause limited disease in humans are endemic in South America and China.

After humans ingest parasite eggs, the eggs hatch in the intestines to form oncospheres, which penetrate the mucosa, enter the circulation, and encyst in specific organs as hydatid cysts. *E granulosus* forms cysts most commonly in the liver (65%) and lungs (25%), but the cysts may develop in any organ, including the brain, bones, skeletal muscles, kidneys, and spleen. Cysts are most commonly single. The cysts can persist and slowly grow for many years.

▶ Clinical Findings

A. Symptoms and Signs

Infections are commonly asymptomatic and may be noted incidentally on imaging studies or present with symptoms caused by an enlarging or superinfected mass. Findings may include abdominal or chest pain, biliary obstruction, cholangitis, portal hypertension, cirrhosis, bronchial obstruction leading to segmental lung collapse, and abscesses. Cyst leakage or rupture may be accompanied by a severe allergic reaction, including fever and hypotension. Seeding of cysts after rupture may extend the infection to new areas.

E multilocularis generally causes a more aggressive disease than *E granulosus*, with initial infection of the liver,

but then local and distant spread commonly suggesting a malignancy. Symptoms based on the areas of involvement gradually worsen over years, with the development of obstructive findings in the liver and elsewhere.

B. Laboratory Findings

Serologic tests, including ELISA and immunoblot, offer sensitivity and specificity over 80% for *E granulosus* liver infections, but lower sensitivity for involvement of other organs. Serologic tests may also distinguish the two major echinococcal infections.

C. Imaging

Diagnosis is usually based on imaging studies, including ultrasonography, CT, and MRI. In *E granulosus* infection, a large cyst containing daughter cysts is highly suggestive of the diagnosis. In *E multilocularis* infection, imaging shows an irregular mass, often with areas of calcification.

▶ Treatment

Treatment of cystic hydatid disease has traditionally involved cautious surgical resection of cysts, with care not to rupture cysts during removal. Injection of a cysticidal agent was used to limit spread in the case of rupture. Newer management algorithms include treatment with albendazole, often in conjunction with surgery. When used alone, as in cases where surgery is not possible, albendazole (10–15 mg/kg/d orally) has demonstrated efficacy, with courses of 3 months or longer duration, in some cases with alternating cycles of treatment and rest. Mebendazole (40–50 mg/kg/d orally) is an alternative drug, and praziquantel may also be effective. In some cases, medical therapy is begun, with surgery performed if disease persists after some months of therapy. Another approach, in particular with inoperable cysts, is percutaneous aspiration, injection, and reaspiration (PAIR). In this approach (which should not be used if cysts communicate with the biliary tract), patients receive antihelminthic therapy, and the cyst is partially aspirated. After diagnostic confirmation by examination for parasite protoscolices, a scolicidal agent (such as 95% ethanol, hypertonic saline, or 0.5% cetrizide) is injected. PAIR includes a small risk of anaphylaxis, which has been reported in about 2% of procedures, but death due to anaphylaxis has been rare. Treatment of alveolar cyst disease is challenging, generally relying on wide surgical resection of lesions. Therapy with albendazole before or during surgery may be beneficial and may also provide improvement or even cure in inoperable cases.

3. Other Invasive Cestode Infections

Ingestion of aquatic copepods infected with larvae of *Spirometra* canine or feline tapeworms can lead to sparganosis, especially in South America and East Asia. Infection can also come from ingestion of undercooked infected meat (including mammals, birds, reptiles, and amphibians) or from use of frog or snake-meat poultices. The worms penetrate the intestinal wall or skin and migrate to various tissues. Inflammatory lesions, most commonly of the skin

or eyes, are typically present. In cerebral sparganosis, an intense inflammatory response to worms can lead to severe neurologic disease. Diagnosis is by biopsy or visualization of the parasite. Treatment consists of surgical resection or local injection of ethanol. Anthelmintics do not appear to be helpful. Other non-human tapeworms can also cause localized and CNS inflammatory lesions. These are also managed with surgical resection.

INTESTINAL NEMATODE (ROUNDWORM) INFECTIONS

ASCARIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Transient cough, urticaria, pulmonary infiltrates, eosinophilia.
- ▶ Nonspecific abdominal symptoms.
- ▶ Eggs in stool; adult worms occasionally passed.

General Considerations

Ascaris lumbricoides is the most common of the intestinal helminths, infecting about a quarter of the world's population, with estimates of over a billion infections, 12 million acute cases, and 10,000 or more deaths annually. Prevalence is high wherever there is poor hygiene and sanitation or where human feces are used as fertilizer. Heavy infections are most common in children.

Infection follows ingestion of eggs in contaminated food. Larvae hatch in the small intestine, penetrate into the bloodstream, migrate to the lungs, and then travel via airways back to the gastrointestinal tract, where they develop to adult worms, which can be up to 40 cm in length, and live for 1–2 years.

Clinical Findings

Most persons with *Ascaris* infection are asymptomatic. In a small proportion of patients, symptoms develop during migration of worms through the lungs, with fever, nonproductive cough, chest pain, dyspnea, and eosinophilia, occasionally with eosinophilic pneumonia. Rarely, larvae lodge ectopically in the brain, kidney, eye, spinal cord, and other sites and may cause local symptoms.

Light intestinal infections usually produce no symptoms. With heavy infection, abdominal discomfort may be seen. Adult worms may also migrate and be coughed up, be vomited, or may emerge through the nose or anus. They may also migrate into the common bile duct, pancreatic duct, appendix, and other sites, which may lead to cholangitis, cholecystitis, pyogenic liver abscess, pancreatitis, obstructive jaundice, or appendicitis. With very heavy infestations, masses of worms may cause intestinal obstruction, volvulus, intussusception, or death. Although severe manifestations of infection are uncommon, the very high prevalence of ascariasis leads to large numbers of individuals, especially children, with important sequelae. Moderate to high worm loads in children are also associated with nutritional abnormalities due to decreased appetite and food intake, and also decreased absorption of nutrients.

The diagnosis of ascariasis is made after adult worms emerge from the mouth, nose, or anus, or by identifying characteristic eggs in the feces. Due to the very high egg burden, concentration techniques are generally not needed. Imaging studies demonstrate worms, with filling defects in contrast studies and at times evidence of intestinal or biliary obstruction. Eosinophilia is marked during worm migration but may be absent during intestinal infection.

Treatment

All infections should ideally be treated. Treatments of choice are albendazole (single 400 mg oral dose), mebendazole (single 500 mg oral dose or 100 mg twice daily for 3 days), or pyrantel pamoate (single 11 mg/kg oral dose, maximum 1 g). These drugs are all well tolerated but may cause mild gastrointestinal toxicity. They are considered safe for children above 1 year of age and in pregnancy, although use in the first trimester is best avoided. Intestinal obstruction usually responds to conservative management and anthelmintic therapy. Surgery may be required for appendicitis and other gastrointestinal complications.

TRICHURIASIS

Trichuris trichiura, the whipworm, infects about a billion persons throughout the world, particularly in humid tropical and subtropical environments. Infection is heaviest and most frequent in children. Infections are acquired by ingestion of eggs. The larvae hatch in the small intestine and mature in the large bowel to adult worms of about 4 cm in length. The worms do not migrate through tissues.

Most infected persons are asymptomatic. Heavy infections may be accompanied by abdominal cramps, tenesmus, diarrhea, distention, nausea, and vomiting. The *Trichuris* dysentery syndrome may develop, particularly in malnourished

young children, with findings resembling inflammatory bowel disease including bloody diarrhea and rectal prolapse. Chronic infections in children can lead to iron deficiency anemia, growth retardation, and clubbing of the fingers.

Trichuriasis is diagnosed by identification of characteristic eggs and sometimes adult worms in stools. Concentration techniques are not needed. Eosinophilia is common. Treatment is with albendazole (400 mg/d orally) or mebendazole (200 mg/d orally), for 1–3 days for light infections or 3–7 days for heavy infections, but cure rates are lower than for ascariasis or hookworm infection. The addition of ivermectin (200 mcg/kg orally daily for 1–2 days) to these drugs improves outcomes.

HOOKWORM DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Transient pruritic skin rash and pulmonary symptoms.
- ▶ Anorexia, diarrhea, abdominal discomfort.
- ▶ Iron deficiency anemia.
- ▶ Characteristic eggs and occult blood in the stool.

▶ General Considerations

Infection with the hookworms *Ancylostoma duodenale* and *Necator americanus* is very common, especially in most tropical and subtropical regions. Both worms are broadly distributed. Prevalence is estimated at about 1 billion, causing approximately 65,000 deaths each year. When eggs are deposited on warm moist soil they hatch, releasing larvae that remain infective for up to a week. With contact, the larvae penetrate skin and migrate in the bloodstream to the pulmonary capillaries. In the lungs, the larvae penetrate into alveoli and then are carried by ciliary action upward to the bronchi, trachea, and mouth. After being swallowed, they reach and attach to the mucosa of the upper small bowel, where they mature to adult worms. *Ancylostoma* infection can also be acquired by ingestion of the larvae in food or water. Hookworms attach to the intestinal mucosa and suck blood. Blood loss is proportionate to the worm burden.

▶ Clinical Findings

A. Symptoms and Signs

Most infected persons are asymptomatic. A pruritic maculopapular rash (ground itch) may occur at the site of larval penetration, usually in previously sensitized persons. Pulmonary symptoms may be seen during larval migration through the lungs, with dry cough, wheezing, and low-grade fever, but these symptoms are less common than with ascariasis. About 1 month after infection, as maturing worms attach to the small intestinal mucosa, gastrointestinal symptoms may develop, with epigastric pain, anorexia, and diarrhea, especially in previously unexposed individuals. Persons chronically infected with large worm burdens

may have abdominal pain, anorexia, diarrhea, and findings of marked iron-deficiency anemia and protein malnutrition. Anemia can lead to pallor, weakness, dyspnea, and congestive heart failure, and protein loss can lead to hypoalbuminemia, edema, and ascites. These findings may be accompanied by impairment in growth and cognitive development in children. Infection with the dog hookworm *Ancylostoma caninum* can uncommonly lead to abdominal pain, diarrhea, and eosinophilia, with intestinal ulcerations and regional lymphadenitis.

B. Laboratory Findings

Diagnosis is based on the demonstration of characteristic eggs in feces; concentration techniques are usually not needed. Microcytic anemia, occult blood in the stool, and hypoalbuminemia are common. Eosinophilia is common, especially during worm migration.

▶ Treatment

Treatment is with albendazole (single 400 mg oral dose) or mebendazole (100 mg orally twice daily for 3 days). These drugs are teratogenic, but experience suggests that they are safe in children over 1 year of age and during the second and third trimesters of pregnancy. Occasional adverse effects are diarrhea and abdominal pain. Pyrantel pamoate and levamisole are also effective. Anemia should be managed with iron replacement and, for severe symptomatic anemia, blood transfusion. Mass treatment of children with single doses of albendazole or mebendazole at regular intervals limits worm burdens and the extent of disease and is advocated by the WHO.

STRONGYLOIDIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Transient pruritic skin rash and pulmonary symptoms.
- ▶ Anorexia, diarrhea, abdominal discomfort.
- ▶ Hyperinfection syndrome in the immunocompromised.
- ▶ Larvae detected in stool.
- ▶ With hyperinfection, larvae detected in sputum or other fluids.
- ▶ Eosinophilia.

▶ General Considerations

Strongyloidiasis is caused by infection with *Strongyloides stercoralis*. Although much less prevalent than ascariasis, trichuriasis, or hookworm infections, strongyloidiasis is nonetheless a significant problem, infecting tens of millions of individuals in tropical and subtropical regions. Infection is also endemic in some temperate regions of North America, Europe, Japan, and Australia. Of particular

importance is the predilection of the parasite to cause severe infections in immunocompromised individuals due to its ability to replicate in humans. A related parasite, *Strongyloides fuelleborni*, infects humans in parts of Africa and New Guinea.

Among nematodes, *S stercoralis* is uniquely capable of maintaining its full life cycle both within the human host and in soil. Infection occurs when filariform larvae in soil penetrate the skin, enter the bloodstream, and are carried to the lungs, where they escape from capillaries into alveoli, ascend the bronchial tree, and are then swallowed and carried to the duodenum and upper jejunum, where maturation to the adult stage takes place. Females live embedded in the mucosa for up to 5 years, releasing eggs that hatch in the intestines as free rhabditiform larvae that pass to the ground via the feces. In moist soil, these larvae metamorphose into infective filariform larvae. Autoinfection can occur in humans, when some rhabditiform larvae develop into filariform larvae that penetrate the intestinal mucosa or perianal skin, and enter the circulation. The most dangerous manifestation of *S stercoralis* infection is the **hyperinfection syndrome**, with dissemination of large numbers of filariform larvae to the lungs and other tissues in immunocompromised individuals. Mortality with this syndrome approaches 100% without treatment and has been about 25% with treatment. The hyperinfection syndrome is seen in patients receiving corticosteroids and other immunosuppressive medications; patients with hematologic malignancies, malnutrition, or alcoholism; or persons with AIDS. The risk seems greatest for those receiving corticosteroids, and considering the large number of at risk individuals, the risk in those with AIDS seems relatively low.

► Clinical Findings

A. Symptoms and Signs

As with other intestinal nematodes, most infected persons are asymptomatic. An acute syndrome can be seen at the time of infection, with a pruritic, erythematous, maculopapular rash, usually of the feet. These symptoms may be followed by pulmonary symptoms (including dry cough, dyspnea, and wheezing) and eosinophilia after a number of days, followed by gastrointestinal symptoms after some weeks, as with hookworm infections. Chronic infection may be accompanied by epigastric pain, nausea, diarrhea, and anemia. Maculopapular or urticarial rashes of the buttocks, perineum, and thighs, due to migrating larvae, may be seen. Large worm burdens can lead to malabsorption or intestinal obstruction. Eosinophilia is common but may fluctuate.

With **hyperinfection** large numbers of larvae can migrate to many tissues, including the lungs, CNS, kidneys, and liver. Gastrointestinal symptoms can include abdominal pain, nausea, vomiting, diarrhea, and more severe findings related to intestinal obstruction, perforation, or hemorrhage. Bacterial sepsis, probably secondary to intestinal ulcerations, is a common presenting finding. Pulmonary findings include pneumonitis, cough, hemoptysis, and respiratory failure. Sputum may contain adult worms, larvae, and eggs. CNS disease includes meningitis

and brain abscesses; the CSF may contain larvae. Various presentations can progress to shock and death.

B. Laboratory Findings

The diagnosis of strongyloidiasis can be difficult, as eggs are seldom found in feces. Diagnosis is usually based on the identification of rhabditiform larvae in the stool or duodenal contents. These larvae must be distinguished from hookworm larvae, which may hatch after stool collection. Repeated examinations of stool or examination of duodenal fluid may be required for diagnosis because the sensitivity of individual tests is only about 30%. Hyperinfection is diagnosed by the identification of large numbers of larvae in stool, sputum, or other body fluids. An ELISA from the CDC offers about 90% sensitivity and specificity, but cross-reactions with other helminths may occur. Eosinophilia and mild anemia are common, but eosinophilia may be absent with hyperinfection. Hyperinfection may include extensive pulmonary infiltrates, hypoproteinemia, and abnormal liver function studies.

C. Screening

It is important to be aware of the possibility of strongyloidiasis in persons with even a distant history of residence in an endemic area, since the infection can be latent for decades. Screening of at-risk individuals for infection is appropriate before institution of immunosuppressive therapy. Screening can consist of serologic tests, with stool examinations in those with positive serologic tests, but consideration of presumptive treatment even if the stool evaluations are negative (see below).

► Treatment

Full eradication of *S stercoralis* is more important than with other intestinal helminths due to the ability of the parasite to replicate in humans. The treatment of choice for routine infection is ivermectin (200 mcg orally daily for 1–2 days). This treatment has replaced thiabendazole (25 mg/kg orally twice daily for 3 days), which is relatively poorly tolerated, and albendazole (400 mg orally twice daily for 3 days), which is less effective. For hyperinfection, ivermectin should be administered daily until the clinical syndrome has resolved and larvae have not been identified for at least 2 weeks. Follow-up examinations for larvae in stool or sputum are necessary, with repeat dosing if the infection persists. With continued immunosuppression, eradication may be difficult, and regular repeated doses of antihelminthic therapy (eg, monthly ivermectin) may be required.

ENTEROBIASIS

ESSENTIALS OF DIAGNOSIS

- Nocturnal perianal pruritus.
- Identification of eggs or adult worms on perianal skin or in stool.

► General Considerations

Enterobius vermicularis, the pinworm, is a common cause of intestinal infections worldwide, with maximal prevalence in school-age children. Enterobiasis is transmitted person-to-person via ingestion of eggs after contact with the hands or perianal region of an infected individual, food or fomites that have been contaminated by an infected individual, or infected bedding or clothing. Autoinfection also occurs. Eggs hatch in the duodenum and larvae migrate to the cecum. Females mature in about a month, and remain viable for about another month. During this time they migrate through the anus to deposit large numbers of eggs on the perianal skin. Due to the relatively short lifespan of these helminths, continuous reinfection, as in institutional settings, is required, for long-standing infection.

► Clinical Findings

A. Symptoms and Signs

Most individuals with pinworm infection are asymptomatic. The most common symptom is perianal pruritus, particularly at night, due to the presence of the female worms or deposited eggs. Insomnia, restlessness, and enuresis are common in children. Perianal scratching may result in excoriation and impetigo. Many mild gastrointestinal symptoms have also been attributed to enterobiasis, but associations are not proven. Serious sequelae are uncommon. Rarely, worm migration results in inflammation or granulomatous reactions of the gastrointestinal or genitourinary tracts. Colonic ulceration and eosinophilic colitis have been reported.

B. Laboratory Findings

Pinworm eggs are usually not found in stool. Diagnosis is made by finding adult worms or eggs on the perianal skin. A common test is to apply clear cellophane tape to the perianal skin, ideally in the early morning, followed by microscopic examination for eggs. The sensitivity of the tape test is reported to be about 50% for a single test and 90% for three tests. Nocturnal examination of the perianal area or gross examination of stools may reveal adult worms, which are about 1 cm in length. Eosinophilia is rare.

► Treatment

Treatment is with single oral doses of albendazole (400 mg), mebendazole (100 mg) or pyrantel pamoate (11 mg/kg, to a maximum of 1 g). The dose is repeated in 2 weeks due to frequent reinfection. Other infected family members should be treated concurrently, and treatment of all close contacts may be appropriate when rates of reinfection are high in family, school, or institutional settings. Standard handwashing and hygiene practices are helpful in limiting spread. Perianal scratching should be discouraged. Washing of clothes and bedding should kill pinworm eggs.

INVASIVE NEMATODE (ROUNDWORM) INFECTIONS

DRACUNCULIASIS

ESSENTIALS OF DIAGNOSIS

- Tender cutaneous ulcer and worm protruding from the skin of an individual who has ingested untreated water in rural Africa.

► General Considerations

Dracunculiasis is caused by the nematode *Dracunculus medinensis*, or Guinea worm. It causes chronic cutaneous ulcers with protruding worms in rural Africa. It occurs only in humans and is a major cause of disability, although recent control efforts have been remarkably successful, with decreased annual incidence from about 3.5 million cases in the late 1980s to 1793 reported cases in 2010. Dracunculiasis has been eradicated from Asia, but remains endemic in a few countries in West and Northeast Africa, with > 90% of cases in South Sudan. The disease occurs almost exclusively in isolated rural areas; all ages are affected, and prevalence may reach 60%.

Infection occurs after swallowing water containing the infected intermediate host, the crustacean *Cyclops* (known as copepods or water fleas). In the stomach, larvae escape from the copepods and migrate through the intestinal mucosa to the retroperitoneum, where mating occurs. Females then migrate to subcutaneous tissue, usually of the legs, over about a year. A subcutaneous ulcer then forms. Upon contact with water, the parasite discharges large

numbers of larvae, which are ingested by copepods. Adult worms, which can be up to a meter in length, are gradually extruded. Worm death and disintegration in tissue may provoke a severe inflammatory reaction.

► Clinical Findings

Patients are usually asymptomatic until the time of worm extrusion. At that time a painful papule develops, with erythema, pruritus, and burning, usually on the lower leg. Multiple lesions may be present. At this time, some patients may also develop a short-lived systemic reaction, which may include fever, urticaria, nausea, vomiting, diarrhea, and dyspnea. The skin lesion vesiculates over a few days, followed by ulceration. The ulcer is tender, often with a visible worm. The worm is then extruded or absorbed over a few weeks, followed by ulcer healing. Secondary infections, including infectious arthritis and tetanus, are common. The disease causes significant disability; lesions commonly prevent walking for a month or more.

Diagnosis follows identification of a typical skin ulcer with a protruding worm. When the worm is not visible, larvae may be identified on smears or seen after immersion in cold water. Eosinophilia is usually present.

► Treatment

No drug cures the infection, but metronidazole and mebendazole are sometimes used to limit inflammation and facilitate worm removal. Wet compresses may relieve discomfort. Occlusive dressings improve hygiene and limit shedding of infectious larvae. Worms are typically removed by sequentially rolling them out over a small stick. When available, simple surgical procedures can be used to remove worms. Corticosteroid ointments may hasten healing. Topical antibiotics may limit bacterial superinfection.

► Prevention

Dracunculiasis has proven to be easier to control than most parasitic infections. The disease is prevented by avoidance of contaminated drinking water. This can be accomplished by boiling, chlorination, or filtration through finely woven cloth. A WHO dracunculiasis eradication program, initiated in 1986, has been highly successful.

TRICHINOSIS

ESSENTIALS OF DIAGNOSIS

- Ingestion of inadequately cooked pork or game.
- Transient intestinal symptoms followed by fever, myalgias, and periorbital edema.
- Eosinophilia and elevated serum muscle enzymes.

► General Considerations

Trichinosis (or trichinellosis) is caused worldwide by *Trichinella spiralis* and related *Trichinella* species. The disease is spread by ingestion of undercooked meat, most commonly pork in areas where pigs feed on garbage. When infected raw meat is ingested, *Trichinella* larvae are freed from cyst walls by gastric acid and pass into the small intestine. The larvae then invade intestinal epithelial cells, develop into adults, and the adults release infective larvae. These parasites travel to skeletal muscle via the bloodstream. They invade muscle cells, enlarge, and form cysts. These larvae may be viable for years. Pigs and other animals become infected by eating infected uncooked food scraps or other animals, such as rats.

The worldwide incidence of trichinosis has decreased, but human infections continue to occur sporadically or in outbreaks. In addition to undercooked pork, infections have been transmitted by ingestion of game and other animals, including bear and walrus in North America and wild boar and horse in Europe. In the United States, about 100 infections are reported annually, about three-fourths from pork and the remainder from game animals.

► Clinical Findings

A. Symptoms and Signs

Most infections are asymptomatic. In symptomatic cases, gastrointestinal symptoms, including diarrhea, vomiting, and abdominal pain, develop within the week after ingestion of contaminated meat. These symptoms usually last for less than a week but can occasionally persist for much longer. During the following week, symptoms and signs related to migrating larvae are seen. These findings include, most notably, fever, myalgias, periorbital edema, and eosinophilia. Additional findings may include headache, cough, dyspnea, hoarseness, dysphagia, macular or petechial rash, and subconjunctival and retinal hemorrhages. Systemic symptoms usually peak within 2–3 weeks, and commonly persist for about 2 months. In severe cases, generally with large parasite burdens, muscle involvement can be pronounced, with severe muscle pain, edema, and weakness, especially in the head and neck. Muscle pain may persist for months. Uncommon severe findings include myocarditis, pneumonitis, and meningoencephalitis, sometimes leading to death.

B. Laboratory Findings

The clinical diagnosis is supported by findings of elevated serum muscle enzymes (creatinine kinase, lactate dehydrogenase, aspartate aminotransferase). Serologic tests become positive 3 or more weeks after infection; a variety of techniques are used, including ELISA, immunofluorescence, indirect hemagglutinin, precipitin, and bentonite flocculation assays. Rising antibody titers are highly suggestive of the diagnosis. Muscle biopsy can usually be avoided, but if the diagnosis is uncertain, biopsy of a tender, swollen muscle may identify *Trichinella* larvae. For maximal yield, biopsy material should be examined histologically, and a portion should be enzymatically digested to release larvae, but evaluation before about 3 weeks after infection may not show muscle larvae.

► Treatment

No effective specific therapy for full-blown trichinosis has been identified. However, if infection is suspected early in the course of illness, treatment with mebendazole (2.5 mg/kg orally twice daily) or albendazole (5–7.5 mg/kg orally twice daily) will kill intestinal worms and may limit progression to tissue invasion. Supportive therapy for systemic disease consists of analgesics, antipyretics, bed rest and, in severe illness, corticosteroids. Infection is prevented by cooking to a temperature of at least 71°C for at least 1 minute. Irradiation of meat is also effective in eliminating *Trichinella* larvae, but freezing is not fully reliable.

Gottstein B et al. Epidemiology, diagnosis, treatment, and control of trichinellosis. *Clin Microbiol Rev.* 2009 Jan;22(1):127–45. [PMID: 19136437]

ANGIOSTRONGYLIASIS

Nematodes of rats of the genus *Angiostrongylus* cause two distinct syndromes in humans. *Angiostrongylus cantonensis*, the rat lungworm, causes eosinophilic meningoencephalitis, primarily in Southeast Asia and some Pacific islands. *Angiostrongylus costaricensis* causes gastrointestinal inflammation. In both diseases, human infection follows ingestion of larvae within slugs or snails (and also crabs or prawns for *A cantonensis*) or on material contaminated by these organisms. Since the parasites are not in their natural hosts, they cannot complete their life cycles, but they can cause disease after migrating to the brain or gastrointestinal tract.

► Clinical Findings

A. *A cantonensis* Infection

The disease appears to be caused primarily by worm larvae migrating through the CNS and an inflammatory response to dying worms. After an incubation period of 1 day to 2 weeks, presenting symptoms and signs include headache, stiff neck, nausea, vomiting, cranial nerve abnormalities, and paresthesias. Most cases resolve spontaneously after

2–8 weeks, but serious sequelae and death have been reported. The diagnosis is strongly suggested by the finding of eosinophilic CSF pleocytosis (leukocytosis with over 10% eosinophils) in a patient with a history of travel to an endemic area. Peripheral eosinophilia may not be present. *A cantonensis* larvae have rarely been recovered from the CSF and the eyes.

B. *A costaricensis* Infection

Parasites penetrate ileocecal vasculature and develop into adults, which lay eggs, but do not complete their life cycle. Disease is due to an inflammatory response to dying worms in the intestinal tract, with an eosinophilic granulomatous response, at times including vasculitis and ischemic necrosis. Common findings are abdominal pain, vomiting, and fever. Pain is most commonly localized to the right lower quadrant, and a mass may be appreciated, all mimicking appendicitis. Symptoms may recur over months. Uncommon findings are intestinal perforation or obstruction, or disease due to migration of worms to other sites. Many cases are managed surgically, usually for suspected appendicitis. Biopsy of inflamed intestinal tissue may show worms localized to mesenteric arteries and eosinophilic granulomas.

► Treatment

Anthelmintic therapy may be harmful for *A cantonensis* infection, since responses to dying worms may worsen with therapy. If anthelmintic treatment is to be used, albendazole is probably the best choice. Corticosteroids have been used in severe cases, and these are probably appropriate if anthelmintics are provided. It is not known if anthelmintic therapy is helpful for *A costaricensis* infection.

Ramirez-Avila L et al. Eosinophilic meningitis due to *Angiostrongylus* and *Gnathostoma* species. *Clin Infect Dis.* 2009 Feb 1;48(3):322–7. [PMID: 19123863]

Wang QP et al. Human angiostrongyliasis. *Lancet Infect Dis.* 2008 Oct;8(10):621–30. [PMID: 18922484]

GNATHOSTOMIASIS

A number of species of *Gnathostoma*, which are parasites of carnivores, can occasionally infect humans. Most cases have been seen in Southeast Asia, but the disease has also been described in many other areas. Eggs shed in the feces of mammals are ingested by marine crustaceans, which are then ingested by fish, frogs, snakes, or mammals. Larvae then encyst in muscles. Human infection follows eating undercooked fish, shellfish, chicken, or pork and can also be transmitted by ingesting copepods in contaminated water. After ingestion, larvae cannot complete development in humans, but rather migrate through tissues.

Acute gastrointestinal symptoms, including nausea, vomiting, abdominal pain, and fever, may develop soon after infection and persist for 2–3 weeks. The disease may then progress

to findings consistent with cutaneous or visceral larva migrans. Migratory subcutaneous erythematous swellings may be painful or pruritic. Migrating larvae may also invade other tissues, leading to findings in the eyes, lungs, intestines, and elsewhere. The most serious complications are due to invasion of the CNS, leading to eosinophilic meningoencephalitis and other serious findings. Although a less common cause of eosinophilic meningitis than *A cantonensis* infection, gnathostomiasis tends to be more severe. Severe pain due to migration through spinal roots and focal neurologic findings may be seen. Symptoms are highly variable over time. CSF eosinophilic pleocytosis and peripheral eosinophilia are seen.

The diagnosis of gnathostomiasis is suggested by the history of intermittent subcutaneous swellings and typical CNS findings and established by identification of worms in tissues. Worms can occasionally be identified in skin lesions. Serologic tests may be helpful in establishing a diagnosis. Treatment is with ivermectin (200 mcg/kg orally single dose) or albendazole (400 mg/kg/d orally for 21 days). However, indications for treatment are uncertain with CNS disease, as inflammatory responses to dying worms might worsen outcomes, and corticosteroids may be indicated with antihelminthics in these cases.

Herman JS et al. Gnathostomiasis, another emerging imported disease. *Clin Microbiol Rev.* 2009 Jul;22(3):484–92. [PMID: 19597010]

TOXOCARIASIS

► General Considerations

The dog roundworm *Toxocara canis*, the cat roundworm *Toxocara cati*, and less commonly other helminths may cause visceral larva migrans. *T canis* is highly prevalent in dogs. Humans are infected after ingestion of eggs in material contaminated by dog or other feces. With *T canis*, infection is spread principally by puppies and lactating females, and the eggs must be on the ground for several weeks before they are infectious. After ingestion by humans, larvae migrate to various tissues but cannot complete their life cycle.

► Clinical Findings

Visceral larva migrans is seen principally in young children. Most infections are asymptomatic. The most commonly involved organs are the liver and lungs. Presentations include cough, fever, wheezing, hepatomegaly, splenomegaly, lymphadenopathy, pulmonary infiltrates, and eosinophilia. Involvement of the CNS can occur rarely, leading to eosinophilic meningitis and other abnormalities. Ocular larva migrans is a distinct syndrome, usually in children older than is typical for visceral larva migrans. Children present with visual deficits, pain, and a retinal mass, which can be confused with retinoblastoma. *Baylisascaris procyonis*, a roundworm of raccoons, can rarely cause visceral larva migrans in humans, with typically more severe

manifestations than those with *T canis*, including eosinophilic meningitis and eye disease.

The diagnosis of visceral larva migrans is suggested by the finding of eosinophilia in a child with hepatomegaly or other signs of the disease, especially with a history of exposure to puppies. The diagnosis is confirmed by the identification of larvae in a biopsy of infected tissue, usually performed when other diseases are suspected. Serologic tests may be helpful; an available ELISA was estimated to have 78% sensitivity and 92% specificity. Most patients recover without specific therapy, although symptoms may persist for months.

► Treatment

Treatment with antihelminthics or corticosteroids may be considered in severe cases. No drugs have been proven to be effective, but albendazole (400 mg orally twice daily for 5 days), mebendazole, thiabendazole, diethylcarbamazine, and ivermectin have been used, and albendazole has been recommended as the treatment of choice.

Rubinsky-Elefant G et al. Human toxocariasis: diagnosis, worldwide seroprevalences and clinical expression of the systemic and ocular forms. *Ann Trop Med Parasitol.* 2010 Jan;104(1):3–23. [PMID: 20149289]

CUTANEOUS LARVA MIGRANS (Creeping Eruption)

Cutaneous larva migrans is caused principally by larvae of the dog and cat hookworms, *Ancylostoma braziliense* and *A caninum*. Other animal hookworms, gnathostomiasis, and strongyloidiasis may also cause this syndrome. Infections are common in warm areas, including the southeastern United States. They are most common in children. The disease is caused by the migration of worms through skin; the non-human parasites cannot complete their life cycles, so only cause cutaneous disease.

► Clinical Findings

Intensely pruritic erythematous papules develop, usually on the feet or hands, followed within a few days by serpiginous tracks marking the course of the parasite, which may travel several millimeters per day (Figure 35–8). Several tracks may be present. The process may continue for weeks, with lesions becoming vesiculated, encrusted, or secondarily infected. Systemic symptoms or eosinophilia are uncommon.

The diagnosis is based on the characteristic appearance of the lesions. Biopsy is usually not indicated.

► Treatment

Without treatment, the larvae eventually die and are absorbed. Mild cases do not require treatment. Thiabendazole (10% aqueous suspension) can be applied topically three times daily for 5 or more days. Systemic therapy with albendazole (400 mg orally once or twice daily for 3–5 days) or ivermectin (200 mcg/kg orally single dose) is highly effective.

ANISAKIASIS

Anisakiasis is caused by infection with larvae of parasites of saltwater fish and squid. Multiple species of the family *Anisakidae* may occasionally infect humans. Definitive hosts for these parasites are marine mammals. Eggs are passed in the feces and ingested by crustaceans, which are then eaten by fish and squid. When ingested by humans in undercooked seafood, larvae penetrate the stomach or intestinal wall but cannot complete their life cycle. The disease is most common in Japan.

► Clinical Findings

Clinical manifestations of anisakiasis follow burrowing of worms into the stomach or intestinal wall, leading to localized ulceration, edema, and eosinophilic granuloma formation. Symptoms usually occur within 2 days of parasite ingestion and include severe epigastric or abdominal pain, nausea, and vomiting. Intestinal involvement can mimic appendicitis. Allergic symptoms, including urticaria, angioedema, and anaphylaxis, have also been attributed to acute infection. Acute symptoms generally resolve within 2 weeks, but chronic symptoms may also be seen, suggesting chronic intestinal diseases such as inflammatory bowel disease, diverticulitis, or carcinoma. Rarely, worms may migrate to other sites or be coughed up. Eosinophilia is usually not seen.

The diagnosis of anisakiasis is suggested in those with acute abdominal symptoms after ingestion of raw fish. Radiographic studies may identify stomach or intestinal lesions, and endoscopy may allow visualization and removal of the worm. When surgery is performed due to

consideration of other diagnoses, eosinophilic inflammatory lesions and the invading worms are found.

► Treatment

Specific therapy is not indicated, but endoscopic worm removal hastens recovery. The parasites are killed by cooking or deep freezing fish.

FILARIASIS

LYMPHATIC FILARIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Episodic attacks of lymphangitis, lymphadenitis, and fever.
- ▶ Chronic progressive swelling of extremities and genitals; hydrocele; chyluria; lymphedema.
- ▶ Microfilariae in blood, chyluria, or hydrocele fluid; positive serologic tests.

Lymphatic filariasis is caused by three filarial nematodes: *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*, and is among the most important parasitic diseases of man. Approximately 120 million people are infected with these organisms in tropical and subtropical countries, about a third of these suffer clinical consequences of the infections, and many are seriously disfigured. *W bancrofti* causes about 90% of episodes of lymphatic filariasis. It is transmitted by *Culex*, *Aedes*, and *Anopheles* mosquitoes and is widely distributed in the tropics and subtropics, including subsaharan Africa, Southeast Asia, the western Pacific, India, South America, and the Caribbean. *B malayi* is transmitted by *Mansonia* and *Anopheles* mosquitoes and is endemic in parts of China, India, Southeast Asia, and the Pacific. *B timori* is found only in islands of southeastern Indonesia. *Mansonella* are filarial worms transmitted by midges and other insects in Africa and South America.

Humans are infected by the bites of infected mosquitoes. Larvae then move to the lymphatics and lymph nodes, where they mature over months to thread-like adult worms, and then can persist for many years. The adult worms produce large numbers of microfilariae, which are released into the circulation, and infective to mosquitoes, particularly at night (except for the South Pacific, where microfilaremia peaks during daylight hours).

► Clinical Findings

A. Symptoms and Signs

Many infections remain asymptomatic despite circulating microfilariae. Clinical consequences of filarial infection are principally due to inflammatory responses to developing, mature, and dying worms. The initial manifestation of infection is often acute lymphangitis, with fever, painful lymph nodes, edema, and inflammation spreading peripherally from involved lymph nodes (in contrast to bacterial lymphangitis, which spreads centrally). Lymphangitis and lymphadenitis of the upper and lower extremities is common (Figure 35–9); genital involvement, including epididymitis and orchitis, with scrotal pain and tenderness, occurs principally only with *W bancrofti* infection. Acute attacks of lymphangitis last for a few days to a week and may recur a few times per year. Filarial fevers may also occur without lymphatic inflammation.

The most common chronic manifestation of lymphatic filariasis is swelling of the extremities or genitals due to chronic lymphatic inflammation and obstruction. Extremities become increasingly swollen, with a progression over time from pitting edema, to nonpitting edema, to sclerotic changes of the skin that are referred to as elephantiasis. Genital involvement, particularly with *W bancrofti*, occurs more commonly in men, progressing from painful epididymitis to hydroceles that are usually painless but can become very large, with inguinal lymphadenopathy, thickening of the spermatic cord, scrotal lymphedema, thickening and fissuring of the scrotal skin, and occasionally chyluria. Lymphedema of the female genitalia and breasts may also occur.

Tropical pulmonary eosinophilia is a distinct syndrome principally affecting young adult males with either *W bancrofti* or *B malayi* infection but typically without microfilaremia. This syndrome is characterized by asthma-like symptoms, with cough, wheezing, dyspnea, and low-grade

fevers, usually at night. Without treatment, tropical pulmonary eosinophilia can progress to interstitial fibrosis and chronic restrictive lung disease. *Mansonella* can inhabit serous cavities, the retroperitoneum, the eye, or the skin, and cause abnormalities related to inflammation at these sites.

B. Laboratory Findings

The diagnosis of lymphatic filariasis is strongly suggested by characteristic findings of lymphangitis or lymphatic obstruction in persons with risk factors for the disease. The diagnosis is confirmed by finding microfilariae, usually in blood, but this may be difficult. In addition, microfilariae may be absent, especially early in the disease progression (first 2–3 years) or with chronic obstructive disease. To increase yields, blood samples are obtained at about midnight in most areas, but not in the South Pacific, where microfilaremia is diurnal. Smears are evaluated by wet mount to identify motile parasites and by Giemsa staining; these examinations can be delayed until the following morning, with storage of samples at room temperature. Of note, the periodicity of microfilaremia is variable, and daytime samples may yield positive results. Microfilariae may also be identified in hydrocele fluid or chylous urine. Eosinophilia is usually absent, except during acute inflammatory syndromes. Available serologic tests, including bentonite flocculation, indirect hemagglutination, ELISA, and indirect fluorescent antibody tests, may be helpful but cannot distinguish between past and active infections. Rapid antigen tests with sensitivity and specificity over 90% are available, and these are increasingly used to guide control programs. Adult worms may also be found in lymph node biopsy specimens (although biopsy is not usually clinically indicated) or by ultrasound of a scrotal hydrocele or lymphedematous breast. When microfilaremia is lacking, especially if sophisticated techniques are not available, diagnoses may need to be made on clinical grounds alone.

► Treatment & Control

A. Drug Treatment

Treatment is somewhat controversial, as no drug can fully control or reverse the disease, and treatment may cause serious acute inflammatory symptoms. Diethylcarbamazine is the drug of choice, but it cannot cure infections due to its limited action against adult worms. Asymptomatic infection and acute lymphangitis are treated with this drug (2 mg/kg orally three times daily) for 10–14 days, leading to a marked decrease in microfilaremia. Therapy may be accompanied by allergic symptoms, including fever, headache, malaise, hypotension, and bronchospasm, probably due to release of antigens from dying worms. For this reason, treatment courses may begin with a lower dosage, with escalation over the first 4 days of treatment. Single annual doses of diethylcarbamazine (6 mg/kg orally), alone or with ivermectin (400 mcg/kg orally) or albendazole (400 mg orally) may be as effective as longer courses of diethylcarbamazine. When onchocerciasis or loiasis is suspected, it may be appropriate to withhold diethylcarbamazine to avoid severe reactions to dying microfilariae; rather, ivermectin plus albendazole may

▲ **Figure 35–9.** Elephantiasis of legs due to filariasis. (Public Health Image Library, CDC.)

be given, although these drugs are less active than diethylcarbamazine against adult worms. Appropriate management of advanced obstructive disease is uncertain. Drainage of hydroceles provides symptomatic relief, although they will recur. Therapy with diethylcarbamazine cannot reverse chronic lymphatic changes but is typically provided to lower worm burdens. An interesting approach under study is to treat with doxycycline (100–200 mg/d orally for 4–6 weeks), which kills obligate intracellular *Wolbachia* bacteria, leading to death of adult filarial worms. Doxycycline was also effective at controlling *Mansonella perstans* infection, which does not respond well to standard antifilarial drugs. Secondary bacterial infections must be treated. Surgical correction may be helpful in some cases.

B. Disease Control

Avoidance of mosquitoes is a key measure; preventive measures include the use of screens, bed nets (ideally treated with insecticide), and insect repellents. Community-based treatment with single annual doses of effective drugs offers a highly effective means of control. The current WHO strategy for control includes mass treatment of at risk communities with single annual doses of diethylcarbamazine plus albendazole or, for areas with onchocerciasis, albendazole plus ivermectin; in some circumstances, more frequent dosing offers improved control.

ONCHOCERCIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Severe pruritus; skin excoriations, thickening, and depigmentation; and subcutaneous nodules.
- ▶ Conjunctivitis progressing to blindness.
- ▶ Microfilariae in skin snips and on slit-lamp examination; adult worms in subcutaneous nodules.

▶ General Considerations

Onchocerciasis, or river blindness is caused by *Onchocerca volvulus*. An estimated 18 million persons are infected, of whom 3–4 million have skin disease, 500,000 have severe visual impairment, and 300,000 are blinded. Over 99% of infections are in subsaharan Africa, especially the West African savanna, with about half of cases in Nigeria and Congo. In some hyperendemic African villages, close to 100% of individuals are infected, and 10% or more of the population is blind. The disease is also prevalent in the southwestern Arabian peninsula and Latin America, including southern Mexico, Guatemala, Venezuela, Colombia, Ecuador, and northwestern Brazil. Onchocerciasis is transmitted by simulium flies (blackflies). These insects breed in fast-flowing streams and bite during the day.

After the bite of an infected blackfly, larvae are deposited in the skin, where adults develop over 6–12 months. Adult worms live in subcutaneous connective tissue or muscle nodules for a decade or more. Microfilariae are released from the nodules and migrate through subcutaneous and ocular tissues. Disease is due to responses to worms and to intracellular *Wolbachia* bacteria.

▶ Clinical Findings

A. Symptoms and Signs

After an incubation period of up to 1–3 years, the disease typically produces an erythematous, papular, pruritic rash, which may progress to chronic skin thickening and depigmentation. Itching may be severe and unresponsive to medications, such that more disability-adjusted life years are lost to onchocercal skin problems than to blindness. Numerous firm, nontender, movable subcutaneous nodules of about 0.5–3 cm, which contain adult worms, may be present. Due to differences in vector habits, these nodules are more commonly on the lower body in Africa but on the head and upper body in Latin America. Inguinal and femoral lymphadenopathy is common, at times resulting in a “hanging groin,” with lymph nodes hanging within a sling of atrophic skin. Patients may also have systemic symptoms, with weight loss and musculoskeletal pain.

The most serious manifestations of onchocerciasis involve the eyes. Microfilariae migrating through the eyes elicit host responses that lead to pathology. Findings include punctate keratitis and corneal opacities, progressing to sclerosing keratitis and blindness. Iridocyclitis, glaucoma, choroiditis, and optic atrophy may also lead to vision loss. The likelihood of blindness after infection varies greatly based on geography, with the risk greatest in savanna regions of West Africa.

B. Diagnostic Testing

The diagnosis is made by identifying microfilariae in skin snips, by visualizing microfilariae in the cornea or anterior chamber by slit-lamp examination, by identification of adult worms in a biopsy or aspirate of a nodule or, uncommonly, by identification of microfilariae in urine. Skin snips from the iliac crest (Africa) or scapula (Americas) are allowed to stand in saline for 2–4 hours or longer, and then examined microscopically for microfilariae. Deep punch

biopsies are not needed, and if suspicion persists after a skin snip is negative, the procedure should be repeated. Ultrasound may identify characteristic findings suggestive of adult worms in skin nodules. When the diagnosis remains difficult, the Mazzotti test can be used. In this test, a 50-mg dose of diethylcarbamazine is given. A positive test, with exacerbation of skin rash and pruritus, usually within 3 hours, is highly suggestive of the diagnosis. This test should only be used in suspected lightly infected patients (after other tests are negative), as this treatment can elicit severe skin and eye reactions in heavily infected individuals. A related and safer test using topical diethylcarbamazine is available in some areas. Eosinophilia is a common, but inconsistent finding. Serologic tests are poorly standardized, nonspecific, and generally unhelpful, as in endemic areas positivity is not indicative of acute disease.

▶ Treatment & Control

The treatment of choice is ivermectin, which has replaced diethylcarbamazine due to a much lower risk of severe reactions to therapy. Ivermectin kills microfilariae, but not adult worms, so disease control requires repeat administrations. Treatment is with a single oral dose of 150 mcg/mL, but schedules for re-treatment have not been standardized. One regimen is to treat every 3 months for 1 year, followed by treatment every 6–12 months for the suspected lifespan of adult worms (about 15 years). Treatment results in marked reduction in numbers of microfilariae in the skin and eyes, although its impact on the progression of visual loss remains uncertain. Toxicities of ivermectin are generally mild; fever, pruritus, urticaria, myalgias, edema, hypotension, and tender lymphadenopathy may be seen, presumably due to reactions to dying worms. Ivermectin should be used with caution in patients also at risk for loiasis, since it can elicit severe reactions including encephalopathy. In patients with severe skin findings not controlled by ivermectin, therapy with suramin may be considered. This is the only drug known to kill adult worms, but it is very toxic. As with other filarial infections, doxycycline acts against *O. volvulus* by killing intracellular *Wolbachia* bacteria. A course of 100 mg/day for 6 weeks kills the bacteria and prevents parasite embryogenesis for at least 18 months. Doxycycline is under study for onchocerciasis control but has no clear role in treatment of individual affected patients.

Protection against onchocerciasis includes avoidance of biting flies. Major efforts are underway to control insect vectors in Africa. In addition, mass distribution of ivermectin for intermittent administration at the community level is ongoing, and the prevalence of severe skin and eye disease is decreasing.

LOIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Subcutaneous swellings; adult worms migrating across the eye.
- ▶ Encephalitis, which may be brought on by treatment.
- ▶ Microfilariae in the blood.

▶ General Considerations

Loiasis is a chronic filarial disease caused by infection with *Loa loa*. The infection occurs in humans and monkeys in rainforest areas of West and central Africa. An estimated 3–13 million persons are infected. The disease is transmitted by chrysops flies, which bite during the day. Over 6–12 months after infection, larvae develop into adult worms, which migrate through subcutaneous tissues, including the subconjunctiva (leading to the term “eye worm”). Adults can live for up to 17 years.

▶ Clinical Findings

A. Symptoms and Signs

Many infected persons are asymptomatic, although they may have high levels of microfilaremia and eosinophilia. Transient subcutaneous swellings (Calabar swellings) develop in symptomatic persons. The swellings are non-erythematous, up to 20 cm in diameter, and may be preceded by local pain or pruritus. They usually resolve after 2–4 days but occasionally persist for several weeks. Calabar swellings are commonly seen around joints and may recur at the same or different sites. Visitors from nonendemic areas are more likely to have allergic-type reactions, including pruritus, urticaria, and angioedema. Adult worms may be seen to migrate across the eye, with either no symptoms or conjunctivitis, with pain and edema. The most serious complication of loiasis is encephalitis, which is most common in those with high level microfilaremia and microfilariae in the CSF. Symptoms may range from headache and insomnia to coma and death. Encephalitis may be brought on by treatment with diethylcarbamazine or ivermectin. Other complications of loiasis include kidney disease, with hematuria and proteinuria; endomyocardial fibrosis; and peripheral neuropathy.

B. Laboratory Findings

The diagnosis is established by identifying microfilariae in blood. Blood is evaluated as for lymphatic filariasis, but for loiasis blood should be obtained during the day. The failure to find microfilariae does not rule out the diagnosis. Identification of a migrating eye worm is also diagnostic. Serologic tests may be helpful in persons from nonendemic areas who may be acutely ill without detectable microfilaremia, but such tests have limited utility for residents of endemic areas because most of them will have positive test results. PCR methods have been described to

rule out loiasis before administration of ivermectin for the control of other filarial infections.

► Treatment

The treatment of choice is diethylcarbamazine, which eliminates microfilariae and has some activity against adult worms. Treatment with 8–10 mg/kg/d orally for 21 days is curative in about 50% of amicrofilaremic patients, and repeat courses increase efficacy. Mild side effects are common with therapy, including fever, pruritus, arthralgias, nausea, diarrhea, and Calabar swellings. These symptoms may be lessened by administration of antihistamines or corticosteroids. Patients with large worm burdens are at greater risk for serious complications of therapy, including kidney injury, shock, encephalitis, coma, and death. Treatment with ivermectin, which is highly active against microfilariae, but not adult worms, also entails a high risk of severe reactions. To attempt to avoid these sequelae,

pretreatment with corticosteroids and antihistamines, and escalating dosage of diethylcarbamazine have been used, but this strategy does not prevent encephalitis. The circulating parasite load that indicates particular risk for severe complications with therapy has been estimated at 2500/mL or greater. Strategies to treat patients with high parasite loads include (1) no treatment; (2) apheresis, if available, to remove microfilariae prior to therapy with diethylcarbamazine; or (3) therapy with albendazole, which appears to be well tolerated due to its slow antiparasitic effects, prior to therapy with diethylcarbamazine or ivermectin.

Mycotic Infections

Samuel A. Shelburne, MD, PhD
Richard J. Hamill, MD

36

Fungal infections have assumed an increasingly important role as use of broad-spectrum antimicrobial agents has increased and the number of immunodeficient patients has grown. Some pathogens (eg, *Cryptococcus*, *Candida*, *Pneumocystis*, *Fusarium*) rarely cause serious disease in normal hosts. Other endemic fungi (eg, *Histoplasma*, *Coccidioides*, *Paracoccidioides*) commonly cause disease in normal hosts but tend to be more aggressive in immunocompromised ones. Superficial mycoses are discussed in Chapter 6.

Successful management of most systemic fungal infections requires knowledge of the natural history of these diseases as well as familiarity with the unique pharmacokinetics, adverse effects, and drug interactions of the various therapeutic agents. Furthermore, most affected individuals usually have significant underlying illnesses. Consequently, clinicians with extensive experience in the management of these disorders should be routinely consulted.

CANDIDIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Common normal flora but opportunistic pathogen.
- ▶ Gastrointestinal mucosal disease, particularly esophagitis, most common.
- ▶ Intravenous catheter-associated fungemia occurs in patients who have sustained cutaneous or mucosal injury, undergone instrumentation, or received broad-spectrum antibiotics.

▶ General Considerations

Candida albicans can be cultured from the mouth, vagina, and feces of most people. Cutaneous and oral lesions are discussed in Chapters 6 and 8, respectively. The risk factors for invasive candidiasis include prolonged neutropenia, recent abdominal surgery, broad-spectrum antibiotic therapy, advanced chronic kidney disease, and the presence of

intravascular catheters (especially when providing total parenteral nutrition). Cellular immunodeficiency predisposes to mucocutaneous disease. When no other underlying cause is found, persistent oral or vaginal candidiasis should arouse a suspicion of HIV infection.

▶ Clinical Findings

A. Mucosal Candidiasis

Esophageal involvement is the most frequent type of significant mucosal disease. Presenting symptoms include substernal odynophagia, gastroesophageal reflux, or nausea without substernal pain. Oral candidiasis, though often associated, is not invariably present. Diagnosis is best confirmed by endoscopy with biopsy and culture.

Vulvovaginal candidiasis occurs in an estimated 75% of women during their lifetime. Risk factors include pregnancy, uncontrolled diabetes mellitus, broad-spectrum antimicrobial treatment, corticosteroid use, and HIV infection. Symptoms include acute vulvar pruritus, burning vaginal discharge, and dyspareunia.

B. Candidal Funguria

Most cases of candidal funguria are asymptomatic and represent specimen contamination or bladder colonization. However, signs and symptoms of true *Candida* urinary tract infections are indistinguishable from bacterial urinary tract infections and can include urgency, hesitancy, fever, chills, or flank pain.

C. Disseminated Candidiasis

The diagnosis of disseminated *Candida* infection is problematic because *Candida* species are often isolated from mucosal sites in the absence of invasive disease while blood cultures are positive only 50% of the time in disseminated infection. Serologic tests have not proved useful for distinguishing colonization from invasive disease. Isolation of *Candida* species from blood cultures may represent a benign, self-limited process, but until proven otherwise it should be considered a sign of serious, complicated disease.

Another form of invasive disease is hepatosplenic candidiasis. This results from aggressive chemotherapy and prolonged neutropenia in patients with underlying hematologic cancers. Typically, fever and variable abdominal pain present weeks after chemotherapy, when neutrophil counts have recovered. Blood cultures are generally negative. Hepatic enzymes reveal an alkaline phosphatase elevation that may be marked.

D. Candidal Endocarditis

Candidal endocarditis is a rare infection that is most frequently associated with exposure to a healthcare setting. Candidal endocarditis occurs with increased frequency on prosthetic valves in the first few months following surgery. The diagnosis is established definitively by culturing *Candida* from emboli or from vegetations at the time of valve replacement.

► Treatment

A. Mucosal Candidiasis

Therapy of **esophageal candidiasis** depends on the severity of disease. If patients are able to swallow and take adequate amounts of fluid orally, fluconazole, 100 mg/d (or itraconazole solution, 10 mg/mL, 200 mg/d), for 10–14 days usually suffices. In the individual who is more ill or in whom esophagitis has developed while taking fluconazole, options include oral or intravenous voriconazole, 200 mg twice daily; intravenous amphotericin B, 0.3 mg/kg/d; intravenous caspofungin, 50 mg/d; intravenous anidulafungin, 100 mg on day 1, then 50 mg/d; or intravenous micafungin, 150 mg/d. Relapse is common with all agents when there is underlying HIV infection without adequate immune reconstitution.

Various topical azole preparations (eg, clotrimazole, 100 mg vaginal tablet for 7 days, or miconazole, 200 mg vaginal suppository for 3 days) are effective against **vulvovaginal candidiasis**. One 150 mg oral dose of fluconazole has been shown to have equivalent efficacy with better patient acceptance. Disease recurrence is common but can be decreased with weekly fluconazole therapy (150 mg weekly).

B. Candidal Funguria

Candidal funguria frequently resolves with discontinuance of antibiotics or removal of bladder catheters. Clinical benefit from treatment of asymptomatic candiduria has not been demonstrated, but persistent funguria should raise the suspicion of disseminated infection. When symptomatic funguria persists, oral fluconazole, 200 mg/d for 7–14 days, can be used. Newer generation azoles (eg, voriconazole) and echinocandins are not considered standard therapy for candidal urinary tract infections due to low levels of active drug in the urine.

C. Disseminated Candidiasis

The decision to treat for disseminated *Candida* when organisms are isolated from urine or sputum (or both) needs to be individualized for each patient. A randomized

trial of empiric fluconazole for patients at high risk for, but not proven to have, disseminated candidiasis showed no clinical benefit compared with placebo.

The 2009 guidelines for treatment of invasive candidiasis recommend fluconazole (loading dose of 800 mg [12 mg/kg] intravenously, then 400 mg [6 mg/kg] intravenously daily) for less critically ill patients who have had no recent azole exposure. For patients with moderately severe to severe illness or for patients who have had recent azole exposure, an echinocandin such as caspofungin (loading dose of 70 mg intravenously once, then 50 mg intravenously daily), micafungin (100 mg intravenously daily), anidulafungin (loading dose of 200 mg intravenously once, then 100 mg intravenously daily) is favored. Therapy for candidemia should be continued for 2 weeks after the last positive blood culture and resolution of symptoms and signs of infection. A dilated fundoscopic examination is recommended for all patients with candidemia to exclude endophthalmitis and repeat blood cultures should be drawn to demonstrate organism clearance. Once patients have become clinically stable, parenteral therapy can be discontinued and oral fluconazole, 200–800 mg orally given as one or two doses daily, is used to complete treatment for isolates known to be or likely to be susceptible to fluconazole. Removal or exchange of intravascular catheters is generally recommended for non-neutropenic patients, since this may decrease the duration of candidemia and overall mortality, which approaches 30%.

Non-*albicans* species of *Candida* account for over 50% of clinical bloodstream isolates and often have resistance patterns that are different from *C. albicans*. An echinocandin is recommended for treatment of *Candida glabrata* infection with a transition to oral fluconazole or voriconazole reserved for patients whose isolates are known to be susceptible to these agents. Similarly, *Candida krusei* is generally fluconazole-resistant and so should be treated with an alternative agent, such as echinocandin or voriconazole. Fluconazole is the treatment of choice for *Candida parapsilosis* due to possible echinocandin resistance in such isolates.

Treatment for hepatosplenic candidiasis is with fluconazole, 400 mg orally daily, or a lipid formulation of amphotericin B should be given until clinical and radiographic improvement occurs.

D. Candidal Endocarditis

Amphotericin, either in a lipid or standard formulation, has long been considered the optimal therapy for candidal endocarditis, given in a dosage of 0.5–1 mg/kg/d intravenously, and can be given along with 5-flucytosine (25 mg/kg four times daily). Alternatively, fluconazole can be added to amphotericin B at dosages greater than 400 mg/d, followed by long-term oral suppressive therapy. Aggressive surgical intervention appears to be beneficial. There are now more data regarding the usefulness of echinocandins in this setting.

In high-risk patients undergoing induction chemotherapy, bone marrow transplantation, or liver transplantation, prophylaxis with antifungal agents has been shown to prevent invasive fungal infections although the effect on mortality and the preferred agent remain debated.

HISTOPLASMOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Epidemiologically linked to bird droppings and bat exposure; common along river valleys (especially the Ohio River and the Mississippi River valleys).
- ▶ Most patients asymptomatic; respiratory illness most common clinical problem.
- ▶ Widespread disease especially common in AIDS or other immunosuppressed states, with poor prognosis.
- ▶ Biopsy of affected organs with culture or urinary polysaccharide antigen most useful in disseminated disease.

▶ General Considerations

Histoplasmosis is caused by *Histoplasma capsulatum*, a dimorphic fungus that has been isolated from soil contaminated with bird or bat droppings in endemic areas (central and eastern United States, eastern Canada, Mexico, Central America, South America, Africa, and southeast Asia). Infection presumably takes place by inhalation of conidia. These convert into small budding cells that are engulfed by phagocytes in the lungs. The organism proliferates and undergoes lymphohematogenous spread to other organs.

▶ Clinical Findings

A. Symptoms and Signs

Most cases of histoplasmosis are asymptomatic or mild and thus go unrecognized. Past infection is recognized by pulmonary and splenic calcification noted on incidental radiographs. Symptomatic infection may present with mild influenza-like illness, often lasting 1–4 days. Moderately severe infections are frequently diagnosed as atypical pneumonia. These patients have fever, cough, and mild central chest pain lasting 5–15 days.

Clinically evident infections occur in several forms: (1) **Acute histoplasmosis** frequently occurs in epidemics, often when soil containing infected bird or bat droppings is disturbed. It is a relatively severe disease manifested by marked prostration, fever, and comparatively few pulmonary complaints even when radiographs show diffuse

pneumonia. The illness may last from 1 week to 6 months but is almost never fatal. (2) **Progressive disseminated histoplasmosis** is commonly seen in patients with underlying HIV infection (with CD4 cell counts usually < 100 cells/mL) or other conditions causing immunosuppression. Disseminated histoplasmosis has been more frequently reported in patients from endemic areas taking tumor necrosis factor (TNF)-blocking agents. It is characterized by fever and multiple organ system involvement. Chest radiographs may show a miliary pattern. Presentation may be fulminant, simulating septic shock, with death ensuing rapidly unless treatment is provided. Symptoms usually consist of fever, dyspnea, cough, loss of weight, and prostration. Ulcers of the mucous membranes of the oropharynx may be present. The liver and spleen are nearly always enlarged, and all the organs of the body are involved, particularly the adrenal glands, though this infrequently results in adrenal insufficiency. Gastrointestinal involvement may mimic inflammatory bowel disease. (3) **Subacute/chronic progressive pulmonary histoplasmosis** is usually seen in older patients with various lesions including apical cavities, infiltrates, and nodules found on radiographs. (4) **Chronic progressive disseminated histoplasmosis** usually occurs in middle-aged to elderly men with no known condition causing immunosuppression. Presentation is similar to acute disseminated histoplasmosis except for the chronicity of symptoms; it can result in death if not treated. (5) **Complications of pulmonary histoplasmosis** include granulomatous mediastinitis characterized by persistently enlarged mediastinal lymph nodes and fibrosing mediastinitis in which an excessive fibrotic response to *Histoplasma* infection results in compromise of the great vessels.

B. Laboratory Findings

Most patients with progressive pulmonary disease show anemia of chronic disease. Bone marrow involvement may be prominent in disseminated forms with occurrence of pancytopenia. Alkaline phosphatase and marked lactate dehydrogenase (LDH) and ferritin elevations are also common as are mild elevations of serum aspartate aminotransferase, although alanine aminotransferase is often normal.

With pulmonary involvement, sputum culture is rarely positive except in chronic disease; antigen testing of bronchoalveolar lavage fluid may be helpful in acute disease. The combination of a urine and serum antigen assay has an 83% sensitivity for the diagnosis of acute pulmonary histoplasmosis. Blood or bone marrow cultures from immunocompromised patients with acute disseminated disease are positive more than 80% of the time but may take several weeks for growth. The urine antigen assay has a sensitivity of > 90% for disseminated disease in immunocompromised patients and a declining titer can be used to follow response to therapy.

▶ Treatment

For progressive localized disease and for mild to moderately severe nonmeningeal disseminated disease in immunocompetent or immunocompromised patients,

itraconazole, 200–400 mg/d orally divided into two doses, is the treatment of choice with an overall response rate of approximately 80%. The oral solution is better absorbed than the capsule formulation, which requires gastric acid for absorption. Duration of therapy ranges from weeks to several months depending on the severity of illness. Intravenous amphotericin B formulations are used in patients with more severe illness such as meningitis, with guidelines favoring the use of liposomal or lipid complex amphotericin formulations at a dose of 3 mg/kg/d over amphotericin B deoxycholate. Patients with AIDS-related histoplasmosis require lifelong suppressive therapy with itraconazole, 200–400 mg/d orally, although secondary prophylaxis may be discontinued if immune reconstitution occurs in response to antiretroviral therapy. There is no clear evidence that antifungal or anti-inflammatory agents are of benefit for patients with granulomatous mediastinitis or fibrosing mediastinitis although oral itraconazole is often used. Reported outcomes in patients with fibrosing mediastinitis treated with either surgical procedures or nonsurgical intravascular interventions appear to be relatively good.

COCCIDIOIDOMYCOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Influenza-like illness with malaise, fever, backache, headache, and cough.
- ▶ Erythema nodosum common with acute infection.
- ▶ Dissemination may result in meningitis, bony lesions, or skin and soft tissue abscesses.
- ▶ Chest radiograph findings vary from pneumonitis to cavitation.
- ▶ Serologic tests useful; spherules containing endospores demonstrable in sputum or tissues.

▶ General Considerations

Coccidioidomycosis should be considered in the diagnosis of any obscure illness in a patient who has lived in or visited an endemic area.

Infection results from the inhalation of arthroconidia of *Coccidioides immitis* or *C. posadasii*; both organisms are molds that grow in soil in certain arid regions of the southwestern United States, in Mexico, and in Central and South America.

Less than 1% of immunocompetent persons show dissemination, but among these patients, the mortality rate is high.

In HIV-infected people in endemic areas, coccidioidomycosis is a common opportunistic infection. In these patients, disease manifestations range from focal pulmonary infiltrates to widespread miliary disease with multiple organ involvement and meningitis; severity is inversely related to the extent of control of the HIV infection.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms of **primary coccidioidomycosis** occur in about 40% of infections. Symptom onset (after an incubation period of 10–30 days) is usually that of a respiratory tract illness with fever and occasionally chills. Coccidioidomycosis is a common, frequently unrecognized, etiology of community-acquired pneumonia in endemic areas.

Arthralgia accompanied by periarticular swelling, often of the knees and ankles, is common. Erythema nodosum may appear 2–20 days after onset of symptoms. Persistent pulmonary lesions, varying from cavities and abscesses to parenchymal nodular densities or bronchiectasis, occur in about 5% of diagnosed cases.

Disseminated disease occurs in about 0.1% of white and 1% of nonwhite patients. Filipinos and blacks are especially susceptible, as are pregnant women of all races. Any organ may be involved. Pulmonary findings usually become more pronounced, with mediastinal lymph node enlargement, cough, and increased sputum production. Lung abscesses may rupture into the pleural space, producing an empyema. These may also extend to bones and skin, and pericardial and myocardial involvement has been occasionally observed. Fungemia may occur and is characterized clinically by a diffuse miliary pattern on chest radiograph and by early death. The course may be particularly rapid in immunosuppressed patients. Clinicians caring for immunosuppressed patients in endemic areas need to consider that patients may be latently infected.

Meningitis occurs in 30–50% of cases of dissemination. Subcutaneous abscesses and verrucous skin lesions are especially common in fulminating cases. Lymphadenitis may occur and may progress to suppuration. HIV-infected persons with disseminated disease have a higher incidence of miliary infiltrates, lymphadenopathy, and meningitis, but skin lesions are uncommon.

B. Laboratory Findings

In **primary coccidioidomycosis**, there may be moderate leukocytosis and eosinophilia. Serologic testing is useful for both diagnosis and prognosis. The immunodiffusion tube precipitin test and enzyme-linked immunosorbent assay (ELISA) detect IgM antibodies and are both useful for diagnosis early in the disease process. Historically, a persistent rising IgG complement fixation titer ($\geq 1:16$) has been considered suggestive of disseminated disease; in addition, complement fixation titers can be used to assess the adequacy of therapy. Serum complement fixation titer may be

low when there is meningitis but no other disseminated disease. In patients with HIV-related coccidioidomycosis, the false-negative rate may be as high as 30%.

Demonstrable complement-fixing antibodies in spinal fluid are diagnostic of coccidioidal meningitis. These are found in over 90% of cases. Spinal fluid findings include increased cell count with lymphocytosis and reduced glucose. Spinal fluid culture is positive in approximately 30% of meningitis cases. Spherules filled with endospores may be found in biopsy specimens of soft tissues and bone; though they are not infectious, they convert to the highly contagious arthroconidia when grown in culture media. Blood cultures are rarely positive.

C. Imaging

Radiographic findings vary, but patchy, nodular pulmonary infiltrates and thin-walled cavities are most common. Hilar lymphadenopathy may be visible and is seen in localized disease; mediastinal lymphadenopathy suggests dissemination. There may be pleural effusions and lytic lesions in bone with accompanying complicated soft-tissue collections.

► Treatment

General symptomatic therapy is given as needed for disease limited to the chest with no evidence of progression. For progressive pulmonary or extrapulmonary disease, amphotericin B intravenously is used although oral azoles may be used for mild cases (see Chapter 30). Duration of therapy is determined by a declining complement fixation titer and a favorable clinical response. For meningitis, treatment usually is with high-dose oral fluconazole (400–800 mg/d, or higher) although lumbar or cisternal intrathecal administration of amphotericin B daily in increasing doses up to 1–1.5 mg/d is used initially by some physicians or in cases refractory to fluconazole. Systemic therapy with amphotericin B, 0.6 mg/kg/d intravenously, is generally given concurrently with intrathecal therapy but is not sufficient alone for the treatment of meningeal disease. Voriconazole or posaconazole may be alternatives to intrathecal amphotericin B in patients who do not respond to fluconazole. Once the patient is clinically stable, oral therapy with an azole, usually with fluconazole (400 mg daily) and given lifelong, is the recommended alternative to intrathecal amphotericin B therapy.

Itraconazole, 400 mg orally daily divided into two doses, or fluconazole, 200–400 mg, or higher, orally once or twice daily should be given for disease in the chest, bones, and soft tissues; however, therapy must be continued for 6 months or longer after the disease is inactive to prevent relapse. In some patients with disease refractory to itraconazole or fluconazole, voriconazole or posaconazole may be beneficial. Response to therapy should be monitored by following the clinical response and progressive decrease in serum complement fixation titers.

Surgical drainage is necessary for management of soft tissue abscesses, necrotic bone and complicated pulmonary disease (eg, rupture of coccidioidal cavity).

► Prognosis

The prognosis for patients with limited disease is good, but persistent pulmonary cavities may cause complications such as hemoptysis or rupture producing pyopneumothorax. Nodules, cavities, and fibrotic residuals may rarely progress after long periods of stability or regression. Serial complement fixation titers should be performed after therapy for patients with coccidioidomycosis; rising titers warrant reinstitution of therapy because relapse is likely. Late central nervous system complications of adequately treated meningitis include cerebral vasculitis and hydrocephalus that may require shunting. Disseminated and meningeal forms still have mortality rates exceeding 50% in the absence of therapy.

PNEUMOCYSTOSIS (*Pneumocystis jiroveci* Pneumonia)

ESSENTIALS OF DIAGNOSIS

- Fever, dyspnea, nonproductive cough.
- Bilateral diffuse interstitial disease without hilar adenopathy by chest radiograph.
- Bibasilar crackles on auscultation in many cases; others have no findings.
- Reduced partial pressure of oxygen.
- *P jiroveci* in sputum, bronchoalveolar lavage fluid, or lung tissue.

► General Considerations

Pneumocystis jiroveci, the *Pneumocystis* species that affects humans, is distributed worldwide. Although symptomatic *P jiroveci* disease is rare in the general population, serologic evidence indicates that asymptomatic infections have occurred in most persons by a young age. The overt infection is an acute interstitial plasma cell pneumonia that occurs with high frequency among two groups: (1) as epidemics of primary infections among premature or debilitated or marasmic infants on hospital wards in underdeveloped parts of the world, and (2) as sporadic cases among older children and adults who have an abnormal or altered cellular immunity. Cases occur most commonly in patients with cancer or severe malnutrition and

debility, in patients treated with immunosuppressive or cytotoxic drugs or irradiation for the management of organ transplants and cancer and, most frequently, in patients with AIDS (see Chapter 31).

The mode of transmission in primary infection is unknown, but the evidence suggests airborne transmission. Following asymptomatic primary infection, latent and presumably inactive organisms are sparsely distributed in the alveoli. Whether acute disease in older children and adults results from *de novo* infection or from reactivation of latent infection is not entirely clear, although both mechanisms probably contribute.

Pneumocystis pneumonia occurs in up to 80% of AIDS patients not receiving prophylaxis and is a major cause of death. Its incidence increases in direct proportion to the fall in CD4 cells, with most cases occurring at CD4 cell counts < 200/mcL. In non-AIDS patients receiving immunosuppressive therapy, symptoms frequently begin after corticosteroids have been tapered or discontinued.

► Clinical Findings

A. Symptoms and Signs

Findings are usually limited to the pulmonary parenchyma; extrapulmonary disease is reported rarely. In the sporadic form of the disease associated with deficient cell-mediated immunity, the onset is typically abrupt, with fever, tachypnea, shortness of breath, and usually nonproductive cough. Pulmonary physical findings may be slight and disproportionate to the degree of illness and the radiologic findings; many patients have bibasilar crackles, but others do not. Without treatment, the course is usually one of rapid deterioration and death. Adult patients may present with spontaneous pneumothorax, usually in patients with previous episodes or those receiving aerosolized pentamidine prophylaxis. Patients with AIDS will usually have other evidence of HIV-associated disease, including fever, fatigue, and weight loss, for weeks or months preceding the illness.

B. Laboratory Findings

Chest radiographs most often show diffuse “interstitial” infiltration, which may be heterogeneous, miliary, or patchy early in infection. There may also be diffuse or focal consolidation, cystic changes, nodules, or cavitation within nodules. Pleural effusions are not seen. About 5–10% of patients with *Pneumocystis* pneumonia have normal chest films. High-resolution chest CT scans may be quite suggestive of *P jiroveci* pneumonia, helping distinguish it from other causes of pneumonia.

Arterial blood gas determinations usually show hypoxemia with hypocapnia but may be normal; however, rapid desaturation occurs if patients are exercised before samples are drawn. Isolated elevation or rising levels of serum LDH are very sensitive but not specific findings for *P jiroveci*. Serologic tests are not helpful in diagnosis, but several studies have suggested that elevated (1→3)- β -D-glucan levels have reasonably good sensitivity and specificity for the diagnosis of *Pneumocystis* pneumonia. Specific

diagnosis depends on morphologic demonstration of the organisms in clinical specimens using specific stains. The organism cannot be cultured. Adequate specimens can sometimes be obtained with induced sputum by having patients inhale an aerosol of hypertonic saline (3%) produced by an ultrasonic nebulizer. Specimens are then stained with Giemsa stain or methenamine silver, either of which allows detection of cysts. The use of monoclonal antibody with immunofluorescence has increased the sensitivity of diagnosis. Alternative techniques for obtaining specimens include bronchoalveolar lavage (sensitivity 86–97%) followed by transbronchial lung biopsy (85–97%), if necessary. Open lung biopsy and needle lung biopsy are infrequently done but may need to be performed to diagnose a granulomatous form of *Pneumocystis* pneumonia.

► Treatment

See Table 31–5. It is appropriate to start empiric therapy for *P jiroveci* pneumonia if the disease is suspected clinically; however, in both AIDS patients and non-AIDS patients with mild to moderately severe disease, continued treatment should be based on a proved diagnosis because of clinical overlap with other infections, the toxicity of therapy, and the possible coexistence of other infectious organisms. Oral trimethoprim-sulfamethoxazole (TMP-SMZ) is the preferred agent because of its low cost and excellent bioavailability in both AIDS patients and non-AIDS patients with mild to moderately severe disease. Patients suffering from nausea and vomiting or intractable diarrhea should be given intravenous TMP-SMZ until they can tolerate the oral formulation. The impact of resistance of *Pneumocystis* to TMP-SMZ is unclear, although increasing rates of mutations in the *DHFR* gene that mediate TMP-SMZ resistance have been reported. The best-studied second-line option is a combination of primaquine and clindamycin, although dapsone/trimethoprim, pentamidine, and atovaquone have also been used. Therapy should be continued with the selected drug for at least 5–10 days before considering changing agents, as fever, tachypnea, and pulmonary infiltrates persist for 4–6 days after starting treatment. Some patients have a transient worsening of their disease during the first 3–5 days, which may be related to an inflammatory response secondary to the presence of dead or dying organisms. Early addition of corticosteroids may attenuate this response (see Chapter 31). Some clinicians prefer to treat episodes of AIDS-associated *Pneumocystis* pneumonia for 21 days rather than the usual 14 days recommended for non-AIDS cases.

A. Trimethoprim-Sulfamethoxazole

The dosage of TMP/SMZ is 15–20 mg/kg/d (based on trimethoprim component) given orally or intravenously daily in three or four divided doses for 14–21 days. Patients with AIDS have a high frequency of hypersensitivity reactions (approaching 50%), which may include fever, rashes (sometimes severe), malaise, neutropenia, hepatitis, nephritis, thrombocytopenia, hyperkalemia, and hyperbilirubinemia.

B. Primaquine/Clindamycin

Although there are strong data indicating that trimethoprim-sulfamethoxazole is optimal first-line therapy for *Pneumocystis* pneumonia, the data on alternative agents is less clear. A meta-analysis suggested that primaquine, 15–30 mg/d, plus clindamycin, 600 mg three times daily, is the best second-line therapy with superior results when compared with pentamidine. Primaquine may cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD)-deficiency.

C. Pentamidine Isethionate

The use of pentamidine has decreased as alternative agents have been studied. This drug is administered intravenously (preferred) or intramuscularly as a single dose of 3–4 mg (salt)/kg/d for 14–21 days. Pentamidine causes side effects in nearly 50% of patients. Hypoglycemia (often clinically inapparent), hyperglycemia, hyponatremia, and delayed nephrotoxicity with azotemia may occur. Rarely, a variety of other severe adverse reactions may occur, including anemia, thrombocytopenia, ventricular arrhythmias, and fatal pancreatitis. Blood glucose levels should be monitored. Inadvertent rapid intravenous infusion may cause precipitous hypotension.

D. Atovaquone

Atovaquone is approved by the US Food and Drug Administration (FDA) for patients with mild to moderate disease who cannot tolerate TMP-SMZ or pentamidine, but failure is reported in 15–30% of cases. Mild side effects are common, but no serious reactions have been reported. The dosage is 750 mg three times daily for 21 days. Atovaquone should be administered with a fatty meal.

E. Other Drugs

Trimethoprim, 15 mg/kg/d in three divided doses daily, plus dapsone, 100 mg/d, is an alternative oral regimen for mild to moderate disease or for continuation of therapy after intravenous therapy is no longer needed.

F. Prednisone

Based on studies done in patients with AIDS, prednisone is given for moderate to severe pneumonia (when PaO₂ on admission is < 70 mm Hg or oxygen saturation is < 90%) in conjunction with antimicrobials. The dosage of prednisone is 40 mg twice daily orally for 5 days, then 40 mg daily for 5 days, and then 20 mg daily until therapy is completed. The role of prednisone in non-AIDS patients is unclear, especially in patients in whom symptoms developed following tapering doses of corticosteroids.

G. Supportive Care

Oxygen therapy is indicated to maintain the oxygen saturation over 90% by pulse oximetry.

► Prevention

Primary prophylaxis for *Pneumocystis* pneumonia in HIV-infected patients should be given to persons with CD4 counts < 200 cells/mL, a CD4 percentage below 14%, or weight loss or oral candidiasis (see Table 31–4). Primary prophylaxis is often used in patients with hematologic malignancy and transplant recipients, although the clinical characteristics of persons with these conditions who would benefit from *Pneumocystis* prophylaxis have not been clearly defined. Patients with a history of *Pneumocystis* pneumonia should receive secondary prophylaxis until they have had a durable virologic response to antiretroviral therapy for at least 3–6 months and maintain a CD4 count of > 200 cells/mL.

► Prognosis

In the absence of early and adequate treatment, the fatality rate for the endemic infantile form of *Pneumocystis* pneumonia is 20–50%; for the sporadic form in immunodeficient persons, the fatality rate is nearly 100%. Early treatment reduces the mortality rate to about 3% in the former and 10–20% in AIDS patients. The mortality rate in other immunodeficient patients is still 30–50%, probably because of failure to make a timely diagnosis. In immunodeficient patients who do not receive prophylaxis, recurrences are common (30% in AIDS).

CRYPTOCOCCOSIS

ESSENTIALS OF DIAGNOSIS

- Most common cause of fungal meningitis.
- Predisposing factors: Hematologic cancer chemotherapy, Hodgkin disease, corticosteroid therapy, transplant recipients, TNF inhibitor therapy, HIV infection.
- Symptoms of headache, abnormal mental status; meningismus seen occasionally, though rarely in HIV-infected patients.
- Demonstration of capsular polysaccharide antigen in cerebrospinal fluid is diagnostic; 95% of HIV-infected and solid-organ transplant patients also have a positive serum antigen.

► General Considerations

Cryptococcosis is mainly caused by *Cryptococcus neoformans*, an encapsulated budding yeast that has been found worldwide in soil and on dried pigeon dung. *C gattii* is a closely related species that also causes disease in humans although *C gattii* may affect more immunocompetent persons. It has been emerging as a major cause of cryptococcosis in the Pacific Northwestern region of the United States and may result in more severe disease than *C neoformans*.

Infections are acquired by inhalation. In the lung, the infection may remain localized, heal, or disseminate. Clinically apparent cryptococcal pneumonia rarely develops in immunocompetent persons, except in those individuals infected by *C gattii*. Progressive lung disease and dissemination most often occur in the setting of cellular immunodeficiency, including underlying hematologic cancer under treatment, Hodgkin disease, long-term corticosteroid therapy, solid-organ transplant, TNF-inhibitor therapy, or HIV infection.

► Clinical Findings

A. Symptoms and Signs

Pulmonary disease ranges from simple nodules to widespread infiltrates leading to respiratory failure. Disseminated disease may involve any organ, but central nervous system disease predominates. Headache is usually the first symptom of meningitis. Confusion and other mental status changes as well as cranial nerve abnormalities, nausea, and vomiting may be seen as the disease progresses. Nuchal rigidity and meningeal signs occur about 50% of the time but are uncommon in HIV-infected patients. Communicating hydrocephalus may complicate the course. *C gattii* infection frequently presents with neurologic signs caused by space-occupying lesions. Primary *C neoformans* infection of the skin may mimic bacterial cellulitis, especially in immunocompromised persons. Clinical worsening associated with improved immunologic status has been reported in HIV-positive and transplant patients with cryptococcosis; this entity has been labeled the immune reconstitution inflammatory syndrome (IRIS).

B. Laboratory Findings

Respiratory tract disease is diagnosed by culture of respiratory secretions or pleural fluid. For suspected meningeal disease, lumbar puncture is the preferred diagnostic procedure. Spinal fluid findings include increased opening pressure, variable pleocytosis, increased protein, and decreased glucose, though as many as 50% of AIDS patients have no pleocytosis. Gram stain of the cerebrospinal fluid usually reveals budding, encapsulated fungal cells. Cryptococcal capsular antigen in cerebrospinal fluid and culture together establish the diagnosis over 90% of the time. Patients with AIDS often have the antigen in both cerebrospinal fluid and serum, and extrameningeal disease (lungs, blood, urinary tract) is common. In patients with AIDS, the serum

cryptococcal antigen is also a sensitive screening test for meningitis, being positive in over 95% of cases. MRI is more sensitive than CT in finding central nervous system abnormalities such as cryptococcomas.

► Treatment

Because of decreased efficacy, initial therapy with an azole alone is not recommended for treatment of acute cryptococcal meningitis. Consequently, amphotericin B, 0.7–1 mg/kg/d intravenously is used for 14 days, followed by an additional 8 weeks of fluconazole, 400 mg/d orally. This regimen has been quite effective, achieving clinical responses and cerebrospinal fluid sterilization in about 70% of patients. Lipid amphotericin B preparations (eg, liposomal amphotericin B, 3–4 mg/kg/d) have equivalent efficacy to conventional amphotericin B with reduced nephrotoxicity. The addition of flucytosine has been associated with improved survival, but toxicity is common. Flucytosine is administered orally at a dose of 100 mg/kg/d divided into four equal doses and given every 6 hours. Hematologic parameters should be closely monitored during flucytosine therapy, and it is important to adjust the dose for any decreases in renal function. Fluconazole (800–1200 mg orally daily) may be given with amphotericin B when flucytosine is not available or patients cannot tolerate it. Frequent, repeated lumbar punctures or ventricular shunting should be performed to relieve high cerebrospinal fluid pressures or if hydrocephalus is a complication. Failure to adequately relieve raised intracranial pressure is a major cause of morbidity and mortality. The end points for amphotericin B therapy and for switching to oral fluconazole are a favorable clinical response (decrease in temperature; improvement in headache, nausea, vomiting, and mini-mental status scores), improvement in cerebrospinal fluid biochemical parameters and, most importantly, conversion of cerebrospinal fluid culture to negative.

A similar approach is reasonable for patients with cryptococcal meningitis in the absence of AIDS, though the mortality rate is considerably higher. Therapy is generally continued until cerebrospinal fluid cultures become negative. Maintenance antifungal therapy is important after treatment of an acute episode in HIV-related cases, since otherwise the rate of relapse is > 50%. Fluconazole, 200 mg/d orally, is the maintenance therapy of choice, decreasing the relapse rate approximately tenfold compared with placebo and threefold compared with weekly amphotericin B in patients whose cerebrospinal fluid has been sterilized by the induction therapy. After successful therapy of cryptococcal meningitis, it is possible to discontinue secondary prophylaxis with fluconazole in individuals with AIDS who have had a satisfactory response to antiretroviral therapy (eg, CD4 cell count > 100–200 cells/mL for at least 6 months). Among practitioners treating patients without AIDS, there has been a trend in recent years to prescribe a course (eg, 6–12 months) of fluconazole as maintenance therapy following successful treatment of the acute illness; recently published guidelines suggest this as an option.

► Prognosis

Factors that indicate a poor prognosis include the activity of the predisposing conditions, older age, organ failure, lack of spinal fluid pleocytosis, high initial antigen titer in either serum or cerebrospinal fluid, decreased mental status, increased intracranial pressure, and the presence of disease outside the nervous system.

ASPERGILLOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Most common cause of non-candidal invasive fungal infection in stem cell or organ transplant patients.
- ▶ Predisposing factors: leukemia, bone marrow or organ transplant, late HIV infection.
- ▶ Pulmonary, sinus, and CNS are most common disease sites.
- ▶ Demonstration of galactomannan or β -D-glucan in serum or other body fluid samples is useful for early diagnosis and treatment.

► General Considerations

Aspergillus fumigatus is the usual cause of aspergillosis, though many species of *Aspergillus* may cause a wide spectrum of disease. The lungs, sinuses, and brain are the organs most often involved. Clinical illness results either from an aberrant immunologic response or tissue invasion.

► Clinical Findings

A. Allergic Bronchopulmonary Aspergillosis

This form of aspergillosis occurs in patients with preexisting asthma who develop worsening bronchospasm and fleeting pulmonary infiltrates accompanied by eosinophilia, high levels of IgE, and IgG *Aspergillus* precipitins in the blood. It also may complicate cystic fibrosis.

B. Invasive Aspergillosis

Invasive manifestations may be seen in immunocompetent or only mildly immunocompromised adults. These include

chronic **sinusitis**, colonization of preexisting pulmonary cavities (**aspergilloma**), and chronic necrotizing pulmonary aspergillosis.

1. Sinusitis—Sinus involvement is usually diagnosed histologically after patients with chronic sinus disease undergo surgery.

2. Aspergillomas—Aspergillomas of the lung occur when preexisting lung cavities become secondarily colonized with *Aspergillus* species. These may be found by incidental radiographic studies but may also present with significant hemoptysis.

3. Chronic necrotizing aspergillosis—This invasive manifestation is a relatively rare disease seen in patients with some degree of immunocompromise and presents with a protracted course compared with the more common acute invasive form of the disease. Fibrosis and cavity formation may be prominent.

4. Life-threatening invasive aspergillosis—Severe invasive aspergillosis most commonly occurs in profoundly immunodeficient patients, particularly in patients who have undergone hematopoietic stem cell transplants; in those with prolonged, severe neutropenia; and in patients with chronic granulomatous disease. Specific risk factors in patients who have undergone a hematopoietic stem cell transplant include cytopenias, corticosteroid use, iron overload, cytomegalovirus disease, and graft-versus-host disease. Pulmonary disease is most common, with patchy infiltration leading to a severe necrotizing pneumonia. Invasive sinus disease also occurs. There is often tissue infarction as the organism grows into blood vessels; clues to this are the development of pleuritic chest pain and elevation of serum LDH. At any time, there may be hematogenous dissemination to the central nervous system, skin, and other organs. Early diagnosis and reversal of any correctable immunosuppression are essential. Blood cultures have very low yield. Detection of galactomannan by ELISA or β -D-glucan, or both, has been used for the early diagnosis of invasive disease, though multiple determinations should be done. Higher galactomannan levels are correlated with increased mortality. False-positive galactomannan tests have been reported in patients receiving β -lactam antibiotics. Isolation of *Aspergillus* from pulmonary secretions does not necessarily imply invasive disease, although its positive predictive value increases with more advanced immunosuppression. Therefore, a definitive diagnosis requires demonstration of *Aspergillus* in tissue or culture from a sterile site. CT scan of the chest may show characteristics quite suggestive of invasive aspergillosis (eg, “halo sign”).

► Prevention

The high mortality rate and difficulty in diagnosis of invasive aspergillosis often leads clinicians to institute prophylactic therapy for patients with profound immunosuppression. The best-studied agents include fluconazole, itraconazole, voriconazole, and posaconazole, although patient and agent selection criteria remain undefined. Widespread use of broad-spectrum azoles raises concern for development of invasive disease by highly resistant fungi.

► Treatment

A. Allergic Bronchopulmonary Aspergillosis

For acute exacerbations, oral prednisone is begun at a dose of 1 mg/kg/d and then tapered slowly over several months. Itraconazole at a dose of 200 mg daily for 16 weeks appears to improve pulmonary function and decrease corticosteroid requirements in these patients, although voriconazole may become the preferred oral agent. Some patients treated with the anti-IgE monoclonal antibody omalizumab have shown improvement in respiratory symptoms and lung function.

B. Invasive Aspergillosis

1. Sinusitis—These patients may require protracted courses of antifungals (itraconazole, 200 mg twice daily, for weeks to months) in addition to the surgical debridement.

2. Aspergilloma—The most effective therapy for symptomatic aspergilloma remains surgical resection.

3. Chronic necrotizing aspergillosis—Guidelines suggest some benefits from prolonged oral voriconazole (200 mg twice daily) or itraconazole (200 mg twice daily) therapy.

4. Life-threatening invasive aspergillosis—When severe invasive aspergillosis is considered clinically likely or is demonstrable by laboratory testing, rapid institution of voriconazole, high doses of liposomal amphotericin B (3–5 mg/kg/d), or caspofungin may be life-saving. Voriconazole (6 mg/kg intravenously twice on day 1, then 4 mg/kg/d thereafter) has been shown to be more effective, improve survival, and be associated with fewer severe side effects than conventional amphotericin B when used as initial therapy in invasive aspergillosis. Oral dosing of voriconazole at 4 mg/kg twice daily can be used for less serious infections or as a step-down strategy after intravenous therapy.

Caspofungin (70 mg intravenously on day 1, then 50 mg/d thereafter) is approved for the treatment of invasive aspergillosis in patients who do not respond to or are intolerant of other treatments. Other options include micafungin (100–150 mg/d intravenously) and posaconazole (200 mg orally four times daily). In critically ill patients who are not responding to conventional antifungal treatment, there may be a role for the addition of caspofungin to liposomal amphotericin B or voriconazole therapy, although randomized trials are lacking. Surgical debridement is generally done for sinusitis, and there is increasing data regarding resection of focal pulmonary lesions, especially for treatment of life-threatening hemoptysis. The mortality rate of pulmonary or disseminated disease in the immunocompromised patient remains well above 50%, particularly in patients with refractory neutropenia.

MUCORMYCOSIS

The term “mucormycosis” (zygomycosis, phycomycosis) is applied to opportunistic infections caused by members of the genera *Rhizopus*, *Mucor*, *Absidia*, and *Cunninghamella*. Predisposing conditions include hematologic malignancy, stem cell transplantation, solid organ transplantation, diabetic ketoacidosis, chronic kidney disease, desferoxamine therapy, and treatment with corticosteroids or cytotoxic drugs. These organisms appear in tissues as broad, branching nonseptate hyphae. Biopsy with histologic examination is almost always required for diagnosis; cultures are frequently negative. Invasive disease of the sinuses, orbits, and the lungs may occur. Widely disseminated disease is seen in patients who have received aggressive chemotherapy and broad-spectrum antifungal prophylaxis. A prolonged course of a lipid preparation of amphotericin B should be started early. Based on in vitro susceptibility and reports of successful salvage therapy, there may be a role for posaconazole in the treatment of these infections following control of acute infection by amphotericin. Other azoles are not effective. There are limited data suggesting beneficial synergistic activity when amphotericin and caspofungin are used in combination for mucormycosis. Despite favorable animal studies, a recent pilot study in humans incorporating adjunctive iron chelation therapy with deferasirox demonstrated a higher mortality rate than antifungal therapy alone. Control of diabetes and other underlying conditions, along with extensive repeated surgical removal of necrotic, nonperfused tissue, is essential. Even when these measures are introduced in a timely fashion, the prognosis is poor, with a 30–50% mortality rate for localized disease and higher rates in disseminated cases.

BLASTOMYCOSIS

Blastomycosis occurs most often in men infected during occupational or recreational activities out of doors and in a geographically limited area of the south central and midwestern United States and Canada. Disease usually occurs in immunocompetent individuals.

Chronic pulmonary infection is most common and may be asymptomatic. When dissemination takes place, lesions are most frequently seen in the skin, bones, and urogenital system.

Cough, moderate fever, dyspnea, and chest pain are common. These may resolve or progress, with purulent sputum production, pleurisy, fever, chills, loss of weight, and prostration. Radiologic studies, either chest radiographs or CT scans, usually reveal airspace consolidation or masses.

Raised, verrucous cutaneous lesions are commonly present in disseminated blastomycosis. Bones—often the ribs and vertebrae—are frequently involved. Epididymitis, prostatitis, and other involvement of the male urogenital system may occur. Although they do not appear to be at greater risk for acquisition of disease, infection in HIV-infected persons may progress rapidly, with dissemination common.

Laboratory findings usually include leukocytosis and anemia, though these are not specific. The organism is found in clinical specimens, such as expectorated sputum or tissue biopsies, as a thick-walled cell 5–20 μm in diameter that may have a single broad-based bud. It grows readily on culture. Serologic tests are not well standardized. A urinary antigen test is available, but it has considerable cross reactivity with *Histoplasma*; consequently, its usefulness in diagnosis and in assessing response to therapy is unclear.

Itraconazole, 200–400 mg/d orally for at least 2–3 months, is the therapy of choice for nonmeningeal disease, with a response rate of over 80%. Amphotericin B, 0.7–1.0 mg/kg/d intravenously (or lipid formulation amphotericin B), is given for severe disease, treatment failures, or central nervous system involvement.

Clinical follow-up for relapse should be made regularly for several years so that therapy may be resumed or another drug instituted.

Saccante M et al. Clinical and laboratory update on blastomycosis. *Clin Microbiol Rev*. 2010 Apr;23(2):367–81. [PMID: 20375357]

PARACOCIDIOIDOMYCOSIS (South American Blastomycosis)

Paracoccidioides brasiliensis infections have been found only in patients who have resided in South or Central America or Mexico. Long asymptomatic periods enable patients to travel far from the endemic areas before developing clinical problems. Weight loss, pulmonary complaints, or mucosal ulcerations are the most common symptoms. Cutaneous papules may ulcerate and enlarge both peripherally and deeper into the subcutaneous tissue. Differential diagnosis includes mucocutaneous leishmaniasis and syphilis. Extensive coalescent ulcerations may eventually result in destruction of the epiglottis, vocal cords, and uvula. Extension to the lips and face may occur. Eating and drinking are extremely painful. Skin lesions may occur, usually on the face. Variable in appearance, they may have a necrotic central crater with a hard hyperkeratotic border. Lymph node enlargement may follow mucocutaneous lesions, eventually ulcerating and forming draining sinuses; in some patients, it is the presenting symptom. Hepatosplenomegaly may be present as well. HIV-infected patients with paracoccidioidomycosis are more likely to have extra-pulmonary dissemination and a more rapid clinical disease course.

Laboratory findings are nonspecific. Serology by immunodiffusion is positive in 98% of cases. Complement fixation titers correlate with progressive disease and fall with effective therapy. The fungus is found in clinical specimens as a spherical cell that may have many buds arising from it. If direct examination of secretions does not reveal the organism, biopsy with Gomori staining may be helpful.

Itraconazole, 100 mg twice daily orally, is the treatment of choice and generally results in a clinical response within 1 month and effective control after 2–6 months. Voriconazole, 200 mg twice daily orally, appears to be as effective as itraconazole. Amphotericin B intravenously is the drug of choice for severe and life-threatening infection.

SPOROTRICHOSIS

Sporotrichosis is a chronic fungal infection caused by *Sporothrix schenckii*. It is worldwide in distribution; most patients have had contact with soil, sphagnum moss, or decaying wood. Transmission from animals to humans has also been reported. Infection takes place when the organism is inoculated into the skin—usually on the hand, arm, or foot, especially during gardening.

The most common form of sporotrichosis begins with a hard, nontender subcutaneous nodule. This later becomes adherent to the overlying skin and ulcerates. Within a few days to weeks, similar nodules develop along the lymphatics draining this area, and these may ulcerate as well.

Disseminated sporotrichosis is rare in the immunocompetent person but may present with widespread cutaneous, lung, bone, joint, and central nervous system involvement in immunocompromised patients, especially those with AIDS and alcohol abuse.

Cultures are needed to establish diagnosis. Antibody tests may be useful for diagnosis of disseminated disease, especially meningitis.

Itraconazole, 200–400 mg orally daily for several months, is the treatment of choice for localized disease and some milder cases of disseminated disease. Terbinafine, 500 mg orally twice daily, also appears to have good efficacy in lymphocutaneous disease. Amphotericin B intravenously, 1–2 g, is used for severe systemic infection. Surgery is usually contraindicated except for simple aspiration of secondary nodules. Joint involvement may require arthrodesis.

The prognosis is good for lymphocutaneous sporotrichosis; pulmonary, joint, and disseminated disease respond less favorably.

PENICILLIUM MARNEFFI INFECTIONS

Penicillium marneffi is a dimorphic fungus, endemic in southeast Asia, that causes systemic infection in both healthy and immunocompromised hosts. There have been reports of travelers with advanced AIDS returning from southeast Asia with disseminated infection. Clinical manifestations include fever, generalized umbilicated papular rash, lymphadenopathy, cough, and diarrhea. Central nervous system infection has been reported. Diagnosis is made by identification of the organism on smears or histopathologic specimens or by culture, where the fungus produces a characteristic red pigment. The best sites for isolation of the fungus include the skin, blood, bone marrow, respiratory tract, and lymph nodes. Antigen and antibody tests have been developed in endemic regions. Patients with mild to moderate infection can be treated with itraconazole, 400 mg divided into two doses daily by mouth for 8 weeks. Amphotericin B, 0.5–0.7 mg/kg/d intravenously, is the drug of choice for severe disease and should be continued until patients have had a satisfactory clinical response, at which time they can be switched to itraconazole. Because the relapse rate after successful treatment is 30%, maintenance therapy with itraconazole, 200–400 mg daily orally, is indicated indefinitely, or until immune reconstitution occurs.

Wong SY et al. *Penicillium marneffi* infection in AIDS. *Patholog Res Int.* 2011 Feb 10;2011:764293. [PMID: 21331327]

CHROMOBLASTOMYCOSIS (Chromomycosis)

Chromoblastomycosis is a chronic, principally tropical cutaneous infection usually affecting young men who are agricultural workers and caused by several species of closely related black molds; *Cladophialophora carrionii* and *Fonsecaea pedrosoi* are the most common etiologic agents.

Lesions usually follow puncture wounds and are slowly progressive, occurring most frequently on a lower extremity. The lesion begins as a papule or ulcer. Over months to years, papules enlarge to become vegetating, papillomatous, verrucous elevated nodules. Satellite lesions may appear along the lymphatics. There may be secondary bacterial infection. Elephantiasis may result.

The fungus is seen as brown, thick-walled, spherical, sometimes septate cells in potassium hydroxide preparations of pus or skin scrapings, which are quite sensitive for diagnosis. The type of reproduction found in culture determines the species.

Itraconazole, 200–400 mg/d orally for 6–18 months, achieves a response rate of 65%. Terbinafine at 500–1000 mg/d orally may have similar efficacy to itraconazole and may be useful in combination, especially in difficult to treat cases. Cryosurgery alone for smaller lesions or combined with itraconazole for larger lesions is beneficial.

Queiroz-Telles F et al. Chromoblastomycosis: an overview of clinical manifestations, diagnosis and treatment. *Med Mycol.* 2009 Feb;47(1):3–15. [PMID: 19085206]

MYCETOMA (Maduromycosis & Actinomycetoma)

Mycetoma is a chronic local, slowly progressive destructive infection, usually involving the foot, that begins in subcutaneous tissues, frequently after localized trauma, and then spreads to contiguous structures. Maduromycosis (also known as eumycetoma) is the term used to describe mycetoma caused by the true fungi and by phylogenetically diverse organisms. Actinomycetoma is caused by *Nocardia* and *Actinomadura* species. The disease begins as a papule, nodule, or abscess that over months to years progresses slowly to form multiple abscesses and sinus tracts ramifying deep into the tissue. Secondary bacterial infection may result in large open ulcers. Radiographs may show destructive changes in the underlying bone. Tissue Gram stain reveals fine branching hyphae with actinomycetoma. Larger hyphae are seen with fungal mycetoma; the causative species can often be identified by the color of the characteristic grains within the infected tissues.

The prognosis is good for patients with actinomycetoma, since they usually respond well to sulfonamides and sulfones, especially if treated early. TMP-SMZ, 160/800 mg orally twice a day, or dapsone, 100 mg twice daily after meals, has been reported to be effective. Streptomycin, 14 mg/kg/d intramuscularly, may be useful during the first month of therapy. All oral medications must be taken for months and continued for several months after clinical cure to prevent relapse. Debridement assists healing.

The prognosis for maduromycosis is poor, though surgical debridement along with prolonged itraconazole therapy may result in a response rate of 70%. The various etiologic agents may respond differently to antifungal agents, so culture results are invaluable. Amputation is necessary in far advanced cases.

Garnica M et al. Difficult mycoses of the skin: advances in the epidemiology and management of eumycetoma, phaeohyphomycosis and chromoblastomycosis. *Curr Opin Infect Dis.* 2009 Dec;22(6):559–63. [PMID: 19773651]

OTHER OPPORTUNISTIC MOLD INFECTIONS

Fungi previously considered to be harmless colonizers, including *Pseudallescheria boydii* (*Scedosporium apiospermum*), *Scedosporium prolificans*, *Fusarium*, *Paecilomyces*, *Trichoderma longibrachiatum*, and *Trichosporon*, are emerging as significant pathogens in immunocompromised patients. This occurs most often in patients being treated for hematopoietic malignancies and in those receiving broad-spectrum antifungal prophylaxis. Infection may be localized in the skin, lungs, or sinuses, or widespread disease may appear with lesions in multiple organs. Fusariosis should be suspected in severely immunosuppressed persons in whom multiple, painful skin lesions develop; blood cultures are often positive. Sinus infection may cause bony erosion. Infection in subcutaneous tissues following traumatic implantation may develop as a well-circumscribed cyst or as an ulcer.

Nonpigmented septate hyphae are seen in tissue and are indistinguishable from those of *Aspergillus* when infections

are due to *S apiospermum* or species of *Fusarium*, *Paecilomyces*, *Penicillium*, or other hyaline molds. Spores or mycetoma-like granules are rarely present in tissue. The differentiation of *S apiospermum* and *Aspergillus* is particularly important, since the former is uniformly resistant to amphotericin B but may be sensitive to azole antifungals (eg, voriconazole). Infection by any of a number of black molds is designated as phaeohyphomycosis. These black molds (eg, *Exophiala*, *Bipolaris*, *Cladophialophora*, *Curvularia*, *Alternaria*) are common in the environment, especially on decaying vegetation. Human disease due to these agents is rarely encountered but may result in soft tissue abscesses due to traumatic inoculation or may occur as a sequela of chronic sinusitis or profound immunosuppression. In tissues of patients with phaeohyphomycosis, the mold is seen as black or faintly brown hyphae, yeast cells, or both. Culture on appropriate medium is needed to identify the agent. Histologic demonstration of these organisms is definitive evidence of invasive infection; positive cultures must be interpreted cautiously and not

assumed to be contaminants in immunocompromised hosts. Some isolates are sensitive to antifungal agents.

ANTIFUNGAL THERAPY

Table 36–1 summarizes the major properties of currently available antifungal agents. Two different lipid-based amphotericin B formulations are used to treat systemic candidiasis, invasive aspergillosis and other disseminated mold infections, disseminated histoplasmosis, and

Table 36–1. Agents for systemic mycoses.

Drug	Dosing	Renal Clearance?	CSF Penetration?	Toxicities	Spectrum of Activity
Amphotericin B	0.3–1.5 mg/kg/d intravenously	No	Poor	Rigors, fever, azotemia, hypokalemia, hypomagnesemia, renal tubular acidosis, anemia	All major pathogens except <i>Scedosporium</i>
Amphotericin B lipid complex	5 mg/kg/d intravenously	No	Poor	Fever, rigors, nausea, hypotension, anemia, azotemia, tachypnea	Same as amphotericin B, above
Amphotericin B, liposomal	3–6 mg/kg/d intravenously	No	Poor	Fever, rigors, nausea, hypotension, azotemia, anemia, tachypnea, chest tightness	Same as amphotericin B, above
Anidulafungin	100 mg intravenous loading dose, followed by 50 mg/d intravenously in one dose	< 1%	Poor	Diarrhea, hepatic enzyme elevations, histamine-mediated reactions	Mucosal and invasive candidiasis
Caspofungin acetate	70 mg intravenous loading dose, followed by 50 mg/d intravenously in one dose	< 50% ¹	Poor	Transient neutropenia; hepatic enzyme elevations when used with cyclosporine	Aspergillosis, mucosal and invasive candidiasis, empiric antifungal therapy in febrile neutropenia
Fluconazole	100–800 mg/d in one or two doses intravenously or orally	Yes	Yes	Nausea, rash, alopecia, headache, hepatic enzyme elevations	Mucosal candidiasis (including urinary tract), cryptococcosis, histoplasmosis, coccidioidomycosis
Flucytosine (5-FC)	100–150 mg/kg/d orally in four divided doses	Yes	Yes	Leukopenia, ² rash, diarrhea, hepatitis, nausea, vomiting	Cryptococcosis, ³ candidiasis, ³ chromomycosis
Itraconazole	100–400 mg/d orally in one or two doses with a meal or carbonated beverage	No	Variable	Nausea, hypokalemia, edema, hypertension, peripheral neuropathy	Histoplasmosis, coccidioidomycosis, blastomycosis, paracoccidioidomycosis, mucosal candidiasis (except urinary), sporotrichosis, aspergillosis, chromomycosis

(continued)

Table 36-1. Agents for systemic mycoses. (continued)

Drug	Dosing	Renal Clearance?	CSF Penetration?	Toxicities	Spectrum of Activity
Ketoconazole	200-800 mg/d orally in one or two doses with a meal or carbonated beverage	No	Poor	Anorexia, nausea, suppression of testosterone and cortisol, rash, headache, hepatic enzyme elevations, hepatic failure	Nonmeningeal histoplasmosis and coccidioidomycosis, blastomycosis, paracoccidioidomycosis, mucosal candidiasis (except urinary)
Micafungin sodium	150 mg intravenously in one dose (treatment) 50 mg (prophylaxis)	No	Poor	Rash, rigors, headache, phlebitis	Mucosal and invasive candidiasis, prophylaxis in hematopoietic stem cell transplantation
Posaconazole	400-800 mg/d orally in one or two doses ⁵	No	Yes	Nausea, vomiting, abdominal pain, diarrhea, and headache	Broad range of activity including zygomycosis
Terbinafine	250 mg/d orally in one dose	Yes	Poor	Nausea, abdominal pain, taste disturbance, rash, diarrhea, and hepatic enzyme elevations	Dermatophytes, sporotrichosis
Voriconazole	200-400 mg/d orally in two doses or 12 mg/kg intravenously as loading dose for 2 days followed by 6 mg/kg/d intravenously in two doses ⁵	Yes	Yes	Transient visual disturbances, rash, photosensitivity, fluoride excess with periostitis, peripheral neuropathy, hepatic enzyme elevations ⁴	All major pathogens except zygomycetes and sporotrichosis

¹No dosage adjustment required for chronic kidney disease; dosage adjustment necessary with moderate to severe hepatic dysfunction.

²Use should be monitored with blood levels to prevent this or the dose adjusted according to creatinine clearance.

³In combination with amphotericin B.

⁴Administration with drugs that are metabolized by the cytochrome P450 system is contraindicated or requires careful monitoring.

⁵Some authorities advocate therapeutic drug monitoring in patients who are not responding to therapy.

cryptococcal meningitis. Their principal advantage appears to be substantially reduced nephrotoxicity, allowing administration of much higher doses. Three agents of the echinocandin class, caspofungin acetate, anidulafungin, and micafungin sodium, are currently approved. The echinocandins have relatively few adverse effects and are useful for the treatment of invasive *Candida* infections. Caspofungin acetate is also approved for use in refractory cases of invasive aspergillosis. Voriconazole has excellent activity against a broad range of fungal pathogens and has been FDA approved for use in invasive *Aspergillus* cases, *Fusarium* and *Scedosporium* infections, *Candida* esophagitis, deep *Candida* infections, and candidemia. Posaconazole has good activity against a broad range of filamentous fungi, including the zygomycetes. Some experts now recommend therapeutic drug monitoring in individuals with severe invasive fungal infections receiving these newer azoles because of unreliable serum levels due to either metabolic alterations as a result of

genetic polymorphisms (voriconazole) or erratic absorption (posaconazole). As a result of their more frequent and sometimes extended use, newly recognized adverse drug effects are being recognized with the azoles, including peripheral neuropathy (itraconazole and voriconazole) and fluoride excess resulting in periostitis and alkaline phosphatase elevations (voriconazole).

Disorders Related to Environmental Factors

Jacqueline A. Nemer, MD, FACEP

37

COLD & HEAT

The human body maintains a steady temperature through the balance of internal heat production and environmental heat loss. Heat exchange between the body and environment occurs via four common processes: radiation, evaporation, conduction, and convection. In extreme temperatures, the body's thermoregulation may fail. This results in the body's internal temperature moving toward the temperature of the external environment.

Temperature-related conditions may arise in any individual, regardless of sex, race, age, or underlying health status. Cold and heat exposure may cause a wide spectrum of conditions; the severity varies considerably among individuals. The likelihood and severity of extreme temperature-related conditions depends on physiologic and environmental factors. Physiologic risk factors include underlying medical conditions (cardiopulmonary, vascular, neurologic, psychiatric, musculoskeletal, immunologic, hematologic, endocrine [hypothyroidism, adrenal insufficiency, hypopituitarism], renal, hepatic, and infectious diseases); extremes of age; cognitive impairment; poor physical conditioning/sedentary lifestyle; poor acclimatization; concurrent injury; inadequate thermoregulation; prior temperature-related injury; and pharmacologic effects (ie, medications, recreational drugs, tobacco, and alcohol). Environmental risk factors include inadequate clothing, inadequate housing, occupational or recreational exposure.

ACCIDENTAL SYSTEMIC HYPOTHERMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Hypothermia is a reduction of core body temperature below 35°C.
- ▶ To accurately measure hypothermia, an intravascular, esophageal, rectal, or bladder probe that measures temperatures as low as 25°C is required; oral, axillary, and otic temperatures are inaccurate and unreliable.

- ▶ Rewarming is the initial, imperative treatment. Refreezing must be avoided to reduce further damage.
- ▶ The core temperature must be over 32°C before terminating resuscitation efforts.

General Considerations

Systemic hypothermia is defined as core body temperature < 35°C. This may be primary (from exposure to prolonged ambient extremely low temperature) or secondary (due to thermoregulatory dysfunction). Primary and secondary hypothermia may also be present at the same time. Hypothermia risk factors include prior cold weather injury as well as those factors listed in the Cold & Heat section. Heat loss occurs more rapidly with high wind velocity ("windchill factor"), water exposure (including wet clothing), or direct contact with a cold surface.

The human body generates internal heat through muscle activity (ie, shivering or increased physical exertion) and preserves heat loss via peripheral vasoconstriction. In prolonged or repetitive cold exposure, these thermoregulatory responses can become impaired; hypothermia ensues. Hypothermia diagnosis can be easily overlooked and delayed in a critically ill or injured patient. Hypothermia should be considered in any patient with prolonged exposure to ambient or cold environment, trauma, inadequate clothing, or altered mental status.

Systemic hypothermia depresses physiologic function, resulting in decreased respiratory drive, oxygen consumption, central and peripheral nerve conduction, gastrointestinal motility, myocardial repolarization, and coagulation cascade.

Accidental hypothermia may occur iatrogenically in the hospital setting. This section does not cover induced hypothermia post-resuscitation by critical care specialists.

Clinical Findings

Symptoms and signs of hypothermia are typically non-specific and markedly variable based on the patient's

▲ **Figure 37-1.** Electrocardiogram shows leads II and V5 in a patient whose body temperature is 24°C. Note the bradycardia and Osborn waves. These findings become more prominent as the body temperature lowers, and gradually resolve with rewarming. Osborn waves have an extra positive deflection in the terminal portion of the QRS complex and are best seen in the inferior and lateral precordial leads (most notably in leads II, V₅, and V₆).

underlying health and circumstances of hypothermia. At body core temperature between 32°C and 35°C, symptoms include tachypnea, tachycardia, hypertension, shivering, impaired coordination, poor judgment, and apathy. At body core temperature between 32°C and 28°C, the body slows down. Shivering stops; bradycardia, dilated pupils, slowed reflexes, cold diuresis, and confusion and lethargy ensue. The electrocardiogram (ECG) may reveal a J wave or Osborn wave (positive deflection in the terminal portion of the QRS complex, most notable in leads II, V₅, and V₆) (Figure 37-1). In extreme hypothermia (body core temperature below 28°C), the skin may appear blue or puffy; coma, apnea, loss of reflexes, asystole, or ventricular fibrillation may lead the clinician to assume that patient is dead. Prolonged hypothermia may lead to dysrhythmias and conduction abnormalities, acidemia, hyperkalemia, rhabdomyolysis, pulmonary edema, kidney disease, pneumonia, pancreatitis, hypoglycemia or hyperglycemia, and coagulopathy. Death from systemic hypothermia is usually due to ventricular fibrillation, asystole, or kidney disease.

► Treatment

Resuscitation begins with rapid assessment and support of airway, breathing and circulation, initiation of rewarming, and prevention of further heat loss. Rewarming is the initial, imperative treatment. All cold, wet clothing must be removed and replaced with warm, dry clothing. To accurately measure hypothermia, an intravascular, esophageal, rectal or bladder probe that measures temperatures as low as 25°C is required; oral, axillary, and otic temperatures are inaccurate and unreliable. The patient should be evaluated for associated conditions of hypoglycemia, trauma, overdose and peripheral cold injury. Rewarming methods are

determined by the degree of hypothermia and the resources available.

During rewarming, continuous monitoring of temperature and other vital signs, cardiac rhythm, and blood sugar must be done. Common complications of rewarming occur as colder peripheral blood returns to central circulation. This may result in core temperature afterdrop, rewarming acidosis from shunting lactate into the circulation, rewarming shock from peripheral vasodilation and hypovolemia, ventricular fibrillation and other cardiac arrhythmias. Extreme caution must be taken when handling the hypothermic patient to avoid triggering arrhythmias. During the rewarming process, essential testing includes ECG, chest radiograph, arterial blood gases, and bedside glucose. Laboratory evaluation should assess for potential complications of lactic acidosis; rhabdomyolysis; electrolyte abnormalities; infection; and dysfunction of the pancreas, liver, kidneys, and coagulation. False laboratory values will occur if the blood sample is warmed to 37°C for the testing. Antibiotics are not routinely given. Comatose patients have a high risk of aspiration pneumonia.

A. Passive and Active External Rewarming Methods

Patients with mild hypothermia (rectal temperature > 33°C) who have been otherwise healthy usually respond well to passive and active external warming. **Passive external rewarming** involves removal of cold wet clothing, then drying and covering the patient with blankets to prevent further heat loss. The patient will rewarm due to the body's internal heat production through shivering and increased metabolism. **Active external rewarming** is highly effective and safe for mild hypothermia. This is a noninvasive method of applying external heat to the patient's skin. Examples include warm bedding, heated blankets, heat packs, and immersion into a 40°C bath. Afterdrop can be lessened by active external rewarming of the trunk but not the extremities and by avoiding any muscle movement by the patient.

B. Active Internal (Core) Rewarming Methods

Active internal core rewarming methods are required for patients with core temperatures of < 33°C. Patients with milder degrees of hypothermia may also benefit from these methods. Warm humidified oxygen (43–46°C) is an easy, safe, and highly effective method. Warmed intravenous saline infusions (43°C) should be used instead of lactated Ringer solution. Volume resuscitation is needed to prevent shock as vasodilation occurs during rewarming. Other rewarming methods are based on the availability of equipment and skilled personnel (ie, warm solution lavage; esophageal rewarming tubes; endovascular warming devices; and hemodialysis).

For patients with core temperature < 30°C, initial treatment includes active rewarming, cardiopulmonary resuscitation (CPR), one shock attempt for dysrhythmia, and withholding of intravenous medications. Once the core temperature reaches 30°C, cardiac medications can be given but at intervals longer than standard intervals because metabolism is slowed and there is a risk of toxic

accumulation as circulation is restored. Defibrillation may be performed as needed. Resuscitative efforts should be continued until the patient's core temperature increases to at least 32°C.

► Prognosis

Prognosis is directly related to the patient's underlying health and comorbidities, circumstances surrounding the hypothermia (duration, extent, and the severity of associated conditions), and degree of metabolic acidosis. Prognosis is poor with low pH (≤ 6.6), elevated potassium (≥ 4.0 mEq/L or ≥ 4.0 mmol/L), serious underlying condition, or treatment delay. If treated early, most otherwise healthy patients may survive moderate or severe hypothermia.

► When to Admit

- Hypothermia patients must undergo close monitoring for potential complications. This is typically done during an inpatient admission or prolonged emergency department observation depending on the comorbidities and home care situation.
- Monitoring includes vital signs, temperature, cardiac rhythm, oximetry, serial examinations (including extremity cold-induced injuries), and serial laboratory studies (electrolyte abnormalities, renal or hepatic dysfunction, cardiac ischemia, and infection).

HYPOTHERMIA OF THE EXTREMITIES

ESSENTIALS OF DIAGNOSIS

- Extremities suffering cold-induced injuries should not be exercised, rubbed, or massaged during rewarming.
- Rewarming of extremities affected by cold-induced injuries must be performed as soon as possible after there is no risk of refreezing.

► Clinical Findings

Cold-induced injuries to the extremities (ie, frostnip, chilblain, trench foot, and frostbite) range from mild to severe. Cold exposure of the extremities produces immediate localized vasoconstriction followed by generalized vasoconstriction. When the skin temperature falls to 25°C, tissue demand for oxygen is greater than what is supplied by the slowed circulation: the area becomes cyanotic. At 15°C, tissue damage occurs due to marked reduction in tissue metabolism and oxyhemoglobin dissociation. This gives a deceptive pink, well-oxygenated appearance to the skin. Tissue damage may result from ischemia and intravascular thromboses, endothelial damage, or by actual freezing. Freezing (frostbite) may occur when the skin temperature drops below -4 to -10°C or at higher

temperatures in the presence of wind, water, immobility, malnutrition, or vascular disease.

► Prevention

"Keep warm, keep dry, and keep moving." Individuals should wear warm, dry clothing, preferably several layers, with a windproof outer garment. Arms, legs, fingers, and toes should be exercised to maintain circulation. Wet clothing, socks, and shoes should be replaced with dry ones. Extra socks, mittens, and insoles should always be carried in a pack during travel in cold or icy areas. Caution must be taken to avoid cramped positions; constrictive clothing; prolonged dependency of the feet; use of tobacco, alcohol, and sedative medications; and exposure to wet muddy ground and windy conditions.

FROSTNIP & CHILBLAIN (Erythema Pernio)

Frostnip is a mild temporary form of cold-induced injury. The involved area has local paresthesias that completely resolve with passive external rewarming. Rewarming can be done by placing cold fingers in the armpits and, in the case of the toes or heels, by removing footwear, drying feet, rewarming, and covering with adequate dry socks or other protective footwear.

Chilblains or **erythema pernio** are inflammatory skin changes caused by exposure to cold without actual freezing of the tissues. These skin lesions may be red or purple papular lesions, which are painful or pruritic, with burning or paresthesias. They may be associated with edema or blistering and aggravated by warmth. With continued exposure, ulcerative or hemorrhagic lesions may appear and progress to scarring, fibrosis, and atrophy. This may resemble vasculitis or peripheral thromboemboli. A detailed history of cold exposure will differentiate chilblains from these other conditions, thereby avoiding unnecessary diagnostic testing.

Treatment consists of elevating and passively externally rewarming the affected part. Caution must be taken to avoid rubbing or massaging injured tissues and to avoid applying ice or heat. The area must be protected from trauma, secondary infection, and further cold exposure.

IMMERSION FOOT OR TRENCH FOOT

Immersion foot (or hand) is caused by prolonged immersion in cool or cold water or mud, usually $< 10^{\circ}\text{C}$. **Prehyperemic stage** is marked by early symptoms, which include cold and anesthesia of the affected area. **Hyperemic stage** follows with hot sensation, intense burning, and shooting pains. With ongoing cold exposure, the affected part becomes pale or cyanotic with diminished pulsations due to vasospasm (**posthyperemic stage**). This may result in blistering, swelling, redness, ecchymoses, hemorrhage, necrosis, peripheral nerve injury, or gangrene and secondary complications such as lymphangitis, cellulitis, and thrombophlebitis.

Treatment is best instituted during the hyperemic stage. Treatment consists of air drying, protecting the extremities from trauma and secondary infection, and

gradual rewarming by exposure to air at room temperature (not ice or heat). Caution must be taken to avoid massaging or moistening the skin and to avoid further water immersion. Bed rest is required until all ulcers have healed. Affected parts are elevated to aid in removal of edema fluid. Pressure sites (ie, heels) are protected with pillows. Prevention involves properly fitting footwear, improved foot hygiene, and sock changes to keep feet clean and dry.

FROSTBITE

Frostbite is injury from tissue freezing and formation of ice crystals in the tissue. Most tissue destruction follows the reperfusion of the frozen tissues, with damaged endothelial cells and progressive microvascular thrombosis resulting in further tissue damage. In mild cases, only the skin and subcutaneous tissues are involved; the symptoms are numbness, prickling, itching, and pallor. With increasing severity, deep frostbite involves deeper structures. The skin appears white or yellow, loses its elasticity, and becomes immobile. Edema, hemorrhagic blisters, necrosis, and gangrene may appear. This may cause paresthesias and stiffness.

► Treatment

A. Immediate Treatment

Evaluate and treat the patient for associated systemic hypothermia and injury. Avoid secondary exposure to cold. Early use of systemic analgesics is recommended for nonfrozen injuries. Fluids and electrolytes should be monitored.

1. Rewarming—Rapid rewarming at temperatures slightly above body heat may significantly decrease tissue necrosis and reverse the tissue crystallization. If there is any possibility of refreezing, the frostbitten part should not be thawed, even if this might mean prolonged walking on frozen feet. Refreezing results in increased tissue necrosis. Rewarming is best accomplished by warm bath immersion. The frozen extremity is immersed for several minutes in a moving water bath heated to 40–42°C until the distal tip of the part being thawed flushes. Dry heat (ie, stove or open fire) is more difficult to regulate, increases likelihood of accidental burns and is not recommended. Thawing may cause tenderness and burning pain. Once the frozen part has thawed and returned to normal temperature (usually in about 30 minutes), discontinue external heat. *In the early stage, rewarming by exercise, rubbing, or friction is contraindicated.* The patient must be kept at bed rest with the affected parts elevated and uncovered at room temperature. Casts, occlusive dressings, or bandages are not applied. Blisters should be left intact unless signs of infection supervene.

2. Anti-infective measures and wound care—Frostbite increases susceptibility to tetanus and infection. Tetanus prophylaxis must be considered. Infection risk may be reduced by aseptic wound care and protection of skin blebs

from physical contact. Wounds should be kept open and allowed to dry before applying dressings. Nonadherent sterile gauze and fluffy dressing should be loosely applied to wounds and cushions used for all areas of pressure. Antibiotics should not be administered empirically. Systemic antibiotics are reserved for deep infections not responding to local wound care.

B. Medical and Surgical Treatment Options

With the availability of telemedicine, specialists are able to provide advice on early field treatment of cold-injured patients in remote areas, thereby improving outcome. Eschar formation without evidence of infection may be conservatively treated. The underlying skin may heal spontaneously with the eschar acting as a biologic dressing. Intra-arterial thrombolytic administration within 24 hours of exposure has resulted in improved tissue perfusion and has reduced amputation.

C. Follow-Up Care

Gentle, progressive physical therapy to promote circulation should be instituted as tolerated. Debridement and amputation should be considered only after it is established that the tissues are necrotic.

► Prognosis

Recovery from frostbite depends on the underlying comorbidities, the extent of initial tissue damage, the rewarming reperfusion injury, and the late sequelae. The involved extremity may be at increased susceptibility for discomfort and injury upon reexposure to cold. Neuropathic sequelae such as pain, numbness, tingling, hyperhidrosis, and cold sensitivity of the extremities, and nerve conduction abnormalities may persist for many years after the cold injury.

► When to Admit

- Patients with local cold-induced injury may require admission for management of tissue damage, comorbidities, associated injuries, or an inadequate living situation, which could compromise patient safety or recovery.

DISORDERS DUE TO HEAT

ESSENTIALS OF DIAGNOSIS

- ▶ There is a spectrum of preventable heat-related illnesses: heat cramps, heat exhaustion, heat syncope, and heat stroke.
- ▶ Pre-event planning and adequate preparation are the best preventive measures. Salt tablets are not recommended without medical supervision.
- ▶ The hallmarks of heat stroke are hyperthermia with cerebral dysfunction in a patient with heat exposure.
- ▶ The best outcome is related to early recognition, initiation of rapid cooling, and avoidance of shivering during cooling.
- ▶ The best choice of cooling method depends on which can be instituted the fastest with the least compromise to the overall care of the patient. Delays in cooling result in higher morbidity and mortality in heat stroke victims.

▶ General Considerations

Hyperthermia results from the body's inability to maintain normal internal temperature through heat loss. The body's heat source is a result of internal metabolic function and environmental conditions (temperature, humidity). Heat loss occurs through sweating and peripheral vasodilation.

There is a spectrum of preventable heat-related illnesses related to environmental exposure, ranging from mild forms, such as heat cramps and heat exhaustion, to severe forms, such as heat syncope and heat stroke. The common comorbidities and risk factors leading to heat-related conditions are listed in the chapter's introduction "Cold & Heat" section. Additional risk factors include duration of exertion, hot environment, physical inactivity, and insufficient acclimatization, skin disorders or other medical conditions that inhibit sweat production or evaporation, obesity, dehydration, prolonged seizures, hypotension, reduced cutaneous blood flow, reduced cardiac output, the use of drugs that increase metabolism or muscle activity or impair sweating, and withdrawal syndromes. Nonexertional heat-related illness can also occur in a hot relaxing environment (ie, hot bath, steam room, or sauna).

▶ Prevention

Public education is necessary to improve prevention and early recognition of heat-related disorders. Individuals should take steps to reduce personal risk factors and to acclimatize to the hot environment. Acclimatization is achieved by scheduled regulated exposure to hot environments and by gradually increasing the duration of exposure and the workload until the body adjusts. Proper acclimatization must be achieved before heavy physical exertion is performed in hot environments. Heat-related

illnesses are the leading cause of morbidity and mortality in high school sports in the United States. All children's athletic programs must set heat-acclimatization guidelines. Parents, coaches, athletic trainers and athletes must be educated about heat-related illness, specifically about prevention, risks, signs and symptoms, and treatment.

Medical evaluation and monitoring should be used to identify the individuals and the weather conditions that increase risk of heat-related disorders. Athletic events should be organized with attention to thermoregulation. Guidance regarding heat hazard is found in the National Weather Service's Heat Index, which rates weather conditions based on humidity and temperature measurements (<http://www.nws.noaa.gov/os/heat/index.shtml>).

Those who are physically active in a hot environment should increase fluid consumption before, during, and after physical activities. Fluid consumption should include balanced electrolyte fluids and water. Water consumption alone may lead to electrolyte imbalance, particularly hyponatremia. *It is not recommended to have salt tablets available for use without medical supervision.* Close monitoring of fluid and electrolyte intake and early intervention are recommended in situations necessitating exertion or activity in hot environments. Exertional heat-related disorders are common in unconditioned participants in strenuous activities in hot humid conditions. Classic (non-exertional) heat-related disorders occur when extreme environmental conditions (heat, humidity) affect patients who are not physically active, in the extremes of ages, or with chronic medical or psychiatric illnesses.

SPECIFIC SYNDROMES DUE TO HEAT EXPOSURE

1. Heat Syncope or Collapse

Heat syncope or sudden collapse may result in unconsciousness from volume depletion and cutaneous vasodilation with consequent systemic and cerebral hypotension. Exercise-associated postural hypotension is usually the cause of this: it may occur during or immediately following exercise. There is usually a history of prolonged vigorous physical activity or prolonged standing in a hot humid environment. Typically, the skin is cool and moist, the pulse is weak, and the systolic blood pressure is low.

Treatment consists of rest and recumbency in a cool place and fluid and electrolyte rehydration by mouth (or intravenously if necessary).

2. Heat Cramps

Fluid and electrolyte depletion may result in slow, painful skeletal muscle contractions ("cramps") and severe muscle spasms lasting 1–3 minutes, usually of the muscles most heavily used. The skin is moist and cool. The muscles are tender, hard and lumpy, and muscle twitching may be present. The patient is alert, with stable vital signs, and may be agitated and complaining of focal pain. The body temperature may be normal or slightly increased. There is almost always a history of vigorous activity just preceding the onset of symptoms.

The patient should be moved to a cool environment and given oral saline solution (4 tsp of salt per gallon of water) to replace both salt and water. *Oral salt tablets are not recommended.* The patient may have to rest for 1–3 days with continued dietary supplementation before returning to work or resuming strenuous activity in the heat.

3. Heat Exhaustion

Heat exhaustion results from prolonged strenuous activity with inadequate water or salt intake in a hot environment. It is characterized by dehydration, sodium depletion, or isotonic fluid loss with accompanying cardiovascular changes.

The diagnosis is based on symptoms and clinical findings of a rectal temperature over 37.8°C, increased pulse, and moist skin. Symptoms are similar to those associated with heat syncope and heat cramps. Additional symptoms include nausea, vomiting, malaise, myalgias, hyperventilation, thirst, and weakness. Central nervous system symptoms include headache, dizziness, fatigue, anxiety, paresthesias, hysteria, impaired judgment, and occasionally psychosis. Heat exhaustion may progress to heat stroke if sweating ceases and mental status declines.

Treatment consists of moving patient to a shaded, cool environment, providing adequate hydration (1–2 L over 2–4 hours), oral salt replenishment, and active cooling (ie, fans, cool packs) if necessary. Physiologic saline or isotonic glucose solution should be administered intravenously when oral administration is not appropriate. At least 24 hours of rest and rehydration are recommended.

4. Heat Stroke

Heat stroke is a life-threatening medical emergency. *The hallmarks of heat stroke are cerebral dysfunction with core temperature over 40°C.* It presents in one of two forms: classic and exertional. **Classic heat stroke** occurs in patients with impaired thermoregulatory mechanisms; **exertional heat stroke** occurs in healthy persons undergoing strenuous exertion in a hot or humid environment. Persons at greatest risk are those who are at the extremes of age, chronically debilitated, and taking medications that interfere with heat-dissipating mechanisms (ie, anticholinergics, antihistamines, phenothiazines).

Heat stroke is associated with high morbidity and mortality from cerebral, cardiovascular, liver, or kidney damage. Increased mortality rates are associated with a high Simplified Acute Physiology Score II, high body temperature, prolonged prothrombin time, use of vasoactive drugs within the first day in the intensive care unit (ICU), and an ICU without air conditioning.

► Clinical Findings

A. Symptoms and Signs

Heat stroke must be considered in any patient with hyperthermia and cerebral dysfunction. Presenting symptoms include all those seen in heat exhaustion with additional symptoms of dizziness, weakness, emotional lability, confusion, delirium, blurred vision, convulsions, collapse, and

unconsciousness. Physical examination findings include core temperature usually over 40°C, hot skin, initially covered with perspiration, then later it dries; strong pulse initially; widened pulse pressure; blood pressure is slightly elevated at first, but hypotension develops later; tachycardia; and hyperventilation. Exertional heat stroke may present with sudden collapse and loss of consciousness followed by irrational behavior. Sweating may not be present. Multiorgan dysfunction or failure is a common and serious complication.

B. Laboratory Findings

Laboratory evaluation may reveal dehydration; leukocytosis; elevated blood urea nitrogen (BUN); hyperuricemia; hemoconcentration; acid-base abnormalities (lactic acidosis, respiratory alkalosis); decreased serum glucose, sodium, calcium, and phosphorus; thrombocytopenia, fibrinolysis, and coagulopathy; elevated creatine kinase (CK); elevated aminotransferase levels and liver dysfunction; and elevated cardiac markers. Urine is concentrated, with proteinuria, hematuria, tubular casts, and myoglobinuria. Potassium may be high or low. ECG findings may include ST–T changes consistent with myocardial ischemia. PCO₂ may be < 20 mm Hg.

► Treatment

Treatment is aimed at rapidly reducing the core temperature (within 1 hour) while supporting circulatory and organ system function to prevent irreversible tissue damage and death. Clinicians must assess for possibility of concurrent conditions (infection, trauma, and drug effects, including adverse side effects, withdrawal, or overdose). Circulatory failure in heat-related illness is mostly due to shock from relative or absolute hypovolemia. Intravascular volume status should be assessed and managed early to reduce the risk of hypovolemic shock. Central venous monitoring is useful to guide volume status. Oral or intravenous fluid administration must be provided to ensure adequate urinary output. Fluid output should be monitored through the use of an indwelling urinary catheter.

Cooling methods are evaporative and conductive-based. Systemic review of the research found that there are comparable effects of these cooling methods whether used singly or in combination. No single cooling method is found to be superior. Choice of cooling method depends on which can be instituted the fastest with the least compromise to the overall care of the patient.

Evaporative cooling is a noninvasive, effective, quick and easy way to reduce temperature. Large fans circulate the room air while the entire undressed body is sprayed with lukewarm water (20°C). Inhalation of cool air or oxygen is also effective.

Conductive-based cooling involves cool fluid infusion, lavage, ice packs, and immersion into ice water or cool water. Intravascular heat exchange catheter systems as well as hemodialysis using cold dialysate (30–35°C) have been successful in reducing core temperature. Research suggests that brain cooling may lessen cerebrovascular injury from heat stroke.

Shivering must be avoided because it inhibits the effectiveness of cooling by increasing internal heat production. Medications that can be used to suppress shivering include magnesium, quick-acting opioid analgesics, benzodiazepines, and quick-acting anesthetic agents. Skin massage is recommended to prevent cutaneous vasoconstriction. *Antipyretics (aspirin, acetaminophen) have no effect on environmentally induced hyperthermia and are contraindicated.* Treatment should be continued until the rectal temperature drops to 39°C.

► Prognosis

Multiorgan dysfunction is the usual cause of heat stroke-related death, and it can be predicted by elevated creatine kinase, metabolic acidosis, coagulopathy and elevated liver enzymes. Multiorgan dysfunction, rhabdomyolysis, acute respiratory distress syndrome (ARDS), and inflammation may continue after temperature is normalized. Following heat stroke, immediate reexposure should be avoided. Sensitivity to high environmental temperature may persist for prolonged periods.

► When to Admit

- All patients with suspected heat stroke must be admitted to the hospital for close monitoring.
- Monitoring includes vital signs, temperature, and cardiac rhythm, and observation for potential complications of metabolic abnormalities, cardiac arrhythmias, coagulopathy, ARDS, hypoglycemia, seizures, organ dysfunction, and infection.

▼ THERMAL BURNS

ESSENTIALS OF DIAGNOSIS

- Estimates of the burn location, size and depth greatly determine treatment plan.
- The first 48 hours of burn care offers the greatest impact on morbidity and mortality of a burn victim.

Epidemiologic data on thermal burn injury show that the incidence and severity have been declining over recent years. Scald, direct thermal, and flame burns account for the majority of such injuries. Over three-fourths of burns involve < 10% of total body surface area. Related injuries include smoke inhalation, fractures, and blast injuries. Subsequent problems include bacterial superinfection, sepsis, respiratory damage, and multiorgan failure.

Telemedicine evaluation of acute burns offers accurate, cost-effective access to a burn specialist during the crucial 48 hours after the burn injury. The first 48 hours after the burn injury offer the greatest opportunity to impact the survival of the patient. Early surgical intervention, wound care, enteral feeding, glucose control and metabolic management, infection control, and prevention of hypothermia and compartment syndrome have contributed to significantly lower mortality rates and shorter hospitalizations.

► General Considerations

A. Classification

Burns are classified by extent, depth, patient age, and associated illness or injury. Accurate estimation of burn size and depth is important since this figure will quantify the parameters of resuscitation.

1. Extent—In adults, the “rule of nines” (Figure 37–2) is useful for rapidly assessing the extent of a burn. It is important to view the entire patient to make an accurate assessment of skin findings on initially and on subsequent examinations. One rule of thumb is that the palm of an open hand constitutes 1% total body surface area in adults. Only second- and third-degree burns are included

▲ **Figure 37–2.** Estimation of body surface area in burns.

in calculating the total burn surface area, since first-degree burns usually do not represent significant injury in terms of prognosis or fluid and electrolyte management. However, first- or second-degree burns may convert to deeper burns, especially if treatment is delayed or bacterial colonization or superinfection occurs.

2. Depth—Judgment of depth of injury is difficult. The **first-degree burn** may be red or gray but will demonstrate excellent capillary refill. First-degree burns are not blistered initially. If the wound is blistered, this represents a partial-thickness injury to the dermis, which is referred to as a **second-degree burn**. As the degree of burn is progressively deeper, there is a progressive loss of adnexal structures, referred to as a **third-degree burn**. Hairs can be easily extracted or are absent, sweat glands become less visible, and the skin appears smoother.

Deep second- and third-degree burns are treated in a similar fashion. Neither will heal appropriately without early debridement and grafting; the resultant skin is thin and scarred.

B. Survival after Burn Injury

The **Prognostic Burn Index** is the sum of the patient's age and percentage of full thickness or deep partial thickness burn. An additional 20% mortality is added if inhalation injury is present. The Prognostic Burn Index is most useful at the extremes of age. Transfer to a burn unit is indicated for large burn size, circumferential burn, or burn involving a joint or high-risk body part, and patients with comorbidities. Mortality rates have been significantly reduced due to treatment advances including improvements in wound care, treatment of infection, early burn excision, skin substitute usage, and early nutritional support through parenteral or enteral feeding. Telemedicine consultation with a burn center is an alternative, cost-effective way to access burn specialists when there are barriers that prevent transfer (distance, bed unavailability, travel risks, etc).

C. Associated Injuries or Illnesses

Smoke inhalation, associated trauma, and electrical injuries are commonly associated with burns. Smoke inhalation (see Chapter 9) must be suspected when a burn victim is found in an enclosed space, or in close proximity to the fire. Electrical injury (see following section of this chapter) may cause deep tissue burns without significant superficial skin findings and may also produce cardiac arrhythmias that require immediate attention. Severe burns from any source may cause gastrointestinal complications including pancreatitis and stress ulcers.

D. Systemic Reactions to Burn Injury

The actual burn injury is only the incipient event leading to cascade of deleterious local tissue and systemic inflammatory reactions causing multisystem organ failure in the severely burned patient. When burns greater than approximately 20% of total body surface area are present, systemic metabolic alterations occur and require intensive support. The inflammatory cascade can result in shock.

► Treatment

A. Initial Resuscitation

1. Primary survey—The clinician must proceed with a full trauma assessment, starting with “ABCDE” (airway, breathing, circulation, disability, exposure). **Airway** assessment and management is the first priority. A patient with an inhalation injury needs to be intubated early to maintain airway patency even though he or she may appear to be breathing normally. To assess and support **breathing and circulation**, the clinician should administer supplemental oxygen and obtain vascular access for fluid resuscitation simultaneously with initial resuscitation. **Disability** assessment is next followed by complete patient **exposure** and thorough examination to assess the extent of burn and associated injuries. Serial assessments of airway and breathing are necessary since endotracheal intubation or tracheotomy may be needed for major burn victims, particularly those with possible inhalation injury. Generalized edema develops during fluid resuscitation, including edema of the soft tissues of the upper airway and perhaps the lungs as well. Chest radiographs are typically normal initially but may develop an ARDS picture in 24–48 hours with severe inhalation injury. The use of corticosteroids or routine use of antibiotic therapy is not indicated.

A. AIRWAY CONTROL—Early intubation is recommended before airway edema occurs in cases of smoke inhalation or direct thermal injury to the upper airway (look for singed eyebrows or facial hair, carbonaceous sputum).

B. VASCULAR ACCESS—Large bore peripheral venous catheter access should be established. Femoral lines provide good temporary access during resuscitation if central venous access is needed. Intraosseous access can be obtained if venous access is unsuccessful or contraindicated. *Venous access catheters placed in the emergency department should be changed within 24 hours because of the high risk of non-sterile placement.* An arterial line is useful for monitoring mean arterial pressure and for drawing serial blood gases and other laboratory tests in critically ill patients.

C. FLUID RESUSCITATION—Generalized capillary leak results from burn injury over more than 20% of total body surface area. This often necessitates replacement with large volumes of crystalloid. There are many guidelines for fluid resuscitation. The **Parkland formula** relies on the use of lactated Ringer injection. The fluid requirement in the first 24 hours is estimated as 4 mL/kg body weight per percent of body surface area burned. Half the calculated fluid is given in the first 8-hour period. The remaining fluid, divided into two equal parts, is delivered over the next 16 hours. An extremely large volume of fluid may be required. For example, an injury over 40% of the total body surface area in a 70-kg victim may require 11.2 L in the first 24 hours [$4 \text{ mL} \times 40(\%) \times 70 \text{ (kg)} = 11,200 \text{ mL}$]. The first 8-hour period is measured from the hour of injury. These guidelines may be inadequate, since crystalloid solutions alone may be insufficient to restore cardiac preload during the period of burn shock. Deep electrical burns and inhalation injury increase the fluid requirement.

Adequacy of resuscitation is determined by clinical parameters, including urinary output and specific gravity, blood pressure, pulse, temperature, and central venous pressure. Overly aggressive crystalloid administration must be avoided in patients with pulmonary injury or cardiac dysfunction, since significant pulmonary edema can develop in patients with normal pulmonary capillary wedge and central venous pressures. A Foley catheter is essential for monitoring urinary output. Diuretics have no role in this phase of patient management unless fluid overload has occurred.

The need for fluid replacement of more than 150% of calculated values indicates possible unrecognized injury, possible comorbidities, and a worse prognosis.

B. Management

1. Chemoprophylaxis—

A. TETANUS IMMUNIZATION—For all burns deeper than superficial thickness, tetanus immunization must be updated. Tetanus toxoid-containing vaccine should be given intramuscularly to all patients with wounds regardless of how recently the patient received tetanus immunization. In addition, if a patient has not completed the recommended three doses of primary immunization or this is unknown, then tetanus immunoglobulin should also be administered intramuscularly in a different site than the tetanus toxoid. (See Chapter 33)

B. ANTIBIOTICS—All nonsuperficial depth wounds should be covered with topical antibiotics. Prophylaxis with systemic antibiotics is not indicated.

2. Surgical management—

A. ABDOMINAL COMPARTMENT SYNDROME—Abdominal compartment syndrome is emerging as a potentially lethal condition in severely burned patients, even if abdominal decompression is performed. Markedly increased intra-abdominal pressures can cause pulmonary damage and multisystem organ failure. Only 40% of patients with this complication survive. Bladder pressures over 30 mm Hg establish the diagnosis in at-risk patients. Surgical abdominal decompression may be indicated to improve ventilation and oxygen delivery, but even after this surgery, survival remains low.

B. ESCHAROTOMY—As edema fluid accumulates, ischemia may develop under any constricting eschar of an extremity, neck, chest, or trunk if the full-thickness burn is circumferential. Escharotomy incisions through the anesthetic eschar can save life and limb and can be performed in the emergency department or operating room.

C. FASCIOTOMY—Similar to escharotomy, fasciotomy is indicated to prevent further soft tissue, vascular, and nerve damage when soft tissue edema produces high pressures in the deep tissue compartments in the arms and legs since these compartments are divided by unyielding fascia.

D. DEBRIDEMENT, DRESSINGS, AND TOPICAL AND SYSTEMIC ANTIBIOTIC THERAPY—Minor burn wounds should be debrided at the bedside to determine the depth of the

burn and then thoroughly cleansed. Thereafter, the wound should be debrided daily and dressed with a topical antibiotic and a wound dressing. Patient compliance and adequate pain treatment is essential for successful outpatient treatment. The wound should be reevaluated by the treating clinician within 24–72 hours to evaluate for signs of infection.

The goal of burn wound management is to protect the wound from desiccation and avoid further injury or infection. Regular and thorough cleansing of burned areas is a critically important intervention in burn units. Minor burn wounds (first- and superficial second-degree types, partial thickness) will spontaneously reepithelialize in 7–10 days. Topical wound agents should be applied. Topical antibiotic wound agents are painless, easy to apply, and effective against most skin pathogens.

For severely burned patients, early excision and grafting of burned areas may be performed as soon as 24 hours after burn injury or when the patient can hemodynamically tolerate the excision and grafting procedure. Meticulous prevention of infections, seromas, hypergranulation tissue formation, and malnutrition all decrease the time to complete wound healing in skin-grafted patients. Skin autograft is the most definitive treatment. Prevention of autograft infection is paramount since autograft loss is most commonly due to autograft infection.

Systemic infection remains a leading cause of morbidity among patients with major burn injuries, with nearly all severely burned patients having one or more septicemic episodes during the hospital course. Healthcare-associated infections are increasingly common. Routine use of blood culture in the severely burned population is indicated to elucidate systemic blood infections that do not manifest these clinical predictors of sepsis.

E. WOUND CLOSURE—The goal of therapy after fluid resuscitation is rapid and stable closure of the wound. Wounds that will not heal spontaneously in 7–10 days (ie, deep second-degree or third-degree burns) are best treated by excision and autograft.

With severe burns, skin substitution with cultured grafts can be lifesaving. However, although the replaced dermis does have nearly normal histologic dermal elements, there are no adnexal structures present and very few, if any, elastic fibers. Wound infection is the top cause of skin graft rejection and failure.

C. Patient Support

Burn patients require extensive supportive care, both physiologically and psychologically. It is important to maintain normal core body temperature and avoid hypothermia (by maintaining environmental temperature at or above 30°C) in patients with burns over more than 20% of total body surface area. Respiratory injury, sepsis, and multiorgan failure are common. Burn patients require careful assessment and provision of optimal nutritional needs since their metabolism is higher and they require more energy, nutrients, and antioxidants for wound healing. Enteral feedings may be started once the ileus of the resuscitation period has resolved, usually the day after the

injury. There is often a markedly increased metabolic rate after burn injury, due in large part to whole body synthesis and increased fatty acid substrate cycles. Early aggressive nutrition (by parenteral or enteral routes) reduces infections, recovery time, noninfectious complications, length of hospital stay, long-term sequelae, and mortality.

Careful control of the postinjury blood glucose has been associated with improved hepatic function and better survival after severe burns. Occasionally, ARDS or respiratory failure unresponsive to maximal ventilatory support may develop in burn patients. In addition, the incidence of venous thromboembolism is high among burn patients.

Prevention of long-term scars remains a formidable problem in seriously burned patients. Long-term sequelae can be reduced by burn specialist consultation either directly or via telemedicine, prevention of infection, early nutrition, early aggressive rehabilitation, compressive garments, and early and continual psychological support.

► Prognosis

Prognosis depends on the extent and location of the burn tissue damage, associated injuries, comorbidities, and complications. Hyperglycemia from poor glucose control is a predictor of worse outcomes. Psychiatric support may be necessary following burn injury.

► When to Admit

- All burn patients require extensive supportive care, both physiologically and psychologically.
- Patients with significant burns (based on location and extent), comorbidities, and suboptimal home situations must be admitted to the hospital for close monitoring. Burn center consultation can advise which patients require transfer and which can be managed via telemedicine/telephone consultation.
- Monitoring includes vital signs, wound care, and observation for potential complications of electrolyte abnormalities, acute kidney injury, hepatic failure, cardiopulmonary compromise, hypoglycemia, and infection.

ELECTRICAL INJURY

ESSENTIALS OF DIAGNOSIS

- Extent of injury is determined by the type, amount, duration, and pathway of electrical current.
- Resuscitation must be attempted before assuming the electrical injury victim is dead; clinical findings are unreliable.
- Skin findings may be misleading and are not indicative of the degree of deeper tissue injury.

► General Considerations

Electricity-induced injuries are common and most are preventable. These inquiries occur by exposure to electrical current of low voltage, high voltage, or lightning. Electrical current type is either alternating current (AC) or direct current (DC). Electricity causes acute damage by direct tissue damage, muscle tetany, direct thermal injury and coagulation necrosis, and associated trauma.

Alternating current (AC) is bidirectional electrical flow that reverses direction in a sine wave pattern. This may cause muscle tetany, which prolongs the duration and amount of current exposure. AC current can be low voltage or high voltage. **Low voltage** (< 1000 V) is typically household AC current that ranges in severity from minor injury to significant damage and death. **High voltage** (> 1000 V) is most often related to occupational exposure and is associated with deep tissue damage and higher morbidity and mortality. **Direct current (DC)** is unidirectional electrical flow (eg, that associated with lightning, batteries, and automotive electrical systems). It is more likely to cause a single intense muscle contraction and asystole. **Lightning** differs from other high-voltage electrical shock in that lightning is massive DC current of millions of volts lasting a very brief duration (a small fraction of a second).

The extent of damage depends on the following factors: voltage (high or low, whether greater or lesser than 1000 volts), current type, tissue resistance, moisture, pathway; duration of exposure; associated trauma and comorbidities. Current is the most important determinant of tissue damage. Current passes through the tissues of least resistance, and this energy produces heat causing direct thermal injury. Tissue resistance varies throughout the body. Nerve cells are the most vulnerable, and bone is the most resistant to electrical current. Skin resistance depends on thickness and condition of the skin. The entrance and exit points are the most damaged. Current passing through skeletal muscle can cause muscle necrosis and contractions severe enough to result in bone fracture.

► Clinical Findings

Electrical burns are of three distinct types: flash (arcing) burns, flame (clothing) burns, and the direct heating effect of tissues by the electrical current. The latter lesions are usually sharply demarcated, round or oval, painless yellow-brown areas (Joule burn) with inflammatory reaction.

Skin damage does not correlate with the degree of injury. Significant subcutaneous damage can be accompanied by little skin injury, particularly with larger skin surface area electrical contact. Symptoms and signs may range from tingling, superficial skin burns, and myalgias to coma, paralysis, massive tissue damage, or death. Not all electrical injuries cause skin damage; only very minor skin damage may be present with massive internal injuries. The presence of entrance and exit burns signifies an increased risk of deep tissue damage.

Resuscitation must be initiated on all victims of electrical injury since clinical findings are deceptive and unreliable. A victim of electrical current injury may appear dead due to dysrhythmia, respiratory arrest, or autonomic dysfunction resulting in pupils that are fixed, dilated, or asymmetric.

► Complications

Complications include dysrhythmias, altered mental status, seizures, paralysis, headache, pneumothorax, vascular injury, tissue edema and necrosis, compartment syndrome, associated traumatic injuries, rhabdomyolysis, acute kidney injury, hypovolemia from third spacing, infections, and acute or delayed cataract formation.

► Treatment

A. Emergency Measures

The patient must be assessed and treated as a trauma victim since associated traumatic injuries are common. The victim must be safely separated from the electrical current prior to initiation of CPR or other treatment. The rescuer must be protected. Separate the victim using nonconductive implements, such as dry clothing. Resuscitation must then be initiated since clinical findings of death are unreliable.

B. Hospital Measures

The initial assessment involves airway, breathing, and circulation followed by a full trauma protocol. Fluid resuscitation is important to maintain adequate urinary output. Initial evaluation includes cardiac monitoring and ECG, complete blood count, electrolytes, renal function tests, liver biochemical tests, urinalysis, urine myoglobin, serum creatine kinase, and cardiac enzymes. ECG does not show typical patterns of ischemia since the electrical damage is epicardial. Victims must be evaluated for hidden injury.

Electrical burn injury remains the most underrecognized and devastating burn injury, sometimes leading to amputations (often because of unrecognized compartment syndromes) and acute kidney injury, resulting in part from rhabdomyolysis (see Chapter 22).

Superficial skin may appear deceptively benign, leading to a delayed or completely overlooked diagnosis of deep tissue injury. When electrical injury occurs, extensive deep tissue necrosis should be suspected. Deep tissue necrosis leads to profound tissue swelling and this in turn results in the high risk of a compartment syndrome. Early debridement of devitalized tissues and tetanus prophylaxis may reduce the risks of infection. In pregnant patients exposed to electrical injury, the fetus may sustain intrauterine growth retardation, fetal distress, and fetal demise. Fetal monitoring is recommended.

Pain management is important before, during, and after initial treatment and rehabilitation. Multimodal approach to pain is the most effective. Interventions include medications (opioids, acetaminophen, nonsteroidal anti-inflammatory drugs), heat therapy, massage, and cognitive-behavioral therapy.

► Prognosis

Prognosis depends on the degree and location of electrical injury, initial tissue damage, associated injuries, comorbidities, and complications. Psychiatric support may be necessary following lightning or severe electroshock exposures.

► When to Refer

Surgical specialists may be needed to perform fasciotomy for compartment syndrome or devitalized tissue debridement or microvascular reconstruction.

► When to Admit

Indications for hospitalization include high voltage exposure; dysrhythmia or ECG changes; large burn; neurologic, pulmonary, or cardiac symptoms; suspicion of significant deep tissue or organ damage; transthoracic current pathway; history of cardiac disease or other significant comorbidities or injuries; and need for surgery.

▼ RADIATION EXPOSURE

ESSENTIALS OF DIAGNOSIS

- Damage from radiation is determined by the source, type, quantity, duration, bodily location, and susceptibility and accumulation of exposures of the person.
- Radiation exposure from medical diagnostic imaging has dramatically risen over the past few decades; medical imaging radiation dosing needs to be standardized and regulated in order to minimize necessary radiation exposure.
- Clinicians and patients should be educated regarding the risks of medical diagnostic radiation. These radiation risks must be weighed against the benefits of the medical imaging needed.
- All patients should keep records of their medical imaging radiation exposures, and copies of the medical images and interpretations.

Exposure to radiation may occur from environmental, occupational, medical care, accidental, or intentional (ie, terrorism) exposure. With advancements in nuclear technology in the fields of medicine, energy, and industry, there is a growing risk of radiation exposure to patients, occupational workers, and the public. The extent of damage due to radiation exposure depends on the type, quantity, and duration of radiation exposure; the organs exposed; the degree of disruption to DNA; metabolic and cellular function; and the age, underlying condition, susceptibility, and accumulative exposures of the victim.

Professionals who work with radiation or its victims must have a basic understanding of radiation physics in order to identify risk, manage exposure, and minimize preventable spread of exposure. Radiation is energy waves or particles that travel through space. These energetic waves or particles radiate (move outward in all directions) from the source. Radiation occurs from both nonionizing and ionizing radiation sources. **Nonionizing radiation** is low energy, resulting in injuries related to local thermal damage (ie, microwave, ultraviolet, visible light and radio-wave). **Ionizing radiation** is high energy, causing bodily damage in several ways (ie, cellular disruption, DNA damage, and mutations). Ionizing radiation is either electromagnetic (ie, x-rays and gamma rays) or particulate (ie, alpha or beta particles, neutrons, and protons). Exposure may be external, internal, or both.

In **acute radiation exposure**, medical care includes close monitoring of the gastrointestinal, cutaneous, hematologic, and cerebrovascular symptoms and signs from initial exposure and over time.

Radiation exposure results in early and delayed effects. Early effects involve damage of the rapidly dividing cells (ie, the mucosa, skin, and bone marrow). This may be manifested as nausea, vomiting, and decreased lymphocyte count over hours to days after exposure. Delayed effects include malignancy, reproduction abnormalities, liver, kidney, and central nervous system and immune system dysfunction.

ACUTE & DELAYED EFFECTS OF RADIATION EXPOSURE ON NORMAL TISSUES

► Clinical Findings

A. Injury to Superficial Structures

Acute radiation exposure to the skin and mucous membranes may cause erythema, epilation, destruction of fingernails, or epidermolysis, and burns that appear similar to thermal burns but usually have a slower onset and course. Chronic damage includes skin scarring, atrophy, telangiectasis, and xerostomia. Radiation effects on the eyes include cataracts, dry eye syndrome, and retinopathy.

B. Injury to Deep Structures

Hematopoietic system radiation exposure causes injury to the bone marrow that may vary from transient decreases to complete destruction of blood elements. Lymphocytes are most sensitive, followed by polymorphonuclear leukocytes; erythrocytes are the least sensitive. Hematopoietic effects consisting of anemia, thrombocytopenia, and bone marrow suppression can occur 1–3 weeks after radiation

exposures. Bone marrow failure is the main cause of death within the first few months following exposure.

Nervous system structures are sensitive to radiation. The brain and spinal cord are much more sensitive than the peripheral nerves to the acute and delayed effects of radiation.

Cardiovascular system effects of ionizing radiation result in damage to the heart and coronary arteries. Smaller vessels (the capillaries and arterioles) are more susceptible to damage than larger blood vessels. Delayed effects from radiation include obliterative endarteritis; coronary artery disease; pericarditis with effusion; or constrictive pericarditis, which may occur months or years later. Myocarditis is less common.

Pulmonary system radiation with high or repeated moderate doses of radiation may cause pneumonitis or pulmonary fibrosis, which is often delayed for weeks or months.

Gastrointestinal system radiation results in mucositis and mucosal edema within hours or days after exposure. Symptoms include odynophagia, anorexia, nausea, vomiting, dehydration, and weakness. High doses of radiation inhibit gastric secretion and cause inflammation and ulceration of the bowels. Delayed effects include hepatitis, liver dysfunction, and intestinal stenosis. The stomach and colon are the gastrointestinal organs most at risk for cancer induction due to internal radiation.

Urogenital system radiation effects are dose-dependent, varying from transient decrease in fertility to permanent sterility, chromosomal aberrations, fetal damage, or demise. Moderate to heavy irradiation of the embryo results in injury to the fetus or in embryonic death and spontaneous abortion. Microcephaly and other congenital abnormalities may occur in children exposed in utero, especially if the fetus was exposed during early pregnancy. Nephritis and kidney dysfunction may occur as immediate or delayed effects.

Endocrine system organs are relatively resistant to low or moderate doses of radiation. The thyroid gland is the endocrine gland at highest risk for cancer induction from internal radiation exposure. Delayed effects of radiation include thyroid dysfunction (hypothyroidism).

C. Systemic Reaction (Acute Radiation Syndrome)

Clinicians must be educated to recognize and treat acute radiation sickness also referred to as **acute radiation syndrome**. Acute radiation syndrome is due to an exposure to high doses of ionizing radiation over a brief time course. The symptom onset is within hours to days depending on the dose. Symptoms include anorexia, nausea, vomiting, weakness, exhaustion, lassitude and, in some cases, prostration; these symptoms may occur singly or in combination. Dehydration, anemia, and infection may follow. The Centers for Disease Control and Prevention offers web-based information for clinicians regarding acute radiation syndrome (<http://emergency.cdc.gov/radiation/arsphysicianfactsheet.asp>).

► Therapeutic Radiation Exposure

Radiation therapy has been a successful component to treating many malignancies. This growing population of

cancer survivors treated with radiation therapy is an important resource to review and quantify associations between radiation therapy and risk of long-term adverse health and quality of life outcomes. These radiation-treated cancer survivors have a higher risk of development of a second malignancy; obesity; and pulmonary, cardiac and thyroid dysfunction as well as an increased overall risk for chronic health conditions and mortality. Ongoing study of childhood cancer survivors is needed to establish long-term risks and to evaluate the impact of newer techniques such as conformal radiation therapy or proton-beam therapy.

▶ Medical Imaging Radiation Exposure

Medical imaging with ionizing radiation exposure (eg, computed tomography [CT] and nuclear medicine studies) has dramatically increased over the past two decades. In addition, researchers have found that the radiation dose for the same study varies significantly among different machines and different clinicians, within and across institutions, with radiation doses varying by as much as a factor of 10. This finding highlights the urgent safety need for standardization and regulation of radiation dosing for medical diagnostics.

Clinicians and patients must be aware of the dangers of radiation when deciding on an imaging test. The risks and benefits must be carefully weighed. All patients should keep records of their cumulative medical imaging radiation exposures, as well as copies of the medical images and their interpretations. The American College of Radiology website offers additional safety information (<http://www.radiologyinfo.org/en/safety/>).

▶ Occupational and Environmental Radiation Exposure

Prevention of occupational radiation exposure involves adequate training of all persons handling radiation as well as creating safety policies and procedures. This will reduce occupational risk of radiation exposure and improve the emergency response to accidental exposure. Prehospital and hospital disaster plans are required for optimal management of radiation exposure. The Radiation Assistance Center (1-865-576-1005) provides 24-hour access to expert information. The Centers for Disease Control and Prevention "Radiation Emergency" website (<http://emergency.cdc.gov/radiation>) is a useful resource for professionals.

▶ Treatment

Treatment is focused on decontamination, symptomatic relief, supportive care, and psychosocial support. Specific treatments focus on the dose, route, and effects of exposure.

▶ Prognosis

Prognosis is determined by the radiation dose, duration, and frequency as well as by the underlying condition of the victim. Approximate dose of exposure correlates with the early onset and severity of symptoms (ie, nausea, vomiting, anorexia, abdominal pain, bloody diarrhea, weight loss)

and laboratory findings, particularly the decline in lymphocyte count on the complete blood count. Death is usually due to hematopoietic failure (ie, hemorrhage, anemia, and immunosuppression), gastrointestinal mucosal damage, central nervous system damage, widespread vascular injury, or secondary infection.

Carcinogenesis is related to the total dose, duration, accumulation of exposure, and to the susceptibility of the victim. The younger the victim's age at the time of exposure, the greater the risk of acute and long-term damage from radiation. Radiation-related cancer risks persist throughout the exposed person's lifespan. Cancer risk is particularly increased for persons exposed to nuclear radiation (eg, those exposed at Chernobyl, Hiroshima, Nagasaki, and Marshall Island nuclear test detonations). X-rays are classified as carcinogens since exposure causes leukemia and cancers of the thyroid, breast, and lung.

With the increased use of ionizing radiation for medical diagnostics and treatments, there is a growing concern for the iatrogenic increase in radiation-induced cancer risks, especially in children. There are age-related sensitivities to radiation; prenatal and younger age victims are more susceptible to carcinogenesis.

▶ When to Admit

Most patients with significant ionizing radiation exposure require admission for close monitoring and supportive treatment.

NEAR DROWNING

ESSENTIALS OF DIAGNOSIS

- ▶ The first requirement of rescue is immediate basic life support and CPR.
- ▶ Patient must also be assessed for hypothermia, hypoglycemia, concurrent injuries, and medical conditions.
- ▶ Clinical manifestations are hypoxemia, pulmonary edema, and hypoventilation.

► General Considerations

Near drowning describes a submersion event leading to injury. Submersion injury may result in aspiration, laryngospasm, hypoxemia, and acidemia. **Drowning** describes submersion resulting in death. “Wet” drowning is due to aspiration of fluid or foreign material. “Dry” drowning is due to laryngospasm or airway obstruction. The primary effect is hypoxemia due to perfusion of poorly ventilated alveoli, intrapulmonary shunting, and decreased compliance. A patient may be deceptively asymptomatic during the initial recovery period only to deteriorate or die as a result of acute respiratory failure within the following 12–24 hours.

Preventative measures should be taken to reduce morbidity and mortality from drowning. Conditions that increase risk of submersion injury include the following: (1) use of alcohol or other drugs, (2) extreme fatigue from inadequate water safety skills, (3) poor physical health, (4) hyperventilation, (5) sudden acute illness (eg, hypoglycemia, seizure, dysrhythmia, myocardial infarction, asthma flare), (6) acute trauma (particularly brain or spinal cord injury, or both), (7) venomous stings or bites, (8) decompression sickness, (9) dangerous water conditions (temperature and turbulence), and (10) carbon monoxide exposure from boat motors.

► Clinical Findings

A. Symptoms and Signs

The patient’s appearance may vary from asymptomatic, to abnormal vital signs, anxiety, dyspnea, cough, wheezing, trismus, cyanosis, chest pain, dysrhythmia, hypotension, vomiting, diarrhea, headache, altered level of consciousness, neurologic deficit, and apnea. Hypothermia is highly likely with cold water or prolonged submersion.

B. Laboratory Findings

Arterial blood gas results are helpful in determining the degree of injury since initial clinical findings may appear benign. PaO_2 is usually decreased; PaCO_2 may be increased or decreased; pH is decreased. Bedside blood sugar must be checked rapidly. Other testing is based on clinical scenario and may include kidney function, electrolytes, urinalysis, blood count, lactate, cardiac markers, coagulation studies, and alcohol and toxicology levels. Metabolic acidosis is common.

► Prevention

Prevention is multi-faceted. Physical barriers (ie, fences) should be placed around pools and other accessible bodies of water. Safety flotation devices and rescue supplies must be immediately available. Use of alcohol or sedative drugs must be avoided during swimming, boating, or other water-based activities. There must be close supervision of those who cannot swim, and personal flotation devices must be worn when boating or water skiing. Swimming lessons, water and boat safety, and basic life support (BLS) education is necessary for anyone involved in water-based activities.

► Treatment

A. First Aid

The first requirement of rescue is immediate BLS treatment and CPR. At the scene, immediate measures to combat hypoxemia are critical to improve outcome. BLS care includes sustained ventilation, oxygenation, and circulatory support. Hypothermia and associated trauma, especially brain and cervical spine injury, should always be suspected.

1. Standard BLS is initiated. CPR is provided if pulse and respirations are absent.
2. Patient must be assessed for hypothermia, hypoglycemia, trauma, and concurrent medical conditions.
3. Rescuer should not attempt to drain water from the victim’s lungs. The Heimlich maneuver (subdiaphragmatic pressure) should be used only if foreign material airway obstruction is suspected.
4. Resuscitation and BLS efforts must be continued until core temperature reaches 32°C even for seemingly “hopeless” patients. Complete recovery has been reported after prolonged resuscitation of hypothermic patients.

B. Subsequent Management

1. Ensure optimal ventilation and oxygenation—The onset of hypoxemia exists even in the alert, conscious patient who appears to be breathing normally. Oxygen should be administered immediately at the highest available concentration. Oxygen saturation should be maintained at 90% or higher. Endotracheal intubation and mechanical ventilation are necessary for patients unable to maintain an open airway, adequate oxygenation, or ventilation. Continuous positive airway pressure (CPAP) is an effective noninvasive way of reversing hypoxia and hypercarbia in patients with spontaneous respirations and a patent airway. Positive end-expiratory pressure (PEEP) is also effective for treating respiratory insufficiency. Serial physical examinations and chest radiographs should be carried out to detect possible pneumonitis, atelectasis, and pulmonary edema. Bronchodilators may be used to treat wheezing and bronchospasms due to aspiration. Nasogastric suctioning can decompress the stomach, aid in removal of swallowed water, and reduce the risk of aspiration. Antibiotics are reserved for clinical evidence of infection and should not be given prophylactically.

2. Cardiovascular support—Intravascular volume status must be monitored to determine whether vascular fluid replacement and vasopressors or diuretics are needed. Standard therapy for hypotension and pulmonary edema is administered.

3. Correction of blood pH and electrolyte abnormalities—Metabolic acidosis is present in 70% of near-drowning victims, but it is usually corrected through adequate ventilation and oxygenation. Glycemic control improves outcome.

4. Cerebral and spinal cord injury—Central nervous system damage may progress despite apparently adequate treatment of hypoxia and shock. Standard treatment for brain and spinal cord injury must be followed.

5. Hypothermia—Core temperature should be measured and managed as appropriate (see Systemic Hypothermia, above).

► Course & Prognosis

Respiratory damage is often severe in the minutes to hours following a near drowning. With respiratory supportive treatment, improvements typically occur quickly over the first few days following the near drowning. Long-term complications of near drowning may include neurologic impairment, seizure disorder, and pulmonary or cardiac damage. There is a direct correlation between prognosis and the patient's age, submersion time, rapid prehospital resuscitation and rapid transport to a medical facility, clinical status at time of arrival to hospital, Glasgow Coma Scale score, pupillary reactivity, and overall health assessment (APACHE II score).

► When to Admit

Most patients with significant near drowning or concurrent medical or traumatic conditions require inpatient monitoring for 24 hours following near drowning. This includes continuous monitoring of cardiorespiratory, neurologic, renal and metabolic function. Pulmonary edema may not appear for 24 hours.

ENVIRONMENTAL DISORDERS RELATED TO ALTITUDE

DYSBARISM & DECOMPRESSION SICKNESS

ESSENTIALS OF DIAGNOSIS

- Symptoms temporally related to recent altitude or pressure changes (ie, scuba diving).
- Early recognition and prompt treatment of decompression sickness are extremely important.
- Patient must also be assessed for hypothermia, hypoglycemia, concurrent injuries, and medical conditions.
- Consultation with diving medicine or hyperbaric oxygen specialist is indicated.

► General Considerations

Dysbarism and decompression sickness are physiologic problems that result from altitude changes and the environmental pressure effects on gases in the body during underwater descent and ascent, particularly when scuba diving is followed closely by air travel or hiking to high altitudes.

Physics laws describe the mechanisms involved in dysbarism and decompression sickness. As a diver descends, the gases in the body compress; gases dissolve in blood and tissues. During the ascent, gases in the body expand. **Dysbarism** results from gas compression or expansion in parts of the body that are noncompressible or have limited compliance. Lung barotrauma results in pneumomediastinum, pneumothorax, and rupture of the pulmonary vein causing arterial gas embolism. Overpressurization of the bowels may occur, especially if there is underlying pathology. This can result in gastric rupture, bowel obstruction or perforation, or pneumoperitoneum. Less serious conditions can also occur such as mask squeeze, ear squeeze, sinus squeeze, headache, tooth squeeze.

Decompression sickness occurs when the ascent is too rapid and gas bubbles form and cause damage depending on their location (eg, coronary, pulmonary, spinal or cerebral blood vessels, joints, soft tissue). Decompression sickness symptoms depends on the size and number and location of gas bubbles released (notably nitrogen). Risk of decompression sickness depends on the dive details (depth, duration, number of dives, and interval surface time between dives, water conditions) as well as the diver's age, weight, physical condition, physical exertion, the rate of ascent, and the length of time between the low altitude (scuba dive) and high altitude (air travel or ground ascent). Predisposing factors for decompression sickness include obesity, injury, hypoxia, lung or cardiac disease, right to left cardiac shunt, diver's overall health, dehydration, alcohol and medication effects, and panic attacks. Decompression sickness also occurs in those who take hot showers after cold dives. Conservative recommendation is to avoid high altitudes (air travel or ground ascent) for at least 24 hours after surfacing from the dive.

► Clinical Findings

The range of clinical manifestations varies depending on the location of the gas bubble formation or the compressibility of gases in the body. Symptom onset may be immediate, within minutes or hours (in the majority), or present up to 36 hours later. Decompression sickness symptoms include pain in the joints (“the bends”); skin pruritus or burning (skin bends); rashes; spinal cord or cerebral symptoms (“dissociation” symptoms that do not follow typical distribution patterns); labyrinthine decompression sickness (“the staggers,” central vertigo); pulmonary decompression sickness (“the chokes,” inspiratory pain, cough, and respiratory distress); arterial gas embolism (cerebral, pulmonary); barotrauma of the lungs, ear and sinus; dysbaric osteonecrosis; and coma.

The clinician must assess for associated conditions of hypothermia, hypoglycemia, near drowning, trauma, envenomations, or concurrent medical conditions.

► Treatment

Early recognition and prompt treatment are extremely important. Decompression sickness must be considered if symptoms are temporally related to recent diving or altitude or pressure changes within the past 48 hours. Immediate consultation with a diving medicine or hyperbaric oxygen specialist is indicated even if mild symptoms resolved, since relapses with worse outcomes have occurred. Continuous administration of 100% oxygen is indicated and beneficial for all patients. Aspirin may be given for pain. Opioids should be used very cautiously, since these may obscure the response to recompression.

► When to Admit

Rapid transportation to a hyperbaric treatment facility for recompression is imperative for decompression sickness. If air transportation is chosen, the aircraft must maintain pressurization near sea level to avoid worsening decompression sickness. The Divers Alert Network is an excellent worldwide resource for emergency advice 24 hours daily for the management of diving-related conditions (www.diversalertnetwork.org). For diving emergencies, call local emergency responder first, then the Divers Alert Network.

Webb JT et al. Fifty years of decompression sickness research at Brooks AFB, TX: 1960–2010. *Aviat Space Environ Med*. 2011 May;82(5 Suppl):A1–25. [PMID: 21614886]

HIGH-ALTITUDE ILLNESS

ESSENTIALS OF DIAGNOSIS

- ▶ The severity of the high-altitude illness correlates with the rate and height of ascent, and the individual's susceptibility.
- ▶ Prompt recognition and medical attention of early symptoms of high-altitude illness should prevent progression.
- ▶ Immediate descent is the definitive treatment for high-altitude cerebral edema and high-altitude pulmonary edema.

► General Considerations

As altitude increases, hypobaric hypoxia results due to a decrease in both barometric pressure and oxygen partial pressure. High-altitude medical problems are due to hypobaric hypoxia at high altitudes (usually > 2000 meters or 6560 feet). Acclimatization occurs as a physiologic response to the rise in altitude and increasing hypobaric hypoxia. Physiologic changes include increases in alveolar ventilation and oxygen extraction by the tissues and increased hemoglobin level and oxygen binding.

High-altitude illness results when the hypoxic stress is greater than the individual's ability to acclimatize. Risk factors for high-altitude illness include increased physical activity with insufficient acclimatization, inadequate education and preparation, and individual susceptibility (pre-existing medical conditions and medication use), and previous high-altitude illness. The key determinants of high-altitude illness risk and severity include both individual susceptibility factors and altitudinal factors (rapid rate and height of ascent and total change in altitude). Presentations may be acute, subacute, or chronic disturbances that result from hypobaric hypoxia. Acclimatization to altitudes above 5500 m (18,045 ft) is incomplete or physiologically impossible, although individual differences in tolerance to hypoxia exist.

Individual susceptibility factors include underlying conditions such as cardiac and pulmonary dysfunction, patent foramen ovale, blood disorders (ie, sickle cell disease), pregnancy, neurologic condition, recent surgery, and many other chronic medical conditions. Those with symptomatic cardiac or pulmonary disease should avoid high altitudes.

High-altitude illness comprises a spectrum of conditions based on end-organ effects, mostly cerebral and pulmonary. This is a result of fluid shifts from intravascular to extravascular spaces, especially in the brain and lungs. Manifestations of altitude illness include acute and long-term disorders. Acute high-altitude disorders are high-altitude neurologic conditions (acute mountain sickness and high-altitude cerebral edema) and high-altitude pulmonary edema. Long-term exposure to high altitude over months or years with inadequate acclimatization can result in subacute mountain sickness and chronic mountain sickness (Monge disease). (While subacute mountain sickness and Monge disease are mentioned briefly below, a more detailed discussion can be found in the online version of *Current Medical Diagnosis & Treatment*.)

1. High-Altitude–Associated Neurologic Conditions (Acute Mountain Sickness & High-Altitude Cerebral Edema)

There is a spectrum of neurologic conditions caused by high altitude, ranging from acute mountain sickness to a more serious form, high altitude cerebral edema.

Acute mountain sickness includes both neurologic and pulmonary symptoms, such as headache (most severe and persistent symptom), lassitude, drowsiness, dizziness, chilliness, nausea and vomiting, facial pallor, dyspnea, and cyanosis. Later symptoms include facial flushing, irritability, difficulty concentrating, vertigo, tinnitus, visual and auditory disturbances, anorexia, insomnia, increased dyspnea and weakness on exertion, increased headaches (due to cerebral edema), palpitations, tachycardia, Cheyne-Stokes breathing, and weight loss. More severe manifestations include cerebral and pulmonary edema (high-altitude cerebral edema and high-altitude pulmonary edema; see below).

High-altitude cerebral edema appears to be an extension of the central nervous system symptoms of acute mountain sickness and results from cerebral vasogenic

edema and cerebral cellular hypoxia. It usually occurs at elevations above 2500 meters (8250 feet) and is more common in unacclimatized individuals. Hallmarks are altered consciousness and ataxic gait. Severe headaches, confusion, truncal ataxia, urinary retention or incontinence, focal deficits, papilledema, nausea, vomiting, and seizures may also occur. Symptoms may progress to obtundation and coma.

► Treatment

Initial treatment involves oxygen administration by mask. Voluntary periodic hyperventilation will often relieve acute symptoms. Definitive treatment is immediate descent. Descent should be at least 610 meters (2000 feet) and should continue until symptoms improve. Descent is essential if the symptoms are persistent, severe, or worsening or if high-altitude pulmonary edema or high-altitude cerebral edema are present. If immediate descent is not possible, portable hyperbaric chambers can provide symptomatic relief.

Acetazolamide (125–250 mg orally every 8–12 hours, conflicting data as to the optimal dose) remains the most effective medication for treatment of acute mountain sickness and for more severe forms of altitude-related conditions. Adverse reactions include peripheral paresthesias, altered taste of carbonated beverages, polyuria, nausea, drowsiness, erectile dysfunction, and myopia. This is a sulfonamide drug and should be used with caution or avoided in persons with past reactions to this class of drug.

Dexamethasone (dose varies depending on the activity level of the individual, ranging from 2 to 4 mg orally every 6 hours) is effective for treatment of acute mountain sickness and acute cerebral edema; this medication should not be used for prophylaxis and should not be continued beyond 7 days. These medications can be continued for as long as symptoms persist and may be used together in severe cases. In most individuals, symptoms clear within 24–48 hours.

2. Acute High-Altitude Pulmonary Edema

High-altitude pulmonary edema is a serious complication of hypoxia induced pulmonary hypertension. It is the leading cause of death from high altitude illness. The hallmark is markedly elevated pulmonary artery pressure followed by pulmonary edema. It usually occurs at levels above 3000 meters (9840 feet). High altitude increases pulmonary arterial pressure and decreases the oxygen uptake and saturation and alters oxygen kinetics. Early symptoms may appear within 6–36 hours after arrival at a high-altitude area. These include incessant dry cough, shortness of breath disproportionate to exertion, headache, decreased exercise performance, fatigue, dyspnea at rest, and chest tightness. Recognition of the early symptoms may enable the patient to descend before incapacitating pulmonary edema develops. Strenuous exertion should be avoided. An early descent of even 500 or 1000 meters may result in improvement of symptoms. Later, wheezing, orthopnea, and hemoptysis may occur as pulmonary edema worsens. Physical findings include tachycardia, mild fever, tachypnea, cyanosis, prolonged respiration, and rales and rhonchi.

The clinical picture may resemble severe pneumonia. The patient may become confused or comatose. Diagnosis is usually clinical; ancillary tests are nonspecific or unavailable on site. Prompt recognition and medical attention of early symptoms prevent progression.

► Treatment

Treatment must often be initiated under field conditions. The patient must rest in the semi-Fowler position (head raised), and 100% oxygen must be administered. *Immediate descent (at least 610 meters [2000 feet]) is essential.* Recompression in a portable hyperbaric bag will temporarily reduce symptoms if rapid or immediate descent is not possible. To conserve oxygen, lower flow rates (2–4 L/min) may be used until the victim recovers or is evacuated to a lower altitude and $\text{SaO}_2 \geq 90\%$. Treatment for ARDS (see Chapter 9) may be required for some patients. Calcium channel blockers and selective phosphodiesterase type 5 (PDE5) inhibitors are effective for symptomatic relief: nifedipine (30 mg slow-release tablets every 12 hours), tadalafil (10 mg by mouth every 12 hours), and sildenafil (50 mg by mouth every 8 hours) are alternatives.

3. Subacute Mountain Sickness

This occurs most frequently in unacclimatized individuals and at high altitudes for a prolonged period of time. The hypobaric hypoxia results in pulmonary hypertension.

4. Chronic Mountain Sickness (Monge Disease)

This uncommon condition is seen in residents of high-altitude communities who have lost their acclimatization to such a hypobaric hypoxic environment. It is difficult to differentiate from chronic pulmonary disease.

► Prevention of High-Altitude Disorders

Pre-trip preventive measures include participant education, medical prescreening, pre-trip planning, optimal physical conditioning before travel, and adequate rest and sleep the day before travel. Preventive efforts during ascent include reduced food intake; avoidance of alcohol, tobacco, and unnecessary physical activity during travel; slow ascent to allow acclimatization (300 meters per day); and a period of rest and inactivity for 1–2 days after arrival at high altitudes. Mountaineering parties at altitudes of ≥ 3000 meters or higher should carry a supply of oxygen and medical equipment sufficient for several days. Prophylactic medications may be prescribed if no contraindications exist. Prophylactic low-dose acetazolamide (250–500 mg every 12 hours orally or 500 mg extended-release once to twice daily orally) has been shown to reduce the incidence and severity of acute mountain sickness when started 3 days prior to ascent and continued for 48–72 hours at high altitude. Dexamethasone (4 mg every 12 hours orally beginning on the day of ascent, continuing for 3 days at the higher altitude, and then tapering over 5 days) is an alternative prophylactic medication.

▶ When to Admit

- All patients with high-altitude pulmonary edema or high-altitude cerebral edema must be hospitalized for further observation.
- Hospitalization must also be considered for any patient who remains symptomatic after treatment and descent. Pulmonary symptoms and hypoxia may be worsened by pulmonary embolism, bacterial pneumonia, or bronchitis.

SAFETY OF AIR TRAVEL & SELECTION OF PATIENTS FOR AIR TRAVEL

The medical safety of air travel depends on the nature and severity of the traveler's preflight condition and factors such as travel duration, frequency and use of in-flight exercise, cabin pressurization, availability of medical supplies, and presence of health care professionals on board. In-flight medical emergencies are increasing because there are an increasing number of travelers with preexisting medical conditions. Air travel passengers are susceptible to a wide range of flight-related problems: pulmonary (eg, hypoxia, gas expansion), vascular (venous thromboembolism, VTE), infectious, cardiovascular, gastrointestinal, ocular, immunologic, syncope, neuropsychiatric, metabolic, trauma, and substance-related. These air-travel risks are higher for those air travelers with preexisting medical conditions: cardiovascular disease, thromboembolic disease, asthma, chronic obstructive pulmonary disease, epilepsy, stroke, recent surgery or trauma, diabetes mellitus, infectious disease, mental illness, and substance dependence. Occupational and frequent flyers are at risk for these as well as accumulative radiation exposure, cabin air quality, circadian disturbance, and pressurization problems.

Hypobaric hypoxia is the underlying etiology of most serious medical emergencies in flight. Despite commercial aircraft pressurization requirements, there is significant hypoxemia, dyspnea, gas expansion, and stress in travelers with underlying serious cardiopulmonary and other conditions. Patients with underlying respiratory or cardiac conditions are at highest risk for problems stemming from hypobaric hypoxia.

Research also demonstrates an association between VTE and air travel. Air travel has a threefold higher risk of VTE, especially severe pulmonary embolism. The VTE risk increases proportionally with the flight duration. Higher risk of VTE is seen in travelers with thrombophilia, those receiving hormonal therapy, and pregnant travelers.

Air travel is not advised for anyone who is incapacitated, or who has an active pneumothorax, class III and IV pulmonary hypertension, acute worsening of an underlying lung disease, or any unstable conditions. The Air Transport Association of America defines an **incapacitated passenger** as “one who is suffering from a physical or mental disability and who, because of such disability or the effect of the flight on the disability, is incapable of self-care; would endanger the health or safety of such person or other passengers or airline employees; or would cause discomfort or annoyance of other passengers.” **Unstable conditions** include poorly controlled hypertension, dysrhythmias, angina, valvular disease, congestive heart failure, or psychiatric condition; severe anemia or sickle cell disease; recent myocardial infarction, cerebrovascular accident, or deep venous thrombosis; postsurgery, especially heart surgery (unless approved by surgeon); and any active communicable disease (influenza, tuberculosis, measles, chickenpox, or other communicable virulent infections). Risk of transmission increases when there is close contact to infected passengers.

Pregnancy and Infancy

Pregnancy is a hypercoagulable state with fivefold to tenfold increase in VTE risk. Air travel increases this risk of VTE. Pregnant women may be permitted to fly during the first 8 months of pregnancy unless there is a history of pregnancy complications or premature birth. Infants younger than 1 week old should not be flown at high altitudes or for long distances. There is a higher risk of transmission of infection in-flight for pregnant women and infants due to their weaker immune response. Estimates of air travel radiation exposure are available through the Federal Aviation Administration and vary based on frequency and duration of flights.

▶ Prevention

Air travel complications may be reduced by the following preventive measures: passenger education, passenger prescreening, and in-flight positioning and activity. Prescreening is especially important for those who have had recent surgery or an emergency condition, and those with chronic serious medical conditions. Travelers with pulmonary disease must have preflight medical assessment to determine whether supplemental oxygen is required. Travelers can reduce VTE risk by avoiding constrictive clothing, wearing support hose, changing position frequently, avoiding leg crossing, engaging in frequent in-flight leg exercises, and walking. Low-molecular-weight heparin may be prescribed in travelers at high risk for VTE.

Poisoning

Kent R. Olson, MD

INITIAL EVALUATION: POISONING OR OVERDOSE

Patients with drug overdoses or poisoning may initially have no symptoms or they may have varying degrees of overt intoxication. The asymptomatic patient may have been exposed to or may have ingested a lethal dose but not yet exhibit any manifestations of toxicity. It is important to: (1) quickly assess the potential danger, (2) consider gut decontamination to prevent absorption, (3) treat complications if they occur, and (4) observe the asymptomatic patient for an appropriate interval.

▶ Assess the Danger

If the drug or poison is known, its danger can be assessed by consulting a text or computerized information resource or by calling a regional poison control center. (In the United States, dialing 1-800-222-1222 will direct the call to the regional poison control center.) Assessment will usually take into account the dose ingested; the time since ingestion; the presence of any symptoms or clinical signs; pre-existing cardiac, respiratory, kidney, or liver disease; and, occasionally, specific serum drug or toxin levels. Be aware that the history given by the patient or family may be incomplete or unreliable.

IMMEDIATE 24-HOUR TOXICOLOGY CONSULTATION

Call your regional poison control center
U.S. toll-free 1-800-222-1222

▶ Observation of the Patient

Asymptomatic or mildly symptomatic patients should be observed for at least 4–6 hours. Longer observation is indicated if the ingested substance is a sustained-release preparation or is known to slow gastrointestinal motility or may cause a delayed onset of symptoms (such as acetaminophen, colchicine, or hepatotoxic mushrooms). After that time, the patient may be discharged if no symptoms

have developed. Before discharge, psychiatric evaluation should be performed to assess suicide risk. Intentional ingestions in adolescents should raise the possibility of unwanted pregnancy or sexual abuse.

THE SYMPTOMATIC PATIENT

In symptomatic patients, treatment of life-threatening complications takes precedence over in-depth diagnostic evaluation. Patients with mild symptoms may deteriorate rapidly, which is why all potentially significant exposures should be observed in an acute care facility. The following complications may occur, depending on the type of poisoning.

COMA

▶ Assessment & Complications

Coma is commonly associated with ingestion of large doses of antihistamines (eg, diphenhydramine), benzodiazepines and other sedative-hypnotic drugs, ethanol, opioids, antipsychotic drugs, or antidepressants. The most common cause of death in comatose patients is respiratory failure, which may occur abruptly. Pulmonary aspiration of gastric contents may also occur, especially in victims who are deeply obtunded or convulsing. Hypoxia and hypoventilation may cause or aggravate hypotension, arrhythmias, and seizures. Thus, protection of the airway and assisted ventilation are the most important treatment measures for any poisoned patient.

▶ Treatment

A. Emergency Management

The initial emergency management of coma can be remembered by the mnemonic *ABCD*, for *Airway*, *Breathing*, *Circulation*, and *Drugs* (dextrose, thiamine, and naloxone or flumazenil), respectively.

1. Airway—Establish a patent airway by positioning, suction, or insertion of an artificial nasal or oropharyngeal airway. If the patient is deeply comatose or if airway

reflexes are depressed, perform endotracheal intubation. These airway interventions may not be necessary if the patient is intoxicated by an opioid or a benzodiazepine and responds to intravenous naloxone or flumazenil (see below).

2. Breathing—Clinically assess the quality and depth of respiration, and provide assistance if necessary with a bag-valve-mask device or mechanical ventilator. Administer supplemental oxygen, if needed. The arterial blood CO₂ tension is useful in determining the adequacy of ventilation. The arterial blood PO₂ determination may reveal hypoxemia, which may be caused by respiratory arrest, bronchospasm, pulmonary aspiration, or noncardiogenic pulmonary edema. Pulse oximetry provides an assessment of oxygenation but is not reliable in patients with methemoglobinemia or carbon monoxide poisoning, unless a newer pulse oximetry device capable of detecting these forms of hemoglobin is used (eg, the Masimo pulse CO-oximeter).

3. Circulation—Measure the pulse and blood pressure and estimate tissue perfusion (eg, by measurement of urinary output, skin signs, arterial blood pH). Place the patient on continuous ECG monitoring. Insert an intravenous line, and draw blood for glucose, electrolytes, serum creatinine and liver tests, and possible quantitative toxicologic testing.

4. Drugs

A. DEXTROSE AND THIAMINE—Unless promptly treated, severe hypoglycemia can cause irreversible brain damage. Therefore, in all obtunded, comatose or convulsing patients, give 50% dextrose, 50–100 mL by intravenous bolus, unless a rapid bedside blood sugar test is available and rules out hypoglycemia. In alcoholic or very malnourished patients who may have marginal thiamine stores, give thiamine, 100 mg intramuscularly or in the intravenous fluids.

B. OPIOID ANTAGONISTS—Naloxone, 0.4–2 mg intravenously, may reverse opioid-induced respiratory depression and coma. It is often given empirically to any comatose patient with depressed respirations. If opioid overdose is strongly suspected, give additional doses of naloxone (up to 5–10 mg may be required to reverse the effects of potent opioids). **Note:** Naloxone has a shorter duration of action (2–3 hours) than most common opioids; repeated doses may be required, and continuous observation for at least 3–4 hours after the last dose is mandatory. Nalmefene, a newer opioid antagonist, has a duration of effect longer than that of naloxone but still shorter than that of the opioid methadone.

C. FLUMAZENIL—Flumazenil, 0.2–0.5 mg intravenously, repeated as needed up to a maximum of 3 mg, may reverse benzodiazepine-induced coma. **Caution:** Flumazenil should **not** be given if the patient has coingested a tricyclic antidepressant or other potential convulsant, is a user of high-dose benzodiazepines, or has a seizure disorder because its use in these circumstances may precipitate seizures. *In most circumstances, use of flumazenil is not advised as the potential risks outweigh its benefits.* **Note:** Flumazenil has a short duration of effect (2–3 hours), and resedation requiring additional doses may occur.

HYPOTHERMIA

▶ Assessment & Complications

Hypothermia commonly accompanies coma due to opioids, ethanol, hypoglycemic agents, phenothiazines, barbiturates, benzodiazepines, and other sedative-hypnotics and central nervous system depressants. Hypothermic patients may have a barely perceptible pulse and blood pressure. Hypothermia may cause or aggravate hypotension, which will not reverse until the temperature is normalized.

▶ Treatment

Treatment of hypothermia is discussed in Chapter 37. Gradual rewarming is preferred unless the patient is in cardiac arrest.

HYPOTENSION

▶ Assessment & Complications

Hypotension may be due to poisoning by many different drugs and poisons, including antihypertensive drugs, β -blockers, calcium channel blockers, disulfiram (ethanol interaction), iron, trazodone, quetiapine, and other antipsychotic agents and antidepressants. Poisons causing hypotension include cyanide, carbon monoxide, hydrogen sulfide, aluminum phosphide, arsenic, and certain mushrooms.

Hypotension in the poisoned or drug-overdosed patient may be caused by venous or arteriolar vasodilation, hypovolemia, depressed cardiac contractility, or a combination of these effects.

▶ Treatment

Most hypotensive patients respond to empiric treatment with repeated 200 mL intravenous boluses of 0.9% saline or other isotonic crystalloid up to a total of 1–2 L; much larger amounts may be needed if the victim is profoundly volume depleted (eg, as with *Amanita phalloides* mushroom poisoning). Monitoring the central venous pressure (CVP) can help determine whether further fluid therapy is needed. If fluid therapy is not successful, give dopamine or norepinephrine by intravenous infusion. Consider bedside cardiac ultrasound or pulmonary artery catheterization (or both) if hypotension persists.

Hypotension caused by certain toxins may respond to specific treatment. For hypotension caused by overdoses of tricyclic antidepressants or other sodium channel blockers, administer sodium bicarbonate, 50–100 mEq by intravenous bolus injection. Norepinephrine 4–8 mcg/min by intravenous infusion is more effective than dopamine in some patients with overdoses of tricyclic antidepressants or of drugs with predominantly vasodilating effects. For β -blocker overdose, glucagon (5–10 mg intravenously) may be of value. For calcium channel blocker overdose, administer calcium chloride, 1–2 g intravenously (repeated doses may be necessary; doses of 5–10 g and more have been given in some cases). High-dose insulin (0.5–1 units/kg/h intravenously) euglycemic therapy may also be used (see the sections on β -Adrenergic Blockers and Calcium Channel Blockers, below). Intralipid 20% lipid emulsion

has been reported to improve hemodynamics in human case reports or animal studies of intoxication by highly lipid-soluble drugs such as bupivacaine, bupropion, clomipramine, and verapamil.

Jamaty C et al. Lipid emulsions in the treatment of acute poisoning: a systematic review of human and animal studies. *Clin Toxicol (Phila)*. 2010 Jan;48(1):1–27. [PMID: 20095812]

HYPERTENSION

► Assessment & Complications

Hypertension may be due to poisoning with amphetamines, anticholinergics, cocaine, performance-enhancing products (containing caffeine, phenylephrine, ephedrine, or yohimbine), monoamine oxidase (MAO) inhibitors, and other drugs.

Severe hypertension (eg, diastolic blood pressure > 105–110 mm Hg in a person who does not have chronic hypertension) can result in acute intracranial hemorrhage, myocardial infarction, or aortic dissection.

► Treatment

Treat hypertension if the patient is symptomatic or if the diastolic pressure is > 105–110 mm Hg—especially if there is no prior history of hypertension.

Hypertensive patients who are agitated or anxious may benefit from a sedative such as lorazepam, 2–3 mg intravenously. For persistent hypertension, administer phenolamine, 2–5 mg intravenously, or nitroprusside sodium, 0.25–8 mcg/kg/min intravenously. If excessive tachycardia is present, add propranolol, 1–5 mg intravenously, or esmolol, 25–100 mcg/kg/min intravenously, or labetalol 0.2–0.3 mg/kg intravenously. **Caution:** Do not give β -blockers alone, since doing so may paradoxically worsen hypertension as a result of unopposed α -adrenergic stimulation.

Wang NE et al. Hypertensive crisis and NSTEMI after accidental overdose of sustained release pseudoephedrine: a case report. *Clin Toxicol (Phila)*. 2008 Nov;46(9):922–3. [PMID: 18608273]

ARRHYTHMIAS

► Assessment & Complications

Arrhythmias may occur with a variety of drugs or toxins (Table 38–1). They may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkalemia, hypokalemia, hypomagnesemia or hypocalcemia), or following exposure to chlorinated solvents or chloral hydrate overdose. Atypical ventricular tachycardia (torsades de pointes) is often associated with drugs that prolong the QT interval.

► Treatment

Arrhythmias may be caused by hypoxia or electrolyte imbalance, and these conditions should be sought and treated. If

Table 38–1. Common toxins or drugs causing arrhythmias.¹

Arrhythmia	Common Causes
Sinus bradycardia	β -Blockers, calcium channel blockers, clonidine, digitalis glycosides, organophosphates
Atrioventricular block	β -Blockers, calcium channel blockers, class Ia antiarrhythmics (including quinidine), carbamazepine, clonidine, digitalis glycosides, lithium
Sinus tachycardia	β -Agonists (eg, albuterol), amphetamines, anticholinergics, antihistamines, caffeine, cocaine, pseudoephedrine, tricyclic and other antidepressants
Wide QRS complex	Class Ia and class Ic antiarrhythmics, phenothiazines (eg, thioridazine), potassium (hyperkalemia), propranolol, tricyclic antidepressants, bupropion, lamotrigine, diphenhydramine (severe overdose)
QT interval prolongation and torsades de pointes	Arsenic, class Ia and class III antiarrhythmics, citalopram, droperidol, lithium, methadone, pentamidine, sertraline, sotalol, thioridazine, and many other drugs ²
Ventricular premature beats and ventricular tachycardia	Amphetamines, cocaine, ephedrine, caffeine, chlorinated or fluorinated hydrocarbons, digoxin, aconite (found in some Chinese herbal preparations), fluoride, theophylline. QT prolongation can lead to atypical ventricular tachycardia (torsades de pointes)

¹Arrhythmias may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkalemia or hypokalemia, hypocalcemia, hypomagnesemia).

²<http://www.azcert.org/medical-pros/drug-lists/drug-lists.cfm>

ventricular arrhythmias persist, administer lidocaine or amiodarone at usual antiarrhythmic doses. **Note:** Wide QRS complex tachycardia in the setting of tricyclic antidepressant overdose (or diphenhydramine or class Ia antiarrhythmic drugs) should be treated with sodium bicarbonate, 50–100 mEq intravenously by bolus injection. (See discussion of tricyclic antidepressant poisoning.) **Caution:** Avoid class Ia antiarrhythmic agents (eg, procainamide, disopyramide), which may aggravate arrhythmias caused by tricyclic antidepressants. Torsades de pointes associated with prolonged QT interval may respond to intravenous magnesium (2 g intravenously over 2 minutes) or overdrive pacing. Treat digitalis-induced arrhythmias with digoxin-specific antibodies (see discussion of cardiac glycoside poisoning).

For tachyarrhythmias induced by chlorinated solvents, chloral hydrate, Freons, or sympathomimetic agents, use propranolol or esmolol (see doses given above in Hypertension section).

Barnes BJ et al. Drug-induced arrhythmias. *Crit Care Med*. 2010 Jun;38(6 Suppl):S188–97. [PMID: 20502173]

SEIZURES

► Assessment & Complications

Seizures may be due to poisoning with many poisons and drugs, including amphetamines, antidepressants (especially tricyclic antidepressants, bupropion, and venlafaxine), antihistamines (especially diphenhydramine), antipsychotics, camphor, cocaine, isoniazid (INH), chlorinated insecticides, and theophylline. Massive overdose with acetaminophen has caused seizures. The onset of seizures may be delayed for up to 22 hours after sustained-released bupropion overdose.

Seizures may also be caused by hypoxia, hypoglycemia, hypocalcemia, hyponatremia, withdrawal from alcohol or sedative-hypnotics, head trauma, central nervous system infection, or idiopathic epilepsy.

Prolonged or repeated seizures may lead to hypoxia, metabolic acidosis, hyperthermia, and rhabdomyolysis.

► Treatment

Administer lorazepam, 2–3 mg, or diazepam, 5–10 mg, intravenously over 1–2 minutes, or—if intravenous access is not immediately available—midazolam, 5–10 mg intramuscularly. If convulsions continue, administer phenobarbital, 15–20 mg/kg slowly intravenously over no less than 30 minutes. (For drug-induced seizures, phenobarbital is preferred over phenytoin.) Propofol infusion has also been reported effective for some resistant drug-induced seizures.

Seizures due to a few drugs and toxins may require antidotes or other specific therapies (as listed in Table 38–2).

Table 38–2. Seizures related to toxins or drugs requiring special consideration.¹

Toxin or Drug	Comments
Methylenedioxymethamphetamine (MDMA; “Ecstasy”)	Seizures may also be due to hyponatremia or hyperthermia.
Isoniazid	Administer pyridoxine.
Lithium	May indicate need for hemodialysis.
Organophosphates	Administer pralidoxime (2-PAM) and atropine in addition to usual anticonvulsants.
Strychnine	“Seizures” are actually spinally mediated muscle spasms and usually require neuromuscular paralysis and mechanical ventilation.
Theophylline	Seizures indicate need for hemodialysis.
Tricyclic antidepressants	Hyperthermia and cardiotoxicity are common complications of repeated seizures; paralyze early with neuromuscular blockers to reduce muscular hyperactivity.

¹See text for dosages.

 Young AC et al. Late-onset seizures associated with quetiapine poisoning. *J Med Toxicol*. 2009 Mar;5(1):24–6. [PMID: 19191211]

HYPERTHERMIA

► Assessment & Complications

Hyperthermia may be associated with poisoning by amphetamines (especially methylenedioxymethamphetamine [MDMA; “Ecstasy”]), atropine and other anti-cholinergic drugs, cocaine, salicylates, strychnine, tricyclic antidepressants, and various other medications. Overdoses of serotonin reuptake inhibitors (eg, fluoxetine, paroxetine, sertraline) or their use in a patient taking an MAO inhibitor may cause agitation, hyperactivity, myoclonus, and hyperthermia (“serotonin syndrome”). Antipsychotic agents can cause rigidity and hyperthermia (neuroleptic malignant syndrome [NMS]). (See section on schizophrenia and other psychotic disorders in Chapter 25.) Malignant hyperthermia is a rare disorder associated with general anesthetic agents.

Hyperthermia is a rapidly life-threatening complication. Severe hyperthermia (temperature > 40–41°C) can rapidly cause brain damage and multiorgan failure, including rhabdomyolysis, acute renal failure, and coagulopathy (see Chapter 37).

► Treatment

Treat hyperthermia aggressively by removing the patient’s clothing, spraying the skin with tepid water, and fanning. If this is not rapidly effective, as shown by a normal rectal temperature within 30–60 minutes, or if there is significant muscle rigidity or hyperactivity, induce neuromuscular paralysis with a nondepolarizing neuromuscular blocker (eg, rocuronium, vecuronium). Once paralyzed, the patient must be intubated and mechanically ventilated and sedated. While the patient is paralyzed, the absence of visible muscular convulsive movements may give the false impression that brain seizure activity has ceased; bedside electroencephalography may be useful in recognizing continued nonconvulsive seizures.

Dantrolene (2–5 mg/kg intravenously) may be effective for hyperthermia associated with muscle rigidity that does not respond to neuromuscular blockade (ie, malignant hyperthermia). Bromocriptine, 2.5–7.5 mg orally daily, has been recommended for neuroleptic malignant syndrome. Cyproheptadine, 4 mg orally every hour for three or four doses, or chlorpromazine, 25 mg intravenously or 50 mg intramuscularly, has been used to treat serotonin syndrome.

Ables AZ et al. Prevention, recognition, and management of serotonin syndrome. *Am Fam Physician*. 2010 May 1;81(9): 1139–42. [PMID: 20433130]
 Gallelli L et al. A case of neuroleptic malignant syndrome induced by risperidone in a schizophrenic woman. *Curr Drug Saf*. 2009 May;4(2):119–20. [PMID: 19442104]

ANTIDOTES & OTHER TREATMENT

ANTIDOTES

Give an antidote (if available) when there is reasonable certainty of a specific diagnosis (Table 38–3). Be aware that some antidotes themselves may have serious side effects. The indications and dosages for specific antidotes are discussed in the respective sections for specific toxins.

Dart RC et al; Antidote Summit Authorship Group. Expert consensus guidelines for stocking of antidotes in hospitals that provide emergency care. *Ann Emerg Med.* 2009;54(3):386–94. [PMID: 19406507]

DECONTAMINATION OF THE SKIN

Corrosive agents rapidly injure the skin and eyes and must be removed immediately. In addition, many toxins are readily absorbed through the skin, and systemic absorption can be prevented only by rapid action.

Wash the affected areas with copious quantities of lukewarm water or saline. Wash carefully behind the ears, under the nails, and in skin folds. For oily substances (eg, pesticides), wash the skin at least twice with plain soap and shampoo the hair. Specific decontaminating solutions or

solvents (eg, alcohol) are rarely indicated and in some cases may paradoxically enhance absorption. For exposure to chemical warfare poisons such as nerve agents or vesicants, some authorities recommend use of a dilute hypochlorite solution (household bleach diluted 1:10 with water), but not in the eyes.

DECONTAMINATION OF THE EYES

Act quickly to prevent serious damage. Flush the eyes with copious amounts of saline or water. (If available, instill local anesthetic drops in the eye before beginning irrigation.) Remove contact lenses if present. Direct the irrigating stream so that it will flow across the eyes after running off the nasal bridge. Lift the tarsal conjunctiva to look for undissolved particles and to facilitate irrigation. Continue irrigation for 15 minutes or until each eye has been irrigated with at least 1 L of solution. If the toxin is an acid or a base, check the pH of the tears after irrigation, and continue irrigation until the pH is between 6 and 8. Special amphoteric solutions (Diphoterine, Previn) have been introduced in Europe for treatment of alkali injuries to the eye.

After irrigation is complete, perform a careful examination of the eye, using fluorescein and a slit lamp or Wood lamp to identify areas of corneal injury. Patients with serious conjunctival or corneal injury should be immediately referred to an ophthalmologist.

Table 38–3. Some toxic agents for which there are specific antidotes.¹

Toxic Agent	Specific Antidote
Acetaminophen	<i>N</i> -Acetylcysteine
Anticholinergics (eg, atropine)	Physostigmine
Anticholinesterases (eg, organophosphate pesticides)	Atropine and pralidoxime (2-PAM)
Benzodiazepines	Flumazenil (rarely used; see warning in text)
Carbon monoxide	Oxygen (hyperbaric oxygen of uncertain benefit)
Cyanide	Sodium nitrite, sodium thiosulfate, hydroxocobalamin
Digitalis glycosides	Digoxin-specific Fab antibodies
Heavy metals (eg, lead, mercury, iron) and arsenic	Specific chelating agents
Isoniazid	Pyridoxine (vitamin B ₆)
Methanol, ethylene glycol	Ethanol (ethyl alcohol) or fomepizole (4-methylpyrazole)
Opioids	Naloxone, nalmefene
Snake venom	Specific antivenin
Sulfonylurea oral hypoglycemic drugs	Glucose, octreotide

¹See text for indications and dosages.

GASTROINTESTINAL DECONTAMINATION

Removal of ingested poisons was a routine part of emergency treatment for decades. However, prospective randomized studies have failed to demonstrate improved clinical outcome after gastric emptying. For small or moderate ingestions of most substances, toxicologists generally recommend oral activated charcoal alone without prior gastric emptying; in some cases, when the interval after ingestion has been more than 1–2 hours and the ingested is non–life-threatening, even charcoal is withheld. Exceptions are large ingestions of anticholinergic compounds and salicylates, which often delay gastric emptying, and ingestion of sustained-release or enteric-coated tablets, which may remain intact for several hours.

Gastric emptying is not generally used for ingestion of corrosive agents or petroleum distillates, because further esophageal injury or pulmonary aspiration may result. However, in certain cases, removal of the toxin may be more important than concern over possible complications. Consult a medical toxicologist or regional poison control center (1-800-222-1222) for advice.

A. Emesis

Emesis using syrup of ipecac can partially evacuate gastric contents if given very soon after ingestion (eg, at work or at home). However, it may increase the risk of pulmonary aspiration and delay or prevent the use of oral activated charcoal. Therefore, it is no longer used in the routine management of ingestions.

B. Gastric Lavage

Gastric lavage is more effective for liquid poisons or small pill fragments than for intact tablets or pieces of mushroom. It is most useful when started within 60 minutes after ingestion. However, the lavage procedure may delay administration of activated charcoal and may stimulate vomiting and pulmonary aspiration in an obtunded patient.

1. Indications—Gastric lavage is sometimes used after very large ingestions (eg, massive aspirin overdose), for collection and examination of gastric contents for identification of the poison, and make it easier to administer charcoal and oral antidotes.

2. Contraindications—Do *not* use lavage for stuporous or comatose patients with depressed airway protective reflexes unless they are endotracheally intubated beforehand. Some authorities advise against lavage when caustic material has been ingested; others regard it as essential to remove liquid corrosives from the stomach.

3. Technique—In obtunded or comatose patients, the danger of aspiration pneumonia is reduced by performing endotracheal intubation with a cuffed tube before the procedure. Gently insert a lubricated, soft but noncollapsible stomach tube (at least 37–40 F) through the mouth or nose into the stomach. Aspirate and save the contents, and then lavage repeatedly with 50- to 100-mL aliquots of fluid until the return fluid is clear. Use lukewarm tap water or saline.

C. Activated Charcoal

Activated charcoal effectively adsorbs almost all drugs and poisons. Poorly adsorbed substances include iron, lithium, potassium, sodium, mineral acids, and alcohols.

1. Indications—Activated charcoal can be used for prompt adsorption of drugs or toxins in the stomach and intestine. Studies in volunteers show that activated charcoal given alone may be as effective as, or more effective, than ipecac-induced emesis or gastric lavage. However, evidence of benefit in clinical studies is lacking. Administration of charcoal, especially if mixed with sorbitol, can provoke vomiting, which could lead to pulmonary aspiration in an obtunded patient.

2. Contraindications—Activated charcoal should not be used for comatose or convulsing patients unless it can be given by gastric tube and the airway is first protected by a cuffed endotracheal tube. It is also contraindicated for patients with ileus or intestinal obstruction or those who have ingested corrosives for whom endoscopy is planned.

3. Technique—Administer activated charcoal, 60–100 g orally or via gastric tube, mixed in aqueous slurry. Repeated doses may be given to ensure gastrointestinal adsorption or to enhance elimination of some drugs (see below).

D. Catharsis

1. Indications—Cathartics are used by some toxicologists for stimulation of peristalsis to hasten the elimination of unabsorbed drugs and poisons and the activated charcoal

slurry. There is no clinical evidence to support their use, and some agents (eg, sorbitol) can provoke vomiting, increasing the risk of pulmonary aspiration.

2. Contraindications and cautions—Do not give a cathartic to patients with suspected intestinal obstruction. Avoid sodium-based cathartics in patients with hypertension, advanced chronic kidney disease, and congestive heart failure and avoid magnesium-based cathartics in patients with advanced chronic kidney disease. Sorbitol (an osmotic cathartic found in some prepackaged activated charcoal slurry products) can cause hypotension and dehydration due to third-spacing and also causes intestinal cramping and vomiting.

E. Whole Bowel Irrigation

Whole bowel irrigation uses large volumes of a balanced polyethylene glycol-electrolyte solution to mechanically cleanse the entire intestinal tract. Because of the composition of the irrigating solution, there is no significant gain or loss of systemic fluids or electrolytes.

1. Indications—Whole bowel irrigation is particularly effective for massive iron ingestion in which intact tablets are visible on abdominal radiographs. It has also been used for ingestions of lithium, sustained-release and enteric-coated tablets, and swallowed drug-filled packets.

2. Contraindications—Do not use in patients with suspected intestinal obstruction. Use with caution in patients who are obtunded or have depressed airway protective reflexes.

3. Technique—Administer a balanced polyethylene glycol-electrolyte solution (CoLyte, GoLYTELY) into the stomach via gastric tube at a rate of 1–2 L/h until the rectal effluent is clear. This may take several hours. It is most effective when patients are able to sit on a commode to pass the intestinal contents.

F. Increased Drug Removal

1. Urinary manipulation—Forced diuresis is hazardous; the risk of complications (pulmonary edema, electrolyte imbalance) usually outweighs its benefits. Acidic drugs (eg, salicylates, phenobarbital) are more rapidly excreted with an alkaline urine. Acidification (sometimes promoted for amphetamines, phencyclidine) is *not* very effective and is contraindicated in the presence of rhabdomyolysis or myoglobinuria.

2. Hemodialysis—The indications for dialysis are as follows: (1) Known or suspected potentially lethal amounts of a dialyzable drug (Table 38–4); (2) Poisoning with deep coma, apnea, severe hypotension, fluid and electrolyte or acid-base disturbance, or extreme body temperature changes that cannot be corrected by conventional measures; or (3) Poisoning in patients with severe kidney, cardiac, pulmonary, or hepatic disease who will not be able to eliminate toxin by the usual mechanisms.

Continuous renal replacement therapy (also known as continuous venovenous hemodiafiltration or venovenous hemodiafiltration) is of uncertain benefit for elimination

Table 38-4. Recommended use of hemodialysis in poisoning.

Poison	Common Indications ¹
Carbamazepine	Seizures, severe cardiotoxicity; serum level > 60 mg/L
Ethylene glycol	Acidosis, serum level > 50 mg/dL
Lithium	Severe symptoms; level > 4 mEq/L more than 12 hours after last dose. Note: dialysis of uncertain value; CVVHD may be preferable; consult with medical toxicologist.
Methanol	Acidosis, serum level > 50 mg/dL
Phenobarbital	Intractable hypotension, acidosis despite maximal supportive care
Salicylate	Severe acidosis, CNS symptoms, level > 100 mg/dL (acute overdose) or > 60 mg/dL (chronic intoxication)
Theophylline	Serum level > 90–100 mg/L (acute) or seizures and serum level > 40–60 mg/L (chronic)
Valproic acid	Serum level > 900–1000 mg/L or deep coma, severe acidosis

¹See text for further discussion of indications.

CNS, central nervous system; CVVHD, continuous venovenous hemodialysis.

of most poisons but has the advantage of slow removal of the toxin and any accompanying acidosis, and its use has been reported in the management of lithium intoxication.

3. Repeat-dose charcoal—Repeated doses of activated charcoal, 20–30 g orally or via gastric tube every 3–4 hours, may hasten elimination of some drugs (eg, phenytoin, carbamazepine, dapsone) by absorbing drugs excreted into the gut lumen (“gut dialysis”). However, clinical studies have failed to prove better outcome using multiple-dose charcoal. Sorbitol or other cathartics should *not* be used with each dose, or resulting large stool volumes may lead to dehydration or hypernatremia.

DIAGNOSIS OF POISONING

The identity of the ingested substance or substances is usually known, but occasionally a comatose patient is found with an unlabeled container or the patient is unable or unwilling to give a coherent history. By performing a

directed physical examination and ordering common clinical laboratory tests, the clinician can often make a tentative diagnosis that may allow empiric interventions or may suggest specific toxicologic tests.

► Physical Examination

Important diagnostic variables in the physical examination include blood pressure, pulse rate, temperature, pupil size, sweating, and the presence or absence of peristaltic activity. Poisonings may present with one or more of the following common syndromes.

A. Sympathomimetic Syndrome

The blood pressure and pulse rate are elevated, though with severe hypertension reflex bradycardia may occur. The temperature is often elevated, pupils are dilated, and the skin is sweaty, though mucous membranes are dry. Patients are usually agitated, anxious, or frankly psychotic.

Examples: Amphetamines, cocaine, ephedrine and pseudoephedrine.

B. Sympatholytic Syndrome

The blood pressure and pulse rate are decreased and body temperature is low. The pupils are small or even pinpoint. Patients are usually obtunded or comatose.

Examples: Barbiturates, benzodiazepines and other sedative hypnotics, γ -hydroxybutyrate (GHB), clonidine and related antihypertensives, ethanol, opioids.

C. Cholinergic Syndrome

Stimulation of muscarinic receptors causes bradycardia, miosis, sweating, and hyperperistalsis as well as bronchorrhea, wheezing, excessive salivation, and urinary incontinence. Nicotinic receptor stimulation may produce initial hypertension and tachycardia as well as fasciculations and muscle weakness. Patients are usually agitated and anxious.

Examples: Carbamates, nicotine, organophosphates (including nerve agents), physostigmine.

D. Anticholinergic Syndrome

Tachycardia with mild hypertension is common, and the body temperature is often elevated. Pupils are widely dilated. The skin is flushed, hot, and dry. Peristalsis is decreased, and urinary retention is common. Patients may have myoclonic jerking or choreoathetoid movements. Agitated delirium is frequently seen, and severe hyperthermia may occur.

Examples: Atropine, scopolamine, other naturally occurring and pharmaceutical anticholinergics, antihistamines, tricyclic antidepressants.

► Laboratory Tests

The following clinical laboratory tests are recommended for screening of the overdosed patient: measured serum osmolality and osmol gap, electrolytes and anion gap, glucose, creatinine, blood urea nitrogen (BUN), urinalysis (eg, oxalate crystals with ethylene glycol poisoning,

myoglobinuria with rhabdomyolysis), and electrocardiography. Serum acetaminophen and ethanol quantitative levels should be determined in all patients with drug overdoses.

A. Osmol Gap

The osmol gap (see Table 38–5) is increased in the presence of large quantities of low-molecular-weight substances, most commonly ethanol. Common poisons associated with increased osmol gap are acetone, ethanol, ethylene glycol, isopropyl alcohol, methanol, and propylene glycol. **Note:** Severe alcoholic ketoacidosis and diabetic ketoacidosis can also cause an elevated osmol gap resulting from the production of ketones and other low-molecular-weight substances.

B. Anion Gap

Metabolic acidosis associated with an elevated anion gap is usually due to an accumulation of lactic acid or other acids (see Chapter 21). Common causes of elevated anion gap in poisoning include carbon monoxide, cyanide, ethylene glycol, medicinal iron, INH, methanol, metformin, ibuprofen and salicylates. Massive acetaminophen overdose can cause early-onset anion gap metabolic acidosis.

Table 38–5. Use of the osmol gap in toxicology.

The osmol gap (Δosm) is determined by subtracting the calculated serum osmolality from the measured serum osmolality.			
$\text{Calculated osmolality (osm)} = 2[\text{Na}^+ \text{ (mEq/L)}] + \frac{\text{Glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8}$			
$\Delta\text{osm} = \text{Measured osmolality} - \text{Calculated osmolality}$			
Serum osmolality may be increased by contributions of circulating alcohols and other low-molecular-weight substances. Since these substances are not included in the calculated osmolality, there will be a gap proportionate to their serum concentration and inversely proportionate to their molecular weight:			
$\text{Serum concentration (mg/dL)} = \Delta\text{osm} \times \frac{\text{Molecular weight}}{10}$			
	Molecular Weight	Toxic Concentration	Approximate Corresponding Δosm (mosm/L)
Ethanol	46	300	65
Methanol	32	50	16
Ethylene glycol	60	100	16
Isopropanol	60	150	25

Note: The normal osmol gap may vary by as much as ± 10 mosm/L; thus, small osmol gaps may be unreliable in the diagnosis of poisoning.

Adapted, with permission, from Stone CK, Humphries RL (editors): *Current Emergency Diagnosis & Treatment*, 5th ed. McGraw-Hill, 2004.

The osmol gap should also be checked; combined elevated anion and osmol gaps suggests poisoning by methanol or ethylene glycol, though this may also occur in patients with diabetic ketoacidosis and alcoholic ketoacidosis.

C. Toxicology Laboratory Testing

A comprehensive toxicology screen is of little value in the initial care of the poisoned patient because results do not return in time to influence clinical management. Specific quantitative levels of certain drugs may be extremely helpful (Table 38–6) however, especially if specific antidotes or interventions (eg, dialysis) would be indicated based on the results.

If a toxicology screen is required, urine is the best specimen. Many hospitals can perform a quick but limited screen for “drugs of abuse” (typically these screens include

Table 38–6. Specific quantitative levels and potential therapeutic interventions.¹

Drug or Toxin	Treatment
Acetaminophen	Specific antidote (<i>N</i> -acetylcysteine) based on serum level
Carbon monoxide	High carboxyhemoglobin level indicates need for 100% oxygen, consideration of hyperbaric oxygen
Carbamazepine	High level may indicate need for hemodialysis
Digoxin	On basis of serum digoxin level and severity of clinical presentation, treatment with Fab antibody fragments (eg, Digifab) may be indicated
Ethanol	Low serum level may suggest nonalcoholic cause of coma (eg, trauma, other drugs, other alcohols). Serum ethanol may also be useful in monitoring ethanol therapy for methanol or ethylene glycol poisoning.
Iron	Level may indicate need for chelation with deferoxamine
Lithium	Serum levels can guide decision to institute hemodialysis
Methanol, ethylene glycol	Acidosis, high levels indicate need for hemodialysis, therapy with ethanol or fomepizole
Methemoglobin	Methemoglobinemia can be treated with methylene blue intravenously
Salicylates	High level may indicate need for hemodialysis, alkaline diuresis
Theophylline	Immediate hemodialysis or hemoperfusion may be indicated based on serum level
Valproic acid	Elevated levels may indicate need to consider hemodialysis or L-carnitine therapy, or both

¹Some drugs or toxins may have profound and irreversible toxicity unless rapid and specific management is provided outside of routine supportive care. For these agents, laboratory testing may provide the serum level or other evidence required for administering a specific antidote or arranging for hemodialysis.

only opiates, amphetamines, and cocaine, and some add benzodiazepines, barbiturates, methadone, and tetrahydrocannabinol [marijuana]). There are numerous false-positive and false-negative results. For example, synthetic opioids, such as fentanyl, oxycodone, and methadone are usually not detected by routine opiate screening. Blood samples may be saved for possible quantitative testing, but blood is not generally used for screening purposes since it is relatively insensitive for many common drugs, including psychotropic agents, opioids, and stimulants.

▶ Abdominal Radiographs

A plain film of the abdomen may reveal radiopaque iron tablets, drug-filled condoms, or other toxic material. Studies suggest that few tablets are predictably visible (eg, ferrous sulfate, sodium chloride, calcium carbonate, and potassium chloride). Thus, the radiograph is useful only if abnormal.

▶ When to Refer

Consultation with a regional poison control center (1-800-222-1222) or a medical toxicologist is recommended when the diagnosis is uncertain; there are questions about what laboratory tests to order; when dialysis is being considered to remove the drug or poison; or when advice is needed regarding the indications, dose, and side effects of antidotes.

▶ When to Admit

- The patient has symptoms and signs of intoxication that are not expected to clear within a 6–8 hour observation period.
- Delayed absorption of the drug might be predicted to cause a later onset of serious symptoms (eg, after ingestion of a sustained-release product).
- Continued administration of an antidote is required (eg, *N*-acetylcysteine for acetaminophen overdose).
- Psychiatric or social services evaluation is needed for suicide attempt or suspected drug abuse.

Goldfrank LR (editor). *Goldfrank's Toxicologic Emergencies*, 9th ed. McGraw-Hill, 2010.

Olson KR (editor). *Poisoning & Drug Overdose*, 6th ed. McGraw-Hill, 2011.

SELECTED POISONINGS

ACETAMINOPHEN

Acetaminophen (paracetamol in the United Kingdom, Europe) is a common analgesic found in many nonprescription and prescription products. After absorption, it is metabolized mainly by glucuronidation and sulfation, with a small fraction metabolized via the P450 mixed-function oxidase system (2E1) to a highly toxic reactive intermediate. This toxic intermediate is normally detoxified by cellular glutathione. With acute acetaminophen overdose (> 150–200 mg/kg, or 8–10 g in an average adult), hepatocellular glutathione is depleted and the reactive

intermediate attacks other cell proteins, causing necrosis. Patients with enhanced P450 2E1 activity, such as chronic alcoholics and patients taking INH, are at increased risk of developing hepatotoxicity. Hepatic toxicity may also occur after long-term overuse of acetaminophen—eg, as a result of taking two or three acetaminophen-containing products concurrently or exceeding the recommended maximum dose of 4 g/d for several days.

▶ Clinical Findings

Shortly after ingestion, patients may have nausea or vomiting, but there are usually no other signs of toxicity until 24–48 hours after ingestion, when hepatic aminotransferase levels begin to increase. With severe poisoning, fulminant hepatic necrosis may occur, resulting in jaundice, hepatic encephalopathy, advanced chronic kidney disease, and death. Rarely, massive ingestion (eg, serum levels > 500–1000 mg/L [33–66 mmol/L]) can cause early onset of acute coma, seizures, hypotension, and metabolic acidosis unrelated to hepatic injury.

The diagnosis after acute overdose is based on measurement of the serum acetaminophen level. Plot the serum level versus the time since ingestion on the acetaminophen nomogram shown in Figure 38–1. Ingestion of sustained-release products or coingestion of an anticholinergic agent,

▲ **Figure 38–1.** Nomogram for prediction of acetaminophen hepatotoxicity following acute overdosage. The upper line defines serum acetaminophen concentrations associated with a risk of hepatotoxicity; the lower line defines serum levels 25% below those expected to cause hepatotoxicity. In uncomplicated cases, the upper line can be used as an indication for therapy with *N*-acetylcysteine. However, to provide a margin for error in the estimation of the time of ingestion and for patients at higher risk for hepatotoxicity, the lower line is usually used as a guide to treatment. (Adapted, with permission, from Rumack BH et al. Acetaminophen poisoning and toxicity. *Pediatrics*. 1975 Jun;55(6):871–6.)

salicylate, or opioid drug may cause delayed elevation of serum levels and may render the nomogram useless. The nomogram is also not useful after chronic overdose.

► Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p 1567) if it can be given within 1–2 hours of the ingestion. Although charcoal may interfere with absorption of the oral antidote acetylcysteine, this is not considered clinically significant.

B. Specific Treatment

Although the risk is greatest if the serum acetaminophen level is above the upper line on the nomogram (Figure 38–1), many clinicians and published guidelines prefer to use the lower line as a guide to treatment, as it provides an added safety margin. If the precise time of ingestion is unknown or if the patient is at higher risk for hepatotoxicity (eg, alcoholic, liver disease, long-term use of P450-inducing drugs), then some clinicians use a lower threshold for initiation of *N*-acetylcysteine (in some case reports, a level of 100 mg/L [66 mmol/L] at 4 hours was suggested in very high-risk patients).

The antidote *N*-acetylcysteine can be given orally or intravenously. Oral treatment begins with a loading dose of *N*-acetylcysteine, 140 mg/kg, followed by 70 mg/kg every 4 hours. Dilute the solution to about 5% with water, juice, or soda. If vomiting interferes with oral *N*-acetylcysteine administration, consider giving the antidote intravenously (see below). The conventional oral *N*-acetylcysteine protocol in the United States calls for 72 hours of treatment. However, other regimens have demonstrated equivalent success with 20–48 hours of treatment.

The FDA-approved 21-hour intravenous regimen of acetylcysteine (Acetadote) calls for a loading dose of 150 mg/kg given intravenously over 60 minutes, followed by a 4-hour infusion of 50 mg/kg, and a 16-hour infusion of 100 mg/kg. (If Acetadote is not available, the conventional oral formulation may also be given intravenously using a micropore filter and a slow rate of infusion. Call a regional poison control center or medical toxicologist for assistance.)

Treatment with *N*-acetylcysteine is most effective if it is started within 8–10 hours after ingestion.

ACIDS, CORROSIVE

The strong mineral acids exert primarily a local corrosive effect on the skin and mucous membranes. Symptoms include severe pain in the throat and upper gastrointestinal

tract; bloody vomitus; difficulty in swallowing, breathing, and speaking; discoloration and destruction of skin and mucous membranes in and around the mouth; and shock. Severe systemic metabolic acidosis may occur both as a result of cellular injury and from systemic absorption of the acid.

Severe deep destructive tissue damage may occur after exposure to hydrofluoric acid because of the penetrating and highly toxic fluoride ion. Systemic hypocalcemia and hyperkalemia may also occur after fluoride absorption, even following skin exposure.

Inhalation of volatile acids, fumes, or gases such as chlorine, fluorine, bromine, or iodine causes severe irritation of the throat and larynx and may cause upper airway obstruction and noncardiogenic pulmonary edema.

► Treatment

A. Ingestion

Dilute immediately by giving a glass (4–8 oz) of water to drink. Do *not* give bicarbonate or other neutralizing agents, and do *not* induce vomiting. Some experts recommend immediate cautious placement of a small flexible gastric tube and removal of stomach contents followed by lavage, particularly if the corrosive is a liquid or has important systemic toxicity.

In symptomatic patients, perform flexible endoscopic esophagoscopy to determine the presence and extent of injury. CT scan or plain radiographs of the chest and abdomen may also reveal the extent of injury. Perforation, peritonitis, and major bleeding are indications for surgery.

B. Skin Contact

Flood with water for 15 minutes. Use no chemical antidotes; the heat of the reaction may cause additional injury.

For hydrofluoric acid burns, soak the affected area in benzalkonium chloride solution or apply 2.5% calcium gluconate gel (prepared by adding 3.5 g calcium gluconate to 5 oz of water-soluble surgical lubricant, eg, K-Y Jelly); then arrange immediate consultation with a plastic surgeon or other specialist. Binding of the fluoride ion may be achieved by injecting 0.5 mL of 5% calcium gluconate per square centimeter under the burned area. (**Caution:** Do *not* use *calcium chloride*.) Use of a Bier-block technique or intra-arterial infusion of calcium is sometimes required for extensive burns or those involving the nail bed; consult with a hand surgeon or poison control center (1-800-222-1222).

C. Eye Contact

Anesthetize the conjunctiva and corneal surfaces with topical local anesthetic drops (eg, proparacaine). Flood with water for 15 minutes, holding the eyelids open. Check pH with pH 6.0–8.0 test paper, and repeat irrigation, using 0.9% saline, until pH is near 7.0. Check for corneal damage with fluorescein and slit lamp examination; consult an ophthalmologist about further treatment.

D. Inhalation

Remove from further exposure to fumes or gas. Check skin and clothing. Treat pulmonary edema.

Donoghue AM. Diphoterine for alkali chemical splashes to the skin at alumina refineries. *Int J Dermatol*. 2010 Aug;49(8):894–900. [PMID: 21174372]

Pace F et al. What is new in esophageal injury (infection, drug-induced, caustic, stricture, perforation)? *Curr Opin Gastroenterol*. 2009 Jul;25(4):372–9. [PMID: 19530274]

Schmidt SM et al. Corneal injury due to a calcium hydroxide containing food preparation product (“cal”). *Pediatr Emerg Care*. 2008 Jul;24(7):468–70. [PMID: 18633308]

ALKALIES

The strong alkalis are common ingredients of some household cleaning compounds and may be suspected by their “soapy” texture. Those with alkalinity above pH 12.0 are particularly corrosive. Disk (or “button”) batteries are also a source. Alkalis cause liquefactive necrosis, which is deeply penetrating. Symptoms include burning pain in the upper gastrointestinal tract, nausea, vomiting, and difficulty in swallowing and breathing. Examination reveals destruction and edema of the affected skin and mucous membranes and bloody vomitus and stools. Radiographs may reveal evidence of perforation or the presence of radiopaque disk batteries in the esophagus or lower gastrointestinal tract.

► Treatment

A. Ingestion

Dilute immediately with a glass of water. Do *not* induce emesis. Some gastroenterologists recommend immediate cautious placement of a small flexible gastric tube and removal of stomach contents followed by gastric lavage after ingestion of liquid caustic substances to remove residual material.

Prompt endoscopy is recommended in symptomatic patients to evaluate the extent of damage; CT scanning may also aid in assessment. If a radiograph reveals the location of ingested disk batteries in the esophagus, immediate endoscopic removal is mandatory.

The use of corticosteroids to prevent stricture formation is of no proved benefit and is definitely contraindicated if there is evidence of esophageal perforation.

B. Skin Contact

Wash with running water until the skin no longer feels soapy. Relieve pain and treat shock.

C. Eye Contact

Anesthetize the conjunctival and corneal surfaces with topical anesthetic (eg, proparacaine). Irrigate with water or saline continuously for 20–30 minutes, holding the lids open. Amphoteric solutions may be more effective than water or saline and some are available in Europe (Diphoterine, Previn). Check pH with pH test paper, and repeat irrigation for additional 30-minute periods until the pH is near 7.0. Check for corneal damage with fluorescein and slit lamp examination; consult an ophthalmologist for further treatment.

AMPHETAMINES & COCAINE

Amphetamines and cocaine are widely abused for their euphorogenic and stimulant properties. Both drugs may be smoked, snorted, ingested, or injected. Amphetamines and cocaine produce central nervous system stimulation and a generalized increase in central and peripheral sympathetic activity. The toxic dose of each drug is highly variable and depends on the route of administration and individual tolerance. The onset of effects is most rapid after intravenous injection or smoking. Amphetamine derivatives and related drugs include methamphetamine (“crystal meth,” “crank”), MDMA (“Ecstasy”), ephedrine (“herbal ecstasy”), and methcathinone (“cat” or “khat”). Methcathinone derivatives and related synthetic chemicals such as methylenedioxypropylvalerone (MDPV) have become popular drugs of abuse and are often sold as purported “bath salts.” Amphetamine-like reactions have also been reported after use of synthetic cannabinoids (eg, “Spice” and “K2”). Nonprescription medications and nutritional supplements may contain stimulant or sympathomimetic drugs such as ephedrine, yohimbine, or caffeine (see also Theophylline section).

► Clinical Findings

Presenting symptoms may include anxiety, tremulousness, tachycardia, hypertension, diaphoresis, dilated pupils, agitation, muscular hyperactivity, and psychosis. Muscle hyperactivity may lead to metabolic acidosis and rhabdomyolysis. In severe intoxication, seizures and hyperthermia may occur. Sustained or severe hypertension may result in intracranial hemorrhage, aortic dissection, or myocardial infarction. Ischemic colitis has been reported. Hyponatremia has been reported after MDMA use; the mechanism is not known but may involve excessive water intake, syndrome of inappropriate antidiuretic hormone (SIADH), or both.

The diagnosis is supported by finding amphetamines or the cocaine metabolite benzoylecgonine in the urine. Note that many drugs can give a false-positive result on the immunoassay for amphetamines.

► Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Treat seizures as described at the beginning of this chapter (see p 1565). Rapidly lower the body temperature (see hyperthermia, p 1565) in patients who are hyperthermic (temperature > 39–40°C).

B. Specific Treatment

Treat agitation, psychosis, or seizures with a benzodiazepine such as diazepam, 5–10 mg, or lorazepam, 2–3 mg intravenously. Add phenobarbital 15 mg/kg intravenously for persistent seizures. Treat hypertension with a vasodilator drug such as phentolamine (1–5 mg intravenously) or a combined α - and β -adrenergic blocker such as labetalol (10–20 mg intravenously). Do *not* administer a pure β -blocker such as propranolol alone, as this may result in paradoxical worsening of the hypertension as a result of unopposed α -adrenergic effects.

Treat tachycardia or tachyarrhythmias with a short-acting β -blocker such as esmolol (25–100 mcg/kg/min by intravenous infusion). Treat hyperthermia as described above (see p 1565). Treat hyponatremia as outlined in Chapter 21.

ANTICOAGULANTS

Warfarin and related compounds (including ingredients of many commercial rodenticides) inhibit the clotting mechanism by blocking hepatic synthesis of vitamin K-dependent clotting factors.

Anticoagulants may cause hemoptysis, gross hematuria, bloody stools, hemorrhages into organs, widespread bruising, and bleeding into joint spaces. The prothrombin time is increased within 12–24 hours (peak 36–48 hours) after a single overdose. After ingestion of brodifacoum, difenacoum, and related rodenticides (so-called “superwarfarins”), inhibition of clotting factor synthesis may persist for several weeks or even months after a single dose.

► Treatment

A. Emergency and Supportive Measures

Discontinue the drug at the first sign of gross bleeding, and determine the prothrombin time (international normalized ratio, INR). If the patient has ingested an acute overdose, administer activated charcoal (see p 1567).

B. Specific Treatment

Do *not* treat prophylactically with vitamin K—wait for evidence of anticoagulation (elevated prothrombin time). If the INR is elevated, give phytonadione (vitamin K₁), 10–25 mg orally, and increase the dose as needed to restore the prothrombin time to normal. Doses as high as 200 mg/d have been required after ingestion of “superwarfarins.” Give

fresh-frozen plasma, prothrombin complex concentrate, or activated Factor VII as needed to rapidly correct the coagulation factor deficit if there is serious bleeding. If the patient is chronically anticoagulated and has strong medical indications for being maintained in that status (eg, prosthetic heart valve), give much smaller doses of vitamin K (1 mg orally) and fresh-frozen plasma (or both) to titrate to the desired prothrombin time.

If the patient has ingested brodifacoum or a related superwarfarin, prolonged observation (over weeks) and repeated administration of large doses of vitamin K may be required.

Gunja N et al. Management of intentional superwarfarin poisoning with long-term vitamin K and brodifacoum levels. *Clin Toxicol (Phila)*. 2011 Jun;49(5):385–90. [PMID: 21740137]

ANTICONSULSANTS

Anticonvulsants (carbamazepine, phenytoin, valproic acid, and many newer agents) are widely used in the management of seizure disorders and some are also used for treatment of mood disorders or pain.

Phenytoin can be given orally or intravenously. Rapid intravenous injection of phenytoin can cause acute myocardial depression and cardiac arrest owing to the solvent propylene glycol (fosphenytoin does not contain this diluent). Chronic phenytoin intoxication can occur following only slightly increased doses because of zero-order kinetics and a small toxic-therapeutic window. Phenytoin intoxication can also occur following acute intentional or accidental overdose. The overdose syndrome is usually mild even with high serum levels. The most common manifestations are ataxia, nystagmus, and drowsiness. Choreoathetoid movements have been described.

Carbamazepine is used for treatment of trigeminal neuralgia, temporal lobe epilepsy, and other seizure disorders. Intoxication causes drowsiness, stupor and, with high levels, atrioventricular block, coma, and seizures. Dilated pupils and tachycardia are common. Toxicity may be seen with serum levels > 20 mg/L (85 mcmol/L), though severe poisoning is usually associated with concentrations > 30–40 mg/L (127–169 mcmol/L). Because of erratic and slow absorption, intoxication may progress over several hours to days.

Valproic acid intoxication produces a unique syndrome consisting of hypernatremia (from the sodium component of the salt), metabolic acidosis, hypocalcemia, elevated serum ammonia, and mild liver aminotransferase elevation. Hypoglycemia may occur as a result of hepatic metabolic dysfunction. Coma with small pupils may be seen and can mimic opioid poisoning. Encephalopathy and cerebral edema can occur.

The newer anticonvulsants **gabapentin**, **levetiracetam**, **vigabatrin**, and **zonisamide** generally cause somnolence, confusion and dizziness; **felbamate** can cause crystalluria

and kidney dysfunction after overdose, and may cause idiosyncratic aplastic anemia with therapeutic use; **lamotrigine**, **topiramate**, and **tiagabine** have been reported to cause seizures after overdose.

► Treatment

A. Emergency and Supportive Measures

For recent ingestions, give activated charcoal orally or by gastric tube (see p 1567). For large ingestions of carbamazepine or valproic acid—especially of sustained-release formulations—consider whole bowel irrigation (see p 1567). Multiple-dose activated charcoal and whole-bowel irrigation may be beneficial in ensuring gut decontamination for selected large ingestions.

B. Specific Treatment

There are no specific antidotes. Naloxone was reported to have reversed valproic acid overdose in one anecdotal case. Carnitine may be useful in patients with valproic acid-induced hyperammonemia. Consider hemodialysis for massive intoxication with valproic acid or carbamazepine (eg, carbamazepine levels > 60 mg/L [254 μmol/L] or valproic acid levels > 800 mg/L [5544 μmol/L]).

ANTIPSYCHOTIC DRUGS

Promethazine, prochlorperazine, chlorpromazine, haloperidol, droperidol, risperidone, olanzapine, ziprasidone, quetiapine, and aripiprazole are used as antipsychotic agents, and sometimes as antiemetics and potentiators of analgesic and hypnotic drugs.

Phenothiazines (particularly chlorpromazine) induce drowsiness and mild orthostatic hypotension in as many as 50% of patients. Larger doses can cause obtundation, miosis, severe hypotension, tachycardia, convulsions, and coma. Abnormal cardiac conduction may occur, resulting in prolongation of QRS or QT intervals (or both) and ventricular arrhythmias. Among the newer agents, quetiapine is more likely to cause coma and hypotension.

With therapeutic or toxic doses, an acute extrapyramidal dystonic reaction may develop in some patients, with spasmodic contractions of the face and neck muscles, extensor rigidity of the back muscles, carpopedal spasm, and motor restlessness. This reaction is more common with haloperidol and other butyrophenones and less common with newer atypical antipsychotics such as ziprasidone, olanzapine, aripiprazole, and quetiapine. Severe rigidity accompanied by hyperthermia and metabolic acidosis (“neuroleptic malignant syndrome”) may occasionally occur and is life-threatening (see Chapter 25).

► Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p 1567) for large or recent ingestions. For severe hypotension, treatment with intravenous fluids and vasopressor agents may be necessary. Treat hyperthermia as outlined on p 1565. Maintain cardiac monitoring.

B. Specific Treatment

Hypotension and cardiac arrhythmias associated with widened QRS intervals on the ECG in a patient with thioridazine poisoning may respond to intravenous sodium bicarbonate as used for tricyclic antidepressants. Prolongation of the QT interval and torsades de pointes is usually treated with intravenous magnesium or overdrive pacing.

For extrapyramidal signs, give diphenhydramine, 0.5–1 mg/kg intravenously, or benztropine mesylate, 0.01–0.02 mg/kg intramuscularly. Treatment with oral doses of these agents should be continued for 24–48 hours.

Bromocriptine (2.5–7.5 mg orally daily) may be effective for mild or moderate neuroleptic malignant syndrome. Dantrolene (2–5 mg/kg intravenously) has also been used for muscle rigidity but is not a true antidote. For severe hyperthermia, rapid neuromuscular paralysis (see p 1565) is preferred.

ARSENIC

Arsenic is found in some pesticides and industrial chemicals, and arsenic trioxide has recently been reintroduced as a chemotherapeutic agent. A massive epidemic of chronic arsenic poisoning has occurred in Bangladesh due to naturally occurring arsenic in deep aquifers used for drinking water. Symptoms of acute poisoning usually appear within 1 hour after ingestion but may be delayed as long as 12 hours. They include abdominal pain, vomiting, watery diarrhea, and skeletal muscle cramps. Profound dehydration and shock may occur. In chronic poisoning, symptoms can be vague but often include pancytopenia, painful peripheral sensory neuropathy, and skin changes including melanosis, keratosis, and desquamating rash. Urinary arsenic levels may be falsely elevated after certain meals (eg, seafood) that contain large quantities of a nontoxic form of organic arsenic.

► Treatment

A. Emergency Measures

After recent ingestion (within 1–2 hours), perform gastric lavage. Activated charcoal is of uncertain benefit because it

binds arsenic poorly. Administer intravenous fluids to replace losses due to vomiting and diarrhea.

B. Antidote

For patients with severe acute intoxication, give dimercaprol injection (British anti-Lewisite, BAL), 10% solution in oil, 3–5 mg/kg intramuscularly every 4–6 hours for 2 days. The side effects include nausea, vomiting, headache, and hypertension. Follow dimercaprol with oral succimer (dimercaptosuccinic acid, DMSA), 10 mg/kg every 8 hours, for 1 week. Consult a medical toxicologist or regional poison control center (1-800-222-1222) for advice regarding chelation.

Rahman MM et al. Chronic exposure of arsenic via drinking water and its adverse health impacts on humans. *Environ Geochem Health.* 2009 Apr;31(Suppl 1):189–200. [PMID: 19190988]

ATROPINE & ANTICHOLINERGICS

Atropine, scopolamine, belladonna, diphenoxylate with atropine, *Datura stramonium*, *Hyoscyamus niger*, some mushrooms, tricyclic antidepressants, and antihistamines are antimuscarinic agents with variable central nervous system effects. The patient complains of dryness of the mouth, thirst, difficulty in swallowing, and blurring of vision. The physical signs include dilated pupils, flushed skin, tachycardia, fever, delirium, myoclonus, ileus, and flushed appearance. Antidepressants and antihistamines may induce convulsions.

Antihistamines are commonly available with or without prescription. Diphenhydramine commonly causes delirium, tachycardia, and seizures. Massive overdose may mimic tricyclic antidepressant poisoning.

► Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p 1567). Tepid sponge baths and sedation, or neuromuscular paralysis in rare cases, are indicated to control high temperatures (see p 1565).

B. Specific Treatment

For severe anticholinergic syndrome (eg, agitated delirium), give physostigmine salicylate, 0.5–1 mg slowly intravenously over 5 minutes, with ECG monitoring; repeat as needed to a total dose of no more than 2 mg. **Caution:** Bradycardias and convulsions are a hazard with physostigmine administration, and the drug should be avoided in patients with cardiotoxic effects from tricyclic antidepressants or other sodium channel blockers.

β-ADRENERGIC BLOCKERS

There are a wide variety of β-adrenergic blocking drugs, with varying pharmacologic and pharmacokinetic properties (see Table 11–7). The most toxic β-blocker is propranolol. Propranolol competitively blocks β₁ and β₂ adrenoceptors and also has direct membrane-depressant and central nervous system effects.

► Clinical Findings

The most common findings with mild or moderate intoxication are hypotension and bradycardia. Cardiac depression from more severe poisoning is often unresponsive to conventional therapy with β-adrenergic stimulants such as dopamine and norepinephrine. In addition, with propranolol and other lipid-soluble drugs, seizures and coma may occur. Propranolol, oxprenolol, acebutolol, and alprenolol also have membrane-depressant effects and can cause conduction disturbance (wide QRS interval) similar to tricyclic antidepressant overdose.

The diagnosis is based on typical clinical findings. Routine toxicology screening does not usually include β-blockers.

► Treatment

A. Emergency and Supportive Measures

Attempts to treat bradycardia or heart block with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion, titrated to the desired heart rate), or an external transcutaneous cardiac pacemaker are often ineffective, and specific antidotal treatment may be necessary (see below).

For drugs ingested within an hour of presentation (or longer after ingestion of an extended-release formulation), administer activated charcoal (see p 1567).

B. Specific Treatment

For persistent bradycardia and hypotension, give glucagon, 5–10 mg intravenously, followed by an infusion of 1–5 mg/h. Glucagon is an inotropic agent that acts at a different receptor site and is therefore not affected by β-blockade. High-dose insulin (0.5–1 units/kg/h intravenously) along with glucose supplementation has been used to reverse severe cardiotoxicity. Membrane-depressant effects (wide QRS interval) may respond to boluses of sodium bicarbonate (50–100 mEq intravenously) as for tricyclic antidepressant poisoning. Intravenous lipid emulsion (Intralipid 20%, 1.5 mL/kg) has been used successfully in severe propranolol overdose.

Jovic-Stosic J et al. Severe propranolol and ethanol overdose with wide complex tachycardia treated with intravenous lipid emulsion: a case report. *Clin Toxicol (Phila)*. 2011 Jun; 49(5):426–30. [PMID: 21740142]

Page C et al. The use of high-dose insulin-glucose euglycemia in beta-blocker overdose: a case report. *J Med Toxicol*. 2009 Sep; 5(3):139–43. [PMID: 19655287]

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers are used to treat angina pectoris, hypertension, supraventricular tachycardia, migraine, and other disorders. In therapeutic doses, nifedipine, nicaldipine, amlodipine, felodipine, isradipine, nisoldipine, and nimodipine act mainly on blood vessels, while verapamil and diltiazem act mainly on cardiac contractility and conduction. However, these selective effects can be lost after acute overdose. Patients may present with bradycardia, atrioventricular (AV) nodal block, hypotension, or a combination of these effects. Hyperglycemia is common due to blockade of insulin release. With severe poisoning, cardiac arrest may occur.

► Treatment

A. Emergency and Supportive Measures

For ingested drugs, administer activated charcoal (see p 1567). In addition, whole bowel irrigation (see p 1567) should be initiated as soon as possible if the patient has ingested a sustained-release product.

B. Specific Treatment

If bradycardia and hypotension are not reversed with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion), or a transcutaneous cardiac pacemaker, administer calcium intravenously. Start with calcium chloride 10%, 10 mL, or calcium gluconate 10%, 20 mL. Repeat the dose every 3–5 minutes. The optimum (or maximum) dose has not been established, but many toxicologists recommend raising the ionized serum calcium level to as much as twice the normal level. Calcium is most useful in reversing negative inotropic effects and is less effective for AV nodal blockade and bradycardia. Epinephrine infusion (1–4 mcg/min initially) and glucagon (5–10 mg intravenously) have also been recommended. In addition, high doses of insulin (0.5–1 units/kg intravenous bolus followed by 0.5–1 units/kg/h infusion) along with sufficient dextrose to maintain euglycemia have been reported to be beneficial but there are no controlled studies. Infusion of Intralipid 20% lipid emulsion has been reported to improve hemodynamics in animal models and case reports of calcium channel blocker poisoning.

CARBON MONOXIDE

Carbon monoxide is a colorless, odorless gas produced by the combustion of carbon-containing materials. Poisoning may occur as a result of suicidal or accidental exposure to automobile exhaust, smoke inhalation in a fire, or accidental exposure to an improperly vented gas heater, generator, or other appliance. Carbon monoxide avidly binds to hemoglobin, with an affinity approximately 250 times that of oxygen. This results in reduced oxygen-carrying capacity and altered delivery of oxygen to cells (see also Smoke Inhalation in Chapter 9).

► Clinical Findings

At low carbon monoxide levels (carboxyhemoglobin saturation 10–20%), victims may have headache, dizziness, abdominal pain, and nausea. With higher levels, confusion, dyspnea, and syncope may occur. Hypotension, coma, and seizures are common with levels > 50–60%. Survivors of acute severe poisoning may develop permanent obvious or subtle neurologic and neuropsychiatric deficits. The fetus and newborn may be more susceptible because of high carbon monoxide affinity for fetal hemoglobin.

Carbon monoxide poisoning should be suspected in any person with severe headache or acutely altered mental status, especially during cold weather, when improperly vented heating systems may have been used. Diagnosis depends on specific measurement of the arterial or venous carboxyhemoglobin saturation, although the level may have declined if high-flow oxygen therapy has already been administered, and levels do not always correlate with clinical symptoms. Routine arterial blood gas testing and pulse oximetry are not useful because they give falsely normal PaO₂ and oxyhemoglobin saturation determinations, respectively. (A specialized pulse oximetry device, the Masimo pulse CO-oximeter, is capable of distinguishing oxyhemoglobin from carboxyhemoglobin.)

► Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Remove the victim from exposure. Treat patients with coma, hypotension, or seizures as described at the beginning of this chapter (see pp 1562, 1563, 1565).

B. Specific Treatment

The half-life of the carboxyhemoglobin (CoHb) complex is about 4–5 hours in room air but is reduced dramatically by high concentrations of oxygen. Administer 100% oxygen by tight-fitting high-flow reservoir face mask or endotracheal tube. Hyperbaric oxygen (HBO) can provide 100% oxygen under higher than atmospheric pressures, further shortening the half-life; it may also reduce the incidence of subtle neuropsychiatric sequelae. Randomized controlled studies disagree about the benefit of HBO, but commonly recommended indications for HBO in patients with carbon monoxide poisoning include a history of loss of

consciousness, CoHb > 25%, metabolic acidosis, age over 50 years, and cerebellar findings on neurologic examination.

CLONIDINE & OTHER SYMPATHOLYTIC ANTIHYPERTENSIVES

Overdosage with these agents (clonidine, guanabenz, guanfacine, methyl dopa) causes bradycardia, hypotension, miosis, respiratory depression, and coma. (Transient hypertension occasionally occurs after acute overdosage, a result of peripheral α -adrenergic effects in high doses.) Symptoms are usually resolved in < 24 hours, and deaths are rare. Similar symptoms may occur after ingestion of topical nasal decongestants chemically similar to clonidine (oxymetazoline, tetrahydrozoline, naphazoline). Brimonidine and apraclonidine are used as ophthalmic preparations for glaucoma. Tizanidine is a centrally acting muscle relaxant structurally related to clonidine; it produces similar toxicity in overdose.

► Treatment

A. Emergency and Supportive Measures

Give activated charcoal (see p 1567). Maintain the airway and support respiration if necessary. Symptomatic treatment is usually sufficient even in massive overdose. Maintain blood pressure with intravenous fluids. Dopamine can also be used. Atropine is usually effective for bradycardia.

B. Specific Treatment

There is no specific antidote. Although tolazoline has been recommended for clonidine overdose, its effects are unpredictable and it should not be used. Naloxone has been reported to be successful in a few anecdotal and poorly substantiated cases.

COCAINE

See Amphetamines & Cocaine.

CYANIDE

Cyanide is a highly toxic chemical used widely in research and commercial laboratories and many industries. Its gaseous form, hydrogen cyanide, is an important component of smoke in fires. Cyanide-generating glycosides are also found in the pits of apricots and other related plants.

Cyanide is generated by the breakdown of nitroprusside, and poisoning can result from rapid high-dose infusions. Cyanide is also formed by metabolism of acetonitrile, a solvent found in some over-the-counter fingernail glue removers. Cyanide is rapidly absorbed by inhalation, skin absorption, or ingestion. It disrupts cellular function by inhibiting cytochrome oxidase and preventing cellular oxygen utilization.

► Clinical Findings

The onset of toxicity is nearly instantaneous after inhalation of hydrogen cyanide gas but may be delayed for minutes to hours after ingestion of cyanide salts or cyanogenic plants or chemicals. Effects include headache, dizziness, nausea, abdominal pain, and anxiety, followed by confusion, syncope, shock, seizures, coma, and death. The odor of “bitter almonds” may be detected on the victim’s breath or in vomitus, though this is not a reliable finding. The venous oxygen saturation may be elevated (> 90%) in severe poisonings because tissues have failed to take up arterial oxygen.

► Treatment

A. Emergency and Supportive Measures

Remove the victim from exposure, taking care to avoid exposure to rescuers. For suspected cyanide poisoning due to nitroprusside infusion, stop or slow the rate of infusion. (Metabolic acidosis and other signs of cyanide poisoning usually clear rapidly.)

For cyanide ingestion, administer activated charcoal (see p 1567). Although charcoal has a low affinity for cyanide, the usual doses of 60–100 g are adequate to bind typically ingested lethal doses (100–200 mg).

B. Specific Treatment

In the United States, there are two available cyanide antidote regimens. The conventional cyanide antidote package (Taylor Pharmaceuticals) (Table 38–7) contains nitrites (to induce methemoglobinemia, which binds free cyanide) and thiosulfate (to promote conversion of cyanide to the less toxic thiocyanate). Administer amyl nitrite by crushing an ampule under the victim’s nose or at the end of the endotracheal tube, and administer 3% sodium nitrite solution, 10 mL intravenously. **Caution:** Nitrites may induce hypotension and dangerous levels of methemoglobin. Also administer 25% sodium thiosulfate solution, 50 mL intravenously (12.5 g).

The other approved cyanide treatment in the United States is hydroxocobalamin (Cyanokit, EMD Pharmaceuticals), a newer and potentially safer antidote. The adult dose of hydroxocobalamin is 5 g intravenously (children’s dose is, 70 mg/kg).

Table 38-7. Currently available cyanide (CN) antidote kits.

Antidote	Contents	Action
Conventional cyanide antidote kit ¹	Amyl nitrite, 0.3 mL aspirol for inhalation; sodium nitrite 300 mg in a 10-mL vial; sodium thiosulfate 12.5 g in a 50-mL vial	Nitrites induce methemoglobinemia, which binds CN; thiosulfate hastens CN conversion to less toxic thiocyanate
Cyanokit ²	Hydroxocobalamin 5 g in two 2.5-g vials	Converts CN to cyanocobalamin (vitamin B ₁₂)

¹In the United States, manufactured by Taylor Pharmaceuticals.

²Manufactured by EMD Pharmaceuticals.

DIETARY SUPPLEMENTS & HERBAL PRODUCTS

Following passage of the Dietary Supplement Health and Education Act (DSHEA) in 1994, there has been an increase in the use of dietary supplements and herbal medicines in the United States. Unlike prescription and over-the-counter pharmaceuticals, dietary supplements do not require FDA approval, do not undergo the same pre-marketing evaluation of safety and efficacy as drugs, and purveyors may or may not adhere to good manufacturing practices and quality control standards. Supplements may cause illness as a result of intrinsic toxicity, misidentification or mislabeling, drug-herb reactions, or adulteration with pharmaceuticals. If you suspect a dietary supplement or herbal product may be the cause of an otherwise unexplained illness, contact the FDA (1-888-463-6332) or the regional poison control center (1-800-222-1222), or consult one of the following online databases: <http://www.naturaldatabase.therapeuticresearch.com> and, <http://www.fda.gov/food/dietarysupplements/default.htm>.

Table 38-8 lists selected examples of clinical toxicity from some of these products.

Ashar BH. The Dietary Supplement Health and Education Act: time for a reassessment: comment on "acute selenium toxicity associated with a dietary supplement". *Arch Intern Med.* 2010 Feb 8;170(3):261-3. [PMID: 20142571]
 Shaw D. Toxicological risks of Chinese herbs. *Planta Med.* 2010 Dec;76(17):2012-8. [PMID: 21077025]

DIGITALIS & OTHER CARDIAC GLYCOSIDES

Cardiac glycosides are derived from a variety of plants and are widely used to treat heart failure and supraventricular arrhythmias. These drugs paralyze the Na⁺-K⁺-ATPase pump and have potent vagotonic effects. Intracellular effects include enhancement of calcium-dependent contractility and shortening of the action potential duration. A number of plants (eg, oleander, foxglove, lily-of-the-valley)

Table 38-8. Examples of potential toxicity associated with some dietary supplements and herbal medicines.

Product	Common Use	Possible Toxicity
Azarcon (Greta)	Mexican folk remedy for abdominal pain, colic	Contains lead (see p 1581)
Comfrey	Gastric upset, diarrhea	Contains pyrrolizidine alkaloids, can cause hepatic veno-occlusive disease
Creatine	Athletic performance enhancement	Nausea, diarrhea, abdominal cramps; elevated serum creatinine
Ginkgo	Memory improvement, tinnitus	Antiplatelet effects, hemorrhage; abdominal pain, diarrhea
Ginseng	Immune system; stress	Decreased glucose; increased cortisol
Guarana	Athletic performance enhancement, appetite suppression	Contains caffeine: can cause tremor, tachycardia, vomiting
Kava	Anxiety, insomnia	Drowsiness, hepatitis, skin rash
Ma huang	Stimulant; athletic performance enhancement	Contains ephedrine: anxiety, insomnia, hypertension, tachycardia, seizures
Spirulina	Body building	Niacin-like flushing reaction
Yohimbine	Sexual enhancement	Hallucinations, hypertension, tachycardia
Zinc	Cold/flu symptoms	Nausea, oral irritation, anosmia

Adapted, with permission, from Table II-30 by Haller C in "Herbal and Alternative Products," In: Olson KR (ed.) *Poisoning & Drug Overdose*, 5th edition, McGraw Hill, 2007.

contain cardiac glycosides. Bufotenin, a cardiotoxic steroid found in certain toad secretions and used as an herbal medicine and a purported aphrodisiac, has pharmacologic properties similar to cardiac glycosides.

► Clinical Findings

Intoxication may result from acute single exposure or chronic accidental overmedication. After acute overdosage, nausea and vomiting, bradycardia, hyperkalemia, and AV block frequently occur. Patients in whom toxicity develops gradually during long-term therapy may be hypokalemic and hypomagnesemic owing to concurrent diuretic treatment and more commonly present with ventricular arrhythmias (eg, ectopy, bidirectional ventricular tachycardia, or ventricular fibrillation). Digoxin levels may be only slightly elevated in patients with intoxication from cardiac glycosides other than digoxin because of limited cross-reactivity of immunologic tests.

► Treatment

A. Emergency and Supportive Measures

After acute ingestion, administer activated charcoal (see p 1567). Monitor potassium levels and cardiac rhythm closely. Treat bradycardia initially with atropine (0.5–2 mg intravenously) or a transcutaneous external cardiac pacemaker.

B. Specific Treatment

For patients with significant intoxication, administer digoxin-specific antibodies (digoxin immune Fab [ovine]; Digibind or DigiFab). Estimation of the Digibind dose is based on the body burden of digoxin calculated from the ingested dose or the steady-state serum digoxin concentration, as described below. More effective binding of digoxin may be achieved if the dose is given partly as a bolus and the remainder as an infusion over a few hours.

1. From the ingested dose—Number of vials = approximately $1.5\text{--}2 \times$ ingested dose (mg).

2. From the serum concentration—Number of vials = serum digoxin (ng/mL) \times body weight (kg) $\times 10^{-2}$. **Note:** This is based on the equilibrium digoxin level; after acute overdose, serum levels may be falsely high before tissue distribution is complete, and overestimation of the Digibind or DigiFab dose is likely.

3. Empiric dosing—Empiric titration of Digibind or DigiFab may be used if the patient's condition is relatively stable and an underlying condition (eg, atrial fibrillation) favors retaining a residual level of digitalis activity. Start with one or two vials and reassess the patient's clinical condition after 20–30 minutes. For cardiac glycosides other than digoxin or digitoxin, there is no formula for estimation of vials needed and treatment is entirely based on response to empiric dosing.

Note: After administration of digoxin-specific Fab antibody fragments, serum digoxin levels may be falsely elevated depending on the assay technique.

Rajapakse S. Management of yellow oleander poisoning. *Clin Toxicol (Phila)*. 2009 Mar;47(3):206–12. [PMID: 19306191]

ETHANOL, BENZODIAZEPINES, & OTHER SEDATIVE-HYPNOTIC AGENTS

The group of agents known as sedative-hypnotic drugs includes a variety of products used for the treatment of anxiety, depression, insomnia, and epilepsy. Besides common benzodiazepines, such as lorazepam, alprazolam, clonazepam, diazepam, oxazepam, chlordiazepoxide, and triazolam, this group includes the newer benzodiazepine-like hypnotics zolpidem and zaleplon, and the muscle relaxant carisoprodol. Ethanol and other selected agents are also popular recreational drugs. All of these drugs depress the central nervous system reticular activating system, cerebral cortex, and cerebellum.

► Clinical Findings

Mild intoxication produces euphoria, slurred speech, and ataxia. Ethanol intoxication may produce hypoglycemia, even at relatively low concentrations, in children and in fasting adults. With more severe intoxication, stupor, coma, and respiratory arrest may occur. Carisoprodol (Soma) commonly causes muscle jerking or myoclonus. Death or serious morbidity is usually the result of pulmonary aspiration of gastric contents. Bradycardia, hypotension, and hypothermia are common. Patients with massive intoxication may appear to be dead, with no reflex responses and even absent electroencephalographic activity. Diagnosis and assessment of severity of intoxication are usually based on clinical findings. Ethanol serum levels > 300 mg/dL (0.3 g/dL; 65 mmol/L) can produce coma in persons who are not chronically abusing the drug, but regular users may remain awake at much higher levels.

► Treatment

A. Emergency and Supportive Measures

Administer activated charcoal if the patient has ingested a massive dose and the airway is protected (see p 1567). Repeat-dose charcoal may enhance elimination of phenobarbital, but it has not been proved to improve clinical outcome. Hemodialysis may be necessary for patients with severe phenobarbital intoxication.

B. Specific Treatment

Flumazenil is a benzodiazepine receptor-specific antagonist; it has no effect on ethanol, barbiturates, or other sedative-hypnotic agents. If used, flumazenil is given slowly intravenously, 0.2 mg over 30–60 seconds, and repeated in

0.2-0.5 mg increments as needed up to a total dose of 3–5 mg. **Caution:** Flumazenil may induce seizures in patients with preexisting seizure disorder, benzodiazepine addiction, or concomitant tricyclic antidepressant or other convulsant overdose. If seizures occur, diazepam and other benzodiazepine anticonvulsants will not be effective. As with naloxone, the duration of action of flumazenil is short (2–3 hours) and resedation may occur, requiring repeated doses.

Cantrell FL et al. Death on the doorstep of a border community—intentional self-poisoning with veterinary pentobarbital. *Clin Toxicol (Phila)*. 2010 Oct;48(8):849–50. [PMID: 20738183]

 Lakhal K et al. Protracted deep coma after bromazepam poisoning. *Int J Clin Pharmacol Ther*. 2010 Jan;48(1):79–83. [PMID: 20040343]

γ-HYDROXYBUTYRATE (GHB)

GHB has become a popular drug of abuse. It originated as a short-acting general anesthetic and is occasionally used in the treatment of narcolepsy. It gained popularity among bodybuilders for its alleged growth hormone stimulation and found its way into social settings, where it is consumed as a liquid. It has been used to facilitate sexual assault (“date-rape” drug). Symptoms after ingestion include drowsiness and lethargy followed by coma with respiratory depression. Muscle twitching and seizures are sometimes observed. Recovery is usually rapid, with patients awakening within a few hours. Other related chemicals with similar effects include butanediol and γ-butyrolactone (GBL). A prolonged withdrawal syndrome has been described in some heavy users.

▶ Treatment

Monitor the airway and assist breathing if needed. There is no specific treatment. Most patients recover rapidly with supportive care. GHB withdrawal syndrome may require very large doses of benzodiazepines.

 Zvosec DL et al. Case series of 226 γ-hydroxybutyrate-associated deaths: lethal toxicity and trauma. *Am J Emerg Med*. 2011 Mar;29(3):319–32. [PMID: 20825811]

HYPOGLYCEMIC DRUGS

Medications used for diabetes mellitus include insulin, sulfonylureas and other insulin secretagogues, α-glucosidase inhibitors (acarbose, miglitol), biguanides (metformin), thiazolidinediones (pioglitazone, rosiglitazone), and newer peptide analogs (pramlintide, exenatide) or enhancers (sitagliptin) (see Chapter 27). Of these, insulin and the insulin secretagogues are the most likely to cause hypoglycemia. Metformin can cause lactic acidosis, especially in

patients with renal insufficiency or after intentional drug overdose. Table 27–7 lists the duration of hypoglycemic effect of oral hypoglycemic agents and Figure 27–3 the extent and duration of various types of insulins.

▶ Clinical Findings

Hypoglycemia may occur quickly after injection of short-acting insulins or may be delayed and prolonged, especially if a large amount has been injected into a single area, creating a “depot” effect. Hypoglycemia after sulfonylurea ingestion is usually apparent within a few hours but may be delayed several hours, especially if food or glucose-containing fluids have been given.

▶ Treatment

Give sugar and carbohydrate-containing food or liquids by mouth, or intravenous dextrose if the patient is unable to swallow safely. For severe hypoglycemia, start with D50W, 50 mL intravenously (25 g dextrose); repeat, if needed. Follow up with dextrose-containing intravenous fluids (D5W or D10W) to maintain a blood glucose > 70–80 mg/dL.

For hypoglycemia caused by sulfonylureas and related insulin secretagogues, consider use of octreotide, a synthetic somatostatin analog that blocks pancreatic insulin release. A dose of 50–100 mcg octreotide subcutaneously every 6–12 hours can reduce the need for exogenous dextrose and prevent rebound hypoglycemia from excessive dextrose dosing.

Admit all patients with symptomatic hypoglycemia after sulfonylurea overdose. Observe asymptomatic overdose patients for at least 12 hours.

IRON

Iron is widely used therapeutically for the treatment of anemia and as a daily supplement in multiple vitamin preparations. Most children’s preparations contain about 12–15 mg of elemental iron (as sulfate, gluconate, or fumarate salt) per dose, compared with 60–90 mg in most adult-strength preparations. Iron is corrosive to the gastrointestinal tract and, once absorbed, has depressant effects on the myocardium and on peripheral vascular resistance. Intracellular toxic effects of iron include disruption of Krebs cycle enzymes.

▶ Clinical Findings

Ingestion of < 30 mg/kg of elemental iron usually produces only mild gastrointestinal upset. Ingestion of > 40–60 mg/kg

may cause vomiting (sometimes with hematemesis), diarrhea, hypotension, and acidosis. Death may occur as a result of profound hypotension due to massive fluid losses and bleeding, metabolic acidosis, peritonitis from intestinal perforation, or sepsis. Fulminant hepatic failure may occur. Survivors of the acute ingestion may suffer permanent gastrointestinal scarring.

Serum iron levels > 350–500 mcg/dL are considered potentially toxic, and levels > 1000 mcg/dL are usually associated with severe poisoning. A plain abdominal radiograph may reveal radiopaque tablets.

▶ Treatment

A. Emergency and Supportive Measures

Treat hypotension aggressively with intravenous crystalloid solutions (0.9% saline or lactated Ringer solution). Fluid losses may be massive owing to vomiting and diarrhea as well as third-spacing into injured intestine.

Perform whole bowel irrigation to remove unabsorbed pills from the intestinal tract (see p 1567). Activated charcoal is not effective but may be appropriate if other ingestants are suspected.

B. Specific Treatment

Deferoxamine is a selective iron chelator. It is not useful as an oral binding agent. For patients with established manifestations of toxicity—and particularly those with markedly elevated serum iron levels (eg, > 800–1000 mcg/dL)—administer 10–15 mg/kg/h by constant intravenous infusion; higher doses (up to 40–50 mg/kg/h) have been used in massive poisonings. Hypotension may occur. The presence of an iron-deferoxamine complex in the urine may give it a “vin rosé” appearance. Deferoxamine is safe for use in pregnant women with acute iron overdose. **Caution:** Prolonged infusion of deferoxamine (> 36–48 hours) has been associated with development of acute respiratory distress syndrome (ARDS)—the mechanism is not known.

ISONIAZID

INH is an antibacterial drug used mainly in the treatment and prevention of tuberculosis. It may cause hepatitis with long-term use, especially in alcoholic patients and elderly persons. It produces acute toxic effects by competing with pyridoxal 5-phosphate, resulting in lowered brain γ -aminobutyric acid (GABA) levels. Acute ingestion of as little as 1.5–2 g of INH can cause toxicity, and severe poisoning is likely to occur after ingestion of more than 80–100 mg/kg.

▶ Clinical Findings

Confusion, slurred speech, and seizures may occur abruptly after acute overdose. Severe lactic acidosis—out of proportion to the severity of seizures—is probably due to inhibited metabolism of lactate. Peripheral neuropathy and acute hepatitis may occur with long-term use.

Diagnosis is based on a history of ingestion and the presence of severe acidosis associated with seizures. INH is not usually included in routine toxicologic screening, and serum levels are not readily available.

▶ Treatment

A. Emergency and Supportive Measures

Seizures may require higher than usual doses of benzodiazepines (eg, lorazepam, 3–5 mg intravenously) or administration of pyridoxine as an antidote (see below).

Administer activated charcoal (see p 1567) after large recent ingestion, but with caution because of the risk of abrupt onset of seizures.

B. Specific Treatment

Pyridoxine (vitamin B₆) is a specific antagonist of the acute toxic effects of INH and is usually successful in controlling convulsions that do not respond to benzodiazepines. Give 5 g intravenously over 1–2 minutes or, if the amount ingested is known, give a gram-for-gram equivalent amount of pyridoxine. Patients taking INH are usually given 25–50 mg of pyridoxine orally daily to help prevent neuropathy.

LEAD

Lead is used in a variety of industrial and commercial products, such as storage batteries, solders, paints, pottery, plumbing, and gasoline and is found in some traditional Hispanic and Ayurvedic ethnic medicines. Lead toxicity usually results from chronic repeated exposure and is rare after a single ingestion. Lead produces a variety of adverse effects on cellular function and primarily affects the nervous system, gastrointestinal tract, and hematopoietic system.

▶ Clinical Findings

Lead poisoning often goes undiagnosed initially because presenting symptoms and signs are nonspecific and exposure is not suspected. Common symptoms include colicky abdominal pain, constipation, headache, and irritability. Severe poisoning may cause coma and convulsions. Chronic intoxication can cause learning disorders (in children) and motor neuropathy (eg, wrist drop). Lead-containing bullet fragments in or near joint spaces can result in chronic lead toxicity.

Diagnosis is based on measurement of the blood lead level. Whole blood lead levels < 10 mcg/dL are usually considered nontoxic. Levels between 10 and 25 mcg/dL have been associated with impaired neurobehavioral development in children. Levels of 25–50 mcg/dL may be associated with headache, irritability, and subclinical neuropathy. Levels of 50–70 mcg/dL are associated with moderate toxicity, and levels > 70–100 mcg/dL are often associated with severe poisoning. Other laboratory findings of lead poisoning include microcytic anemia with basophilic stippling and elevated free erythrocyte protoporphyrin.

▶ Treatment

A. Emergency and Supportive Measures

For patients with encephalopathy, maintain a patent airway and treat coma and convulsions as described at the beginning of this chapter.

For recent acute ingestion, if a large lead-containing object (eg, fishing weight) is still visible in the stomach on abdominal radiograph, whole bowel irrigation (see p 1567), endoscopy, or even surgical removal may be necessary to prevent subacute lead poisoning. (The acidic gastric contents may corrode the metal surface, enhancing lead absorption. Once the object passes into the small intestine, the risk of toxicity declines.)

Conduct an investigation into the source of the lead exposure.

Workers with a single lead level > 60 mcg/dL (or three successive monthly levels > 50 mcg/dL) or construction workers with any single blood lead level > 50 mcg/dL must by federal law be removed from the site of exposure. Contact the regional office of the United States Occupational Safety and Health Administration (OSHA) for more information. Several states mandate reporting of cases of confirmed lead poisoning.

B. Specific Treatment

The indications for chelation depend on the blood lead level and the patient's clinical state. A medical toxicologist or regional poison control center (1-800-222-1222) should be consulted for advice about selection and use of these antidotes.

Note: It is impermissible under the law to treat asymptomatic workers with elevated blood lead levels in order to keep their levels < 50 mcg/dL rather than remove them from the exposure.

1. Severe toxicity—Patients with severe intoxication (encephalopathy or levels > 70–100 mcg/dL) should receive edetate calcium disodium (ethylenediaminetetraacetic acid, EDTA), 1500 mg/m²/kg/d (approximately 50 mg/kg/d) in four to six divided doses or as a continuous intravenous infusion. Most clinicians also add dimercaprol (BAL), 4–5 mg/kg intramuscularly every 4 hours for 5 days, for patients with encephalopathy.

2. Less severe toxicity—Patients with less severe symptoms and asymptomatic patients with blood lead levels between 55 and 69 mcg/dL may be treated with edetate calcium disodium alone in dosages as above. An oral chelator,

succimer (DMSA), is available for use in patients with mild to moderate intoxication. The usual dose is 10 mg/kg orally every 8 hours for 5 days, then every 12 hours for 2 weeks.

Bradberry S et al. Dimercaptosuccinic acid (succimer; DMSA) in inorganic lead poisoning. *Clin Toxicol (Phila)*. 2009 Aug; 47(7):617–31. [PMID: 19663612]

LITHIUM

Lithium is widely used for the treatment of bipolar depression and other psychiatric disorders. The only normal route of lithium elimination is via the kidney, so patients with chronic kidney disease are at risk for accumulation of lithium resulting in gradual onset (chronic) toxicity. Intoxication resulting from chronic accidental overmedication or renal impairment is more common and usually more severe than that seen after acute oral overdose.

▶ Clinical Findings

Mild to moderate toxicity causes lethargy, confusion, tremor, ataxia, and slurred speech. This may progress to myoclonic jerking, delirium, coma, and convulsions. Recovery may be slow and incomplete following severe intoxication. Laboratory studies in patients with chronic intoxication often reveal an elevated serum creatinine and an elevated BUN/creatinine ratio due to underlying volume contraction. The white blood cell count is often elevated. ECG findings include T-wave flattening or inversion, and sometimes bradycardia or sinus node arrest. Nephrogenic diabetes insipidus can occur with overdose or with therapeutic doses. Lithium levels may be difficult to interpret. Lithium has a low toxic:therapeutic ratio and chronic intoxication can be seen with levels only slightly above the therapeutic range (0.8–1.2 mEq/L). In contrast, patients with acute ingestion may have transiently very high levels (up to 10 mEq/L reported) without any symptoms before the lithium fully distributes into tissues. **Note:** Falsely high lithium levels (as high as 6–8 mEq/L) can be measured if a green-top blood specimen tube (containing lithium heparin) is used instead of a red- or marbled-top tube.

▶ Treatment

After acute oral overdose, consider gastric lavage (see p 1567) or whole bowel irrigation (see p 1567) to prevent systemic absorption (lithium is not adsorbed by activated charcoal). In all patients, evaluate renal function and volume status, and give intravenous saline-containing fluids as needed. Monitor serum lithium levels, and seek assistance with their interpretation and the need for dialysis from a medical toxicologist or regional poison control center (1-800-222-1222). Consider hemodialysis if the patient is markedly symptomatic or if the serum level

exceeds 10 mEq/L after an acute overdose. Continuous renal replacement hemofiltration may be an effective alternative to hemodialysis.

Bailey AR et al. Comparison of intermittent haemodialysis, prolonged intermittent renal replacement therapy and continuous renal replacement haemofiltration for lithium toxicity: a case report. *Crit Care Resusc.* 2011 Jun;13(2):120–2. [PMID: 21627581]

LSD & OTHER HALLUCINOGENS

A variety of substances—ranging from naturally occurring plants and mushrooms to synthetic substances such as phencyclidine (PCP), toluene and other solvents, dextromethorphan, and lysergic acid diethylamide (LSD)—are abused for their hallucinogenic properties. The mechanism of toxicity and the clinical effects vary for each substance.

Many hallucinogenic plants and mushrooms produce anticholinergic delirium, characterized by flushed skin, dry mucous membranes, dilated pupils, tachycardia, and urinary retention. Other plants and mushrooms may contain hallucinogenic indoles such as mescaline and LSD, which typically cause marked visual hallucinations and perceptual distortion, widely dilated pupils, and mild tachycardia. PCP, a dissociative anesthetic agent similar to ketamine, can produce fluctuating delirium and coma, often associated with vertical and horizontal nystagmus. Toluene and other hydrocarbon solvents (butane, trichloroethylene, “chemo,” etc) cause euphoria and delirium and may sensitize the myocardium to the effects of catecholamines, leading to fatal dysrhythmias. Newer drugs used for their psychostimulant effects include synthetic cannabinoid receptor agonists (street names include “spice” and “K2”), *Salvia divinorum*, and mephedrone. See www.erowid.org for very thorough descriptions of a variety of hallucinogenic substances.

► Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist respirations if necessary. Treat coma, hyperthermia, hypertension, and seizures as outlined at the beginning of this chapter. For recent large ingestions, consider giving activated charcoal orally or by gastric tube (see p 1567).

B. Specific Treatment

Patients with anticholinergic delirium may benefit from a dose of physostigmine, 0.5–1 mg intravenously, not to exceed 1 mg/min. Dysphoria, agitation, and psychosis associated with LSD or mescaline intoxication may respond to benzodiazepines (eg, lorazepam, 1–2 mg orally or intravenously) or haloperidol (2–5 mg intramuscularly or intravenously) or another antipsychotic drug (eg, olanzapine or ziprasidone). Monitor patients who have sniffed solvents for cardiac dysrhythmias (most commonly premature ventricular contractions, ventricular tachycardia, ventricular fibrillation); treatment with β -blockers such as propranolol (1–5 mg intravenously) or esmolol (250–500 mcg/kg intravenously,

then 50 mcg/kg/min by infusion) may be more effective than lidocaine or amiodarone.

Atwood BK et al. JWH018, a common constituent of ‘Spice’ herbal blends, is a potent and efficacious cannabinoid CB receptor agonist. *Br J Pharmacol.* 2010 Jun;160(3):585–93. [PMID: 20100276]

MERCURY

Acute mercury poisoning usually occurs by ingestion of inorganic mercuric salts or inhalation of metallic mercury vapor. Ingestion of the mercuric salts causes a burning sensation in the throat, discoloration and edema of oral mucous membranes, abdominal pain, vomiting, bloody diarrhea, and shock. Direct nephrotoxicity causes acute kidney injury. Inhalation of high concentrations of metallic mercury vapor may cause acute fulminant chemical pneumonia. Chronic mercury poisoning causes weakness, ataxia, intention tremors, irritability, and depression. Exposure to alkyl (organic) mercury derivatives from highly contaminated fish or fungicides used on seeds has caused ataxia, tremors, convulsions, and catastrophic birth defects. Nearly all fish have some traces of mercury contamination; the US Environmental Protection Agency (EPA) advises consumers to avoid swordfish, shark, king mackerel, and tilefish because they contain higher levels. Fish that are generally low in mercury content include shrimp, canned light tuna (not albacore “white” tuna), salmon, pollock, and catfish. Dental fillings composed of mercury amalgam pose a very small risk of chronic mercury poisoning and their removal is rarely justified.

► Treatment

A. Acute Poisoning

There is no effective specific treatment for mercury vapor pneumonitis. Remove ingested mercuric salts by lavage, and administer activated charcoal (see p 1567). For acute ingestion of mercuric salts, give dimercaprol (BAL) at once, as for arsenic poisoning. Unless the patient has severe gastroenteritis, consider succimer (DMSA), 10 mg/kg orally every 8 hours for 5 days and then every 12 hours for 2 weeks. Unithiol (DMPS) is a chelator that can be given orally or parenterally, but is not commonly available in the United States. Maintain urinary output. Treat oliguria and anuria if they occur.

B. Chronic Poisoning

Remove from exposure. Neurologic toxicity is not considered reversible with chelation, although some authors recommend a trial of succimer or unithiol (contact a regional poison center or medical toxicologist for advice).

Vearrier D et al. Care of patients who are worried about mercury poisoning from dental fillings. *J Am Board Fam Med*. 2010 Nov-Dec;23(6):797-8. [PMID: 21057078]

METHANOL & ETHYLENE GLYCOL

Methanol (wood alcohol) is commonly found in a variety of products, including solvents, duplicating fluids, record cleaning solutions, and paint removers. It is sometimes ingested intentionally by alcoholic patients as a substitute for ethanol and may also be found as a contaminant in bootleg whiskey. Ethylene glycol is the major constituent in most antifreeze compounds. The toxicity of both agents is caused by metabolism to highly toxic organic acids—methanol to formic acid; ethylene glycol to glycolic and oxalic acids. Diethylene glycol is a nephrotoxic solvent that has been improperly substituted for glycerine in various liquid medications (cough syrup, teething medicine, acetaminophen) causing numerous deaths in Haiti, Panama, and Nigeria.

► Clinical Findings

Shortly after ingestion of methanol or ethylene glycol, patients usually appear “drunk.” The serum osmolality (measured with the freezing point device) is usually increased, but acidosis is often absent early. After several hours, metabolism to toxic organic acids leads to a severe anion gap metabolic acidosis, tachypnea, confusion, convulsions, and coma. Methanol intoxication frequently causes visual disturbances, while ethylene glycol often produces oxalate crystalluria and acute renal failure.

► Treatment

A. Emergency and Supportive Measures

For patients presenting within 30–60 minutes after ingestion, empty the stomach by aspiration through a nasogastric tube (see p 1567). Charcoal is not very effective but should be administered if other poisons or drugs have also been ingested.

B. Specific Treatment

Patients with significant toxicity (manifested by severe metabolic acidosis, altered mental status, and markedly elevated osmol gap) should undergo hemodialysis as soon as possible to remove the parent compound and the toxic metabolites. Treatment with folic acid, thiamine, and pyridoxine may enhance the breakdown of toxic metabolites.

Ethanol blocks metabolism of the parent compounds by competing for the enzyme alcohol dehydrogenase. Fomepizole (4-methylpyrazole; Antizol) blocks alcohol dehydrogenase and is much easier to use than ethanol. If started before onset of acidosis, fomepizole may be used as the sole treatment for ethylene glycol ingestion in some cases. A regional poison control center (1-800-222-1222) should be contacted for indications and dosing.

METHEMOGLOBINEMIA-INDUCING AGENTS

A large number of chemical agents are capable of oxidizing ferrous hemoglobin to its ferric state (methemoglobin), a form that cannot carry oxygen. Drugs and chemicals known to cause methemoglobinemia include benzocaine (a local anesthetic found in some topical anesthetic sprays and a variety of nonprescription products), aniline, propanil (an herbicide), nitrites, nitrogen oxide gases, nitrobenzene, dapsone, phenazopyridine (Pyridium), and many others. Dapsone has a long elimination half-life and may produce prolonged or recurrent methemoglobinemia.

► Clinical Findings

Methemoglobinemia reduces oxygen-carrying capacity and may cause dizziness, nausea, headache, dyspnea, confusion, seizures, and coma. The severity of symptoms depends on the percentage of hemoglobin oxidized to methemoglobin; severe poisoning is usually present when methemoglobin fractions are > 40–50%. Even at low levels (15–20%), victims appear cyanotic because of the “chocolate brown” color of methemoglobin, but they have normal PO_2 results on arterial blood gas determinations. Conventional pulse oximetry gives inaccurate oxygen saturation measurements; the reading is often between 85% and 90%. (A newer pulse oximetry device [Masimo Pulse CO-oximeter] is capable of estimating the methemoglobin level.) Severe metabolic acidosis may be present. Hemolysis may occur, especially in patients susceptible to oxidant stress (ie, those with glucose-6-phosphate dehydrogenase deficiency).

► Treatment

A. Emergency and Supportive Measures

Administer high-flow oxygen. If the causative agent was recently ingested, administer activated charcoal (see p 1567). Repeat-dose activated charcoal may enhance dapsone elimination (see p 1568).

B. Specific Treatment

Methylene blue enhances the conversion of methemoglobin to hemoglobin by increasing the activity of the enzyme methemoglobin reductase. For symptomatic patients, administer 1–2 mg/kg (0.1–0.2 mL/kg of 1% solution)

intravenously. The dose may be repeated once in 15–20 minutes if necessary. Patients with hereditary methemoglobin reductase deficiency or glucose-6-phosphate dehydrogenase deficiency may not respond to methylene blue treatment. In severe cases where methylene blue is not available or is not effective, exchange blood transfusion may be necessary.

MONOAMINE OXIDASE INHIBITORS

Overdoses of MAO inhibitors (isocarboxazid, phenelzine, selegiline, moclobemide) cause ataxia, excitement, hypertension, and tachycardia, followed several hours later by hypotension, convulsions, and hyperthermia.

Ingestion of tyramine-containing foods may cause a severe hypertensive reaction in patients taking MAO inhibitors. Foods containing tyramine include aged cheese and red wines. Hypertensive reactions may also occur with any sympathomimetic drug. Severe or fatal hyperthermia (serotonin syndrome) may occur if patients receiving MAO inhibitors are given meperidine, fluoxetine, paroxetine, fluvoxamine, venlafaxine, tryptophan, dextromethorphan, tramadol, or other serotonin-enhancing drugs. This reaction can also occur with the newer selective MAO inhibitor moclobemide, and the antibiotic linezolid, which has MAO-inhibiting properties. The serotonin syndrome has also been reported in patients taking selective serotonin reuptake inhibitors (SSRIs) in large doses or in combination with other SSRIs, even in the absence of an MAO inhibitor or meperidine. It is characterized by fever, agitation, delirium, diaphoresis, hyperreflexia, and clonus (spontaneous, inducible, or ocular). Hyperthermia can be life-threatening.

▶ Treatment

Administer activated charcoal (see p 1567). Treat severe hypertension with nitroprusside, phentolamine, or other rapid-acting vasodilators (see p 1564). Treat hypotension with fluids and positioning, but avoid use of pressor agents if possible. Observe patients for at least 24 hours, since hyperthermic reactions may be delayed. Treat hyperthermia with aggressive cooling; neuromuscular paralysis may be required (see p 1565). Cyproheptadine, 4 mg orally (or by gastric tube) every hour for three or four doses, or chlorpromazine, 25 mg intravenously, has been reported to be effective against serotonin syndrome.

Sun-Edelstein C et al. Drug-induced serotonin syndrome. *Expert Opin Drug Saf*. 2008 Sep;7(5):587–96. [PMID: 18759711]

Wu ML et al. Serotonin toxicity caused by moclobemide too soon after paroxetine-selegiline. *J Chin Med Assoc*. 2009 Aug;72(8):446–9. [PMID: 19687003]

MUSHROOMS

There are thousands of mushroom species that cause a variety of toxic effects. The most dangerous species of mushrooms are *A phalloides*, *Amanita ocreata*, *Amanita verna*, *Amanita virosa*, *Gyromitra esculenta*, and the *Galerina* species, all of which contain potent cytotoxins (amatoxins). Ingestion of even a portion of one mushroom of a dangerous species may be sufficient to cause death.

The characteristic pathologic finding in fatalities from amatoxin-containing mushroom poisoning is acute massive necrosis of the liver.

▶ Clinical Findings (Table 38–9)

A. Symptoms and Signs

Amatoxin-containing mushrooms typically cause a delayed onset (8–12 hours after ingestion) of severe abdominal cramps, vomiting and profuse diarrhea, followed by hepatic necrosis, hepatic encephalopathy, and frequently acute kidney injury in 1–2 days. Cooking the mushrooms does not prevent poisoning.

Monomethylhydrazine poisoning (*Gyromitra* and *Helvella* species) is more common following ingestion of uncooked mushrooms, as the toxin is water-soluble. Vomiting, diarrhea, hepatic necrosis, convulsions, coma, and hemolysis may occur after a latent period of 8–12 hours.

The clinical effects of these and other mushrooms are described in Table 38–9.

▶ Treatment

A. Emergency Measures

After the onset of symptoms, efforts to remove the toxic agent are probably useless, especially in cases of amatoxin or gyromitrin poisoning, where there is usually a delay of 12 hours or more before symptoms occur and patients seek medical attention. However, induction of vomiting or administration of activated charcoal is recommended for any recent ingestion of an unidentified or potentially toxic mushroom (see p 1567).

B. Specific Treatment

A variety of purported antidotes (eg, thiocetic acid, penicillin, corticosteroids) have been suggested for amatoxin-type mushroom poisoning, but controlled studies are lacking and experimental data in animals are equivocal. Aggressive fluid replacement for diarrhea and intensive supportive care for hepatic failure are the mainstays of treatment. Silymarin (silibinin), a derivative of milk thistle, is commonly used in Europe but is currently only commercially available in the United States as a nutritional supplement given orally. The European intravenous product (Legalon-SIL) can be obtained in the United States under an emergency IND provided by the FDA. Contact the regional poison control center (1-800-222-1222) for more information.

Interruption of enterohepatic circulation of the amatoxin by the administration of activated charcoal or by cannulation and drainage of the bile duct may be of value

Table 38-9. Poisonous mushrooms.

Toxin	Genus	Symptoms and Signs	Onset	Treatment
Amanitin	<i>Amanita (A phalloides, A verna, A virosa)</i>	Severe gastroenteritis followed by delayed hepatic failure and acute kidney injury after 48–72 hours	6–24 hours	Supportive. Correct dehydration. Give repeated doses of activated charcoal orally. Consider intravenous silibinin (Legalon-SIL) (see text).
Muscarine	<i>Inocybe, Clitocybe</i>	Muscarinic (salivation, miosis, bradycardia, diarrhea)	30–60 minutes	Supportive. Give atropine, 0.5–2 mg intravenously, for severe cholinergic symptoms and signs.
Ibotenic acid, muscimol	<i>Amanita muscaria</i> (“fly agaric”)	Anticholinergic (mydriasis, tachycardia, hyperpyrexia, delirium)	30–60 minutes	Supportive. Give physostigmine, 0.5–2 mg intravenously, for severe anticholinergic symptoms and signs.
Coprine	<i>Coprinus</i>	Disulfiram-like effect occurs with ingestion of ethanol	30–60 minutes	Supportive. Abstain from ethanol for 3–4 days.
Monomethylhydrazine	<i>Gyromitra</i>	Gastroenteritis; occasionally seizures, hemolysis, hepatic failure, and acute kidney injury	6–12 hours	Supportive. Correct dehydration. Pyridoxine, 2.5 mg/kg intravenously, may be helpful for seizures.
Orellanine	<i>Cortinarius</i>	Nausea, vomiting; acute kidney injury after 1–3 weeks	2–14 days	Supportive.
Psilocybin	<i>Psilocybe</i>	Hallucinations	15–30 minutes	Supportive.
Gastrointestinal irritants	Many species	Nausea and vomiting, diarrhea	1/2–2 hours	Supportive. Correct dehydration.

in removing some of the toxin, based on animal studies and isolated case reports.

Liver transplant may be the only hope for survival in gravely ill patients—contact a liver transplant center early.

OPIATES & OPIOIDS

Prescription and illicit opiates and opioids (morphine, heroin, codeine, oxycodone, fentanyl, hydromorphone, etc) are popular drugs of misuse and abuse and the cause of frequent hospitalizations for overdose. These drugs have widely varying potencies and durations of action; for example, some of the illicit fentanyl derivatives are up to 2000 times more potent than morphine. All of these agents decrease central nervous system activity and sympathetic outflow by acting on opiate receptors in the brain. Tramadol is an analgesic that is unrelated chemically to the opioids but acts on opioid receptors. Buprenorphine is a partial agonist-antagonist opioid used for the outpatient treatment of opioid addiction.

► Clinical Findings

Mild intoxication is characterized by euphoria, drowsiness, and constricted pupils. More severe intoxication may cause

hypotension, bradycardia, hypothermia, coma, and respiratory arrest. Pulmonary edema may occur. Death is usually due to apnea or pulmonary aspiration of gastric contents. Methadone has been associated with QT interval prolongation and torsades de pointes. Tramadol, dextromethorphan, and meperidine also occasionally cause seizures. With meperidine, the metabolite normeperidine is probably the cause of seizures and is most likely to accumulate with repeated dosing in patients with chronic kidney disease. While the duration of effect for heroin is usually 3–5 hours, methadone intoxication may last for 48–72 hours or longer. Propoxyphene may cause seizures and prolongs the QRS interval; it has now been removed from the US market by the FDA. Many opioids, including fentanyl, tramadol, oxycodone, and methadone, are not detected on routine urine toxicology “opiate” screening. Wound botulism has been associated with skin-popping, especially involving “black tar” heroin. Buprenorphine added to an opioid regimen may produce acute narcotic withdrawal symptoms.

► Treatment

A. Emergency and Supportive Measures

Protect the airway and assist ventilation. Administer activated charcoal (see p 1567) for recent large ingestions.

B. Specific Treatment

Naloxone is a specific opioid antagonist that can rapidly reverse signs of narcotic intoxication. Although it is structurally related to the opioids, it has no agonist effects of its own. Administer 0.2–2 mg intravenously, and repeat as needed to awaken the patient and maintain airway protective

reflexes and spontaneous breathing. Very large doses (10–20 mg) may be required for patients intoxicated by some opioids (eg, codeine, fentanyl derivatives). **Caution:** The duration of effect of naloxone is only about 2–3 hours; repeated doses may be necessary for patients intoxicated by long-acting drugs such as methadone. Continuous observation for at least 3 hours after the last naloxone dose is mandatory.

PESTICIDES: CHOLINESTERASE INHIBITORS

Organophosphorus and carbamate insecticides (organophosphates: parathion, malathion, etc; carbamates: carbaryl, aldicarb, etc) are widely used in commercial agriculture and home gardening and have largely replaced older, more environmentally persistent organochlorine compounds such as DDT and chlordane. The organophosphates and carbamates—also called anticholinesterases because they inhibit the enzyme acetylcholinesterase—cause an increase in acetylcholine activity at nicotinic and muscarinic receptors and in the central nervous system. There are a variety of chemical agents in this group, with widely varying potencies. Most of them are poorly water-soluble, are often formulated with an aromatic hydrocarbon solvent such as xylene, and are well absorbed through intact skin. Most chemical warfare “nerve agents” (such as GA [tabun], GB [sarin], GD [soman] and VX) are organophosphates.

► Clinical Findings

Inhibition of cholinesterase results in abdominal cramps, diarrhea, vomiting, excessive salivation, sweating, lacrimation, miosis (constricted pupils), wheezing and bronchospasm, seizures, and skeletal muscle weakness. Initial tachycardia is usually followed by bradycardia. Profound skeletal muscle weakness, aggravated by excessive bronchial secretions and wheezing, may result in respiratory arrest and death. Symptoms and signs of poisoning may persist or recur over several days, especially with highly lipid-soluble agents such as fenthion or dimethoate.

The diagnosis should be suspected in patients who present with miosis, sweating, and hyperperistalsis. Serum and red blood cell cholinesterase activity is usually depressed at least 50% below baseline in those victims who have severe intoxication.

► Treatment

A. Emergency and Supportive Measures

If the agent was recently ingested, consider gut decontamination by aspiration of the liquid using a nasogastric tube

followed by administration of activated charcoal (see p 1567). If the agent is on the victim's skin or hair, wash repeatedly with soap or shampoo and water. Providers should take care to avoid skin exposure by wearing gloves and waterproof aprons. Dilute hypochlorite solution (eg, household bleach diluted 1:10) is reported to help break down organophosphate pesticides and nerve agents on equipment or clothing.

B. Specific Treatment

Atropine reverses excessive muscarinic stimulation and is effective for treatment of salivation, bronchial hypersecretion, wheezing, abdominal cramping, and sweating. However, it does not interact with nicotinic receptors at autonomic ganglia and at the neuromuscular junction and has no direct effect on muscle weakness. Administer 2 mg intravenously, and if there is no response after 5 minutes, give repeated boluses in rapidly escalating doses (eg, doubling the dose each time) as needed to dry bronchial secretions and decrease wheezing; as much as several hundred milligrams of atropine has been given to treat severe poisoning.

Pralidoxime (2-PAM, Protopam) is a specific antidote that reverses organophosphate binding to the cholinesterase enzyme; therefore, it should be effective at the neuromuscular junction as well as other nicotinic and muscarinic sites. It is most likely to be clinically effective if started very soon after poisoning, to prevent permanent binding of the organophosphate to cholinesterase. However, clinical studies have yielded conflicting results regarding the effectiveness of pralidoxime in reducing mortality. Administer 1–2 g intravenously as a loading dose, and begin a continuous infusion (200–500 mg/h, titrated to clinical response). Continue to give pralidoxime as long as there is any evidence of acetylcholine excess. Pralidoxime is of questionable benefit for carbamate poisoning, because carbamates have only a transitory effect on the cholinesterase enzyme. Other, unproven therapies for organophosphate poisoning include magnesium, sodium bicarbonate, clonidine, and extracorporeal removal.

PETROLEUM DISTILLATES & SOLVENTS

Petroleum distillate toxicity may occur from inhalation of the vapor or as a result of pulmonary aspiration of the liquid during or after ingestion. Acute manifestations of aspiration pneumonitis are vomiting, coughing, and bronchopneumonia. Some hydrocarbons—ie, those with aromatic or halogenated subunits—can also cause severe systemic poisoning after oral ingestion. Hydrocarbons can also cause systemic intoxication by inhalation. Vertigo,

muscular incoordination, irregular pulse, myoclonus, and seizures occur with serious poisoning and may be due to hypoxemia or the systemic effects of the agents. Chlorinated and fluorinated hydrocarbons (trichloroethylene, Freons, etc) and many other hydrocarbons can cause ventricular arrhythmias due to increased sensitivity of the myocardium to the effects of endogenous catecholamines.

► Treatment

Remove the patient to fresh air. For simple aliphatic hydrocarbon ingestion, gastric emptying and activated charcoal are not recommended, but these procedures may be indicated if the preparation contains toxic solutes (eg, an insecticide) or is an aromatic or halogenated product. Observe the victim for 6–8 hours for signs of aspiration pneumonitis (cough, localized crackles or rhonchi, tachypnea, and infiltrates on chest radiograph). Corticosteroids are not recommended. If fever occurs, give a specific antibiotic only after identification of bacterial pathogens by laboratory studies. Because of the risk of arrhythmias, use bronchodilators with caution in patients with chlorinated or fluorinated solvent intoxication. If tachyarrhythmias occur, use esmolol intravenously 25–100 mcg/kg/min.

QUINIDINE & RELATED ANTIARRHYTHMICS

Quinidine, procainamide, and disopyramide are class Ia antiarrhythmic agents, and flecainide and propafenone are class Ic agents. These drugs have membrane-depressant effects on the sodium-dependent channel responsible for cardiac cell depolarization. Manifestations of cardiotoxicity include arrhythmias, syncope, hypotension, and widening of the QRS complex on the ECG (> 100–120 ms). With type Ia drugs, a lengthened QT interval and atypical or polymorphous ventricular tachycardia (torsades de pointes) may occur. The antimalarials chloroquine and hydroxychloroquine, and the tricyclic antidepressants, have similar cardiotoxic effects in overdose.

► Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p 1567); consider gastric lavage (see p 1567) after large recent overdose. Assist ventilation if needed. Perform continuous cardiac monitoring.

B. Specific Treatment

Treat cardiotoxicity (hypotension, QRS interval widening) with intravenous boluses of sodium bicarbonate, 50–100 mEq. Torsades de pointes may be treated with intravenous magnesium or overdrive pacing.

Gunja N et al. Survival after massive hydroxychloroquine overdose. *Anaesth Intensive Care.* 2009 Jan;37(1):130–3. [PMID: 19157361]

SALICYLATES

Salicylates (aspirin, methyl salicylate, etc) are found in a variety of over-the-counter and prescription medications. Salicylates uncouple cellular oxidative phosphorylation, resulting in anaerobic metabolism and excessive production of lactic acid and heat, and they also interfere with several Krebs cycle enzymes. A single ingestion of more than 200 mg/kg of salicylate is likely to produce significant acute intoxication. Poisoning may also occur as a result of chronic excessive dosing over several days. Although the half-life of salicylate is 2–3 hours after small doses, it may increase to 20 hours or more in patients with intoxication.

► Clinical Findings

Acute ingestion often causes nausea and vomiting, occasionally with gastritis. Moderate intoxication is characterized by hyperpnea (deep and rapid breathing), tachycardia, tinnitus, and elevated anion gap metabolic acidosis. Serious intoxication may result in agitation, confusion, coma, seizures, cardiovascular collapse, pulmonary edema, hyperthermia, and death. The prothrombin time is often elevated owing to salicylate-induced hypoprothrombinemia. Central nervous system intracellular glucose depletion can occur despite normal measured serum glucose levels.

Diagnosis of salicylate poisoning is suspected in any patient with metabolic acidosis and is confirmed by measuring the serum salicylate level. Patients with levels > 100 mg/dL (1000 mg/L or 7.2 mmol/L) after an acute overdose are more likely to have severe poisoning. On the other hand, patients with subacute or chronic intoxication may suffer severe symptoms with levels of only 60–70 mg/dL (4.3–5 mmol/L). The arterial blood gas typically reveals a respiratory alkalosis with an underlying metabolic acidosis.

► Treatment

A. Emergency and Supportive Measures

Administer activated charcoal orally (see p 1567). Gastric lavage followed by administration of extra doses of activated charcoal may be needed in patients who ingest more than 10 g of aspirin (see p 1567). The desired ratio of charcoal to aspirin is about 10:1 by weight; while this cannot always be given as a single dose, it may be administered over the first 24 hours in divided doses every 2–4 hours along with whole bowel irrigation (see p 1567). Give glucose-containing fluids to reduce the risk of cerebral hypoglycemia. Treat metabolic acidosis with intravenous sodium bicarbonate. This is critical because acidosis (especially acidemia, pH < 7.40) promotes greater entry of salicylate into cells, worsening toxicity. **Warning:** Sudden and severe deterioration can occur after rapid sequence intubation and controlled ventilation if the pH is allowed to fall during the apneic period.

B. Specific Treatment

Alkalinization of the urine enhances renal salicylate excretion by trapping the salicylate anion in the urine. Add 100 mEq (two ampules) of sodium bicarbonate to 1 L of 5% dextrose in 0.2% saline, and infuse this solution intravenously at a rate of about 150–200 mL/h. Unless the patient is oliguric or hyperkalemic, add 20–30 mEq of potassium chloride to each liter of intravenous fluid. Patients who are volume-depleted often fail to produce an alkaline urine (paradoxical aciduria) unless potassium is given.

Hemodialysis may be lifesaving and is indicated for patients with severe metabolic acidosis, markedly altered mental status, or significantly elevated salicylate levels (eg, > 100–120 mg/dL [1000–1200 mg/L or 7.2–8.6 mmol/L] after acute overdose or > 60–70 mg/dL [600–700 mg/L or 4.3–5 mmol/L] with subacute or chronic intoxication).

SEAFOOD POISONINGS

A variety of intoxications may occur after eating certain types of fish or other seafood. These include scombroid, ciguatera, paralytic shellfish, and puffer fish poisoning. The mechanisms of toxicity and clinical presentations are described in Table 38–10. In the majority of cases, the seafood has a normal appearance and taste (scombroid may have a peppery taste).

► Treatment

A. Emergency and Supportive Measures

Caution: Abrupt respiratory arrest may occur in patients with acute paralytic shellfish and puffer fish poisoning. Observe patients for at least 4–6 hours. Replace fluid and electrolyte losses from gastroenteritis with intravenous saline or other crystalloid solution.

For recent ingestions, it may be possible to adsorb residual toxin in the gut with activated charcoal, 50–60 g orally (see p 1567).

B. Specific Treatment

There is no specific antidote for paralytic shellfish or puffer fish poisoning.

1. Ciguatera—There are anecdotal reports of successful treatment of acute neurologic symptoms with mannitol, 1 g/kg intravenously, but this approach is not widely accepted.

2. Scombroid—Antihistamines such as diphenhydramine, 25–50 mg intravenously, and the H₂-blocker cimetidine, 300 mg intravenously, are usually effective. For severe reactions, give also epinephrine, 0.3–0.5 mL of a 1:1000 solution subcutaneously.

SNAKE BITES

The venom of poisonous snakes and lizards may be predominantly neurotoxic (coral snake) or predominantly cytolytic (rattlesnakes, other pit vipers). Neurotoxins

Table 38–10. Common seafood poisonings.

Type of Poisoning	Mechanism	Clinical Presentation
Ciguatera	Reef fish ingest toxic dinoflagellates, whose toxins accumulate in fish meat. Commonly implicated fish in the United States are barracuda, jack, snapper, and grouper.	1–6 hours after ingestion, victims develop abdominal pain, vomiting, and diarrhea accompanied by a variety of neurologic symptoms, including paresthesias, reversal of hot and cold sensation, vertigo, headache, and intense itching. Autonomic disturbances, including hypotension and bradycardia, may occur.
Scombroid	Improper preservation of large fish results in bacterial degradation of histidine to histamine. Commonly implicated fish include tuna, mahimahi, bonita, mackerel, and kingfish.	Allergic-like (anaphylactoid) symptoms are due to histamine, usually begin within 15–90 minutes, and include skin flushing, itching, urticaria, angioedema, bronchospasm, and hypotension as well as abdominal pain, vomiting, and diarrhea.
Paralytic shellfish poisoning	Dinoflagellates produce saxitoxin, which is concentrated by filter-feeding mussels and clams. Saxitoxin blocks sodium conductance and neuronal transmission in skeletal muscles.	Onset is usually within 30–60 minutes. Initial symptoms include perioral and intraoral paresthesias. Other symptoms include nausea and vomiting, headache, dizziness, dysphagia, dysarthria, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.
Puffer fish poisoning	Tetrodotoxin is concentrated in liver, gonads, intestine, and skin. Toxic effects are similar to those of saxitoxin. Tetrodotoxin is also found in some North American newts and Central American frogs.	Onset is usually within 30–40 minutes but may be as short as 10 minutes. Initial perioral paresthesias are followed by headache, diaphoresis, nausea, vomiting, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.

cause respiratory paralysis; cytolytic venoms cause tissue destruction by digestion and hemorrhage due to hemolysis and destruction of the endothelial lining of the blood vessels. The manifestations of rattlesnake envenomation are mostly local pain, redness, swelling, and extravasation of blood. Perioral tingling, metallic taste, nausea and vomiting, hypotension, and coagulopathy may also occur. Thrombocytopenia can persist for several days after a rattlesnake bite. Neurotoxic envenomation may cause ptosis, dysphagia, diplopia, and respiratory arrest.

▶ Treatment

A. Emergency Measures

Immobilize the patient and the bitten part in a neutral position. Avoid manipulation of the bitten area. Transport the patient to a medical facility for definitive treatment. Do *not* give alcoholic beverages or stimulants; do *not* apply ice; do *not* apply a tourniquet. The potential trauma to underlying tissues resulting from incision and suction performed by unskilled people is probably not justified in view of the small amount of venom that can be recovered.

B. Specific Antidote and General Measures

1. Pit viper (eg, rattlesnake) envenomation—For local signs such as swelling, pain, and ecchymosis but no systemic symptoms, give 4–6 vials of crotalid antivenin (CroFab) by slow intravenous drip in 250–500 mL saline. Repeated doses of 2 vials every 6 hours for up to 18 hours has been recommended. For more serious envenomation with marked local effects and systemic toxicity (eg, hypotension, coagulopathy), higher doses and additional vials may be required. Monitor vital signs and the blood coagulation profile. Type and cross-match blood. The adequacy of venom neutralization is indicated by improvement in symptoms and signs, and the rate that swelling slows. Prophylactic antibiotics are not indicated after a rattlesnake bite.

2. Elapid (coral snake) envenomation—Give 1–2 vials of specific antivenom as soon as possible. To locate antisera for exotic snakes, call a regional poison control center (1-800-222-1222).

SPIDER BITES & SCORPION STINGS

The toxin of most species of spiders in the United States causes only local pain, redness, and swelling. That of the more venomous black widow spiders (*Latrodectus mactans*)

causes generalized muscular pains, muscle spasms, and rigidity. The brown recluse spider (*Loxosceles reclusa*) causes progressive local necrosis as well as hemolytic reactions (rare).

Stings by most scorpions in the United States cause only local pain. Stings by the more toxic *Centruroides* species (found in the southwestern United States) may cause muscle cramps, twitching and jerking, and occasionally hypertension, convulsions, and pulmonary edema. Stings by scorpions from other parts of the world are not discussed here.

▶ Treatment

A. Black Widow Spider Bites

Pain may be relieved with parenteral opioids or muscle relaxants (eg, methocarbamol, 15 mg/kg). Calcium gluconate 10%, 0.1–0.2 mL/kg intravenously, may transiently relieve muscle rigidity, though its effectiveness is unproven. *Latrodectus* antivenom is very effective, but because of concerns about acute hypersensitivity reactions (horse serum-derived), it is often reserved for very young or elderly patients or those who do not respond promptly to the above measures. Horse serum sensitivity testing is required. (Instruction and testing materials are included in the antivenin kit.)

B. Brown Recluse Spider Bites

Because bites occasionally progress to extensive local necrosis, some authorities recommend early excision of the bite site, whereas others use oral corticosteroids. Anecdotal reports have claimed success with dapsone and colchicine. All of these treatments remain of unproved value.

C. Scorpion Stings

No specific treatment other than analgesics is required for envenomations by most scorpions found in the United States. For *Centruroides* stings, a specific antivenom developed in Arizona was proved effective and was granted FDA approval in 2011.

Bawaskar HS et al. Efficacy and safety of scorpion antivenom plus prazosin compared with prazosin alone for venomous scorpion (*Mesobuthus tamulus*) sting: randomised open label clinical trial. *BMJ*. 2011 Jan 5;342:c7136. [PMID: 21209062]

THEOPHYLLINE & CAFFEINE

Theophylline may cause intoxication after an acute single overdose, or intoxication may occur as a result of chronic

accidental repeated overmedication or reduced elimination resulting from hepatic dysfunction or interacting drug (eg, cimetidine, erythromycin). The usual serum half-life of theophylline is 4–6 hours, but this may increase to more than 20 hours after overdose. Caffeine and caffeine-containing herbal products can produce similar toxicity.

► Clinical Findings

Mild intoxication causes nausea, vomiting, tachycardia, and tremulousness. Severe intoxication is characterized by ventricular and supraventricular tachyarrhythmias, hypotension, and seizures. Status epilepticus is common and often intractable to the usual anticonvulsants. After acute overdose (but not chronic intoxication), hypokalemia, hyperglycemia, and metabolic acidosis are common. Seizures and other manifestations of toxicity may be delayed for several hours after acute ingestion, especially if a sustained-release preparation such as Theo-Dur was taken.

Diagnosis is based on measurement of the serum theophylline concentration. Seizures and hypotension are likely to develop in acute overdose patients with serum levels > 100 mg/L (555 μmol/L). Serious toxicity may develop at lower levels (ie, 40–60 mg/L [222–333 μmol/L]) in patients with chronic intoxication.

► Treatment

A. Emergency and Supportive Measures

After acute ingestion, administer activated charcoal (see p 1567). Repeated doses of activated charcoal may enhance theophylline elimination by “gut dialysis.” Addition of whole bowel irrigation should be considered for large ingestions involving sustained-release preparations (see p 1567).

Hemodialysis is effective in removing theophylline and is indicated for patients with status epilepticus or markedly elevated serum theophylline levels (eg, > 100 mg/L [555 μmol/L] after acute overdose or > 60 mg/L [333 μmol/L] with chronic intoxication).

B. Specific Treatment

Treat seizures with benzodiazepines (lorazepam, 2–3 mg intravenously, or diazepam, 5–10 mg intravenously) or phenobarbital (10–15 mg/kg intravenously). Phenytoin is not effective. Hypotension and tachycardia—which are mediated through excessive β-adrenergic stimulation—may respond to β-blocker therapy even in low doses. Administer esmolol, 25–50 mcg/kg/min by intravenous infusion, or propranolol, 0.5–1 mg intravenously.

Rudolph T et al. A case of fatal caffeine poisoning. *Acta Anaesthesiol Scand*. 2010 Apr;54(4):521–3. [PMID: 20096021]
Trabulo D et al. Caffeinated energy drink intoxication. *Emerg Med J*. 2011 Aug;28(8):712–4. [PMID: 21788240]

TRICYCLIC & OTHER ANTIDEPRESSANTS

Tricyclic and related cyclic antidepressants are among the most dangerous drugs involved in suicidal overdose. These

drugs have anticholinergic and cardiac depressant properties (“quinidine-like” sodium channel blockade). Tricyclic antidepressants produce more marked membrane-depressant cardiotoxic effects than the phenothiazines.

Newer antidepressants such as trazodone, fluoxetine, citalopram, paroxetine, sertraline, bupropion, venlafaxine, and fluvoxamine are not chemically related to the tricyclic antidepressant agents and do not generally produce quinidine-like cardiotoxic effects. However, they may cause seizures in overdoses and they may cause serotonin syndrome (see Monoamine Oxidase Inhibitors section).

► Clinical Findings

Signs of severe intoxication may occur abruptly and without warning within 30–60 minutes after acute tricyclic overdose. Anticholinergic effects include dilated pupils, tachycardia, dry mouth, flushed skin, muscle twitching, and decreased peristalsis. Quinidine-like cardiotoxic effects include QRS interval widening (> 0.12 s; Figure 38–2), ventricular arrhythmias, AV block, and hypotension. Rightward-axis deviation of the terminal 40 ms of the QRS has also been described. Prolongation of the QT interval and torsades de pointes have been reported with several of the newer antidepressants. Seizures and coma are common with severe intoxication. Life-threatening hyperthermia may result from status epilepticus and anticholinergic-induced impairment of sweating. Among newer agents, bupropion and venlafaxine have been associated with a greater risk of seizures.

The diagnosis should be suspected in any overdose patient with anticholinergic side effects, especially if there is widening of the QRS interval or seizures. For

▲ **Figure 38-2.** Cardiac arrhythmias resulting from tricyclic antidepressant overdose. **A:** Delayed intraventricular conduction results in prolonged QRS interval (0.18 s). **B** and **C:** Supraventricular tachycardia with progressive widening of QRS complexes mimics ventricular tachycardia. (Reproduced, with permission, from Benowitz NL, Goldschlager N. Cardiac disturbances in the toxicologic patient. In: Haddad LM, Winchester JF [editors], *Clinical Management of Poisoning and Drug Overdose*, 3rd edition. Saunders/Elsevier, 1998.)

intoxication by most tricyclic antidepressants, the QRS interval correlates with the severity of intoxication more reliably than the serum drug level.

Serotonin syndrome should be suspected if agitation, delirium, diaphoresis, tremor, hyperreflexia, clonus (spontaneous, inducible, or ocular), and fever develop in a patient taking serotonin reuptake inhibitors.

► Treatment

A. Emergency and Supportive Measures

Observe patients for at least 6 hours, and admit all patients with evidence of anticholinergic effects (eg, delirium, dilated pupils, tachycardia) or signs of cardiotoxicity (see above).

Administer activated charcoal (see p 1567) and consider gastric lavage (see p 1567) after recent large ingestions. All of these drugs are highly tissue-bound and are not effectively removed by hemodialysis procedures.

B. Specific Treatment

Cardiotoxic sodium channel-depressant effects of tricyclic antidepressants may respond to boluses of sodium bicarbonate (50–100 mEq intravenously). Sodium bicarbonate provides a large sodium load that alleviates depression of the sodium-dependent channel. Reversal of acidosis may

also have beneficial effects at this site. Maintain the pH between 7.45 and 7.50. Alkalinization does not promote excretion of tricyclic antidepressants. Prolongation of the QT interval or torsades de pointes is usually treated with intravenous magnesium or overdrive pacing. Severe cardiotoxicity in patients with overdoses of lipid-soluble drugs (eg, amitriptyline, bupropion) has responded to intravenous lipid emulsion (Intralipid).

Mild serotonin syndrome may be treated with benzodiazepines and withdrawal of the antidepressant. Moderate cases may respond to cyproheptadine (4 mg orally or via gastric tube hourly for three or four doses) or chlorpromazine (25 mg intravenously). Severe hyperthermia should be treated with neuromuscular paralysis and endotracheal intubation in addition to external cooling measures.

The major features of this chapter are the clinical aspects of cancer, including etiology and prevention; staging; diagnosis and treatment of common cancers; and recognition and management of complications from cancer. Additional information may be obtained from the National Cancer Institute (NCI) website at www.cancer.gov/cancer topics, the American Society of Clinical Oncology website at www.asco.org, and the National Comprehensive Cancer Network (NCCN) website at www.nccn.org. The NCCN website provides detailed, evidence-based recommendations for management of specific cancers as well as guidelines for cancer screening and for supportive care. General reviews in oncology can be obtained from Medscape Hematology/Oncology (www.medscape.com).

► Etiology

Cancer is the second most common cause of death in the United States. In 2011 an estimated 1,596,670 cases of cancer were diagnosed, and 571,950 persons died as a result of cancer. Based on cancer rates determined in 2003–2005, more than 40% of people born today will have cancer diagnosed at some point in their lifetime. Table 39–1 lists the 10 leading cancer types in men and women by site.

However, the incidence of cancer in both men and women is decreasing. In 2008, the American Cancer Society, NCI, and the Centers for Disease Control and Prevention reported that the incidence of all cancers for both sexes decreased 0.8% per year from 1999 through 2005. As the incidence of cancer is decreasing, the survival rate is increasing. In 2010, using information from the Surveillance Epidemiology and End Results (SEER) database, the NCI reported a survival rate of 68% for individuals in whom cancer was diagnosed between 1999 and 2006 compared to 50% for those in whom cancer was diagnosed between 1975 and 1977.

Reductions in cancer incidence and mortality reflect a successful implementation of a broad strategy of prevention, detection, and treatment.

► Modifiable Risk Factors

Tobacco is the most common preventable cause of cancer death; it is estimated that at least 30% of all cancer deaths

in the United States are directly linked to tobacco. A total of 171,000 cancer deaths in the United States and 1.42 million cancer deaths worldwide can be directly attributed to tobacco abuse. Clear evidence links at least 15 cancers to tobacco use. The most dramatic link is with lung cancer, the most common non-dermatologic malignancy; 87% of lung cancer cases occur in smokers. Any strategy for cancer control must include the goal of markedly reducing if not eliminating tobacco use.

Strategies for tobacco control should involve a focus on the individual as well as society as a whole. Tobacco cessation directed toward the individual should start with the clinician providing counseling. Simple, concise advice from a clinician can yield cessation rates of 10–20%. Additive strategies include more intensive counseling; nicotine replacement therapy with patches, gum, or lozenges; and prescription medication with bupropion or varenicline. Perhaps a more intriguing phenomenon, with potential for significant impact on cessation rates, is the influence of social contact behavior on an individual smoker's abstinence decision. For instance, analysis of the Framingham Heart Study demonstrated that smoking cessation by a spouse resulted in a 67% decrease in the subject's likelihood of continuing to smoke, and smoking cessation by a friend resulted in a 36% decrease in the subject's likelihood of smoking.

On a societal level, many initiatives have been put into place to actively discourage tobacco use. State or local laws regulating tobacco use in restaurants, the workplace, and other public places have resulted in declines in tobacco use. Countermarketing with aggressive anti-tobacco advertisements has also contributed to tobacco cessation and abstinence. The key recipients of these messages are children; 80% of smokers will start by age 18. Preventing the start of addiction in this vulnerable population should be a top priority (see Chapter 1).

There are encouraging signs of success with tobacco control. The prevalence of smoking for United States adults based on the 2011 National Health Interview Survey is 19.4%, which is a remarkable reduction from the 1955 peak of 57% for males and the 1965 peak of 34% for females but still falls short of the Healthy People 2010 goal of < 12%. See Chapter 1 for additional material on smoking cessation techniques.

Table 39-1. Estimated 10 most common cancer cases in the United States in males and females (all races).

Rank	Males	Females
	Total Cases = 822,300 (percent)	Total Cases = 774,370 (percent)
1	Prostate (29)	Breast (30)
2	Lung and bronchus (14)	Lung and bronchus (14)

6	Melanoma (5)	Lymphoma (4)
7	Kidney and renal pelvis (5)	Melanoma (4)
8	Oral cavity and pharynx (3)	Kidney and renal pelvis (3)
9	Leukemia (3)	Ovary (3)
10	Pancreas (3)	Pancreas (3)
	Other sites (18)	Other sites (19)

Data from the American Cancer Society, 2011.

For those Americans who do not use tobacco, the most modifiable risk factors would be nutrition and physical activity. Epidemiologic studies suggest that fruit- and vegetable-rich diets lower risks of several gastrointestinal malignancies, including esophageal, stomach, and colon cancers. Excessive consumption of alcohol is linked to increased risks of head and neck cancers as well as cancers of the esophagus and liver. Lastly, being overweight is linked to several malignancies, including breast and uterine cancers in women and colorectal, esophageal, and kidney cancers in both men and women. More importantly, weight reduction can decrease the risks of these cancers.

Another modifiable risk factor is radiation from radiographic studies. A 2009 study reported that the use of computed tomography (CT) in diagnostic algorithms exposes individuals to significant radiation doses that may increase the lifetime risk of developing cancer. Both standardization of CT radiation doses and limiting testing will be important steps in minimizing this risk.

Smith-Bindman R et al. Radiation dose associated with common computed tomography examinations and the associated lifetime attributable risk of cancer. *Arch Intern Med.* 2009 Dec 14;169(22):2078–86. [PMID: 20008690]

► Staging

The most commonly used staging system at the time of diagnosis is the TNM (Tumor, Nodes, Metastasis) system (see www.cancerstaging.org). Rules for staging for individual cancers are established and published by the American

Joint Committee on Cancer (AJCC). Elements used for staging include tumor location, size and level of tumor invasion (T), absence or presence and extent of nodal metastases (N), and presence or absence of systemic metastases (M). Once the TNM designations have been determined, an overall stage is assigned, stage I, II, III, or IV. Clinical staging utilizes physical examination, laboratory and imaging tests as well as results from biopsies; pathologic staging relies on the results from surgery. In some instances, other classifications may be used for certain cancers such as the Ann Arbor staging system for lymphomas.

Other characteristics of cancers, not reflected in the TNM stage, may be used as another indicator of prognosis. Pathologic features seen on routine histologic examination for some cancers are very important; examples include the Gleason score for prostate cancer and the grade of sarcomas. Cancer specimens may also be sent for targeted molecular diagnostic testing; results are used to determine prognosis as well as treatment. Examples include testing for *HER-2/neu* in breast and gastric cancers, *KRAS* and *BRAF* mutations in colorectal cancers, and *EGFR* and *KRAS* mutations in lung cancer. In the future, as the pathways for oncogenesis and relationships of mutations to treatment and prognosis are better delineated, analysis for detection of chromosomal alterations and oncogene products will continue to be increasingly incorporated into routine practice.

THE PARANEOPLASTIC SYNDROMES

The clinical manifestations of cancer are usually due to pressure effects of local tumor growth, infiltration or metastatic deposition of tumor cells in a variety of organs in the body, or certain systemic symptoms. General problems observed in many patients with advanced or widespread metastatic cancer include anorexia, malaise, weight loss, and sometimes fever. These characteristics must be considered when evaluating a patient with an undiagnosed illness. Except in the case of functioning tumors such as those of the endocrine glands, systemic symptoms of cancer usually are not specific, often consisting of weakness, anorexia, and weight loss. The term “paraneoplastic” refers to features of disease considered to be due to the remote effects of a cancer. These features cannot be attributed either to a cancer’s direct invasive or metastatic properties and are often considered to be due to aberrant hormonal or metabolic effects not observed in a cancer’s normal tissue equivalent. In the paraneoplastic syndromes, clinical findings may resemble those of primary endocrine, metabolic, hematologic, or neuromuscular disorders. At present, the mechanisms for such remote effects can be classified into three groups: (1) effects initiated by a tumor product (eg, carcinoid syndrome, ectopic hormone production), (2) effects of destruction of normal tissues by tumor (eg, hypercalcemia with osteolytic skeletal metastases), and (3) effects due to unknown mechanisms. In paraneoplastic syndromes associated with ectopic hormone production, tumor tissue itself secretes the hormone that produces the syndrome. Ectopic hormones secreted by neoplasms are often pro-hormones of higher molecular weight than those

secreted by the more differentiated normal endocrine cell. Such ectopic hormone production by cancer cells is believed to result from activation of genes in the malignant cells that are suppressed in the normal tissue equivalent and in most somatic cells. Autocrine growth factors secreted by neoplastic cells may also result in paraneoplastic syndromes. Small cell lung cancer is the one type of cancer most likely to be associated with paraneoplastic syndromes.

The paraneoplastic syndromes are clinically important for the following reasons:

(1) They sometimes accompany relatively limited neoplastic growth and may provide the clinician with an early clue to the presence of certain types of cancer.

(2) The metabolic or toxic effects of the syndrome may constitute a more urgent hazard to the patient's life than the underlying cancer (eg, hypercalcemia, hyponatremia).

(3) Effective treatment of the tumor should be accompanied by resolution of the paraneoplastic syndrome and, conversely, recurrence of the cancer may be heralded by return of the systemic symptoms. In some instances, rapid response to cytotoxic chemotherapy may briefly increase the severity of the paraneoplastic syndrome in association with tumor lysis (eg, hyponatremia with inappropriate antidiuretic hormone excretion). In some instances the identical symptom complex (eg, hypercalcemia) may be induced by entirely different mechanisms. A single syndrome such as hypercalcemia may be due to any one of a variety of humoral factors, such as secretion of parathyroid hormone precursors or homologs or 1,25 dihydroxyvitamin D. Effective antitumor treatment usually results in return of serum calcium to normal.

Common paraneoplastic syndromes and endocrine secretions associated with functional cancers are summarized in Table 39–2.

TYPES OF CANCER

LUNG CANCER

Sunny Wang, MD

BRONCHOGENIC CARCINOMA

ESSENTIALS OF DIAGNOSIS

- ▶ New cough, or change in chronic cough.
- ▶ Dyspnea, hemoptysis, anorexia, weight loss.
- ▶ Enlarging nodule or mass; persistent opacity, atelectasis, or pleural effusion on chest radiograph or CT scan.
- ▶ Cytologic or histologic findings of lung cancer in sputum, pleural fluid, or biopsy specimen.

General Considerations

Lung cancer is the leading cause of cancer deaths in both men and women. The American Cancer Society estimates

226,160 new diagnoses and 160,340 deaths from lung cancer in the United States in 2012, accounting for approximately 14% of new cancer diagnoses and 28% of all cancer deaths. More Americans die of lung cancer than of colorectal, breast, and prostate cancers combined.

Cigarette smoking causes 85–90% of cases of lung cancer. Lung cancer was a previously reportable disease until the widespread use of manufactured cigarettes in the 20th century. The causal connection between cigarettes and lung cancer is established not only epidemiologically but also through identification of carcinogens in tobacco smoke and analysis of the effect of these carcinogens on specific oncogenes expressed in lung cancer.

Since the early 1990s, mortality from lung cancer fell among men while it increased among women and is only now peaking among women, reflecting changing patterns of tobacco use over the past 30 years (see Chapter 1). Other environmental risk factors for the development of lung cancer include exposure to environmental tobacco smoke, radon gas (among uranium miners and in areas where radium in the soil causes significant indoor air contamination), asbestos (60- to 100-fold increased risk in smokers with asbestos exposure), metals (arsenic, chromium, nickel, iron oxide), and industrial carcinogens (bis-chloromethyl ether). A familial predisposition to lung cancer is recognized. Certain diseases are associated with an increased risk of lung cancer, including pulmonary fibrosis, chronic obstructive pulmonary disease, and sarcoidosis. Second primary lung cancers are more frequent in patients who survive their initial lung cancer.

The median age at diagnosis of lung cancer in the United States is 71; it is unusual under the age of 40. After the diagnosis of lung cancer is made, approximately 41% of patients survive 1 year. The combined relative 5-year survival rate for all stages of lung cancer is currently 16%, slightly improved from 13% for lung cancers diagnosed in the 1970–80s.

Five histologic categories of bronchogenic carcinoma account for more than 90% of cases of primary lung cancer. **Squamous cell carcinoma** (20% of cases) arises from the bronchial epithelium, typically as a centrally located, intraluminal sessile or polypoid mass. Squamous cell tumors are more likely to present with hemoptysis and more frequently diagnosed by sputum cytology. They spread locally and may be associated with hilar adenopathy and mediastinal widening on chest radiography. **Adenocarcinoma** (35–40% of cases) arises from mucus glands or, in the case of **bronchioloalveolar cell carcinoma** (2% of cases), from any epithelial cell within or distal to the terminal bronchioles. Adenocarcinomas usually present as peripheral nodules or masses. Bronchioloalveolar cell carcinoma, now known as **adenocarcinoma in situ**, spreads along preexisting alveolar structures (lepidic growth) without evidence of invasion. **Large cell carcinoma** (3–5% of cases) is a heterogeneous group of relatively undifferentiated tumors that share large cells and do not fit into other categories. Large cell carcinomas typically have rapid doubling times and an aggressive clinical course. They present as central or peripheral masses. Tumors that are not better differentiated on pathologic review other than carcinoma

unspecified make up about 20–25% of cases. **Small cell carcinoma** (10–15% of cases) is a tumor of bronchial origin that typically begins centrally, infiltrating submucosally to cause narrowing or obstruction of the bronchus without a discrete luminal mass. Hilar and mediastinal abnormalities are common on chest radiography.

For purposes of staging and treatment, bronchogenic carcinoma is divided into small cell lung cancer (SCLC) and the other four types, conveniently labeled non–small cell lung cancer (NSCLC). This practical classification reflects different natural histories and different treatment. SCLC is prone to early hematogenous spread. It is rarely amenable to surgical resection and has a very aggressive course with a median survival (untreated) of 6–18 weeks. The four histologic categories comprising NSCLC spread more slowly. They may be cured in the early stages following resection, and for advanced disease, chemotherapy is tailored to specific histologies and molecular mutations found within NSCLC.

► Clinical Findings

Lung cancer is symptomatic at diagnosis in 75–90% of patients. The clinical presentation depends on the type and location of the primary tumor, the extent of local spread, and the presence of distant metastases and any paraneoplastic syndromes.

A. Symptoms and Signs

Anorexia, weight loss, or asthenia occurs in 55–90% of patients presenting with a new diagnosis of lung cancer. Up to 60% of patients have a new cough or a change in a chronic cough; 6–31% have hemoptysis; and 25–40% complain of pain, either nonspecific chest pain or pain from bony metastases to the vertebrae, ribs, or pelvis. Local spread may cause endobronchial obstruction with atelectasis and postobstructive pneumonia, pleural effusion (12–33%), change in voice (compromise of the recurrent laryngeal nerve), superior vena cava syndrome (obstruction of the superior vena cava with supraclavicular venous engorgement), and Horner syndrome (ipsilateral ptosis, miosis, and anhidrosis from involvement of the inferior cervical ganglion and the paravertebral sympathetic chain). Distant metastases to the liver are associated with asthenia and weight loss. Brain metastases (10% in NSCLC, more common in adenocarcinoma, and 20–30% in SCLC) may present with headache, nausea, vomiting, seizures, dizziness, or altered mental status.

Paraneoplastic syndromes are incompletely understood patterns of organ dysfunction related to immune-mediated or secretory effects of neoplasms. These syndromes occur in 10–20% of lung cancer patients. They may precede, accompany, or follow the diagnosis of lung cancer and do not necessarily indicate metastatic disease. In patients with small cell carcinoma, the syndrome of inappropriate antidiuretic hormone (SIADH) can develop in 10–15%; in those with squamous cell carcinoma, hypercalcemia can develop in 10% (Table 39–2). Digital clubbing is seen in up to 20% of patients at diagnosis (see Figure 6–41). Other common paraneoplastic syndromes include

increased ACTH production, anemia, hypercoagulability, peripheral neuropathy, and the Eaton-Lambert myasthenia syndrome. Their recognition is important because treatment of the primary tumor may improve or resolve symptoms even when the cancer is not curable.

B. Laboratory Findings

The diagnosis of lung cancer rests on examination of a tissue or cytology specimen. Sputum cytology is highly specific but insensitive; the yield is highest when there are lesions in the central airways. Thoracentesis (sensitivity 50–65%) can be used to establish a diagnosis of lung cancer in patients with malignant pleural effusions. If cytologic examination of an adequate sample (50–100 mL) of pleural fluid is nondiagnostic, the procedure should be repeated; approximately 30% of second samples are positive when the first sample is negative. If results remain negative, thoracoscopy is preferred to blind pleural biopsy. Fine-needle aspiration (FNA) of palpable supraclavicular or cervical lymph nodes is frequently diagnostic. Serum tumor markers are neither sensitive nor specific enough to aid in diagnosis.

Fiberoptic bronchoscopy allows visualization of the major airways, cytology brushing of visible lesions or lavage of lung segments with cytologic evaluation of specimens, direct biopsy of endobronchial abnormalities, blind transbronchial biopsy of the pulmonary parenchyma or peripheral nodules, and FNA biopsy of mediastinal lymph nodes. Diagnostic yield varies widely (10–90%) depending on the size of the lesion and its location. The use of fluorescence bronchoscopy improves the ability to identify early endobronchial lesions, while endobronchial and transesophageal endoscopic ultrasound enhance the direction and yield of FNA of mediastinal nodes. Transthoracic needle aspiration (TTNA) has a sensitivity between 50% and 97%. Mediastinoscopy, video-assisted thoracoscopic surgery (VATS), and thoracotomy are necessary in cases where less invasive techniques fail to yield a diagnosis.

C. Imaging

Nearly all patients with lung cancer have abnormal findings on chest radiography or CT scan. These findings are rarely specific for a particular diagnosis. Interpretation of characteristic findings in isolated nodules is described in Chapter 9.

D. Special Examinations

1. Staging—Accurate staging is crucial (1) to provide the clinician with information to guide treatment, (2) to provide the patient with accurate information regarding prognosis, and (3) to standardize entry criteria for clinical trials to allow interpretation of results.

There are two essential principles of staging NSCLC. First, the more extensive the disease, the worse the prognosis; second, surgical resection offers the best chance for cure. Staging of NSCLC uses two integrated systems. The **TNM international staging system** attempts a physical description of the neoplasm: T describes the size and location of the primary tumor; N describes the presence and location of nodal metastases; and M refers to the presence

Table 39-3. Approximate survival rates following treatment for lung cancer.

Non-Small Cell Lung Cancer: Mean 5-Year Survival Following Resection		
Stage	Clinical Staging	Surgical Staging
IA (T1N0M0)	60%	74%
IB (T2N0M0)	38%	61%
IIA (T1N1M0)	34%	55%
IIB (T2N1M0, T3N0M0)	23%	39%
IIIA	9–13%	22%
IIIB ¹	3–12%	
IV ¹	4%	
Small Cell Lung Cancer: Survival Following Chemotherapy		
Stage	Mean 2-Year Survival	Median Survival
Limited	15–20%	14–20 months
Extensive	< 3%	8–13 months

¹Independent of therapy, generally not surgical patients. Data from multiple sources. Modified and reproduced, with permission, from Reif MS et al. Evidence-based medicine in the treatment of non-small cell cancer. Clin Chest Med. 2000;21:107.

or absence of distant metastases. These TNM stages are grouped into prognostic categories (stages I–IV) using the results of clinical trials. This classification is used to guide therapy. Many patients with stage I and stage II disease are cured through surgery. Patients with stage IIIB and stage IV disease do not benefit from surgery (Table 39–3). Patients with stage IIIA disease have locally invasive disease that may benefit from surgery in certain circumstances.

SCLC is not staged using the TNM system because micrometastases are assumed to be present on diagnosis. SCLC is divided into two categories: **limited disease** (30%), when the tumor is limited to the unilateral hemithorax (including contralateral mediastinal nodes); or **extensive disease** (70%), when the tumor extends beyond the hemithorax (including pleural effusion). For both SCLC and NSCLC, staging begins with a thorough history and physical examination. A complete examination is essential to exclude obvious metastatic disease to lymph nodes, skin, and bone. A detailed history is essential because the patient's performance status is a powerful predictor of disease course. All patients should have measurement of a complete blood count, electrolytes including calcium, creatinine, liver tests, lactate dehydrogenase, albumin, and a chest radiograph. Further evaluation will follow the results of these tests.

NSCLC patients being considered for surgery require meticulous evaluation to identify those with resectable disease. CT imaging is the most important modality for staging candidates for resection. A chest CT scan precisely defines the size of parenchymal lesions and identifies atelectatic lung or pleural effusions. However, CT imaging is less accurate at determining invasion of the chest wall

(sensitivity 62%) or mediastinum (sensitivity 60–75%). The sensitivity and specificity of CT imaging for identifying lung cancer metastatic to the mediastinal lymph nodes are 57% (49–66%) and 82% (77–86%), respectively. Therefore, chest CT imaging does not provide definitive information on staging. CT imaging does help in making the decision about whether to proceed to resection of the primary tumor and sample the mediastinum at thoracotomy (common if there are no lymph nodes > 1 cm) or to use TTNA, mediastinoscopy, esophageal ultrasound with transesophageal needle aspiration, or limited thoracotomy to biopsy suspected metastatic disease (common where there are lymph nodes > 1–2 cm).

Positron emission tomography (PET) using 2-[¹⁸F] fluoro-2-deoxyglucose (FDG) is an important modality for identifying metastatic foci in the mediastinum or distant sites. The sensitivity and specificity of PET for detecting mediastinal spread of primary lung cancer depend on the size of mediastinal nodes or masses. When only normalized (< 1 cm) mediastinal lymph nodes are present, the sensitivity and specificity of PET for tumor involvement of nodes are 74% and 96%, respectively. When CT shows enlarged (> 1 cm) lymph nodes, the sensitivity and specificity are 95% and 76%, respectively.

The combined modalities of PET and CT imaging have improved preoperative staging compared with CT or PET alone. Many lung cancer specialists find whole body fusion PET-CT imaging most useful to confirm lack of metastatic disease in NSCLC patients who are candidates for surgical resection. There is evidence that PET-CT imaging reduces futile thoracotomies by identifying mediastinal and distant metastases in patients with NSCLC. Disadvantages of PET imaging include limited resolution below 1 cm; the expense of FDG; limited availability; and false-positive scans due to sarcoidosis, tuberculosis, or fungal infections. PET-CT scans are also inadequate for evaluating brain metastases due to the high FDG uptake there. Obtaining an MRI of the brain is important to rule out brain metastases in patients with at least stage II disease.

2. Preoperative assessment—See Chapter 3.

3. Pulmonary function testing—

Many patients with NSCLC have moderate to severe chronic lung disease that increases the risk of perioperative complications as well as long-term pulmonary insufficiency following lung resection. All patients considered for surgery require spirometry. In the absence of other comorbidities, patients with good lung function (preoperative FEV₁ ≥ 2 L) are at low risk for complications from lobectomy or pneumonectomy. If the FEV₁ is < 2 L, then an estimated postoperative FEV₁ should be calculated. The postresection FEV₁ may be estimated from considering preoperative spirometry and the amount of lung to be resected; in severe obstructive disease, a quantitative lung perfusion scan may improve the estimate. A predicted post-lung resection FEV₁ > 800 mL (or > 40% of predicted FEV₁) is associated with a low incidence of perioperative complications. High-risk patients include those with a predicted postoperative FEV₁ < 700 mL (or < 40% of predicted FEV₁). In these patients and in those with borderline spirometry, cardiopulmonary

exercise testing may be helpful. A maximal oxygen uptake ($\dot{V}O_2$) of > 15 mL/kg/min identifies patients with an acceptable incidence of complications and mortality. Patients with a $\dot{V}O_2$ of < 10 mL/kg/min have a very high mortality rate at thoracotomy. Hypoxemia and hypercapnia are not independent predictors of outcome.

4. Screening—Prior data showed that chest radiographs and analysis of expectorated sputum as lung cancer screening modalities did not improve survival. The National Lung Screening Trial, a multicenter randomized national trial involving over 53,000 current and former heavy smokers, published results showing a 20% reduction in lung cancer deaths. It compared low-dose helical CT with standard chest radiographs as screening modalities for lung cancer. Given these findings, clinical guidelines and policy recommendations on lung cancer screening are currently being discussed. Risk-benefit and cost-effective analyses are underway. The implications of widespread screening of smokers raise issues of false positives (96% in this study), surgical and medical complications from additional testing, risks of cumulative exposure to radiation, and risks of increasing patient anxiety and stress on an already limited pool of resources.

► Treatment

A. Non-Small Cell Carcinoma

Cure of NSCLC is unlikely without resection. Therefore, the initial approach to the patient is determined by the answers to two questions: (1) Is complete surgical resection technically feasible? (2) If yes, is the patient able to tolerate the surgery with acceptable morbidity and mortality? Clinical features that preclude complete resection include extrathoracic metastases or a malignant pleural effusion; or tumor involving the heart, pericardium, great vessels, esophagus, recurrent laryngeal or phrenic nerves, trachea, main carina, or contralateral mediastinal lymph nodes. Accordingly, stage I and stage II patients are treated with surgical resection where possible. Stage II, and possibly a subset of stage IB, are additionally recommended to receive adjuvant chemotherapy. Stage IIIA patients have poor outcomes when treated with resection alone. They should be referred to multimodality protocols, including chemotherapy or radiotherapy, or both. Stage IIIB patients treated with concurrent chemotherapy and radiation therapy have improved survival. Stage IV patients are treated with chemotherapy or symptom-based palliative therapy, or both (see below).

Surgical approach affects outcome. The North American Lung Cancer Study Group conducted a prospective trial of stage IA patients randomized to lobectomy versus limited resection. They reported a threefold increased rate of local recurrence in the limited resection group ($P = 0.008$) and a trend toward an increase in overall death rate (increase of 30%, $P = 0.08$) and increase in death rate due to cancer (increase of 50%, $P = 0.09$), compared with patients receiving lobectomy. There are inadequate outcome data on which to base a comparison of VATS with standard thoracotomy. Radiation therapy following surgery improves local control but does not improve survival.

Patients with small early-stage primary lung cancers who are not candidates for surgery because of significant comorbidity or other surgical contraindication may be candidates for stereotactic body radiotherapy. Stereotactic body radiotherapy (cyberknife), which is composed of multiple non-parallel radiation beams that converge, allows the delivery of a relatively large dose of radiation to a small, well-defined target. For small, early-stage cancers, 3-year local control rates with cyberknife exceed 90%, and 3-year survival is estimated at over 55%. Patients with locally advanced disease (stages IIIA and IIIB) who are not surgical candidates have improved survival when treated with concurrent chemotherapy and radiation therapy compared with no therapy, radiation alone, or even sequential chemotherapy and radiation.

Neoadjuvant chemotherapy consists of giving anti-neoplastic drugs in advance of surgery or radiation therapy. There is no consensus on the impact of neoadjuvant therapy on survival in stage I and stage II NSCLC. Such therapy is not recommended outside of ongoing clinical trials. Neoadjuvant therapy is more widely used in selected patients with stage IIIA or stage IIIB disease. Some studies suggest a survival advantage. This remains an area of active research.

Adjuvant chemotherapy consists of administering antineoplastic drugs following surgery or radiation therapy. Cisplatin-containing regimens have been shown to confer an overall survival benefit in at least stage II disease and possibly a subset of stage IB disease. The Lung Adjuvant Cisplatin Evaluation Collaborative Group published a meta-analysis of the five largest cisplatin-based adjuvant trials. They reported a 5% absolute benefit in 5-year overall survival with a cisplatin-containing doublet regimen following surgery ($P = 0.005$) in patients with at least stage II disease. For patients with poor performance status (Eastern Cooperative Oncology Group Score ≤ 2), there is no evidence of survival benefit for adjuvant chemotherapy; rather, it may be detrimental. Novel targeted agents with less toxicity are in clinical trials, and gene expression profiling has shown promise in defining a subset of patients who may benefit from adjuvant therapy.

Although not curative, chemotherapy has been shown in multiple clinical trials to provide a modest increase in overall survival and performance status in patients with stage IIIB and stage IV NSCLC compared with supportive care alone, with median survival increased from 5 months to a range of 7–11 months. Palliative chemotherapy also leads to improved quality of life and symptom control, with first-line therapy involving a platinum-based regimen. Platinum-based doublet regimens consist of cisplatin or carboplatin (agents that bind DNA to form adducts that inhibit their synthesis and function) combined with another agent, such as gemcitabine, taxane, vinorelbine, or pemetrexed. When compared in phase III trials for advanced NSCLC, these doublet regimens have shown comparable efficacy with varying toxicity profiles. Investigators have shown that the choice of chemotherapeutic agent can be tailored to histologic subtype in NSCLC. For nonsquamous histologies, patients have modestly improved overall survival when treated with a platinum agent plus pemetrexed

(an inhibitor of folate-dependent enzymes important in purine and pyrimidine synthesis). Patients with squamous cell lung carcinomas have modestly improved overall survival when a platinum agent is combined with gemcitabine (a deoxycytidine analog that inhibits DNA synthesis). For good performance status patients with nonsquamous histologies, bevacizumab (a monoclonal antibody to vascular endothelial growth factor [VEGF]) can be added to a traditional platinum doublet regimen with further modest increase in survival benefit. Cetuximab (a monoclonal antibody to the epidermal growth factor receptor [EGFR]) added to a platinum doublet regimen for all histologies of NSCLC has also shown a small survival benefit.

With the advent of molecular profiling, targeted therapy has played a significant role in NSCLC. For the subgroup of patients with EGFR mutations, an EGFR inhibitor (erlotinib and gefitinib) rather than platinum-based chemotherapy is the first-line treatment. Response rates with EGFR inhibitors in patients with EGFR mutation are at least 60%, and median overall survival is estimated at 27–30 months. EGFR mutations are found in approximately 10–15% of the white population and 30–40% in the Asian population and are usually found among nonsmokers to light-smokers, females, and adenocarcinoma histology. Approximately 5% of all patients with NSCLC carry a different mutation, the EML4-ALK fusion gene product. This is found in a comparatively younger population, with adenocarcinoma histology, and nonsmoking to light-smoking history. Based on early single-arm trials showing 60% response rates, crizotinib, an ALK and MET inhibitor, was approved by the US Food and Drug Administration (FDA) to treat EML4-ALK-positive NSCLCs. Finally, KRAS mutations are found among 25% of patients with adenocarcinomas, are associated with smoking, indicate a poor prognosis, and typically do not respond to EGFR inhibition. These three mutations are mutually exclusive. Ongoing research seeks to define the role of these targeted agents in early stage and locally advanced lung cancers, and identification of new novel mutations.

B. Small Cell Carcinoma

Response rates of SCLC to cisplatin and etoposide are excellent with 80–90% response in limited-stage disease (50–60% complete response), and 60–80% response in extensive stage disease (15–20% complete response). However, remissions tend to be short-lived with a median duration of 6–8 months. Once the disease has recurred, median survival is 3–4 months. Overall 2-year survival is 20–40% in limited-stage disease and < 5% in extensive-stage disease. Thoracic radiation therapy improves survival in patients with limited SCLC and is given concurrently with chemotherapy. Thoracic radiation therapy is not beneficial for patients with extensive disease, and they should receive chemotherapy alone. There is a high rate of brain metastasis in patients with SCLC, even following a good response to chemotherapy, because chemotherapy does not adequately penetrate the blood-brain barrier. Prophylactic cranial irradiation has been shown to decrease the incidence of central nervous system disease and improve survival in patients with limited stage disease who respond to chemotherapy and a subset of

patients with extensive stage disease who have had an excellent response to chemotherapy.

Occasionally, a patient may have a peripheral nodule resected that turns out to be SCLC. Five-year survival following resection of the equivalent of stage I and stage II SCLC is higher than in patients treated with chemotherapy.

C. Palliative Therapy

Photoresection with the Nd:YAG laser is sometimes performed on central tumors to relieve endobronchial obstruction, improve dyspnea, and control hemoptysis. External beam radiation therapy is also used to control dyspnea, hemoptysis, endobronchial obstruction, pain from bony metastases, obstruction from superior vena cava syndrome, and symptomatic brain metastases. Resection of a *solitary* brain metastasis improves quality of life when combined with radiation therapy, and if there is no evidence of other metastatic disease, it may improve survival. Intraluminal radiation (brachytherapy) is an alternative approach to endobronchial disease. Pain syndromes are very common in advanced disease. As patients approach the end of life, meticulous efforts at pain control are essential (see Chapter 5). In addition to standard oncologic care, early consultation with—or referral to—a palliative care specialist is recommended in advanced disease to aid in symptom management; it may even modestly improve survival.

► Prognosis

The overall 5-year survival rate for lung cancer is approximately 15%. Predictors of survival include the type of tumor (SCLC versus NSCLC), molecular typing, the stage of the tumor, the patient's performance status, and weight loss in the past 6 months. Patients with EGFR mutation have better overall survival when compared with those without EGFR mutation, even when receiving similar cytotoxic chemotherapy.

PULMONARY METASTASES

Pulmonary metastasis results from the spread of an extrapulmonary malignant tumor through vascular or lymphatic channels or by direct extension. Almost any cancer can metastasize to the lung, including primary lung carcinomas. Metastases usually occur via the pulmonary artery and typically present as multiple nodules or masses on chest radiography. The radiographic differential diagnosis of multiple pulmonary nodules also includes pulmonary arteriovenous malformation, pulmonary abscesses, granulomatous infection, sarcoidosis, rheumatoid nodules, and granulomatosis with polyangiitis (formerly Wegener granulomatosis). Metastases to the lungs are found in 20–55% of patients dying of various malignancies. Most are intraparenchymal. Endobronchial metastases occur in < 5% of patients dying of nonpulmonary cancer. Carcinoma of the kidney, breast, rectum, colon, and cervix and malignant melanoma are the most likely primary tumors. Head and neck cancers with extensive or lower cervical nodal involvement have a 30% risk for distant metastasis; half of these metastases present in the lungs.

Lymphangitic carcinomatosis denotes diffuse involvement of the pulmonary lymphatic network by primary or metastatic lung cancer, probably a result of extension of tumor from lung capillaries to the lymphatics. **Tumor embolization** from extrapulmonary cancer (renal cell carcinoma, hepatocellular carcinoma, choriocarcinoma) is an uncommon route for tumor spread to the lungs. Metastatic cancer may also present as a malignant pleural effusion.

► Clinical Findings

A. Symptoms and Signs

Symptoms are uncommon but include cough, hemoptysis and, in advanced cases, dyspnea and hypoxemia. Symptoms are more often referable to the site of the primary tumor.

B. Laboratory Findings

The diagnosis of metastatic cancer involving the lungs is usually established by identifying a primary tumor. Appropriate studies should be ordered if there is a suspicion of any primary cancer, such as breast, thyroid, testis, colorectal, or prostate, for which specific treatment is available.

For example, an elevated prostate-specific antigen (PSA) may indicate prostate cancer, carcinoembryonic antigen (CEA) tests for colorectal cancer, and β -human chorionic gonadotropin (β HCG) and α -fetoprotein test for germ cell tumors. Based on the clinical setting, imaging studies should be ordered (see below). If the history, physical examination, and initial studies fail to reveal the site of the primary tumor, attention is better focused on the lung, where tissue samples obtained by bronchoscopy, percutaneous needle biopsy, VATS, or thoracotomy may establish the histologic diagnosis and suggest the most likely primary cancer. Occasionally, cytologic studies of pleural fluid or pleural biopsy reveal the diagnosis. Sputum cytology is rarely helpful.

If the initial histologic review does not reveal a primary diagnosis, immunohistochemical staining should be done on the biopsy specimen. For example, PSA and thyroglobulin staining are highly specific for prostate and thyroid cancer, respectively. Thyroid transcription factor-1 (TTF-1) is relatively specific for primary lung adenocarcinoma, while also positive for SCLC and thyroid carcinoma. An adenocarcinoma that demonstrates negative TTF-1 staining strongly suggests a nonpulmonary primary cancer. Positive estrogen receptor (ER) and progesterone receptor (PR) stains suggest primary breast cancer.

C. Imaging

Chest radiographs usually show multiple spherical densities with sharp margins. The size of metastatic lesions varies from a few millimeters (miliary densities) to large masses. Nearly all are < 5 cm in diameter. The lesions are usually bilateral, pleural or subpleural in location, and more common in lower lung zones. Cavitation suggests squamous cell tumor; calcification suggests osteosarcoma. Lymphangitic spread and solitary pulmonary nodule are less common radiographic presentations of pulmonary metastasis. Conventional chest radiography is less sensitive than CT scan in detecting pulmonary metastases. Mammography should be considered in women to search for possible primary breast cancer. CT imaging of the chest, abdomen, and pelvis may reveal the site of a primary tumor and will help determine feasibility of surgical resection of the metastatic lung tumors. PET-CT scan may also help in identifying the site of a primary cancer or identifying other areas of extrathoracic metastasis.

► Treatment

Once the diagnosis has been established, management consists of treatment of the primary neoplasm and any pulmonary complications. Surgical resection of a *solitary* pulmonary nodule is often prudent in the patient with known current or previous extrapulmonary cancer. Local resection of one or more pulmonary metastases is feasible in a few carefully selected patients with various sarcomas and carcinomas (breast, testis, colon, and kidney). Surgical resection should be considered only if the primary tumor is under control, if the patient is a good surgical risk, if all of the metastatic tumor can be resected, if effective non-surgical approaches are not available, and if there are no

metastases elsewhere in the body. Relative contraindications to resection of pulmonary metastases include (1) malignant melanoma primary, (2) requirement for pneumonectomy, and (3) pleural involvement. Data from the International Registry of Lung Metastases report an overall 5-year survival rate of 36% and 10-year survival rate of 26% after complete resection of pulmonary metastases. Patients who are not surgical candidates but have solitary or limited metastatic disease to the lungs may be candidates for stereotactic radiosurgery, radioablation, or cryotherapy. For patients with progressive disease, diligent attention to palliative care is essential (see Chapter 5).

MESOTHELIOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Unilateral, nonpleuritic chest pain and dyspnea.
- ▶ Distant (> 20 years earlier) history of exposure to asbestos.
- ▶ Pleural effusion or pleural thickening or both on chest radiographs.
- ▶ Malignant cells in pleural fluid or tissue biopsy.

▶ General Considerations

Mesotheliomas are primary tumors arising from the surface lining of the pleura (80% of cases) or peritoneum (20% of cases). About three-fourths of pleural mesotheliomas are diffuse (usually malignant) tumors, and the remaining one-fourth are localized (usually benign). Men outnumber women by a 3:1 ratio. Numerous studies have confirmed the association of **malignant pleural mesothelioma** with exposure to asbestos (particularly the crocidolite form). The lifetime risk to asbestos workers of developing malignant pleural mesothelioma is as high as 10%. Sixty to 80 percent of patients with malignant mesothelioma report

a history of asbestos exposure. The latent period between exposure and onset of symptoms ranges from 20 to 40 years. The clinician should inquire about asbestos exposure through mining, milling, manufacturing, shipyard work, insulation, brake linings, building construction and demolition, roofing materials, and a variety of asbestos products (pipe, textiles, paint, tile, gaskets, panels). Although cigarette smoking significantly increases the risk of bronchogenic carcinoma in asbestos workers and aggravates asbestosis, there is no association between smoking and mesothelioma.

▶ Clinical Findings

A. Symptoms and Signs

The average interval between onset of symptoms and diagnosis is 2–3 months; the median age at diagnosis is 69 years in Western countries. Symptoms include the insidious onset of shortness of breath, nonpleuritic chest pain, and weight loss. Physical findings include dullness to percussion, diminished breath sounds and, in some cases, digital clubbing.

B. Laboratory Findings

Pleural fluid is exudative and often hemorrhagic. Cytologic tests of pleural fluid are often negative. VATS biopsy is usually necessary to obtain an adequate specimen for histologic diagnosis. The histologic variants of malignant pleural mesothelioma are epithelial (50–60%), sarcomatoid (10%), and biphasic (30–40%). Since distinction from benign inflammatory conditions and metastatic adenocarcinoma may be difficult, immunohistochemical stains are important to confirm the diagnosis. Epithelial mesothelioma stains are positive for pankeratin, calretinin, keratin 5/6, and WT1 and are negative for epithelial markers, such as CEA, MOC-31, TTF-1, CD15, and B72.3 (usually three needed). Soluble mesothelin-related peptide also may be found in serum or pleural fluid (or both) of patients with mesothelioma, epithelioid type.

C. Imaging

Radiographic abnormalities consist of nodular, irregular, unilateral pleural thickening and varying degrees of unilateral pleural effusion. Sixty percent of patients have right-sided disease, while only 5% have bilateral involvement. CT scans demonstrate the extent of pleural involvement. PET-CT is increasingly used to help differentiate benign from malignant pleural disease, improve staging accuracy, and identify candidates for aggressive surgical approaches.

▶ Complications

Malignant pleural mesothelioma progresses rapidly as the tumor spreads along the pleural surface to involve the pericardium, mediastinum, and contralateral pleura. The tumor may eventually extend beyond the thorax to involve abdominal lymph nodes and organs. Progressive pain and dyspnea are characteristic. Local invasion of thoracic

structures may cause superior vena cava syndrome, hoarseness, Horner syndrome, arrhythmias, and dysphagia. Paraneoplastic syndromes associated with mesothelioma include thrombocytosis, hemolytic anemia, disseminated intravascular coagulopathy, hypercalcemia, and migratory thrombophlebitis.

► Treatment

Chemotherapy is the mainstay of treatment, unless there is localized disease that can be surgically resected. Surgery, radiotherapy, chemotherapy, or a combination of modalities may be attempted, but treatments are generally unsuccessful. For localized disease, pleurectomy and decortication (surgical stripping of the pleura and pericardium from apex of the lung to diaphragm) is one surgical approach and can be effective in controlling malignant pleural effusion. Previously, some thoracic surgeons favored a trimodality approach for localized disease with extrapleural pneumonectomy, adjuvant radiation, and chemotherapy, based on limited retrospective data that it prolongs survival in highly selected patients. Extrapleural pneumonectomy is a radical surgical procedure involving removal of the ipsilateral lung, parietal and visceral pleura, pericardium, and most of the hemidiaphragm. However, the Mesothelioma and Radical Surgery (MARS) trial, a small randomized study comparing extrapleural pneumonectomy with no extrapleural pneumonectomy after induction chemotherapy in 50 patients, showed that extrapleural pneumonectomy offered no survival benefit and may have caused more harm. In advanced unresectable cases, palliative chemotherapy with cisplatin and pemetrexed can extend survival as well as improve quality of life. Other alternative chemotherapy regimens include gemcitabine, anthracyclines, or vinorelbine. Drainage of pleural effusions, pleurodesis, radiation therapy, and even surgical resection may offer palliative benefit in some patients.

► Prognosis

Most patients die of respiratory failure and complications of local extension. Median survival time from onset of symptoms ranges from 4 months in extensive disease to 16 months in localized disease. Five-year survival is < 5%. Tumors that are predominantly sarcomatoid are more resistant to therapy and have a worse prognosis, with median survivals < 1 year. Poor prognostic features include poor performance status, non-epithelioid histology, male gender, nodal involvement, elevated lactate dehydrogenase, high white blood cell count, low hemoglobin, and high platelet count.

HEPATOBIILIARY CANCERS

Lawrence S. Friedman, MD

HEPATOCELLULAR CARCINOMA

ESSENTIALS OF DIAGNOSIS

- In Western countries, usually a complication of cirrhosis.
- Characteristic CT and MRI features and elevated serum α -fetoprotein may obviate the need for a confirmatory biopsy.

► General Considerations

Malignant neoplasms of the liver that arise from parenchymal cells are called hepatocellular carcinomas; those that originate in the ductular cells are called cholangiocarcinomas.

Hepatocellular carcinomas are associated with cirrhosis in 80% of cases. Incidence rates are rising rapidly (twofold since 1978) in the United States and other Western countries, presumably because of the increasing prevalence of cirrhosis caused by chronic hepatitis C infection and non-alcoholic fatty liver disease. In Western countries, risk factors for hepatocellular carcinoma in patients known to have cirrhosis are male gender, age > 55 years (although there has been an increase in the number of younger cases), Asian or Hispanic ethnicity, family history in a first-degree relative, overweight, obesity, alcohol use (especially in combination with obesity), diabetes mellitus, hypothyroidism (in women), HCV infection, HBsAg and anti-HBc positivity, a prolonged prothrombin time, a low platelet count, and an elevated serum transferrin saturation. In Africa and most of Asia, hepatitis B is of major etiologic significance, whereas in Western countries and Japan, hepatitis C (particularly genotype 1b and sometimes in combination with “occult” HBV infection) and alcoholic cirrhosis are the most common risk factors. Other associations include high levels of HBV replication, HBV genotype C, hepatitis D coinfection, hemochromatosis (and possibly the C282Y carrier state), aflatoxin exposure (associated with mutation of the *TP53* gene),

α_1 -antiprotease (α_1 -antitrypsin) deficiency, tyrosinemia, and radiation exposure. In patients with the metabolic syndrome, hepatocellular carcinoma may arise from a hepatocellular adenoma in the absence of cirrhosis. Evidence for an association with long-term use of oral contraceptives is inconclusive. Coffee consumption and, in diabetic patients, the use of statins appear to be protective. The fibrolamellar variant of hepatocellular carcinoma occurs in young women and is characterized by a distinctive histologic picture, absence of risk factors, and indolent course. Vinyl chloride exposure is associated with angiosarcoma of the liver.

► Clinical Findings

A. Symptoms and Signs

The presence of a hepatocellular carcinoma may be unsuspected until there is deterioration in the condition of a cirrhotic patient who was formerly stable. Cachexia, weakness, and weight loss are associated symptoms. The sudden appearance of ascites, which may be bloody, suggests portal or hepatic vein thrombosis by tumor or bleeding from a necrotic tumor.

Physical examination may show tender enlargement of the liver, occasionally with a palpable mass. In Africa, the typical presentation in young patients is a rapidly expanding abdominal mass. Auscultation may reveal a bruit over the tumor or a friction rub when the tumor has extended to the surface of the liver.

B. Laboratory Findings

Laboratory tests may reveal leukocytosis, as opposed to the leukopenia that is frequently encountered in cirrhotic patients. Anemia is common, but a normal or elevated hematocrit value may be found in up to one-third of patients owing to elaboration of erythropoietin by the tumor. Sudden and sustained elevation of the serum alkaline phosphatase in a patient who was formerly stable is a common finding. HBsAg is present in a majority of cases in endemic areas, whereas in the United States anti-HCV is found in up to 40% of cases. α -Fetoprotein levels are elevated in up to 70% of patients with hepatocellular carcinoma in Western countries (although the sensitivity is lower in blacks and levels are not elevated in patients with fibrolamellar hepatocellular carcinoma); however, mild elevations (10–200 ng/mL [10–200 mcg/L]) are also often seen in patients with chronic hepatitis. Serum levels of des-gamma-carboxy prothrombin are elevated in up to 90% of patients with hepatocellular carcinoma, but they may also be elevated in patients with vitamin K deficiency, chronic hepatitis, and metastatic cancer. The L3 glycoform of α -fetoprotein (AFP-L3) is under study and may not be sensitive for early hepatocellular carcinoma. Cytologic study of ascitic fluid rarely reveals malignant cells.

C. Imaging

Multiphasic helical CT and MRI with contrast enhancement are the preferred imaging studies for determining the location and vascularity of the tumor. Lesions smaller than

1 cm may be difficult to characterize. Arterial phase enhancement of the lesion followed by delayed hypointensity (“washout”) is most specific for hepatocellular carcinoma. Ultrasonography is less sensitive and operator dependent but is used to screen for hepatic nodules in high-risk patients. Contrast-enhanced ultrasonography has a sensitivity and specificity approaching those of arterial phase helical CT but, unlike CT and MRI, cannot image the entire liver during the short duration of the arterial phase and is associated with false-positive results. In selected cases, endoscopic ultrasonography may be useful. PET is under study.

D. Liver Biopsy and Staging

Liver biopsy is diagnostic, although seeding of the needle tract by tumor is a potential risk (1–3%). For lesions < 1 cm, ultrasonography may be repeated every 3 months followed by further investigation of enlarging lesions. For lesions \geq 1 cm, biopsy can be deferred when characteristic arterial hypervascularity and delayed washout are demonstrated on either multiphasic helical CT or MRI with contrast enhancement (or both) or if surgical resection is planned. Staging in the TNM classification includes the following definitions: T0: no evidence of primary tumor; T1: solitary tumor without vascular invasion; T2: solitary tumor with vascular invasion or multiple tumors none more than 5 cm; T3: multiple tumors more than 5 cm (3a) or tumor involving a major branch of the portal or hepatic vein (3b); and T4: tumor(s) with direct invasion of adjacent organs other than the gallbladder or with perforation of the visceral peritoneum; N1, regional lymph node metastasis; M1, distant metastasis; F0, no to moderate hepatic fibrosis; F1, severe hepatic fibrosis to cirrhosis. The Barcelona Clinic Liver Cancer (BCLC) staging system is preferred and includes the Child-Turcotte-Pugh stage, tumor stage, and liver function and has the advantage of linking overall stage with preferred treatment modalities and with an estimation of life expectancy.

► Screening & Prevention

In the patient with chronic hepatitis B (beginning as early as age 20 in Africans and age 40 in Asians or those with a family history of hepatocellular carcinoma) or cirrhosis caused by HCV, HBV, or alcohol, surveillance for the development of hepatocellular carcinoma is recommended. Although the standard approach is α -fetoprotein testing and ultrasonography every 6 months, the value of α -fetoprotein screening has been questioned because of its low sensitivity. CT and MRI are considered too expensive for screening, but the sensitivity of ultrasonography for detecting early hepatocellular carcinoma is only 63%. The risk of hepatocellular carcinoma in a patient with cirrhosis is 3–5% a year, and patients with tumors detected by surveillance have a less advanced stage on average and greater likelihood that treatment will prolong survival than those not undergoing surveillance. In a population of patients with cirrhosis, over 60% of nodules < 2 cm in diameter detected on a screening ultrasonography prove to be hepatocellular carcinoma. Mass vaccination programs against

HBV in developing countries are leading to reduced rates of hepatocellular carcinoma. Successful treatment of hepatitis B and of hepatitis C in patients with cirrhosis also reduces the subsequent risk of hepatocellular carcinoma.

▶ Treatment

Surgical resection of a solitary hepatocellular carcinoma may result in cure if liver function is preserved (Child class A or possibly B) and portal vein thrombosis is not present. Laparoscopic liver resection has been performed in selected cases. Treatment of underlying chronic viral hepatitis, adjuvant chemotherapy, and adaptive immunotherapy may lower postsurgical recurrence rates. Liver transplantation may be appropriate for small unresectable tumors in a patient with advanced cirrhosis, with reported 5-year survival rates of up to 75%. The recurrence-free survival may be better for liver transplantation than for resection in patients with well-compensated cirrhosis and small tumors (one tumor < 5 cm or three or fewer tumors each < 3 cm in diameter [Milan criteria]) and in those with expanded (University of California, San Francisco) criteria of one tumor ≤ 6.5 cm or three or fewer tumors ≤ 4.5 cm. Patients with stage 2 hepatocellular carcinoma receive an additional 22 points on their Model for End-Stage Liver Disease (MELD) score (see Chapter 16), markedly increasing their chances of undergoing transplantation. However, liver transplantation is often impractical because of the donor organ shortage, and living donor liver transplantation may be considered in these cases. Patients with larger tumors (3–5 cm), a serum α -fetoprotein level ≥ 455 ng/mL (455 mcg/L), or a MELD score ≥ 20 have poor posttransplantation survival. Chemotherapy, hormonal therapy with tamoxifen, and long-acting octreotide have not been shown to prolong life, but transarterial chemoembolization (TACE), transarterial chemoinfusion (TACI), and transarterial radioembolization (TARE) via the hepatic artery are palliative and may prolong survival in patients with a large or multifocal tumor in the absence of extrahepatic spread. TACI and TARE are suitable for patients with portal vein thrombosis. Injection of absolute ethanol into, radiofrequency ablation of, cryotherapy of, or microwave ablation of small tumors (< 2 cm) may prolong survival in patients who are not candidates for resection; these interventions may provide a “bridge” to liver transplantation. Radiofrequency ablation is superior to ethanol injection for tumors > 2 cm in diameter and can be performed after TACE in select cases. Sorafenib (an oral multikinase inhibitor of Raf kinase, the VEGF receptor, and the platelet-derived growth factor receptor [and others]), prolongs median survival as well as the time to radiologic progression by 3 months in patients with advanced hepatocellular carcinoma; sorafenib is the standard of care in these patients. New chemotherapy and radiation therapy techniques (eg, radioembolization with yttrium-90 microspheres), novel biologic approaches (eg, bortezomib, a proteasome inhibitor; antiangiogenesis agents; other inhibitors of growth-factor signaling; and gene therapy), and multimodal approaches are under study. For patients whose disease progresses despite treatment or who present with advanced tumors, vascular invasion, or extrahepatic

spread, meticulous efforts at palliative care are essential (see Chapter 5). Severe pain may develop in such patients due to expansion of the liver capsule by the tumor and requires concerted efforts at pain management, including the use of opioids (see Chapter 5).

▶ Prognosis

In the United States, overall 1- and 5-year survival rates for patients with hepatocellular carcinoma are 23% and 5%, respectively. Five-year survival rates rise to 56% for patients with localized resectable disease (T1, T2, selected T3 and T4; N0; M0) but are virtually nil for those with locally unresectable or advanced disease. In patients with HCV-related hepatocellular carcinoma, the serum α -fetoprotein level at the time of diagnosis of cancer has been reported to be an independent predictor of mortality. Contrary to traditional opinion, the fibrolamellar variant does not have a better prognosis than conventional hepatocellular carcinoma without cirrhosis.

▶ When to Refer

All patients with hepatocellular carcinoma should be referred to a specialist.

▶ When to Admit

- Complications of cirrhosis.
- Severe pain.
- For surgery and other interventions.

CARCINOMA OF THE BILIARY TRACT

ESSENTIALS OF DIAGNOSIS

- ▶ Presents with obstructive jaundice, usually painless, often with dilated biliary tree.
- ▶ Pain is more common in gallbladder carcinoma than cholangiocarcinoma.
- ▶ A Courvoisier (dilated) gallbladder may be detected.
- ▶ Diagnosis by cholangiography with biopsy and brushings for cytology.

▶ General Considerations

Carcinoma of the gallbladder occurs in approximately 2% of all people operated on for biliary tract disease. It is

notoriously insidious, and the diagnosis is often made unexpectedly at surgery. Cholelithiasis (often large, symptomatic stones) is usually present. Other risk factors are chronic infection of the gallbladder with *Salmonella typhi*, gallbladder polyps over 1 cm in diameter, mucosal calcification of the gallbladder (porcelain gallbladder), and anomalous pancreaticobiliary ductal junction. Genetic factors include *K-ras* and *TP53* mutations. Spread of the cancer—by direct extension into the liver or to the peritoneal surface—may be the initial manifestation. The TNM classification includes the following stages: Tis, carcinoma in situ; T1a, tumor invades lamina propria, and T1b, tumor invades muscle layer; T2, tumor invades perimuscular connective tissue, no extension beyond serosa (visceral peritoneum) or into liver; T3, tumor perforates the serosa or directly invades the liver or adjacent organ or structure; T4, tumor invades the main portal vein or hepatic artery or invades multiple extrahepatic organs or structures; N1, regional lymph node metastasis; and M1, distant metastasis.

Carcinoma of the bile ducts (cholangiocarcinoma) accounts for 10–25% of all hepatobiliary malignancies and 3% of all cancer deaths in the United States. It is more prevalent in persons aged 50–70, with a slight male predominance, and more common in Asia. Two-thirds arise at the confluence of the hepatic ducts (Klatskin tumors), and one-fourth arise in the distal extrahepatic bile duct; the remainder are intrahepatic (peripheral), the incidence of which has risen dramatically since the 1970s. Staging for extrahepatic cholangiocarcinoma is as follows: T1, tumor is confined to bile duct; T2, tumor spreads beyond the wall of the bile duct (2a) or to the adjacent liver (2b); T3, tumor spreads to unilateral branches of the portal vein or hepatic artery; T4, tumor spreads to main portal vein or its branches bilaterally, common hepatic artery, second-order biliary radicals bilaterally, or various combinations; N1, regional lymph node metastasis; M1, distant metastasis. Staging for intrahepatic cholangiocarcinoma is as follows: T1, solitary tumor without vascular invasion; T2, solitary tumor with vascular invasion or multiple tumors ≤ 5 cm; T3, multiple tumors > 5 cm or involving major branch of portal or hepatic veins; T4, tumor invades adjacent organ (except gallbladder) or perforation of visceral peritoneum; N1, regional lymph node metastasis; and M1, distant metastasis. Other staging systems consider tumor extent and form, vascular encasement, hepatic lobe atrophy, and underlying liver disease. The frequency of carcinoma in persons with choledochal cysts has been reported to be over 14% at 20 years, and surgical excision is recommended. There is an increased incidence in patients with bile duct adenoma; biliary papillomatosis; Caroli disease; a biliary-enteric anastomosis; ulcerative colitis, especially those with primary sclerosing cholangitis; biliary cirrhosis; diabetes mellitus; hyperthyroidism; chronic pancreatitis; heavy alcohol consumption; and past exposure to thorotrast, a contrast agent. In Southeast Asia, hepatolithiasis and infection of the bile ducts with helminths (*Clonorchis sinensis*, *Opisthorchis viverrini*) are associated with chronic cholangitis and an increased risk of cholangiocarcinoma. Hepatitis C virus infection, cirrhosis, HIV infection,

nonalcoholic fatty liver disease, diabetes mellitus, obesity, and tobacco smoking are additional risk factors for intrahepatic cholangiocarcinoma.

► Clinical Findings

A. Symptoms and Signs

Progressive jaundice is the most common and usually the first sign of obstruction of the extrahepatic biliary system. Pain in the right upper abdomen with radiation into the back is usually present early in the course of gallbladder carcinoma but occurs later in the course of bile duct carcinoma. Anorexia and weight loss are common and may be associated with fever and chills due to cholangitis. Rarely, hematemesis or melena results from erosion of tumor into a blood vessel (hemobilia). Fistula formation between the biliary system and adjacent organs may also occur. The course is usually one of rapid deterioration, with death occurring within a few months.

Physical examination reveals profound jaundice. Pruritus and skin excoriations are common. A palpable gallbladder with obstructive jaundice usually is said to signify malignant disease (Courvoisier law); however, this clinical generalization has been proved to be accurate only about 50% of the time. Hepatomegaly due to hypertrophy of the unobstructed liver lobe is usually present and is associated with liver tenderness. Ascites may occur with peritoneal implants.

B. Laboratory Findings

With biliary obstruction, laboratory examination reveals predominantly conjugated hyperbilirubinemia, with total serum bilirubin values ranging from 5 to 30 mg/dL. There is usually concomitant elevation of the alkaline phosphatase and serum cholesterol. AST is normal or minimally elevated. An elevated CA 19-9 level may help distinguish cholangiocarcinoma from a benign biliary stricture (in the absence of cholangitis).

C. Imaging

Ultrasonography and contrast-enhanced, triple-phase, helical CT may show a gallbladder mass in gallbladder carcinoma and intrahepatic mass or biliary dilatation in carcinoma of the bile ducts. CT may also show involved regional lymph nodes and atrophy of a hepatic lobe because of vascular encasement with compensatory hypertrophy of the unaffected lobe. MRI with magnetic resonance cholangiopancreatography (MRCP) and gadolinium enhancement permits visualization of the entire biliary tree and detection of vascular invasion and obviates the need for angiography and, in some cases, direct cholangiography; it is the imaging procedure of choice but may understage malignant hilar strictures. The sensitivity and image quality can be increased with use of ferumoxime enhancement. The features of intrahepatic cholangiocarcinoma on MRI appear to differ from those of hepatocellular carcinoma, with contrast washout in the latter but not the former. In indeterminate cases, PET can detect cholangiocarcinomas as small as 1 cm and lymph node and

distant metastases, but false-positive results occur. The most helpful diagnostic studies before surgery are either percutaneous transhepatic or endoscopic retrograde cholangiography with biopsy and cytologic specimens, although false-negative biopsy and cytology results are common. Digital image analysis and fluorescent in situ hybridization of cytologic specimens improve sensitivity. Endoscopic ultrasonography with FNA of tumors, choledochoscopy, and intraductal ultrasonography may confirm a diagnosis of cholangiocarcinoma in a patient with bile duct stricture and an otherwise indeterminate evaluation.

▶ Treatment

In young and fit patients, curative surgery may be attempted if the tumor is well localized. The 5-year survival rate for carcinoma of the gallbladder invading the lamina propria or muscularis (stage 1, T1a or 1b, N0, M0) is as high as 85% with laparoscopic cholecystectomy but drops to 60%, even with a more extended open resection, if there is perimuscular invasion (T2). The role of radical surgery for T3 and T4 tumors is debatable. If the tumor is unresectable at laparotomy, biliary-enteric bypass (eg, Roux-en-Y hepaticojejunostomy) can be performed. Carcinoma of the bile ducts is curable by surgery in < 10% of cases. If resection margins are negative, the 5-year survival rate may be as high as 47% for intrahepatic cholangiocarcinomas, 41% for hilar cholangiocarcinoma, and 37% for distal cholangiocarcinomas, but the perioperative mortality rate may be as high as 10%. Palliation can be achieved by placement of a self-expandable metal stent via an endoscopic or percutaneous transhepatic route. Covered metal stents may be more cost-effective than uncovered metal stents because of a longer duration of patency, but they are associated with a higher rate of stent migration and cholecystitis due to occlusion of the cystic duct and are not associated with longer survival. For hilar tumors, there is controversy as to whether unilateral or bilateral stents should be inserted. Plastic stents are less expensive but more prone to occlude than metal ones; they are suitable for patients expected to survive only a few months. Photodynamic therapy in combination with stent placement has been demonstrated to prolong survival when compared with stent placement alone in patients with nonresectable cholangiocarcinoma. Radiotherapy may relieve pain and contribute to biliary decompression. There is limited response to chemotherapy with gemcitabine alone, but the combination of cisplatin and gemcitabine prolongs survival by about 3 months in patients with locally advanced or metastatic cholangiocarcinoma. Few patients survive for more than 24 months. Although cholangiocarcinoma is generally considered to be a contraindication to liver transplantation because of rapid tumor recurrence, a 75% 5-year survival rate has been reported in patients with stage I and II cholangiocarcinoma undergoing chemoradiation and exploratory laparotomy followed by liver transplantation.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

▶ When to Refer

All patients with carcinoma of the biliary tract should be referred to a specialist.

▶ When to Admit

- Biliary obstruction.
- Cholangitis.

CARCINOMA OF THE PANCREAS & THE PERIAMPULLARY AREA

ESSENTIALS OF DIAGNOSIS

- ▶ Obstructive jaundice (may be painless).
- ▶ Enlarged gallbladder (may be painful).
- ▶ Upper abdominal pain with radiation to back, weight loss, and thrombophlebitis are usually late manifestations.

▶ General Considerations

Carcinomas involving the head of the pancreas, ampulla of Vater, distal bile duct, and duodenum are considered together because they are usually indistinguishable clinically; of these, carcinomas of the pancreas constitute over 90%. Carcinoma is the most common neoplasm of the pancreas. About 75% are in the head and 25% in the body and tail of the organ. They comprise 2% of all cancers and 5% of cancer deaths. Risk factors include age, tobacco use (which is thought to cause 20–25% of cases), heavy alcohol use, obesity, chronic pancreatitis, prior abdominal radiation, family history, and possibly gastric ulcer. New-onset diabetes mellitus after age 45 years occasionally heralds the onset of pancreatic cancer. In diabetic patients, preliminary data suggest that metformin use reduces the risk but insulin use and glucagon-like peptide-1-based therapy (eg, sitagliptin) increase the risk of pancreatic cancer. About 7% of patients with pancreatic cancer have a family history of pancreatic cancer in a first-degree relative, compared with 0.6% of control subjects. Point mutations in codon 12 of the *K-ras* oncogene are found in 70–100% of pancreatic cancers; inactivation of the tumor suppressor genes *INK4A* on chromosome 9, *TP53* on chromosome 17, and *MADH4* on chromosome 18 is found in 95%, 75%, and 55% of pancreatic cancers,

respectively; and mutation of the palladin gene is reported to be common. In 5–10% of cases, pancreatic cancer occurs as part of several hereditary syndromes, including familial breast cancer (carriers of *BRCA-2* have a 7% lifetime risk of pancreatic cancer), hereditary pancreatitis (*PSS1* mutation), familial atypical multiple mole melanoma (*p16/CDKN2A* mutation), Peutz-Jeghers syndrome (*STK11/LKB1* mutation), ataxia-telangiectasia, and hereditary nonpolyposis colorectal cancer. Polymorphisms of the genes for methylene tetrahydrofolate reductase and thymidylate synthase have been reported to be associated with pancreatic cancer. Neuroendocrine tumors account for 1–2% of pancreatic neoplasms and may be functional (producing gastrin, insulin, glucagon, vasoactive intestinal peptide, somatostatin, growth hormone–releasing hormone, adrenocorticotrophic hormone, and others) or non-functional. Plasma chromogranin A levels are elevated in 88–100% of affected patients. Cystic neoplasms account for only 1% of pancreatic cancers, but they are important because they are often mistaken for pseudocysts. A cystic neoplasm should be suspected when a cystic lesion in the pancreas is found in the absence of a history of pancreatitis. At least 15% of all pancreatic cysts are neoplasms. Whereas serous cystadenomas (which account for 32–39% of cystic pancreatic neoplasms and also occur in patients with von Hippel-Lindau disease) are benign, mucinous cystic neoplasms (defined by the presence of ovarian stroma) (10–45%), intraductal papillary mucinous neoplasms (21–33%), solid pseudopapillary tumors (< 5%), and cystic islet cell tumors (3–5%) may be malignant, although their prognoses are better than the prognosis of adenocarcinoma of the pancreas, unless the neoplasm is locally advanced.

► Clinical Findings

A. Symptoms and Signs

Pain is present in over 70% of cases and is often vague, diffuse, and located in the epigastrium or left upper quadrant when the lesion is in the tail. Radiation of pain into the back is common and sometimes predominates. Sitting up and leaning forward may afford some relief, and this usually indicates that the lesion has spread beyond the pancreas and is inoperable. Diarrhea, perhaps due to maldigestion, is an occasional early symptom. Migratory thrombophlebitis is a rare sign. Weight loss is a common but late finding and may be associated with depression. Occasionally a patient presents with acute pancreatitis in the absence of an alternative cause. Jaundice is usually due to biliary obstruction by a cancer in the pancreatic head. A palpable gallbladder is also indicative of obstruction by neoplasm (Courvoisier law), but there are frequent exceptions. A hard, fixed, occasionally tender mass may be present. In advanced cases, a hard periumbilical (Sister Joseph's) nodule may be palpable.

B. Laboratory Findings

There may be mild anemia. Glycosuria, hyperglycemia, and impaired glucose tolerance or true diabetes mellitus are found in 10–20% of cases. The serum amylase or lipase

level is occasionally elevated. Liver biochemical tests may suggest obstructive jaundice. Steatorrhea in the absence of jaundice is uncommon. Occult blood in the stool is suggestive of carcinoma of the ampulla of Vater (the combination of biliary obstruction and bleeding may give the stools a distinctive silver appearance). CA 19-9, with a sensitivity of 70% and a specificity of 87%, has not proved sensitive enough for early detection of pancreatic cancer; increased values are also found in acute and chronic pancreatitis and cholangitis.

C. Imaging

Multiphase thin-cut helical CT is generally the initial diagnostic procedure and detects a mass in over 80% of cases. CT identifies metastases, delineates the extent of the tumor, and allows for percutaneous FNA for cytologic studies and tumor markers. MRI is an alternative to CT. Ultrasonography is not reliable because of interference by intestinal gas. PET is a sensitive technique for detecting pancreatic cancer and metastases, but PET-CT is not a routine staging procedure. Selective celiac and superior mesenteric arteriography may demonstrate vessel invasion by tumor, a finding that would preclude attempts at surgical resection, but it is less widely used since the advent of multiphase helical CT. Endoscopic ultrasonography is more sensitive than CT for detecting pancreatic cancer and equivalent to CT for determining nodal involvement and resectability. A normal endoscopic ultrasonogram excludes pancreatic cancer. Endoscopic ultrasonography may also be used to guide FNA for tissue diagnosis, tumor markers, and DNA analysis. Endoscopic retrograde cholangiopancreatography (ERCP) may clarify an ambiguous CT scan or MRI study by delineating the pancreatic duct system or confirming an ampullary or biliary neoplasm. MRCP appears to be at least as sensitive as ERCP in diagnosing pancreatic cancer. In some centers, pancreatoscopy or intraductal ultrasonography can be used to evaluate filling defects in the pancreatic duct and assess resectability of intraductal papillary mucinous tumors. With obstruction of the splenic vein, splenomegaly or gastric varices are present, the latter delineated by endoscopy, endoscopic ultrasonography, or angiography.

Cystic neoplasms can be distinguished by their appearance on CT, endoscopic ultrasonography, and ERCP and features of the cyst fluid on gross and cytologic analysis. For example, serous cystadenomas may have a central scar or honeycomb appearance; mucinous cystadenomas are unilocular or multilocular and contain mucin-rich fluid with high carcinoembryonic antigen levels (> 200 ng/mL) (200 mcg/L); and intraductal papillary mucinous neoplasms are associated with a dilated pancreatic duct and extrusion of gelatinous material from the ampulla.

► Staging

Staging of pancreatic cancer by the TNM classification includes the following definitions: Tis: carcinoma in situ; T1: tumor limited to the pancreas, 2 cm or less in greatest dimension; T2: tumor limited to the pancreas, more than

2 cm in greatest dimension; T3: tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery; T4, tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor); N1, regional lymph node metastasis; M1, distant metastasis.

► Treatment

Abdominal exploration is usually necessary when cytologic diagnosis cannot be made or if resection is to be attempted, which includes about 30% of patients. In a patient with a localized mass in the head of the pancreas and without jaundice, laparoscopy may detect tiny peritoneal or liver metastases and thereby avoid resection in 4–13% of patients. Radical pancreaticoduodenal (Whipple) resection is indicated for lesions strictly limited to the head of the pancreas, periampullary area, and duodenum (T1, N0, M0). Five-year survival rates are 20–25% in this group and as high as 40% in those with negative resection margins and without lymph node involvement. Preoperative endoscopic decompression of an obstructed bile duct is often achieved with a plastic stent or short metal stent but does not reduce operative mortality and is associated with complications. The best surgical results are achieved at centers that specialize in the multidisciplinary treatment of pancreatic cancer. Adjuvant or neoadjuvant chemotherapy with gemcitabine or fluorouracil (or both), possibly combined with irradiation, is of benefit (Table 39–4). Chemoradiotherapy downstages about 30% of patients with locally advanced disease to allow resection. When resection is not feasible, endoscopic stenting of the bile duct is performed to relieve jaundice. A plastic stent is generally placed if the patient's anticipated survival is < 6 months (or surgery is planned). A metal stent is preferred when anticipated survival is 6 months or greater. Whether covered metal stents designed to prevent tumor ingrowth offer an advantage over uncovered stents is uncertain because covered stents are associated with higher rates of migration and acute cholecystitis due to occlusion of the cystic duct. Surgical biliary bypass may be considered in patients expected to survive at least 6 months. Surgical duodenal bypass may be considered in patients in whom duodenal obstruction is expected to develop later; alternatively, endoscopic placement of a self-expandable duodenal stent may be feasible. Chemoradiation may be used for palliation of unresectable cancer confined to the pancreas. Chemotherapy has been disappointing in metastatic pancreatic cancer, although improved response rates have been reported with the combination of oxaliplatin, irinotecan, fluorouracil, and leucovorin (FOLFIRINOX). The addition of erlotinib (an inhibitor of the EGFR receptor), capecitabine (an oral fluoropyrimidine), or a platinum agent may improve survival but also increases toxicity. The high rate of *K-ras* mutations in pancreatic cancer limits the benefit of erlotinib. Nucleoside cytidine analogues and topoisomerase inhibitors are under study. Celiac plexus nerve block (under CT or endoscopic ultrasound guidance) or thoracoscopic splanchnicectomy may improve pain control. Photodynamic therapy is under study.

Surgical resection is the treatment of choice for neuroendocrine tumors, when feasible. Metastatic disease may be controlled with long-acting somatostatin analogs, interferon, peptide-receptor radionuclide therapy, and chemoembolization. There is a growing consensus that asymptomatic incidental pancreatic cysts ≤ 2 cm are at low risk for harboring invasive carcinoma. The cysts may be monitored by imaging tests at 6- to 12-month intervals and every 3–6 months in those > 2 cm, with surgery or possibly endoscopic ultrasound-guided cyst ablation performed if a cyst enlarges or exceeds 2.5 cm.

Surgical resection is indicated for mucinous cystic neoplasms, symptomatic serous cystadenomas, solid pseudopapillary tumors (which have a 15% risk of malignant transformation), and cystic tumors > 2 cm in diameter that remain undefined after helical CT, endoscopic ultrasonography, and diagnostic aspiration. All intraductal papillary mucinous neoplasms of the main pancreatic duct should be resected, but those of branch ducts may be followed with serial imaging if they are asymptomatic and exhibit benign features (eg, diameter < 3 cm [some authorities recommend a diameter ≤ 1.5 cm], absence of nodules or a thick wall); most of the latter remain stable on follow-up, but the risk of pancreatic ductal carcinoma and of nonpancreatic cancers may also be increased in this group of patients. In the absence of locally advanced disease, survival is higher for malignant cystic neoplasms than for adenocarcinoma. Endoscopic resection or ablation, with temporary placement of a pancreatic duct stent, may be feasible for ampullary adenomas, but patients must be followed for recurrence.

► Prognosis

Carcinoma of the pancreas, especially in the body or tail, has a poor prognosis; 80–85% of patients present with advanced unresectable disease, and reported 5-year survival rates range from 2% to 5%. Lesions of the ampulla have a better prognosis, with reported 5-year survival rates of 20–40% after resection; jaundice and lymph node involvement are adverse prognostic factors. In carefully selected patients, resection of cancer of the pancreatic head is feasible and results in reasonable survival. In persons with a family history of pancreatic cancer in at least two first-degree relatives, screening with endoscopic ultrasonography and helical CT or MRI/MRCP should be considered beginning at age 40–45 or 10 years before the age at which pancreatic cancer was diagnosed in a family member.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

► When to Refer

All patients with carcinoma involving the pancreas and the periampullary area should be referred to a specialist.

► When to Admit

Patients who require surgery and other interventions should be hospitalized.

Table 39-4. Treatment choices for cancers responsive to systemic agents.

Diagnosis	Current Treatment of Choice	Other Treatments
Acute lymphoblastic leukemia (ALL)	Induction combination chemotherapy: Vincristine, prednisone, daunorubicin, asparaginase, intrathecal methotrexate Consolidation combination chemotherapy: Cyclophosphamide, vincristine, doxorubicin, dexamethasone (hyper-CVAD) alternated with cytarabine, methotrexate Maintenance chemotherapy: Methotrexate, 6-mercaptopurine	Imatinib mesylate (Ph positive ALL), autologous or allogeneic transplantation for high risk or at relapse
Acute myeloid leukemia (AML)	Combination chemotherapy: Cytarabine, daunorubicin or Cytarabine, idarubicin	Mitozantrone, doxorubicin, cladribine, fludarabine, prednisone
Chronic myeloid leukemia (CML)	Imatinib mesylate or nilotinib or dasatinib	Dasatinib, nilotinib, allogeneic bone marrow transplantation, hydroxyurea, interferon- α , cytarabine, busulfan
Chronic lymphocytic leukemia (CLL)	Combination chemotherapy: Fludarabine, cyclophosphamide, rituximab (FCR); or Fludarabine, or Bendamustine or Chlorambucil	Alemtuzumab, bendamustine, pentostatin, cladribine, cyclophosphamide, vincristine, doxorubicin, prednisone
Hairy cell leukemia	Cladribine (2-chlorodeoxyadenosine)	Pentostatin, rituximab, interferon- α
Hodgkin disease (stages III and IV)	Combination chemotherapy: Doxorubicin, bleomycin, vinblastine, dacarbazine (ABVD) or Doxorubicin, vinblastine, mechlorethamine, etoposide, vincristine, bleomycin, prednisone (Stanford V)	Gemcitabine, vinorelbine, ifosfamide, cyclophosphamide, procarbazine, transplantation for relapse
Non-Hodgkin lymphoma (intermediate and high grade)	Combination chemotherapy: Cyclophosphamide, doxorubicin, vincristine, prednisone, rituximab (CHOP-R)	Combination chemotherapy second line: Dexamethasone, cisplatin, cytarabine (DHAP) or Etoposide, methylprednisolone, cytarabine, cisplatin (ESHAP) or Ifosfamide, carboplatin, etoposide (ICE) or Mesna, ifosfamide, mitoxantrone, etoposide (MINE); transplantation for high risk or first relapse
Non-Hodgkin lymphoma (low grade)	Combination chemotherapy: Fludarabine, cyclophosphamide, rituximab (FCR) or Fludarabine, rituximab (FR) or Bendamustine, rituximab or Cyclophosphamide, vincristine, doxorubicin, prednisone, rituximab (CHOP-R), or Cyclophosphamide, vincristine, prednisone, rituximab (CVP-R) or Chlorambucil	^{131}I tositumomab, ^{90}Y ibritumomab tiuxetan, bendamustine, autologous or allogeneic transplantation
Multiple myeloma	Combination chemotherapy (transplant candidates): Bortezomib, dexamethasone, thalidomide or Bortezomib, dexamethasone, lenalidomide or Dexamethasone, thalidomide or Dexamethasone, lenalidomide Followed by autologous or miniallogeneic stem cell transplantation Combination chemotherapy (non-transplant candidates): Melphalan, prednisone, bortezomib, or Melphalan, prednisone, lenalidomide, or Melphalan, prednisone, thalidomide, or Melphalan, prednisone	Bortezomib, lenalidomide, thalidomide, dexamethasone, cyclophosphamide, liposomal doxorubicin
Waldenstrom macroglobulinemia	Plasmapheresis alone or followed by combination chemotherapy: Bortezomib with or without rituximab or, cyclophosphamide, prednisone or thalidomide with or without rituximab	Cladribine, thalidomide, bortezomib, chlorambucil, bendamustine, autologous bone marrow transplantation, prednisone
Polycythemia vera	Phlebotomy, hydroxyurea	Anagrelide, radiophosphorus ^{32}P , interferon- α , busulfan, chlorambucil, cyclophosphamide
Non-small cell lung cancer	Combination chemotherapy: Cisplatin, vinorelbine or Cisplatin, etoposide or Paclitaxel, carboplatin or Cisplatin, gemcitabine (squamous histology) Cisplatin, pemetrexed (nonsquamous histology) All regimens with or without bevacizumab Erlotinib (EGFR mutation positive) Crizotinib (ALK mutation positive)	Docetaxel, vinorelbine, erlotinib, cetuximab

(continued)

Table 39-4. Treatment choices for cancers responsive to systemic agents. (continued)

Diagnosis	Current Treatment of Choice	Other Treatments
Small cell lung cancer	Combination chemotherapy: Cisplatin, etoposide	Irinotecan, cyclophosphamide, doxorubicin, vincristine, topotecan, gemcitabine, paclitaxel
Mesothelioma	Combination chemotherapy: Cisplatin, pemetrexed or Carboplatin, pemetrexed or Gemcitabine, cisplatin	Doxorubicin, vinorelbine
Head and neck cancer	Combination chemotherapy: Cisplatin, fluorouracil or Paclitaxel, carboplatin or Docetaxel, cisplatin, fluorouracil or Cisplatin or cetuximab with radiation therapy	Hydroxyurea, bleomycin, methotrexate, cetuximab
Esophageal cancer	Combination chemotherapy: Cisplatin, fluorouracil or Paclitaxel, carboplatin	Paclitaxel, irinotecan, oxaliplatin, capecitabine, docetaxel, epirubicin
Uterine cancer	Progestins, tamoxifen, aromatase inhibitors or Combination chemotherapy: Cisplatin, doxorubicin, or Paclitaxel or Cisplatin, doxorubicin or Carboplatin, paclitaxel	Fluorouracil, docetaxel, liposomal doxorubicin
Ovarian cancer	Combination chemotherapy: Paclitaxel, carboplatin or Intraperitoneal cisplatin, paclitaxel or Docetaxel, carboplatin or Paclitaxel, cisplatin	Gemcitabine, liposomal doxorubicin, topotecan, cyclophosphamide, etoposide, docetaxel
Cervical cancer	With radiation: Cisplatin Combination chemotherapy: Cisplatin, paclitaxel or Cisplatin, topotecan or Carboplatin, paclitaxel or Cisplatin, gemcitabine	Docetaxel, ifosfamide, vinorelbine, irinotecan, epirubicin, mitomycin, fluorouracil
Breast cancer	Adjuvant endocrine therapy: <i>Premenopausal:</i> Tamoxifen <i>Postmenopausal:</i> Aromatase inhibitors (anastrozole, letrozol, exemestane) Adjuvant chemotherapy (without trastuzumab): Doxorubicin, cyclophosphamide, docetaxel or Doxorubicin, cyclophosphamide, paclitaxel or Docetaxel, cyclophosphamide or Doxorubicin, cyclophosphamide Adjuvant chemotherapy (with trastuzumab): Doxorubicin, cyclophosphamide, paclitaxel, trastuzumab or Docetaxel, carboplatin, trastuzumab	Megestrol, aminoglutethimide, capecitabine, mitoxantrone, cisplatin, etoposide, vinblastine, fluorouracil, ixabepilone, gemcitabine
Choriocarcinoma (trophoblastic neoplasms)	Single agents: Methotrexate or dactinomycin for low risk disease Combination chemotherapy: Etoposide/methotrexate, dactinomycin, cyclophosphamide, vincristine (EMA-CO) for high-risk disease	Vinblastine, cisplatin, mercaptopurine, chlorambucil, doxorubicin
Testicular cancer	Combination chemotherapy: Bleomycin, etoposide, cisplatin (BEP) or Cisplatin, etoposide (EP) or Etoposide, mesna, ifosfamide, cisplatin (VIP)	Vinblastine, ifosfamide, paclitaxel, gemcitabine, oxaliplatin
Kidney cancer	Sunitinib or temsirolimus or bevacizumab or sorafenib, or pazopanib or interleukin-2	Interferon- α , vinblastine, capecitabine, fluorouracil
Bladder cancer	Combination chemotherapy: Gemcitabine, cisplatin or Methotrexate, vinblastine, doxorubicin, cisplatin (MVAC)	Carboplatin, paclitaxel, docetaxel, fluorouracil, pemetrexed, methotrexate
Prostate cancer	Luteinizing hormone-releasing agonist (leuprolide, goserelin, triptorelin, degarelix) plus an antiandrogen (flutamide, bicalutamide, nilutamide)	Ketoconazole, docetaxel, abiraterone, mitoxantrone, cabazitaxel, sipuleucel-T, estramustine, prednisone
Brain cancer (anaplastic astrocytoma and glioblastoma multiforme)	Temozolomide	Bevacizumab, irinotecan, procarbazine, carmustine, lomustine

(continued)

Table 39-4. Treatment choices for cancers responsive to systemic agents. (continued)

Diagnosis	Current Treatment of Choice	Other Treatments
Neuroblastoma	Combination chemotherapy: Cyclophosphamide, doxorubicin, cisplatin, etoposide	Vincristine, topotecan, irinotecan, ifosfamide, carboplatin, 13-cis-retinoic acid, ¹³¹ I-MIBG, autologous or allogeneic transplantation
Thyroid cancer	Radioiodine (¹³¹ I) or sorafenib or vandetanib (medullary thyroid cancer)	Doxorubicin, dacarbazine
Adrenal cancer	Mitotane	Doxorubicin, etoposide, cisplatin
Stomach cancer	Combination chemotherapy: Epirubicin, cisplatin, fluorouracil or Docetaxel, cisplatin, fluorouracil or Fluorouracil, leucovorin, oxaliplatin Trastuzumab added for Her2-neu overexpressing adenocarcinomas	Capecitabine, sorafenib, trastuzumab, irinotecan
Pancreatic cancer	Combination chemotherapy: Gemcitabine, cisplatin or Gemcitabine, erlotinib or Fluorouracil, leucovorin, irinotecan, oxaliplatin (FOLFIRINOX) Gemcitabine	Capecitabine
Colon cancer	Combination chemotherapy: Fluorouracil, leucovorin, oxaliplatin (FOLFOX6) or Capecitabine, oxaliplatin (CapeOx) or Fluorouracil, leucovorin, irinotecan (FOLFIRI) each regimen with or without bevacizumab	Cetuximab, irinotecan, panitumumab
Rectal cancer	Chemotherapy with radiation: Fluorouracil; For advanced disease same regimens used with colon cancer	Cetuximab, irinotecan, panitumumab
Anal cancer	Combination chemotherapy with radiation: Fluorouracil, mitomycin	Cisplatin
Carcinoid	Combination chemotherapy: Streptozocin, fluorouracil or Bevacizumab or sorafenib or sunitinib	Doxorubicin, dacarbazine, octreotide, interferon- α
Insulinoma	Interferon or streptozocin	Doxorubicin, fluorouracil, mitomycin
Osteogenic sarcoma	Combination chemotherapy with two of these agents: Doxorubicin, cisplatin, ifosfamide, high-dose methotrexate	Cyclophosphamide, dacarbazine
Soft tissue sarcomas	Combination chemotherapy: Doxorubicin, dacarbazine (AD) or Doxorubicin, ifosfamide, mesna (AIM) or Mesna, doxorubicin, ifosfamide, dacarbazine (MAID) Imatinib or Sunitinib (Gastrointestinal Stromal Tumors)	Liposomal doxorubicin, methotrexate, gemcitabine, docetaxel, temozolomide
Melanoma	Ipilimumab or vemurafenib or dacarbazine or Temozolomide or high-dose interleukin-2	Paclitaxel, cisplatin, carboplatin, interferon- α , vinblastine
Hepatocellular cancer	Sorafenib	Doxorubicin
Kaposi sarcoma	Liposomal doxorubicin or liposomal daunorubicin	Paclitaxel, vinblastine, vincristine, etoposide, doxorubicin

Robin K. Kelley, MD

ESOPHAGEAL CANCER

ESSENTIALS OF DIAGNOSIS

- ▶ Progressive solid food dysphagia.
- ▶ Weight loss common.
- ▶ Endoscopy with biopsy establishes diagnosis.

► General Considerations

Esophageal cancer usually develops in persons between 50 and 70 years of age. The overall ratio of men to women is 3:1. There are two histologic types: squamous cell carcinoma and adenocarcinoma. In the United States, **squamous cell cancer** is much more common in blacks than in whites. Squamous cell cancer has a high incidence in certain regions of China and Southeast Asia. Half of all cases occur in the distal third of the esophagus. Chronic alcohol and tobacco use are strongly associated with an increased risk of squamous cell carcinoma. The risk of squamous cell cancer is also increased in patients with tylosis, achalasia, caustic-induced esophageal stricture, and other head and neck cancers. **Adenocarcinoma** is more common in whites. It is increasing dramatically in incidence and now is as common as squamous carcinoma. The majority of adenocarcinomas develop as a complication of Barrett metaplasia due to chronic gastroesophageal reflux. Thus, most adenocarcinomas arise in the distal third of the esophagus. Obesity also is strongly associated with adenocarcinoma, even after controlling for gastroesophageal reflux; however, no causal relationship has been convincingly shown.

► Clinical Findings

A. Symptoms and Signs

Most patients with esophageal cancer present with advanced, incurable disease. Over 90% have solid food dysphagia, which progresses over weeks to months. Odynophagia is sometimes present. Significant weight loss is common. Local tumor extension into the tracheobronchial tree may result in a tracheoesophageal fistula, characterized by coughing on swallowing or pneumonia. Chest or back pain suggests mediastinal extension. Recurrent laryngeal involvement may produce hoarseness. Physical examination is often unrevealing. The presence of supraclavicular or cervical lymphadenopathy or of hepatomegaly implies metastatic disease.

B. Laboratory Findings

Laboratory findings are nonspecific. Anemia related to chronic disease or occult blood loss is common. Elevated aminotransferase or alkaline phosphatase concentrations suggest hepatic or bony metastases. Hypoalbuminemia may result from malnutrition.

C. Imaging

A barium esophagogram may be the first study obtained to evaluate dysphagia. The appearance of a polypoid, obstructive, or ulcerative lesion is suggestive of carcinoma and requires endoscopic evaluation. However, even lesions believed to be benign by radiography warrant endoscopic evaluation. Chest radiographs may show adenopathy, a widened mediastinum, pulmonary or bony metastases, or signs of tracheoesophageal fistula such as pneumonia.

D. Upper Endoscopy

Endoscopy with biopsy establishes the diagnosis of esophageal carcinoma with a high degree of reliability. In some cases, significant submucosal spread of the tumor may yield nondiagnostic mucosal biopsies. Repeated biopsy may be necessary.

► Staging

After confirmation of the diagnosis of esophageal carcinoma, the stage of the disease should be determined since doing so influences the choice of therapy. Patients should undergo evaluation with CT of the chest and abdomen to look for evidence of pulmonary or hepatic metastases, lymphadenopathy, and local tumor extension. If there is no evidence of distant metastases or extensive local spread on CT, endoscopic ultrasonography with guided FNA biopsy of lymph nodes should be performed, which is superior to CT in demonstrating the level of local mediastinal extension and local lymph node involvement. PET with fluorodeoxyglucose or integrated PET-CT imaging is indicated to look for regional or distant spread in patients thought to have localized disease after other diagnostic studies. Bronchoscopy is sometimes required in esophageal cancers above the carina to exclude tracheobronchial extension. Laparoscopy to exclude occult peritoneal carcinomatosis should be considered in tumors at gastroesophageal junction.

► Differential Diagnosis

Esophageal carcinoma must be distinguished from other causes of progressive dysphagia, including peptic stricture, achalasia, and adenocarcinoma of the gastric cardia with esophageal involvement. Benign-appearing peptic strictures should be biopsied at presentation to exclude occult malignancy.

► Treatment

The approach to esophageal cancer depends on the tumor stage, patient preference and functional status, and the expertise of the surgeons, oncologists, gastroenterologists, and radiotherapists. There is no consensus about the optimal treatment approach. It is helpful, however, to classify patients into two general categories.

A. Therapy for “Curable” Disease

Superficial esophageal cancers confined to the epithelium (high-grade dysplasia or carcinoma in situ [Tis]), lamina propria (T1a), or submucosal (T1b) are increasingly recognized in endoscopic screening and surveillance programs. Esophagectomy achieves high cure rates for superficial tumors but is associated with mortality (2%) and morbidity. If performed by experienced physicians, endoscopic mucosal resection of superficial cancers (especially Tis and T1a) achieves equivalent long-term survival with less morbidity. For a full discussion of management options in superficial adenocarcinoma, see the section on Barrett Esophagus in Chapter 15.

1. Surgery with or without neoadjuvant chemoradiation therapy

—There is debate over the optimal surgical approach for invasive (non-superficial) but potentially “curable” esophageal cancers (stage I, II, or IIIA). The procedure with the lowest morbidity is transhiatal esophagectomy with anastomosis of the stomach to the cervical esophagus; however, this approach does not involve sampling or removal of mediastinal lymph nodes. Alternatively, surgeons may perform en bloc transthoracic excision of the esophagus with extended dissection of lymph nodes in the mediastinum and upper abdomen. In a randomized controlled trial comparing these two approaches, en bloc resection was associated with higher perioperative morbidity but a nonsignificant trend toward improved 5-year survival (39% vs 27%). Transhiatal resection may be more appropriate for patients who are elderly or have comorbid illness, and en bloc resection more appropriate in younger or healthier patients with a better prognosis.

Patients with stage I tumors have high cure rates with surgery alone and do not require radiation or chemotherapy. If regional lymph node metastases have occurred (stages IIB and III), the rate of cure with surgery alone is reduced to <20%. Meta-analysis of trials comparing neoadjuvant (preoperative) therapy followed by surgery with surgery alone suggests a 13% absolute improvement in 2-year survival with combined therapy. A 2008 randomized phase III trial of surgery alone versus a combined modality approach with neoadjuvant chemoradiation followed by surgery also demonstrated a significant survival benefit, with 5-year survival of 39% in the combined modality group versus 16% for surgery alone. Therefore, preoperative (neoadjuvant) chemoradiation therapy is recommended for stage IIA, IIB, and III tumors in fit patients. The chemotherapy regimens used with radiation include weekly carboplatin plus paclitaxel or two cycles of cisplatin plus 5-fluorouracil, based on the randomized phase III CROSS trial and CALGB 9781, respectively. Perioperative chemotherapy without radiation is also appropriate for tumors of the gastroesophageal junction based on the randomized, multicenter, phase III MAGIC trial.

2. Chemotherapy plus radiation therapy without surgery

—Combined treatment with chemotherapy and radiation therapy is superior to radiation therapy alone and has achieved long-term survival rates in up to 25% of patients. Chemoradiation therapy alone should be considered in patients with localized disease (stage II or IIIA) who are poor surgical candidates due to serious medical illness or poor functional status (Eastern Cooperative Oncology Group score > 2). Chemoradiation alone as definitive, non-surgical therapy is more likely to achieve long-term disease-free survival in patients with squamous cell carcinoma than in patients with adenocarcinoma.

B. Therapy for Incurable Disease

More than half of patients have either locally extensive tumor spread (T4) that is unresectable or distant metastases (M1) ie, stage IIIB and stage IV tumors. Surgery is not warranted in these patients. Since prolonged survival can be achieved in few patients, the primary goal is to provide

relief from dysphagia and pain, optimize quality of life, and minimize treatment side effects. The optimal palliative approach depends on the presence or absence of metastatic disease, expected survival, patient preference, and local institutional experience. Many patients with advanced disease may prefer concerted efforts at pain relief and care directed at symptom management (see Chapter 5).

1. Radiation therapy, chemotherapy, and combined therapy

—Combined radiation therapy and chemotherapy may achieve palliation in two-thirds of patients but is associated with significant side effects. It should be considered for patients with locally advanced tumors without distant metastases (stage IIIB) who have good functional status and no significant medical problems, in whom prolonged survival may be achieved. Improvement in dysphagia occurs within 2–4 weeks in almost 90% of patients.

Combination chemotherapy may be considered in patients with metastatic disease who still have good functional status and expected survival of several months. Although there is no consensus on optimal therapy, three drug combinations are commonly used: (1) epirubicin or a taxane (docetaxel or paclitaxel), (2) cisplatin or oxaliplatin, and (3) a fluoropyrimidine (5-FU or capecitabine). For patients with poor functional status, single-agent therapy with a fluoropyrimidine, a taxane, or irinotecan may be used. In patients with metastatic distal esophageal and gastroesophageal junction adenocarcinomas positive for amplification of the *HER-2* gene (approximately 15% of cases), addition of the monoclonal antibody trastuzumab to chemotherapy is associated with prolonged survival.

Radiation therapy alone may afford short-term relief of pain and dysphagia and may be suitable for patients with poor functional status or underlying medical problems. This can generally be performed in a short course over a few weeks or less, but may be complicated by temporary worsening of dysphagia and odynophagia. For patients with frank obstruction or near obstruction, local anti-tumor therapies may be preferred.

2. Local therapy—Patients with advanced esophageal cancer often have a poor functional and nutritional status with an average survival of < 12 weeks from diagnosis. In patients with poor performance status, chemoradiation or radiation may be associated with greater toxicity than potential for long-term benefit. Rapid palliation of dysphagia may be achieved by peroral placement of permanent expandable wire stents, application of endoscopic laser therapy, or photodynamic therapy. Palliative feeding tube placement may be considered for hydration and nutrition in selected cases if the obstruction is not amenable or if it is refractory to stenting, radiation, or other local therapies. Although dysphagia and quality of life are improved significantly, patients can seldom eat normally. Stents are most commonly used because of their relative ease of placement, although the choice of treatment depends on available expertise and equipment. Complications of stents occur in 20–40% and include perforation, migration, and tumor ingrowth.

► Prognosis

The overall 5-year survival rate of esophageal carcinoma is < 20%. Apart from distant metastasis (M1b), the two most important predictors of poor survival are adjacent mediastinal spread (T4) and lymph node involvement. Whereas cure may be achieved in patients with regional lymph node involvement (stages IIB and III), involvement of nodes outside the chest (M1a) is indicative of metastatic disease (stage IV) that is incurable. For those patients whose disease progresses despite chemotherapy, meticulous efforts at palliative care are essential (see Chapter 5).

► When to Refer

- Patients should be referred to gastroenterologist for evaluation and staging (endoscopy with biopsy, endoscopic ultrasonography) and palliative endoscopic antitumor therapy (stent).
- Patients with metastatic disease and obstructive tumors not amenable or refractory to palliative radiation or stenting may require referral to an interventional radiologist, gastroenterologist, or surgeon for feeding tube placement.
- Patients with curable and resectable disease (stage IIB or IIIA) and those with locally advanced or metastatic disease should be referred to an oncologist for consideration of neoadjuvant chemoradiotherapy or palliative chemotherapy, respectively.

► When to Admit

Patients with high-grade esophageal obstruction with inability to manage oral secretions or maintain hydration should be admitted.

GASTRIC ADENOCARCINOMA

ESSENTIALS OF DIAGNOSIS

- Dyspeptic symptoms with weight loss in patients over age 40 years.
- Iron deficiency anemia: occult blood in stools.
- Abnormality detected on upper gastrointestinal series or endoscopy.

► General Considerations

Gastric adenocarcinoma remains the second most common cause of cancer death worldwide. However, its incidence has declined rapidly over the last 70 years, especially in western countries, which may be attributable to changes in diet (more fruits and vegetables), food refrigeration (allowing more fresh foods and reduced salted, smoked, and preserved foods), reduced toxic environmental exposures, and a decline in *Helicobacter pylori*. The incidence of gastric cancer remains high (70/100,000) in Japan and many developing regions, including eastern Asia, Eastern Europe, Chile, Colombia, and Central America. In the United States, there are an estimated 21,500 new cases and 10,800 deaths/year. The incidence is higher in Latinos, African Americans, and Asian Americans.

There are two main histologic variants of gastric cancer: “intestinal-type” (which resembles intestinal cancers in forming glandular structures) and “diffuse” (which is poorly differentiated, has signet-ring cells, and lacks glandular formation). Although both types are declining in incidence, intestinal-type has had the most dramatic reduction. **Intestinal-type** is still more common (70–80%), occurs twice as often in men as women, primarily affects older people (mean age 63 years), and is more strongly associated with environmental factors. It is believed to arise through a gradual, multi-step progression from inflammation (most commonly due to *H pylori*), to atrophic gastritis, to intestinal metaplasia, and finally dysplasia or cancer. Chronic *H pylori* gastritis is the strong risk factor for gastric carcinoma, increasing the relative risk 3.5- to 20-fold. It is estimated that 60–90% of cases of gastric carcinomas may be attributable to *H pylori*. Other risk factors for

intestinal-type gastric cancer include pernicious anemia, a history of partial gastric resection more than 15 years previously, smoking, and diets that are high in nitrates or salt and low in vitamin C.

Diffuse gastric cancer accounts for 20–30% of gastric cancer. In contrast to intestinal-type cancer, it affects men and women equally, occurs more commonly in young people, is not as strongly related to *H pylori* infection, has a worse prognosis, and has not declined in incidence. Most diffuse gastric cancers are attributable to acquired or hereditary mutations in the genes regulating the E-cadherin cell adhesion protein. Familial diffuse gastric cancer accounts for 1–3% of gastric cancers. The cancer may arise at a young age, is often multifocal and infiltrating with signet ring cell histology, and confers poor prognosis. Many of these families have a germline mutation of E-cadherin *CDH1*, which is inherited in an autosomal dominant pattern and carries a > 60% lifetime risk of gastric cancer. Prophylactic gastrectomy should be considered in patients known to carry this mutation.

Most gastric cancers arise in the body and antrum. These may occur in a variety of morphologic types: (1) polypoid or fungating intraluminal masses; (2) ulcerating masses; (3) diffusely spreading (linitis plastica), in which the tumor spreads through the submucosa, resulting in a rigid, atonic stomach with thickened folds (prognosis dismal); and (4) superficially spreading or “early” gastric cancer—confined to the mucosa or submucosa (with or without lymph node metastases) and associated with a favorable prognosis.

In contrast to the dramatic decline in cancers of the distal stomach, a rise in incidence of tumors of the gastric cardia has been noted. These tumors have demographic and pathologic features that resemble Barrett-associated esophageal adenocarcinomas (see Esophageal Cancer).

▶ Clinical Findings

A. Symptoms and Signs

Gastric carcinoma is generally asymptomatic until the disease is quite advanced. Symptoms are nonspecific and are determined in part by the location of the tumor. Dyspepsia, vague epigastric pain, anorexia, early satiety, and weight loss are the presenting symptoms in most patients. Patients may derive initial symptomatic relief from over-the-counter remedies, further delaying diagnosis. Ulcerating lesions can lead to acute gastrointestinal bleeding with hematemesis or melena. Pyloric obstruction results in postprandial vomiting. Lower esophageal obstruction causes progressive dysphagia. Physical examination is rarely helpful. A gastric mass is palpated in < 20% of patients. Signs of metastatic spread include a left supraclavicular lymph node (Virchow node), an umbilical nodule (Sister Mary Joseph nodule), a rigid rectal shelf (Blumer shelf), and ovarian metastases (Krukenberg tumor). Guaiac-positive stools may be detectable.

B. Laboratory Findings

Iron deficiency anemia due to chronic blood loss or anemia of chronic disease is common. Liver function test

abnormalities, particularly elevation of alkaline phosphatase, may be present if there is metastatic liver spread. Other tumor markers are of no value.

C. Endoscopy

Upper endoscopy should be obtained in all patients over age 55 years with new onset of epigastric symptoms (dyspepsia) and in anyone with dyspepsia that is persistent or fails to respond to a short trial of antisecretory therapy. Endoscopy with biopsies of suspicious lesions is highly sensitive for detecting gastric carcinoma. It can be difficult to obtain adequate biopsy specimens in linitis plastica lesions.

D. Imaging

A barium upper gastrointestinal series is an acceptable alternative when endoscopy is not readily available but may not detect small or superficial lesions and cannot reliably distinguish benign from malignant ulcerations. Any abnormalities detected with this procedure require endoscopic confirmation.

Once a gastric cancer is diagnosed, preoperative evaluation with CT of chest and abdomen (including pelvis in females) and endoscopic ultrasonography is indicated to delineate the local extent of the primary tumor as well as nodal or distant metastases. PET or combined PET-CT imaging may be more sensitive than CT for detection of distant metastasis. Endoscopic ultrasonography is superior to CT in determining the depth of tumor penetration and is useful for evaluation of early gastric cancers that may be removed by endoscopic mucosal resection.

▶ Screening

Because of its unproven efficacy and cost-effectiveness, screening for *H pylori* infection and treating it to prevent gastric cancer is not recommended for asymptomatic adults in the general population but may be considered in patients who have immigrated from regions with a high incidence of gastric cancer or who have a family history of gastric cancer. Because of the high incidence of gastric carcinoma in Japan, screening upper endoscopy is performed to detect early gastric carcinoma. Approximately 40% of tumors detected by screening are early, with a 5-year survival rate of almost 90%. Screening programs are not recommended in the United States.

▶ Staging

Staging is defined according to the TNM system, in which T1 tumors invade the lamina propria (T1a) or submucosa (T1b), T2 invade the muscularis propria, T3 penetrate the serosa, and T4 invade adjacent structures. Lymph nodes are graded as N0 if there is no involvement, and N1, N2, or N3 if there are is involvement of 1–6, 7–15, or more than 15 regional nodes. M1 signifies the presence of metastatic disease.

▶ Differential Diagnosis

Ulcerating gastric adenocarcinomas are distinguished from benign gastric ulcers by biopsies. Approximately 3% of

gastric ulcers initially believed to be benign later prove to be malignant. To exclude malignancy, all gastric ulcers identified at endoscopy should be biopsied. Ulcers that are suspicious for malignancy to the endoscopist or that have atypia or dysplasia on histologic examination warrant repeat endoscopy in 2–3 months to verify healing and exclude malignancy. Nonhealing ulcers should be considered for resection. Infiltrative carcinoma with thickened gastric folds must be distinguished from lymphoma and other hypertrophic gastropathies.

► Treatment

A. Curative Surgical Resection

Surgical resection is the only therapy with curative potential. After preoperative staging, about two-thirds of patients will be found to have localized disease (ie, stages I–III). In Japan and in specialized centers in the United States, endoscopic mucosal resection is performed in selected patients with small (< 1–2 cm), early (intramucosal or T1aN0) gastric cancers after careful staging with endoscopic ultrasonography. Approximately 25% of patients undergoing surgery will be found to have locally unresectable tumors or peritoneal, hepatic, or distant lymph node metastases that are incurable. The remaining patients with confirmed localized disease should undergo radical surgical resection with curative intent. For adenocarcinoma localized to the distal two-thirds of the stomach, a subtotal distal gastrectomy should be performed. For proximal gastric cancer or diffusely infiltrating disease, total gastrectomy is necessary. Vitamin B₁₂ supplementation is required postgastrectomy. Although lymph node dissection should be performed for curative resections, there has been ongoing debate about whether an extended (perigastric; D1), regional (D2), or distant (porta hepatic and periaortic; D3) lymph node dissection is needed. A 2008 large Japanese trial found no difference in survival between patients treated with D2 and D3 (para-aortic) lymphadenectomy. Current NCCN treatment guidelines recommend regional (D2) node resection with 15 or more lymph nodes sampled. The role of preoperative (neoadjuvant) or postoperative (adjuvant) chemotherapy or radiochemotherapy after curative resection is controversial. Recommended options include either adjuvant chemoradiotherapy (commonly 5-FU and leucovorin) or a perioperative chemotherapy regimen of epirubicin, 5-FU, and cisplatin (ECF) without radiation. Treatment of tumors arising in the gastroesophageal junction may be treated following algorithms for either gastric or esophageal primary tumors; multidisciplinary treatment decision-making involving the surgeon, radiation oncologist, and medical oncologist is imperative.

B. Palliative Modalities

Many patients will be found either preoperatively or at the time of surgical exploration to have advanced disease that is not amenable to “curative” surgery due to peritoneal or distant metastases or local invasion of other organs. In some of these cases, palliative resection of the tumor

nonetheless may be indicated to alleviate pain, bleeding, or obstruction. For patients with unresectable disease, gastrojejunostomy may be indicated to prevent obstruction. Alternatively, unresected tumors may be treated with endoscopic laser or stent therapy, radiation therapy, or angiographic embolization to relieve bleeding or obstruction. Chemotherapy may be considered in patients with metastatic disease who still have good functional status and expected survival of several months. Multiple chemotherapy regimens have demonstrated activity in metastatic gastric adenocarcinoma. A combination of epirubicin, cisplatin, and 5-FU or a modification thereof is commonly used in first-line treatment for fit patients. A 2009 randomized, phase III study showed that addition of the biologic agent trastuzumab to standard chemotherapy prolonged survival in the subset (approximately 15%) of patients with advanced gastric adenocarcinomas harboring amplification of the EGFR-2 (HER-2). Trastuzumab is not recommended for combination with anthracyclines such as epirubicin, however, due to risk for cardiotoxicity.

► Prognosis

The long-term survival of gastric carcinoma is < 15%. However, 5-year survival in patients who undergo successful curative resection is over 45%. Survival is related to tumor stage, location, and histologic features. Stage I and stage II tumors resected for cure have a > 50% long-term survival. Patients with stage III tumors have a poor prognosis (< 20% long-term survival) and should be considered for enrollment in clinical trials. Tumors of the diffuse type have a worse prognosis than the intestinal type. Tumors of the proximal stomach (fundus and cardia) carry a far worse prognosis than distal lesions. Even with apparently localized disease, proximal tumors have a 5-year survival of < 15%. For those whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see Chapter 5).

► When to Refer

- Patients with dysphagia, weight loss, protracted vomiting, iron-deficiency anemia, or new-onset of dyspepsia (especially if age 55 years or older or associated with other alarm symptoms) in whom gastric cancer is suspected should be referred to a gastroenterologist for endoscopic screening.
- Patients should be referred to a surgeon for attempt at curative resection in stage I, II, or III cancer as well as to an oncologist to evaluate for adjuvant or neoadjuvant chemotherapy (or both) or chemoradiotherapy.
- Patients who have undergone gastrectomy require consultation with a nutritionist due to propensity for malnutrition and complications, such as dumping syndrome, postoperatively.
- Patients with unresectable or metastatic disease should be referred to an oncologist for consideration of adjuvant chemotherapy or chemoradiotherapy after curative resection or palliative therapy.

▶ When to Admit

Patients with protracted vomiting, inability to maintain oral intake, or acute bleeding.

GASTRIC LYMPHOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Symptoms of dyspepsia, weight loss, or anemia.
- ▶ Variable abnormalities on upper gastrointestinal series or endoscopy including thickened folds, ulcer, mass or infiltrating lesions; diagnosis established by endoscopic biopsy.
- ▶ Abdominal CT and endoscopic ultrasonography required for staging.

▶ General Considerations

Gastric lymphomas may be primary (arising from the gastric mucosa) or may represent a site of secondary involvement in patients with nodal lymphomas. Distinguishing advanced primary gastric lymphoma with adjacent nodal spread from advanced nodal lymphoma with secondary gastric spread can be problematic. Because the prognosis and treatment of primary and secondary gastric lymphomas are entirely different, the distinction is important. Primary lymphoma is the second most common gastric malignancy, accounting for 3% of cancers. More than 95% of these are non-Hodgkin B cell lymphomas. Most primary gastric lymphomas are believed to arise from mucosa-associated lymphoid tissue (MALT). Primary gastric lymphomas comprise two main types: 60% are diffuse large B-cell lymphomas (previously called “high-grade” MALT lymphomas) and 40% are marginal zone B-cell lymphomas of the MALT-type (previously call “low-grade” MALT lymphoma).

Infection with *H pylori* is an important risk factor for the development of primary gastric lymphoma. Chronic infection with *H pylori* causes an intense lymphocytic inflammatory response that may lead to the development of lymphoid follicles. Over 90% of low-grade primary gastric MALT-type lymphomas are associated with *H pylori* infection. It is hypothesized that chronic antigenic stimulation may result in a monoclonal lymphoproliferation that may culminate in low-grade or high-grade lymphoma.

▶ Clinical Findings

The clinical presentation and endoscopic appearance of gastric lymphoma are similar to those of adenocarcinoma. Most patients have abdominal pain, weight loss, or bleeding. Patients with diffuse large B-cell lymphoma are more likely to have systemic symptoms and advanced tumor stage. At endoscopy, lymphoma may appear as an ulcer, mass, or diffusely infiltrating lesion. The diagnosis is established with endoscopic biopsy. All patients should undergo staging with abdominal and chest CT. Endoscopic ultrasonography is the most sensitive test for determining the level of invasion and presence of perigastric lymphadenopathy.

▶ Treatment

Nodal lymphomas with secondary gastrointestinal involvement usually present at an advanced stage with widely disseminated disease and are seldom curable. Their treatment is addressed in Chapter 13. Treatment of primary gastric lymphomas depends on the tumor histology, grade, and stage. Marginal B-cell lymphomas of the MALT type that are low-grade and localized to the stomach wall (stage IE) or perigastric lymph nodes (stage IIE₁) have an excellent prognosis. Endoscopic ultrasonography should be performed to accurately determine tumor stage. Patients with primary gastric MALT-lymphoma should be tested for *H pylori* infection and treated if positive. Complete lymphoma regression after successful *H pylori* eradication occurs in 75% of cases of stage IE and 55% with stage II₁ low-grade lymphoma. Remission may take as long as a year, and relapse occurs in 2% of

cases per year. Endoscopic surveillance after *H pylori* eradication is recommended every 6 months for 2 years to look for recurrence. Remission rates (22%) are much lower in patients whose tumors have an API2-MALT1 gene translocation. Patients with localized marginal zone MALT-type lymphomas who either are not infected with *H pylori* or do not respond to eradication therapy may be treated with radiation therapy or rituximab, if not a candidate for radiation. Data from a 2010 study, however, suggest that many patients with minimal disease after successful *H pylori* eradication may be observed closely without further therapy. The long-term survival of low-grade MALT lymphoma for stage I is over 90% and for stage II is 35–65%. Patients with diffuse large cell (high-grade) lymphomas or disseminated MALT-type lymphomas should be treated with combination chemotherapy (eg, CHOP with rituximab). Because of a low risk of perforation with either radiation therapy or chemotherapy, surgical resection is no longer recommended.

GASTRIC CARCINOID TUMORS

Gastric carcinoids are rare neuroendocrine tumors that make up < 1% of gastric neoplasms. They may occur sporadically or secondary to chronic hypergastrinemia that results in hyperplasia and transformation of enterochromaffin cells in the gastric fundus. Sporadic carcinoids account for 20% of gastric carcinoids. Most are solitary, over 2 cm in size, and have a strong propensity for metastatic spread. Most sporadic carcinoids already have carcinoid syndrome and hepatic or pulmonary metastatic involvement at initial presentation. Localized sporadic carcinoids should be treated with radical gastrectomy.

The majority of carcinoids caused by hypergastrinemia occur in association with either pernicious anemia (75%) or Zollinger-Ellison syndrome (5%). Carcinoids associated with Zollinger-Ellison syndrome occur almost exclusively in patients with MEN 1, in which loss of 11q13 has been reported. Carcinoids caused by hypergastrinemia tend to be multicentric, < 1 cm in size, and have a low potential for metastatic spread or development of carcinoid syndrome. Small lesions may be successfully treated with endoscopic resection followed by periodic endoscopic surveillance. Antrectomy reduces serum gastrin levels and may lead to regression of small tumors. Patients with large or multiple carcinoids should undergo surgical tumor resection (see Carcinoid Tumors section).

GASTROINTESTINAL MESENCHYMAL TUMORS

Gastrointestinal mesenchymal tumors occur throughout the gastrointestinal tract, but approximately two-thirds occur in the stomach. These tumors (which include stromal tumors, leiomyomas, and schwannomas) derive from mesenchymal stem cells and have an epithelioid or spindle cell histologic pattern, resembling smooth muscle. The most common stromal tumors are gastrointestinal stromal tumors (“GISTs”), which appear to originate from interstitial cells of Cajal. GISTs occur throughout the gastrointestinal tract but most commonly in the stomach (50%) and small intestine (30%). About 85–90% of GISTs have mutations in KIT, a receptor tyrosine kinase that binds stem cell factor, or a homologous tyrosine kinase, platelet-derived growth factor alpha that lead to constitutive activation. Approximately 90% of stromal tumors stain positively for CD117 (part of the KIT protein). Other mesenchymal tumors such as leiomyomas, which derive from smooth muscle cells, stain negative for CD117. Mesenchymal tumors may be discovered incidentally on imaging studies or endoscopy or may cause symptoms, mainly obstruction by large tumors or acute or chronic bleeding due to central ulceration within the tumor. At endoscopy, they appear as a submucosal mass that may have central umbilication or ulceration. Endoscopic ultrasonography (possibly with guided FNA biopsy) is the optimal study for diagnosing mesenchymal tumors and distinguishing them from other submucosal lesions. While almost all GISTs have malignant potential, the risk of developing metastasis is related to the tumor size (> 2 cm), location (small bowel is highest risk), and mitotic index (> 5 mitoses per high-powered field); however, mitotic index can only be assessed after resection. It is difficult to distinguish with certainty benign from malignant (sarcoma) tumors before resection by endoscopic ultrasonographic appearance or FNA. In general, lesions that are smaller than 2 cm, have a smooth border, and have a homogeneous echo pattern on endoscopic ultrasonogram are more likely benign.

Surgery is recommended for all patients with tumors that are symptomatic, ≥ 2 cm, are increasing in size, or have an endoscopic ultrasonographic appearance suspicious for malignancy. PET-CT scan should be obtained prior to surgery to look for metastatic disease. The management of asymptomatic benign-appearing lesions ≤ 2 cm in size is problematic. Because of a low risk of malignancy, surgical resection should be considered in younger, otherwise healthy patients; however, other patients may be followed up with serial endoscopic ultrasonographic examinations or, in selected cases, endoscopic resections. (GIST tumors with high-risk features have a 50% 5-year survival rate after complete surgical resection.) Adjuvant therapy with the tyrosine kinase inhibitor imatinib delays recurrence and prolongs survival in patients with high-risk tumors. Three years of adjuvant imatinib is superior to 1 year, although optimal duration remains unknown. Metastatic tumors are aggressive and carry a poor prognosis. Imatinib induces disease control in up to 85% of patients with metastatic disease with a progression free-survival of 20–24 months and median overall survival of almost 5 years. Patients whose

tumors harbor exon 11 mutations in the KIT gene (approximately 70%) are more likely to respond to imatinib than those with exon 9 mutations in the KIT gene (approximately 12%), platelet-derived growth factor receptor alpha (PDGFRA) mutations (5–8%), or wild-type tumors (10–15%). Resistant tumors may respond to high-dose imatinib or to sunitinib, another tyrosine kinase inhibitor that is approved as second-line therapy for metastatic GIST. Clinical trials of potent new KIT inhibitors and other multikinase inhibitors are underway.

MALIGNANCIES OF THE SMALL INTESTINE

1. Adenocarcinoma

These are aggressive tumors that occur most commonly in the duodenum or proximal jejunum. The ampulla of Vater is the most common site of small bowel carcinoma, and the incidence of ampullary carcinoma is increased more than 200-fold in patients with familial adenomatous polyposis. Ampullary carcinoma may present with jaundice due to bile duct obstruction or bleeding. Surgical resection of early lesions is curative in up to 40% of patients. Periodic endoscopic surveillance to detect early ampullary neoplasms therefore is recommended in patients with this disorder. Nonampullary adenocarcinoma of the small intestine accounts for < 3% of all gastrointestinal cancers but one-third of small bowel cancers. Peak incidence is in the sixth decade. Most cases present with symptoms of obstruction, acute or chronic bleeding, or weight loss. The majority of small bowel cancers have already metastasized at the time of diagnosis. Resection is recommended for control of symptoms. The role of adjuvant therapy is unclear but is generally administered using chemotherapy agents active

in colorectal cancer. The prognosis is poor with a 5-year overall survival of 20–30%. Patients with Crohn disease have an increased risk of small intestine adenocarcinoma, most commonly in the ileum, which may be difficult to distinguish from disease-related fibrous strictures. Small bowel adenocarcinoma in young patients or those with a family history of gastrointestinal adenocarcinomas should prompt screening for the Lynch syndrome.

2. Lymphoma

Gastrointestinal lymphomas may arise in the gastrointestinal tract or involve it secondarily with disseminated disease. In Western countries, primary gastrointestinal lymphomas account for 5% of lymphomas and 20% of small bowel malignancies. They occur most commonly in the distal small intestine. The majority are non-Hodgkin high-grade marginal zone B cell lymphomas. There is an increased incidence of small intestinal lymphomas in patients with AIDS, immunosuppressive therapy, and Crohn disease. T cell lymphomas may arise in patients with celiac sprue. In the Middle East, lymphomas may arise in the setting of immunoproliferative small intestinal disease. In this condition, there is diffuse lymphoplasmacytic infiltration with IgA-secreting B lymphocytes of the mucosa and submucosa that results in weight loss, diarrhea, and malabsorption, which may lead to lymphomatous transformation. A characteristic feature of the disease is the presence of α heavy chains in the serum in 70% produced by clones of IgA plasma cells. Other types of intestinal lymphomas include mantle cell and Burkitt.

Presenting symptoms or signs of primary lymphoma include abdominal pain, weight loss, nausea and vomiting, distention, anemia, and occult blood in the stool. Fevers are unusual. Protein-losing enteropathy may result in hypoalbuminemia, but other signs of malabsorption are unusual. Barium radiography or CT enterography helps localize the site of the lesion. The diagnosis requires endoscopic, percutaneous, or laparoscopic biopsy. Imaging and bone marrow biopsy are required to determine stage.

Treatment depends on the tumor histologic grade and stage of disease. Resection of primary intestinal lymphoma, if feasible, is usually recommended. Even in cases of stage III or stage IV disease, surgical debulking may improve survival. In patients with limited disease (stage IE) in whom resection is performed, the role of adjuvant chemotherapy is unclear. Most patients with more extensive disease are treated with combination chemotherapy (eg, CHOP with rituximab) with or without radiation therapy.

3. Carcinoid Tumors

ESSENTIALS OF DIAGNOSIS

- ▶ Majority are asymptomatic and discovered incidentally at endoscopy or surgery.
- ▶ Carcinoid syndrome occurs in < 10%; hepatic metastases are generally present.
- ▶ Risk of metastasis related to tumor size and location.

► General Considerations

Gastrointestinal carcinoids are slow growing neuroendocrine tumors that may arise anywhere in the gastrointestinal tract but most commonly occur in the small intestine (30%), rectum (12%), colon (8%), appendix (8%), and stomach (10–30%; see above). Carcinoids may contain a variety of hormones, including serotonin, somatostatin, gastrin, and substance P that may or may not be secreted, and usually display immunoreactivity to chromogranin A. Although many carcinoids behave in an indolent fashion, the overall 5-year survival rate for patients with carcinoids is 50%, suggesting that most are malignant. The risk of metastatic spread is closely related to tumor size and tumor location. Many small carcinoids are detected incidentally at endoscopy or autopsy. It is not possible by histologic examination to distinguish benign from malignant disease. The best indicator of prognosis is evidence of invasive growth and the presence of regional or distant metastasis.

Carcinoids account for one-third of small intestinal tumors. Small intestinal carcinoids most commonly arise in the ileum. Up to one-third are multicentric. Although 60% are < 2 cm in size, even these small carcinoids may metastasize. Almost all small intestinal carcinoids over 2 cm are associated with metastasis.

Appendiceal carcinoids are identified in 0.3% of appendectomies, usually as an incidental finding. Almost 80% of these tumors are < 1 cm in size, and 90% are < 2 cm. Rectal carcinoids are usually detected incidentally as submucosal nodules during proctoscopic examination. Rectal carcinoids < 1 cm and localized appendiceal carcinoids < 2 cm virtually never metastasize and are treated effectively with local excision or simple appendectomy. Tumors larger than 2 cm are associated with the development of metastasis in over 20% of appendiceal carcinoids and 10% of rectal carcinoids. Hence, in younger patients who are good candidates for surgery, a more extensive cancer resection operation is warranted.

► Clinical Findings

A. Symptoms and Signs

Most smaller lesions (< 1–2 cm) are asymptomatic and difficult to detect by endoscopy or imaging studies. Through local extension or metastasis to mesenteric lymph nodes, carcinoids engender a fibroblastic reaction with contraction and kinking of the bowel or encasement of mesenteric vessels. Small intestinal carcinoids may present with abdominal pain, bowel obstruction, bleeding, or bowel infarction. Appendiceal and rectal carcinoids usually are small and asymptomatic but large lesions can cause bleeding, obstruction, or altered bowel habits. **Carcinoid syndrome** occurs in < 10% of patients. More than 90% of patients with carcinoid syndrome have hepatic metastases, usually from carcinoids of small bowel origin. About 10% of patients with carcinoid syndrome have primary bronchial or ovarian tumors without hepatic metastases. Carcinoid syndrome is caused by tumor secretion of hormonal mediators. The manifestations include facial flushing, edema of the head and neck (especially

with bronchial carcinoid), abdominal cramps and diarrhea, bronchospasm, cardiac lesions (pulmonary or tricuspid stenosis or regurgitation in 10–30%), and telangiectases.

B. Laboratory Findings

Serum chromogranin A (CgA) is elevated in the majority of neuroendocrine tumors, although its sensitivity for small, localized carcinoid tumors is unknown. CgA is elevated in almost 90% of patients with advanced small bowel carcinoid. Urinary 5-hydroxyindoleacetic acid (5-HIAA) and platelet serotonin levels are also elevated in patients with metastatic carcinoid; however, these tests are less sensitive than CgA. There is increased urinary 5-HIAA in carcinoid syndrome; symptomatic patients usually excrete more than 25 mg of 5-HIAA per day in the urine. Ideally, all drugs should be withheld for several days prior to a 24-hour urine collection.

C. Imaging

Abdominal CT may demonstrate a mesenteric mass with tethering of the bowel, lymphadenopathy, and hepatic metastasis. Abdominal CT or enterography may reveal kinking of the bowel, but because the lesion is extraluminal, the diagnosis may be overlooked for several years. Somatostatin receptor scintigraphy, which is positive in up to 90% of patients with metastatic carcinoid, is routinely used in staging. Most patients with carcinoid syndrome have liver metastasis on abdominal imaging.

► Treatment

Small intestinal carcinoids are extremely indolent tumors with slow spread. Patients with disease confined to the small intestine should be treated with surgical excision, for which the cure rate exceeds 85%. In patients with resectable disease who have lymph node involvement, the 5-year disease-free survival is 80%; however, by 25 years, < 25% remain disease free. Even patients with hepatic metastases may have an indolent course with a median survival of 3 years. In patients with advanced disease, therapy historically has been deferred until the patient is symptomatic, although a 2009 phase III, randomized, placebo-controlled trial demonstrated that early initiation of somatostatin analog therapy delayed time to progression of hepatic metastases. Surgery should be directed toward palliation of obstructive symptoms.

In patients with carcinoid syndrome, resection of hepatic metastases may provide dramatic improvement. The somatostatin analog octreotide, 100–500 mcg subcutaneously three times daily or administered as a long-acting intramuscular depot formulation, inhibits hormone secretion from the carcinoid tumor. This results in dramatic relief of symptoms of carcinoid syndrome, including diarrhea or flushing, in 90% of patients for a median period of 1 year. Thereafter, many patients stop responding to octreotide. Hepatic artery occlusion, liver-directed debulking procedures, and chemotherapy may provide symptomatic improvement in some patients with hepatic metastases.

4. Small Intestine Sarcoma

Most small intestine sarcomas arise from stromal tumors (GISTs) that stain positive for CD117; a minority arise from smooth muscle tumors (leiomyosarcomas) (see Gastrointestinal Mesenchymal Tumors above).

Kaposi sarcoma was at one time a common complication in AIDS, but the incidence is declining with highly active antiretroviral therapy (HAART). It is strongly associated with infection with human herpesvirus 8. Lesions may be present anywhere in the intestinal tract. Visceral involvement usually is associated with cutaneous disease. Most lesions are clinically silent; however, large lesions may be symptomatic. Interferon- α induces regression in up to one-third of patients who have a CD4 cell count of > 200 /mL. Widespread involvement may be best treated by systemic chemotherapy using combinations of vincristine, bleomycin, or doxorubicin, to which the tumor is very responsive.

COLORECTAL CANCER

ESSENTIALS OF DIAGNOSIS

- ▶ Personal or family history of adenomatous polyps or colorectal cancer are important risk factors.
- ▶ Symptoms or signs depend on tumor location.
- ▶ Proximal colon: fecal occult blood, anemia.
- ▶ Distal colon: change in bowel habits, hematochezia.
- ▶ Diagnosis established with colonoscopy.

▶ General Considerations

Colorectal cancer is the second leading cause of death due to malignancy in the United States. Colorectal cancer will develop in approximately 6% of Americans and 40% of those will die of the disease. In 2010, there were an estimated 142,570 new cases and 51,370 deaths from colorectal cancer in the United States. Colorectal cancers are almost all adenocarcinomas, which tend to form bulky exophytic masses or annular constricting lesions. Slightly $< 50\%$ of cancers are located distal to the splenic flexure (within the descending colon or rectosigmoid region).

The current belief is that the majority of colorectal cancers arise from malignant transformation of an adenomatous polyp (tubular, tubulovillous, or villous adenoma) or serrated polyp (hyperplastic polyp, traditional serrated adenoma, or sessile serrated adenoma). Polyps that are “advanced” (ie, polyps at least 1 cm in size, adenomas with villous features, or adenomas with high-grade dysplasia) are associated with a greater risk of cancer. Approximately 85% of sporadic colorectal cancers arise from adenomatous polyps and have loss of function of one or more tumor suppressor genes (eg, *p53*, *APC*, or *DCC*) due to a combination of spontaneous mutation of one allele combined with chromosomal instability and aneuploidy (abnormal DNA content) that leads to deletion and loss of heterozygosity of the other allele (eg, 5q, 17q, or 18p deletion). Activation of oncogenes such as *K-ras* and *B-raf* is present in a subset of colorectal cancers with prognostic and therapeutic implications discussed further below.

Approximately 10–20% of colorectal cancers arise from serrated polyps, most of which have hypermethylation of CpG-rich promoter regions that leads to inactivation of the DNA mismatch repair gene *MLH1*, resulting in microsatellite instability, and activation of mutations of the *BRAF* gene. Serrated colon cancers have distinct clinical and pathologic characteristics, including diploid DNA content, predominance in the proximal colon, poor differentiation, and more favorable prognosis.

Up to 5% of colorectal cancers are caused by inherited germline mutations resulting in polyposis syndromes (eg, familial adenomatous polyposis) or hereditary nonpolyposis colorectal cancer (HNPCC or Lynch syndrome). These conditions are discussed further in Chapter 15.

▶ Risk Factors

A number of factors increase the risk of developing colorectal cancer. Recognition of these has impact on screening strategies. However, 75% of all cases occur in people with no known predisposing factors.

A. Age

The incidence of colorectal cancer rises sharply after age 45 years, and 90% of cases occur in persons over the age of 50 years.

B. Family History of Neoplasia

A family history of colorectal cancer is present in 20% of patients with colon cancer. Hereditary factors are believed

to contribute to 20–30% of colorectal cancers; however, the genes responsible for most of these cases have not yet been identified. (See Chapter 15 for discussion of inherited polyposis syndromes.) Approximately 6% of the Ashkenazic Jewish population has a missense mutation in the *APC* gene (*APC I1307K*) that confers a modestly increased lifetime risk of developing colorectal cancer (OR 1.4–1.9) but phenotypically resembles sporadic colorectal cancer rather than familial adenomatous polyposis. Genetic screening is available, and patients harboring the mutation merit intensive screening.

A family history of colorectal cancer or adenomatous polyps is one of the most important risk factors for colorectal cancer. The risk of colon cancer is proportionate to the number and age of affected first-degree family members with colon neoplasia. People with one first-degree family member with colorectal cancer have an increased risk approximately two times that of the general population; however, the risk is almost four times if the family member's cancer was diagnosed at < 45 years of age. Patients with two first-degree relatives have a fourfold, or 25–30% lifetime, risk of developing colon cancer. First-degree relatives of patients with adenomatous polyps also have a twofold increased risk for colorectal neoplasia, especially if the polyp was large (≥ 10 mm) or detected before age 60 years.

C. Inflammatory Bowel Disease

The risk of adenocarcinoma of the colon begins to rise 7–10 years after disease onset in patients with ulcerative colitis and Crohn colitis. The cumulative risk approaches 5–10% after 20 years and 20% after 30 years. Chronic treatment with 5-ASA agents and folate is associated with a lower risk of cancer in patients with ulcerative colitis.

D. Dietary Factors and Chemoprevention

In epidemiologic studies, diets rich in fats and red meat are associated with an increased risk of colorectal adenomas and cancer, whereas diets high in fruits, vegetables, and fiber are associated with a decreased risk. However, prospective, randomized controlled trials failed to demonstrate a risk reduction in the recurrence of adenomatous polyps after treatment with a diet low in fat and high in fiber, fruits, and vegetables, or with fiber supplementation. Calcium carbonate (3 g/d) has been shown in large cohort studies as well as small prospective trials to yield a modest reduction in the relative risk of developing colorectal neoplasia; however, a prospective study of 36,000 women did not show a protective benefit of calcium (500 mg) and vitamin D (200 international units twice daily) in preventing colon cancer. Similarly, the risk of colon cancer is not decreased in persons taking folic acid supplements. The antioxidant vitamins A, C, E, and beta carotene also have not been shown to be of benefit in prospective controlled studies.

A US Preventive Services Task Force meta-analysis of cohort and case-control studies suggest that prolonged (> 6 years) regular use of aspirin (at least 325 mg twice weekly) or NSAIDs is associated with a 22–33% relative risk reduction in the incidence of colorectal cancer. Two

prospective, blinded clinical trials have shown that daily low-dose aspirin (80–325 mg) reduces the number of recurrent adenomas at 1–3 years in patients with a history of colorectal adenomas or cancer; however, two large randomized controlled trials in the United States did not demonstrate a reduction in colorectal cancer incidence in patients taking low-dose aspirin over a 5–10 years. Because long-term aspirin use is associated with a low incidence of serious complications (gastrointestinal hemorrhage, stroke), the US Preventive Services Task Force concluded that it should not be prescribed as a chemopreventive agent in people without polyps or with small adenomas unless there are other medical indications. Long-term administration of low-dose aspirin may be considered in patients with a personal or family history of colorectal cancer or advanced adenomas; however, they do not obviate the need for colonoscopy screening and surveillance.

E. Other Factors

The incidence of colon adenocarcinoma is higher in blacks than in whites. It is unclear whether this is due to genetic or socioeconomic factors (eg, diet or reduced access to screening). Diabetes, metabolic syndrome, obesity, and cigarette smoking are associated with a modest increase in cancer risk.

► Clinical Findings

A. Symptoms and Signs

Adenocarcinomas grow slowly and may be present for several years before symptoms appear. However, some asymptomatic tumors may be detected by the presence of fecal occult blood (see Colorectal Cancer Screening, below). Symptoms depend on the location of the carcinoma. Chronic blood loss from right-sided colonic cancers may cause iron deficiency anemia, manifested by fatigue and weakness. Obstruction, however, is uncommon because of the large diameter of the right colon and the liquid consistency of the fecal material. Lesions of the left colon often involve the bowel circumferentially. Because the left colon has a smaller diameter and the fecal matter is solid, obstructive symptoms may develop with colicky abdominal pain and a change in bowel habits. Constipation may alternate with periods of increased frequency and loose stools. The stool may be streaked with blood, though marked bleeding is unusual. With rectal cancers, patients note tenesmus, urgency, and recurrent hematochezia. Weight loss is uncommon. Physical examination is usually normal except in advanced disease. A mass may be palpable in the abdomen. The liver should be examined for hepatomegaly, suggesting metastatic spread. For cancers of the distal rectum, digital examination is necessary to determine whether there is extension into the anal sphincter or fixation, suggesting extension to the pelvic floor.

B. Laboratory Findings

A complete blood count is obtained to look for evidence of anemia. Elevated liver function tests, particularly the

▲ Figure 39-1. Cecal adenocarcinoma on colonoscopy. (Courtesy of Marvin Derezin, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

alkaline phosphatase, are suspicious for metastatic disease. Carcinoembryonic antigen (CEA) should be measured in all patients with proved colorectal cancer. A preoperative CEA level > 5 ng/mL is a poor prognostic indicator. After complete surgical resection, CEA levels should normalize; persistently elevated levels suggest the presence of persistent disease and warrant further evaluation.

C. Colonoscopy

Colonoscopy is the diagnostic procedure of choice in patients with a clinical history suggestive of colon cancer or in patients with an abnormality suspicious for cancer detected on radiographic imaging. Colonoscopy permits biopsy for pathologic confirmation of malignancy (Figure 39-1). In patients in whom the colonoscope is unable to reach the cecum ($< 5\%$ of cases) or when a nearly obstructing tumor precludes passage of the colonoscope, barium enema or CT colonography examination should be performed.

D. Imaging

Chest, abdominal, and pelvic CT scans are required for preoperative staging. CT scans may demonstrate distal metastases but are less accurate in the determination of the level of local tumor extension (T stage) or lymphatic spread (N stage). Intraoperative assessment of the liver by direct palpation and ultrasonography is more accurate than CT scanning for the detection of hepatic metastases. For rectal cancer, pelvic MRI or endorectal ultrasonography identifies the depth of penetration of the cancer through the rectal wall (T stage) and perirectal lymph nodes, informing decisions about preoperative (neoadjuvant) chemoradiotherapy and operative management. PET is not routinely used for staging or surveillance in colorectal cancers.

► Staging

The TNM system is the commonly used classification to stage colorectal cancer. Staging is important not only because it correlates with the patient's long-term survival but also because it is used to determine which patients should receive adjuvant therapy.

► Differential Diagnosis

The nonspecific symptoms of colon cancer may be confused with those of irritable bowel syndrome, diverticular disease, ischemic colitis, inflammatory bowel disease, infectious colitis, and hemorrhoids. Neoplasm must be excluded in any patient over age 40 years who reports a change in bowel habits or hematochezia or who has an unexplained iron deficiency anemia or occult blood in stool samples.

► Treatment

A. Surgery

Resection of the primary colonic or rectal cancer is the treatment of choice for almost all patients who have resectable lesions and can tolerate general anesthesia. For colon cancer, multiple studies demonstrate that minimally invasive, laparoscopically assisted colectomy results in similar outcomes and rates of recurrence to open colectomy. Regional dissection of at least 12 lymph nodes should be performed to determine staging, which guides decisions about adjuvant therapy.

For rectal carcinoma, preoperative (neoadjuvant) chemoradiation with 5-FU is recommended in all node-positive tumors, and in T3 and greater tumors, due to increased risk of local recurrence. Neoadjuvant chemoradiation is discussed further below. After neoadjuvant therapy, the operative approach depends on the level of the tumor above the anal verge, the size and depth of penetration, and the patient's overall condition. Clinical staging by endorectal ultrasound or MRI with endorectal coil is important in guiding the clinical approach. In carefully selected patients with small, mobile (< 4 cm), well-differentiated T1 or T2 rectal tumors that are < 8 cm from the anal verge and that appear on endosonography to be localized to the rectal wall, transanal excision may be performed. This approach avoids laparotomy and spares the rectum and anal sphincter, preserving normal bowel continence. All other patients will require either a low anterior resection with a colorectal anastomosis or an abdominoperineal resection with a colostomy, depending on how far above the anal verge the tumor is located and the extent of local tumor spread. Careful dissection of the entire mesorectum at the time of surgery has been shown to reduce local recurrence to 8%. With improvements in surgical stapling techniques, it is possible to perform low anterior resection provided there is a margin of at least 2 cm of normal tissue below the tumor. Although low anterior resections obviate a colostomy, they are associated with increased immediate postsurgical complications (leak, dehiscence, stricture) and defecatory complaints (increased stool frequency, defecatory problems, and incontinence).

With unresectable rectal cancer, the patient may be palliated with a diverting colostomy, laser fulguration, or placement of an expandable wire stent.

B. Systemic Chemotherapy for Colon Cancer

Chemotherapy and radiotherapy have been demonstrated to improve overall and tumor-free survival in selected patients with colorectal cancers depending on stage.

1. Stage I—Because of the excellent 5-year survival rate (90–100%), no adjuvant therapy is recommended.

2. Stage II (node-negative disease)—The expected 5-year survival rate is 80%. A survival benefit from adjuvant chemotherapy has not been demonstrated in most controlled trials for stage II colon cancer (see discussion for stage III disease). However, otherwise healthy patients with stage II disease that is at higher risk for recurrence (perforation, obstruction, T4 tumors, or fewer than 12 lymph nodes sampled) may benefit from adjuvant chemotherapy.

3. Stage III (node-positive disease)—With surgical resection alone, the expected 5-year survival rate is 30–50%. Postoperative adjuvant chemotherapy significantly increases disease-free survival as well as overall survival by up to 30% and is recommended for all fit patients. Large, well-designed studies of adjuvant therapy for stage III colon cancer reported a higher rate of disease-free survival at 5 years for patients treated with a combination of oxaliplatin, 5-FU, and leucovorin (FOLFOX) (73.3%) than with 5-FU and leucovorin (FL) alone (67.4%). The addition of oxaliplatin is associated with an increased incidence of diarrhea, myelosuppression, and peripheral sensory neuropathy, all of which generally are reversible. Based on these studies, FOLFOX currently is the preferred adjuvant therapy for most patients with stage III disease (see Table 39–11). The addition of a biologic agent (bevacizumab or cetuximab) to FOLFOX does not improve outcomes in the adjuvant setting.

4. Stage IV (metastatic disease)—Approximately 20% of patients have metastatic disease at the time of initial diagnosis, and another 30% eventually develop metastasis. A subset of these patients has limited disease that is potentially curable with surgical resection. Resection of isolated liver or lung metastases may result in long-term (over 5 years) survival in 35–55% of cases. For those with unresectable hepatic metastases, local ablative techniques (cryosurgery, radio-frequency or microwave coagulation, embolization, hepatic intra-arterial chemotherapy) may provide long-term tumor control. The majority of patients with metastatic disease do not have resectable (curable) disease. In the absence of other treatment, the median survival is only 6 months. The goals of therapy are to slow tumor progression while maintaining a reasonable quality of life for as long as possible. Currently, either FOLFOX (the addition of oxaliplatin to 5-FU and folinic acid) or FOLFIRI (the addition of irinotecan to 5-FU and folinic acid) is the preferred first-line treatment regimens for most patients with metastatic colorectal cancer, increasing median survival to 15–20 months. For convenience, oral capecitabine (instead of intravenous 5-FU and leucovorin) can be used in combination with

oxaliplatin; however, combination with irinotecan should not be used due to increased toxicity (diarrhea). Addition of a biologic agent to combination chemotherapy improves response rates and overall survival and is recommended in the first-line of treatment in suitable patients. Bevacizumab is a monoclonal antibody targeting VEGF. Combination therapy with bevacizumab and FOLFOX or FOLFIRI prolongs mean survival 2–5 months compared with either regimen alone (see Table 39–11). Cetuximab and panitumumab are monoclonal antibodies targeting EGFR. Activating codon 12 and 13 *K-ras* gene mutations downstream of EGFR are present in approximately 35% of patients with metastatic colorectal cancer and are a biomarker for nonresponse to cetuximab and panitumumab, for which reason the use of these agents is restricted to patients with tumors wild-type for *K-ras*. In stage 4 patients with *K-ras* wild-type tumors, the addition of panitumumab or cetuximab to FOLFOX or FOLFIRI prolongs survival by approximately 4 months. Bevacizumab may cause serious side effects, including arterial thromboembolic events, bowel perforation, or serious bleeding, in up to 5% of patients. EGFR-targeted agents cause an acneiform rash in the majority of patients. Cetuximab is associated with anaphylaxis in a small subset.

When disease progresses with FOLFOX or FOLFIRI (often in conjunction with bevacizumab or an EGFR-targeted antibody), therapy is switched to the alternative regimen. Patients progressing with one regimen may respond to the alternative regimen, prolonging mean survival to > 20 months. A phase III study randomizing patients to receive either cetuximab or bevacizumab in addition to standard first-line chemotherapy (FOLFIRI or FOLFOX) is ongoing to determine whether one biologic agent is superior. The simultaneous combination of both classes of biologic agents (anti-EGFR and anti-VEGF) with chemotherapy has been associated with worse outcomes in multiple studies. This is a sobering finding that demonstrates the complexity of the signaling pathways involved. Single-agent, palliative therapy with cetuximab or panitumumab can benefit patients with *K-ras* wild-type tumors whose disease has progressed after first-line and second-line chemotherapies. Clinical trial participation should be considered for eligible patients whose tumors have progressed despite standard treatment, including 5-FU, oxaliplatin, irinotecan, an EGFR-inhibitor (if *K-ras* gene is wild-type), and bevacizumab.

Patients with metastatic colorectal cancer whose tumors harbor a mutation in the *B-raf* oncogene (approximately 8% in metastatic disease) have a significantly worse prognosis than patients whose tumors are wild-type for *B-raf*. Unlike activating *K-ras* mutations, randomized phase 3 data suggest potential benefit from cetuximab or panitumumab in combination with chemotherapy in patients whose tumors harbor an activating *B-raf* mutation (which almost never coexist with *K-ras* mutations).

C. Adjuvant Therapy for Rectal Cancer

Compared with colon cancer, rectal cancer has lower long-term survival rates and significantly higher rates of local

tumor recurrence (25%) due to the difficulty of achieving adequate surgical resection margins. When initial imaging studies suggest stage I disease, surgery may be performed first. Combination therapy with 5-FU (as a radiation sensitizing agent) and radiation has been shown to improve the disease-free survival rate and to decrease pelvic recurrence and is recommended for all patients with stage II and stage III rectal cancers (see Table 39–11). Preoperative chemoradiation has been shown to be superior to postoperative chemoradiation and is recommended for patients with distal rectal cancers that are determined to be stage II or III by endorectal ultrasound or MRI. Following surgical resection with total mesorectal excision, 5-FU–based therapy (generally with the FOLFOX regimen extrapolating from its benefit in patients with similarly-staged colon cancers) may be administered for an additional 4 months.

► Follow-Up after Surgery

Patients who have undergone resections for cure are followed closely to look for evidence of symptomatic or asymptomatic tumor recurrence that may be amenable to curative resection in a small number of patients. The optimal cost-effective strategy is not clear. Two randomized trials reported that intense follow-up with yearly colonoscopy, abdominal CT, and chest radiography did not improve overall outcome compared with most standard follow-up protocols. Patients should be evaluated every 3–6 months for 3–5 years with history, physical examination, and CEA determinations. The NCCN recommends surveillance CT scans of chest, abdomen, and pelvis annually for the first 3 years post-resection in high-risk patients. Patients who had a complete preoperative colonoscopy should undergo another colonoscopy 1 year after surgical resection. Patients who did not undergo full colonoscopy preoperatively also should undergo colonoscopy within 3–6 months postoperatively to exclude other synchronous colorectal neoplasms. If a colonoscopy does not detect new adenomatous polyps 1 year postoperatively, surveillance colonoscopy should be performed every 3–5 years thereafter to look for metachronous polyps or cancer. Because of the high incidence of local tumor recurrence in patients with rectal cancer, proctoscopy surveillance of the low anterior resection anastomotic site may also be performed periodically. New onset of symptoms or a rising CEA warrants investigation with chest, abdominal, and pelvic CT to look for recurrent or metastatic disease that may be amenable to therapy. For patients with a rising CEA with unrevealing CT imaging, a PET scan is more sensitive for the detection of occult metastatic disease.

► Prognosis

The stage of disease at presentation is the most important determinant of long-term survival: stage I, > 90%; stage II, 70–85%; stage III with fewer than four positive lymph nodes, 67%; stage III with more than four positive lymph nodes, 33%; and stage IV, 5–7%. For each stage, rectal cancers have a worse prognosis. For those patients whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see Chapter 5).

► Screening for Colorectal Neoplasms

Colorectal cancer is ideal for screening because it is a common disease that is fatal in almost 50% of cases yet is curable if detected at an earlier stage. Furthermore, most cases arise from benign adenomatous or serrated polyps that progress over many years to cancer, and removal of these polyps has been shown to prevent the majority of cancers. Colorectal cancer screening is endorsed by the US Preventive Services Task Force, the Agency for Health Care Policy and Research, the American Cancer Society, and every professional gastroenterology and colorectal surgery society. Although there is continued debate about the optimal cost-effective means of providing population screening, there is unanimous consent that screening of *some kind* should be offered to every patient over the age of 50 years. Several analyses suggest that screening is cost effective.

It is important for primary care providers to understand the relative merits of various options and to discuss them with their patients. Despite growing awareness of the importance of screening on the part of medical professionals and the public, < 50% of patients have undergone screening of any kind. Discussion and encouragement by the primary care provider are the most important factors in achieving patient compliance with screening programs.

Recommendations for screening from the US Multi-Society Task Force are listed in Table 39–5. Screening is recommended for all men and women ages 50 through 75 years of age who are at average risk for cancer. Some

Table 39–5. Recommendations for colorectal cancer screening.¹

Average-risk individuals ≥ 50 years old²
Annual fecal occult blood testing using higher sensitivity tests (Hemeoccult SENSAs)
Annual fecal immunochemical test (FIT)
Fecal DNA test (interval uncertain)
Flexible sigmoidoscopy every 5 years
Colonoscopy every 10 years
CT colonography every 5 years
Individuals with a family history of a first-degree member with colorectal neoplasia³
Single first-degree relative with colorectal cancer diagnosed at age ≥ 60 years: Begin screening at age 40. Screening guidelines same as average-risk individual; however, preferred method is colonoscopy every 10 years.
Single first-degree relative with colorectal cancer or advanced adenoma diagnosed at age < 60 years, or two first-degree relatives: Begin screening at age 40 or at age 10 years younger than age at diagnosis of the youngest affected relative, whichever is first in time. Recommended screening: colonoscopy every 5 years.

¹For recommendations for families with inherited polyposis syndromes or hereditary nonpolyposis colon cancer, see Chapter 19.

²Joint Guideline from the American Cancer Society, the US Multi-Society Task Force on Colorectal Cancer, and the American College of Radiology. *Gastroenterology* 2008 May; 134(5):1570.

³American College of Gastroenterology. Guidelines for Colorectal Cancer Screening. *Am J Gastroenterol.* 2009 Mar;104(3):739.

guidelines recommend screening for African Americans beginning at age 45. The potential for harm from screening must be weighed against the likelihood of benefit, especially in elderly patients with comorbid illnesses and shorter life expectancy. Although routine screening is not recommended in adults above age 75, it may be considered on a case-by-case basis in adults age 76 through 85 years who have excellent health and functional status. Patients with first-degree relatives with colorectal neoplasms (cancer or adenomatous polyps) are at increased risk; earlier and more frequent screening is recommended (preferably with colonoscopy) for these individuals. Recommendations for screening in families with inherited cancer syndromes or inflammatory bowel disease are provided in Chapter 15. For patients at average risk for colorectal cancer, the recommendations of the Task Force are discussed below. Screening tests may be classified into two broad categories: stool-based tests and exams that visualize the structure of the colon by direct endoscopic inspection or radiographic imaging.

A. Stool-based Tests

1. Fecal occult blood test—Most colorectal cancers and some large adenomas result in increased chronic blood loss. A variety of tests for fecal occult blood are commercially available that have varying sensitivities and specificities for colorectal neoplasia. These include guaiac-based tests (Hemoccult I and II and Hemeoccult SENSAs) that detect the pseudoperoxidase activity of heme or hemoglobin and fecal immunochemical tests (FITs) that detect human globin.

Guaiac-based tests have undergone the most extensive testing and currently have the greatest clinical use. For optimal detection, one specimen card must be prepared from three consecutive bowel movements. To reduce the likelihood of false-positive tests, patients should abstain from aspirin (in doses > 325 mg/d), NSAIDs, red meat, poultry, fish, and vegetables with peroxide activity (turnips, horseradish) for 72 hours. Vitamin C may cause a false-negative test. Slides should be developed within 7 days after preparation. The reported sensitivities of a single guaiac-based test for detection of colorectal cancer vary widely, but are lower for Hemeoccult II (35%) than Hemeoccult SENSAs (65%). When fecal occult blood test is administered to the general population as part of a screening program, 2–6% of tests are positive. Of those with positive tests, 5–18% have colorectal cancer that is more likely to be at an earlier stage (stage I or II).

Several FITs are commercially available. These tests are highly specific for detecting human globin and therefore eliminate the need for pretest dietary restrictions. As with guaiac-based tests, sampling of three consecutive bowel movements is recommended. In clinical trials that compare FIT with guaiac-based tests, FIT had at least comparable sensitivity to Hemeoccult SENSAs for detection of cancers (60–85%) with higher specificity. Because FITs are not affected by diet or medications and have superior accuracy, they are increasingly being substituted for guaiac-based tests despite a higher cost per test (\$10–20).

The US Multi-Society Task Force emphasizes that colon cancer prevention should be the primary goal of screening. For that reason, the lower sensitivity of fecal occult blood tests for advanced neoplasia (cancer and advanced adenomatous polyps) makes them a less attractive choice for population-based screening than endoscopic or radiographic tests. Currently, fecal occult blood tests are most suitable in settings where health care resources are limited or in patients who desire a noninvasive method of screening. The Task Force recommends that tests with higher sensitivity for colorectal cancer (Hemeoccult SENSAs or FIT) be used rather than less sensitive tests (Hemeoccult II). Regardless of which stool-based test is used, patients should understand that annual testing is required to achieve the maximum screening benefit and that a positive test will require evaluation by colonoscopy accompanied by removal of any polyps identified. If colonoscopy reveals no colorectal neoplasm, further screening for colorectal cancer can be deferred for 10 years. In a meta-analysis of four large, prospective, longitudinal studies, annual or biennial screening with Hemeoccult or Hemeoccult II reduced mortality from colorectal cancer by 25% among those who were compliant with regular testing. Long-term studies with more sensitive stool tests (Heme SENSAs or FIT) have not been performed.

2. Multitarget DNA assay—A fecal DNA assay (Pre-Gen Plus) is available for screening for colorectal neoplasia. The test analyzes fecal DNA for 22 gene mutations and DNA integrity. The commercially available first-generation fecal DNA panel detected only one-half of cancers; however, a second-generation assay detected almost 90%. Although the Multi-Society Task Force concluded that fecal DNA is an acceptable option for colorectal cancer screening, this test is not yet practical for population-based screening due to its high cost and cumbersome requirements for stool collection and mailing.

B. Endoscopic Examinations of the Colon

1. Flexible sigmoidoscopy—Use of a 60-cm flexible sigmoidoscope permits visualization of the rectosigmoid and descending colon. It requires no sedation and in many centers is performed by a nurse specialist or physician's assistant. Adenomatous polyps are identified in 10–20% and colorectal cancers in 1% of patients. Case-control studies suggest that screening sigmoidoscopy programs lead to a 60% reduction in colorectal cancer mortality. A 2010 randomized controlled trial in 170,000 participants in the United Kingdom comparing a one-time flexible sigmoidoscopy screening to usual care confirmed a 50% reduction in distal colorectal cancer incidence and 43% reduction in mortality after a median follow-up of 11 years. The risk of serious complications (perforation) associated with flexible sigmoidoscopy is < 1:10,000 patients.

The chief disadvantage of screening with flexible sigmoidoscopy is that it does not examine the proximal colon. The prevalence of proximal versus distal neoplasia is higher in people over age 65 years of age, African Americans, and women. In men, approximately 50%

of advanced neoplasms (cancer, adenomas ≥ 1 cm in size, polyps with villous histology, or high-grade dysplasia) are located in the proximal colon, compared with 60–70% in women. The finding at sigmoidoscopy of an adenomatous polyp in the distal colon increases the likelihood at least twofold that an advanced neoplasm is present in the proximal colon. Therefore, patients found on screening sigmoidoscopy to have an adenomatous polyp of any size should subsequently undergo colonoscopy to evaluate the proximal colon. Using this strategy in men, it is estimated that screening sigmoidoscopy programs will detect approximately 65% of advanced colonic neoplasms. In women, however, sigmoidoscopy screening programs may fail to detect up to 65% of advanced neoplasia.

2. Colonoscopy—Colonoscopy permits examination of the entire colon. In addition to detecting early cancers, colonoscopy allows removal of adenomatous polyps by biopsy or polypectomy, which is believed to reduce the risk of subsequent cancer. Over the past decade, there has been a dramatic increase in screening colonoscopy and a similar decrease in screening sigmoidoscopy due to poor reimbursement and the perceived inferiority of sigmoidoscopy compared with colonoscopy. Colonoscopy requires aggressive bowel cleansing prior to the examination. To alleviate discomfort, intravenous sedation is used for most patients. The incidence of serious complications after colonoscopy (perforation, bleeding, cardiopulmonary events) is 0.1%. In asymptomatic individuals between 50 and 75 years of age undergoing screening colonoscopy, the prevalence of advanced neoplasia is 4–11% and of cancer is 0.1–1%.

Although colonoscopy is believed to be the most sensitive test for detecting adenomas and cancer, it is not infallible. In several studies, the rate of colorectal cancer within 3 years of a screening colonoscopy was 0.7–0.9%, ie, approximately 1 in 110 patients. This may be attributable to adenomatous polyps and early cancers that were overlooked during colonoscopy. Studies of back-to-back colonoscopies confirm that endoscopists overlook 6–12% of polyps > 1 cm and up to 25% of smaller adenomas. Polyps that are small, flat, or located behind folds are easily missed, especially if the bowel preparation is poor. Population-based case-control and cohort studies suggest that colonoscopy is associated with greater reduction in colorectal cancer incidence and mortality in the distal colon than the proximal colon. This may be attributable to incomplete examination of the proximal colon, and differences between the proximal and distal colon that include worse bowel preparation, suboptimal colonoscopic technique, and a higher prevalence of serrated polyps and flat adenomas. The latter are more common than previously recognized, are more likely to contain advanced pathology, and are more difficult to identify than raised (sessile or pedunculated) polyps. To optimize diagnostic accuracy as well as patient safety and comfort, colonoscopy should be performed after optimal bowel preparation by a well-trained endoscopist who spends sufficient time (at least 7 minutes) carefully examining the colon (especially the proximal colon) while withdrawing the endoscope.

C. Radiographic Examinations of the Colon

1. CT colonography—Using helical CT with computer-assisted image reconstruction, two- and three-dimensional views can be generated of the colon lumen that simulate the view of colonoscopy (virtual colonoscopy). CT colonography requires a similar bowel cleansing regimen as colonoscopy as well as insufflation of air into the colon through a rectal tube, which may be associated with discomfort. Nonetheless, this examination is performed rapidly and requires no sedation or intravenous contrast. It has minimal acute risk although there is controversy about potential long-term risks related to radiation exposure from CT examinations. Several large studies have compared the accuracy of virtual colonoscopy with colonoscopy for colorectal screening. Using current imaging software with multidetector helical scanners, the sensitivity is $> 95\%$ for the detection of cancer and > 84 – 92% for the detection of polyps ≥ 10 mm in size. The sensitivity for polyps 6–9 mm in size ranges from 57% to 84%; for polyps 5 mm or less, the sensitivity is extremely poor.

Patients undergoing screening with CT colonography should be managed appropriately. If no polyps are found, the interval for repeat screening examination is uncertain; however, 5 years may be reasonable. All patients with polyps ≥ 10 mm in size should be referred for colonoscopy with polypectomy because of the high prevalence (30%) of advanced pathology (cancer, high-grade dysplasia, or villous features) within these polyps. The optimal management of patients with polyps < 10 mm in size is controversial. The likelihood of advanced pathology in polyps 6–9 mm in size is 4–7% and in polyps 1–5 mm is $< 2\%$. The US Multi-Society Task Force currently recommends that colonoscopy with polypectomy be offered to patients with one or more 6–9 mm polyps. Patients who refuse or who have increased risk of carcinoma should undergo surveillance CT colonography in 3–5 years. At the present time, there is no consensus on the management of patients with polyps < 6 mm; however, some radiologists choose not even to report these findings.

2. Barium enema—Double-contrast barium enema was previously used as a screening technique because it was widely available, relatively inexpensive, and safe. However, compared to CT colonography, it is more time consuming and difficult to perform, less comfortable, and less accurate. Although it continues to be included among recommended screening options, it has been supplanted by CT colonography, where available. A multicenter trial demonstrated that the sensitivity of barium enema is only 50% for polyps ≥ 1 cm and 55–85% for early-stage cancers when compared with colonoscopy. At present, barium enema may be recommended when screening of the entire colon is desired but expertise in CT colonography is unavailable and the patient is unable or unwilling to undergo colonoscopy.

▶ When to Refer

- Patients with symptoms (change in bowel habits, hematochezia), signs (mass on abdominal examination or digital rectal examination [DRE]), or laboratory tests

(iron deficiency anemia) suggestive of colorectal neoplasia should be referred for colonoscopy.

- Patients with suspected cancer or adenomatous polyps of any size should be referred for colonoscopy.
- Virtually all patients with proven colorectal cancer should be referred to a surgeon for resection. Patients with clinical stage T3 or node-positive rectal tumors (or both) also should be referred to an oncologist preoperatively for neoadjuvant therapy. Patients with stage III or IV colorectal tumors should be referred to an oncologist.

▶ When to Admit

- Patients with complications of colorectal cancer (obstruction, acute bleeding) requiring urgent evaluation and intervention.
- Patients with severe complications of chemotherapy.
- Patients with advanced metastatic disease requiring palliative care.

CARCINOMA OF THE ANUS

The anal canal is lined from its proximal to distal extent by columnar, transitional and non-keratinized squamous epithelium, which merges at the anal verge with the keratinized perianal skin. Tumors arising from the mucosa of the anal canal are relatively rare, comprising only 1–2% of all cancers of the anus and large intestine. Squamous cancers make up the majority of anal cancers. Anal cancer is increased among people practicing receptive anal intercourse and those with a history of anorectal warts. In over 80% of cases, HPV may be detected, suggesting that this virus is a major causal factor. Women with anal cancer are at increased risk for cervical cancer, which may be due to a field effect of oncogenic HPV infection, and require gynecologic screening and surveillance. Anal cancer is increased in HIV-infected individuals, possibly due to interaction

with HPV. Bleeding, pain, and local tumor are the most common symptoms. The lesion is often confused with hemorrhoids or other common anal disorders. These tumors tend to become annular, invade the sphincter, and spread upward via the lymphatics into the perirectal mesenteric lymphatic nodes. CT or MRI scans of the abdomen and pelvis are required to identify regional lymphadenopathy or metastatic disease at diagnosis. PET imaging may be used in conjunction.

Treatment depends on the tumor location and histologic stage. Small (< 3 cm) superficial lesions of the perianal skin may be treated with wide local excision. Adenocarcinoma of the anal canal is treated in similar fashion to rectal cancer (see above), commonly by abdominoperineal resection with neoadjuvant chemoradiotherapy and adjuvant chemotherapy. Squamous cancer of the anal canal and large perianal tumors invading the sphincter or rectum are treated with combined-modality therapy that includes external radiation with simultaneous chemotherapy (5-FU and mitomycin). Local control is achieved in approximately 80% of patients. Radical surgery (abdominoperineal resection) is reserved for patients who fail chemotherapy and radiation therapy. Metastatic disease is generally treated with 5-FU in combination with cisplatin. The 5-year survival rate is 60–70% for localized tumors and over 25% for metastatic (stage IV) disease.

CANCERS OF THE GENITOURINARY TRACT

Maxwell V. Meng, MD, FACS

PROSTATE CANCER

ESSENTIALS OF DIAGNOSIS

- ▶ Prostatic induration on DRE or elevation of PSA.
- ▶ Most often asymptomatic.
- ▶ Rarely: systemic symptoms (weight loss, bone pain).

▶ General Considerations

Prostatic cancer is the most common noncutaneous cancer detected in American men and the second leading

cause of cancer-related death. In the United States, over 241,000 new cases of prostate cancer are diagnosed annually, and about 28,000 deaths result. However, the clinical incidence of the disease does not match the prevalence noted at autopsy, where more than 40% of men over 50 years of age are found to have prostatic carcinoma. Most such occult cancers are small and contained within the prostate gland; few are associated with regional or distant disease. The incidence of prostatic cancer increases with age. Whereas 30% of men aged 60–69 years will have the disease, autopsy incidence increases to 67% in men aged 80–89 years. Although the global prevalence of prostatic cancer at autopsy is relatively consistent, the clinical incidence varies considerably (high in North America and European countries, intermediate in South America, and low in the Far East), suggesting that environmental or dietary differences among populations may be important for prostatic cancer growth. A 50-year-old American man has a lifetime risk of 40% for latent cancer, 16% for developing clinically apparent cancer, and a 2.9% risk of death due to prostatic cancer. Blacks, men with a family history of prostatic cancer, and those with a history of high dietary fat intake are at increased risk for developing prostate cancer.

▶ Clinical Findings

A. Symptoms and Signs

Prostate cancer may manifest as focal nodules or areas of induration within the prostate at the time of DRE. However, currently most prostate cancers are associated with palpably normal prostates and are detected solely on the basis of elevations in serum PSA.

Patients rarely present with signs of urinary retention or neurologic symptoms as a result of epidural metastases and cord compression. Obstructive voiding symptoms are most often due to benign prostatic hyperplasia, which occurs in the same age group. Nevertheless, large or locally extensive prostatic cancers can cause obstructive voiding symptoms while lymph node metastases can lead to lower extremity lymphedema. As the axial skeleton is the most common site of metastases, patients may present with back pain or pathologic fractures.

B. Laboratory Findings

1. Serum tumor markers—PSA is a glycoprotein produced only by cells, either benign or malignant, of the prostate gland. The serum level is typically low and correlates with the volume of both benign and malignant prostate tissue. Measurement of serum PSA is useful in detecting and staging prostate cancer, monitoring response to treatment, and detecting recurrence before it becomes clinically evident. As a screening test, PSA will be elevated in 10–15% of men. Approximately 18–30% of men with intermediate degrees of elevation (4.1–10 ng/mL) will be found to have prostate cancer. Between 50% and 70% of those with elevations >10 ng/mL will have prostate cancer. Patients with intermediate levels of PSA usually have localized and therefore potentially curable cancers. It should be remembered that approximately 20% of patients

who undergo radical prostatectomy for localized prostate cancer have normal levels of PSA.

In untreated patients with prostate cancer, the level of PSA correlates with the volume and stage of the disease. Whereas most organ-confined cancers are associated with PSA levels <10 ng/mL, advanced disease (seminal vesicle invasion, lymph node involvement, or occult distant metastases) is more common in patients with PSA levels in excess of 40 ng/mL. Approximately 98% of patients with metastatic prostate cancer will have elevated PSA. However, there are rare cancers that are localized despite substantial elevations in PSA. Therefore, initial treatment decisions cannot be made on the basis of PSA testing alone. A rising PSA after therapy is usually consistent with progressive disease, either locally recurrent or metastatic.

2. Miscellaneous laboratory testing—Patients in urinary retention or those with ureteral obstruction due to loco-regionally advanced prostate cancers may present with elevations in blood urea nitrogen or creatinine. Patients with bony metastases may have elevations in alkaline phosphatase or hypercalcemia. Laboratory and clinical evidence of disseminated intravascular coagulation can occur in patients with advanced prostate cancers.

3. Prostate biopsy—Transrectal ultrasound-guided biopsy is the standard method for detection of prostate cancer. The use of a spring-loaded, 18-gauge biopsy needle has allowed transrectal biopsy to be performed with minimal patient discomfort and morbidity. Local anesthesia is routinely used and increases the tolerability of the procedure. The specimen preserves glandular architecture and permits accurate grading. Prostate biopsy specimens are taken from the apex, mid-portion, and base in men who have an abnormal DRE or an elevated serum PSA, or both. Extended-pattern biopsies, including a total of at least ten biopsies, are associated with improved cancer detection and risk stratification of patients with newly diagnosed disease. Patients with abnormalities of the seminal vesicles can have these structures specifically biopsied to identify local tumor invasion.

C. Imaging

Transrectal ultrasonography has primarily been used for the staging of prostate carcinomas, where tumors typically appear as hypoechoic areas. In addition, transrectal ultrasound-guided, rather than digitally-guided, biopsy of the prostate is a more accurate way to evaluate suspicious lesions. Use of imaging should be tailored to the likelihood of advanced disease in newly diagnosed cases. Asymptomatic patients with well-differentiated to moderately differentiated cancers, thought to be localized to the prostate on DRE and transurethral ultrasound and associated with modest elevations of PSA (ie, < 10 ng/mL), need no further imaging.

MRI allows for evaluation of the prostate as well as regional lymph nodes. The positive predictive value for detection of both capsular penetration and seminal vesicle invasion is similar for transrectal ultrasound and MRI. CT

plays little role because of its inability to accurately identify or stage prostate cancers, but it can be used to detect regional lymphatic metastases and intra-abdominal metastases.

Radionuclide bone scan is superior to conventional plain skeletal radiographs in detecting bony metastases. Most prostate cancer metastases are multiple and most commonly localized to the axial skeleton. Men with more advanced local lesions, symptoms of metastases (eg, bone pain), high-grade disease, or elevations in PSA > 20 ng/mL should undergo radionuclide bone scan. Because of the high frequency of abnormal scans in patients in this age group resulting from degenerative joint disease, plain films are often necessary in evaluating patients with indeterminate findings on bone scan. Cross-sectional imaging either by CT or MRI is usually indicated only in those patients in the latter group who have negative bone scans in an attempt to detect lymph node metastases. Patients found to have enlarged pelvic lymph nodes are candidates for FNA.

Intravenous urography and cystoscopy are not routinely needed to evaluate patients with prostate cancer.

Despite application of modern, sophisticated techniques, understaging of prostate cancer occurs in at least 20% of patients.

► Screening for Prostate Cancer

Whether screening for prostate cancer results in a decrease in mortality rates due to the disease is the subject of much debate. The screening tests currently available include DRE, PSA testing, and transrectal ultrasound. Depending on the patient population being evaluated, detection rates using DRE alone vary from 1.5% to 7%. Unfortunately, most cancers detected in this manner are advanced (stage T3 or greater). Transrectal ultrasound should not be used as a first-line screening tool because of its expense, low specificity (and therefore high biopsy rate), and minimal improvement in detection rate when compared with the combined use of DRE and PSA testing.

PSA testing increases the detection rate of prostate cancers compared with DRE. Approximately 2–2.5% of men older than 50 years of age will be found to have prostate cancer using PSA testing compared with a rate of approximately 1.5% using DRE alone. PSA is not specific for cancer, and there is considerable overlap of values between men with benign prostate hyperplasia and those with prostate cancers. The sensitivity, specificity, and positive predictive value of PSA and DRE are listed in Table 39–6. PSA-detected cancers are more likely to be localized compared with those detected by DRE alone. The Prostate Cancer Prevention Trial provided data demonstrating a significant risk of prostate cancer even in men with PSA less than 4.0 ng/mL (Table 39–7) and a web-based calculator has been developed to estimate the risk of harboring both cancer and high-grade prostate cancer (<http://deb.uthscsa.edu/URORiskCalc/Pages/uroriskcalc.jsp>).

To improve the performance of PSA as a screening test, several investigators have developed alternative methods for its use. These include establishment of age- and race-specific reference ranges, measurement of free serum and protein-bound levels of PSA (percent free

Table 39-6. Screening for prostatic cancer: Test performance.

Test	Sensitivity	Specificity	Positive Predictive Value
Abnormal PSA (> 4 ng/mL)	0.67	0.97	0.43
Abnormal DRE	0.50	0.94	0.24
Abnormal PSA or DRE	0.84	0.92	0.28
Abnormal PSA and DRE	0.34	0.995	0.49

DRE, digital rectal examination; PSA, prostate-specific antigen. Modified, with permission, from Kramer BS et al. Prostate cancer screening: what we know and what we need to know. *Ann Intern Med.* 1993 Nov 1;119(9):914-23.

PSA), and calculation of changes in PSA over time (PSA velocity). Generally, men with PSA free fractions exceeding 25% are unlikely to have prostate cancer, whereas those with free fractions < 10% have an approximately 50% chance of having prostate cancer. The frequency of PSA testing remains a matter of some debate. The traditional yearly screening approach may not be the most efficient, rather, earlier PSA testing at younger age may allow less frequent testing as well as provide information regarding PSA velocity. Studies from the Baltimore Longitudinal Study of Aging suggest that men with PSA above the age-based median when tested between 40 and 60 years are at significantly increased risk for subsequent cancer detection over 25 years. Therefore, men with lower PSA (0.6 ng/mL ages 40–50 and 0.71 ages 50–60) may require less frequent PSA tests. In addition, men with PSA velocity greater than 0.35 ng/mL per year measured 10–15 years before diagnosis had significantly worse cancer-specific survival compared with those with lower PSA velocity. The current NCCN guidelines (http://www.nccn.org/professionals/physician_gls/f_guidelines.asp) for prostate cancer early detection incorporate many of these factors (Figure 39–2).

Table 39-7. Risk of prostate cancer in men with PSA ≤ 4.0 ng/mL.

PSA Level (ng/mL)	Percentage with prostate cancer	Percentage with high-grade prostate cancer
≤ 0.5	6.6	12.5
0.6-1.0	10.1	10.0
1.1-2.0	17.0	11.8
2.1-3.0	23.9	19.1
3.1-4.0	26.9	25.0

Data from Thompson IM et al. Prevalence of prostate cancer among men with a prostate-specific antigen level ≤4.0 ng per milliliter. *N Engl J Med.* 2004 May 27;350(22):2239-46. [PMID: 15163773]

High-grade cancer was defined as Gleason score ≥ 7.

Two large, randomized trials question the benefit of screening men for prostate cancer. In the US Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial, no mortality benefit was observed after combined screening with PSA testing and digital rectal examination during follow-up of 13 years. Although screening resulted in a 12% increase in prostate cancer detection, the cancer-specific mortality rate was similar in the screening and control arms (3.7 and 3.4 deaths per 10,000 person-years, respectively). Similarly in the European Randomized Study of Screening for Prostate Cancer (ERSPC) trial, the benefit of PSA screening was minimal with a 20% relative reduction in death rate from prostate at follow-up of 9 years, with an absolute reduction of 7 prostate cancer deaths per 10,000 men screened. A subset of these patients from Göteborg, Sweden, in an independently designed and initiated population-based screening trial, was analyzed separately. During a median follow-up of 14 years, the absolute risk reduction of death from prostate cancer in the screening group was 40% and the relative risk of prostate-cancer death in the attendees of screening was 0.44. Based on these data, the US Preventive Services Task Force recommended against PSA-based screening for prostate cancer in asymptomatic men (grade D recommendation). Criticisms of the negative PLCO study include use of a relatively high PSA threshold (4 ng/mL), significant screening of men in the 3 years prior to enrolling in the trial (44%), and significant number of men in the control arm undergoing screening during the trial (> 50%).

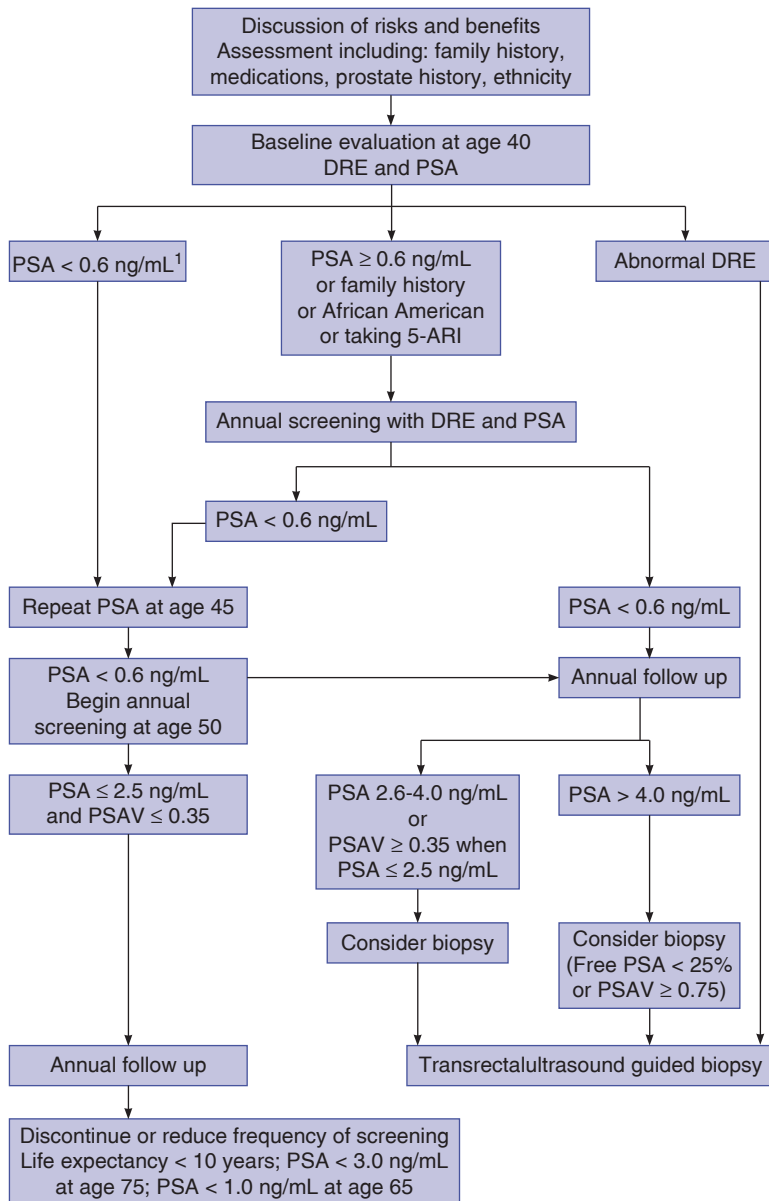

► Staging

The majority of prostate cancers are adenocarcinomas. Most arise in the periphery of the prostate (peripheral zone), though a small percentage arise in the central (5–10%) and transition zones (20%) of the gland. Pathologists utilize the Gleason grading system whereby a “primary” grade is applied to the architectural pattern of malignant glands occupying the largest area of the specimen and a “secondary” pattern is assigned to the next largest area of cancer. Grading is based on architectural rather than histologic criteria, and five “grades” are possible (Figure 39–3). Adding the score of the primary and secondary patterns (grades) gives a Gleason score. Grade correlates with tumor volume, pathologic stage, and prognosis (Figure 39–4).

► Treatment

A. Localized Disease

The optimal treatment for patients with clinically localized prostate cancers remains controversial. Patients need to be advised of all treatment options, including active surveillance, with the specific benefits, risks, and limitations. Currently, treatment decisions are made based on tumor grade and stage as well as the age and health of the patient. Although selected patients may be candidates for surveillance based on age or health and evidence of small-volume or well-differentiated cancers, most men with an anticipated life expectancy in excess of 10 years should be

¹NCCN guidelines utilize PSA threshold of 1.0 ng/mL in men < 50 years, the 75th percentile range for this age group; the median PSA value for men 40–49 years is 0.6 ng/mL.

▲ **Figure 39–2.** An algorithm for prostate cancer early detection. DRE, digital rectal examination; 5-ARI, 5 α -reductase inhibitor; PSAV, PSA velocity (ng/mL/year) calculated on at least three consecutive values over at least an 18–24 month period. (Based on NCCN guidelines, data from the Baltimore Longitudinal Study on Aging, and Prostate Cancer Prevention Trial.)

considered for treatment. Both radiation therapy and radical prostatectomy result in acceptable levels of local control. A large, prospective, randomized trial compared surveillance with radical prostatectomy in 695 men with clinically localized and well-differentiated to moderately differentiated tumors for a median of 12.8 years. Radical prostatectomy significantly reduced disease-specific mortality, overall mortality, and risks of metastasis and local progression. The relative reduction in the risk of death at

15 years was 0.62 in the prostatectomy group, with the number needed to treat to avert one death of 15; the benefit was confined to men younger than 65 years of age. This trial accrued patients in Sweden between 1989 and 1999, thus likely including patients with greater cancer burden compared with that in patients currently diagnosed using PSA screening. Nevertheless, the survival benefit in the trials was still observed in men with low-risk prostate cancer.

▲ **Figure 39-3.** Patterns of prostate cancer according to the 2005 International Society of Urological Pathology modified Gleason system. (Adapted with permission from Epstein JI et al. The 2005 International Society of Urological Pathology (ISUP) Consensus Conference on Gleason Grading of Prostatic Carcinoma. *Am J Surg Pathol.* 2005;29(9):1228-1242.)

B. Radical Prostatectomy

During radical prostatectomy, the seminal vesicles, prostate, and ampullae of the vas deferens are removed. Refinements in technique have allowed preservation of urinary continence in most patients and erectile function

in selected patients. Radical prostatectomy can be performed via open retropubic, transperineal, or laparoscopic (with or without robotic assistance) surgery. Local recurrence is uncommon after radical prostatectomy, and the incidence is related to pathologic stage. Organ-confined

▲ **Figure 39-4.** Prostate cancer mortality as a factor of Gleason grade and age at diagnosis in men managed conservatively. (Adapted, with permission, from Albertsen PC et al. 20-year outcomes following conservative management of clinically localized prostate cancer. *JAMA*. 2005 May 4;293(17):2095-101.)

cancers rarely recur; however, cancers with adverse pathologic features (capsular penetration, seminal vesicle invasion) are associated with higher local (10–25%) and distant (20–50%) relapse rates.

Ideal candidates for prostatectomy include healthy patients with stages T1 and T2 prostate cancers. Patients with advanced local tumors (T4) or lymph node metastases are rarely candidates for prostatectomy alone, although surgery is sometimes used in combination with hormonal therapy and postoperative radiation therapy for select high-risk patients.

Patients with advanced pathologic stage or positive surgical margins are at an increased risk for local and distant tumor relapse. Such patients are candidates for adjuvant therapy (radiation for positive margins or androgen deprivation for lymph node metastases). Two randomized clinical trials (EORTC 22911 and SWOG 8794) have demonstrated improved progression-free and metastasis-free survival with early radiotherapy in these men, and subsequent analysis of SWOG 8794 showed improved overall survival in men receiving adjuvant radiation therapy. Evidence suggests that salvage radiotherapy after radical prostatectomy, within 2 years of PSA relapse, increases prostate cancer-specific survival in men with shorter PSA doubling time (< 6 months).

C. Radiation Therapy

Radiation can be delivered by a variety of techniques including use of external beam radiotherapy and transperineal implantation of radioisotopes. Morbidity is limited, and the survival of patients with localized cancers (T1, T2, and selected T3) approaches 65% at 10 years. As with surgery, the likelihood of local failure correlates with technique and tumor characteristics. The likelihood of a positive prostate biopsy more than 18 months after radiation varies between 20% and 60%. Patients with local recurrence are at an increased risk of cancer progression and cancer death compared with those who have negative biopsies. Ambiguous target definitions, inadequate radiation doses, and understaging of the tumor may be responsible for the failure noted in some series. Newer techniques of radiation (implantation, conformal therapy using three-dimensional reconstruction of CT-based tumor volumes, heavy particle, charged particle, and heavy charged particle) may improve local control rates. Three-dimensional conformal radiation delivers a higher dose because of improved targeting and appears to be associated with greater efficacy as well as lower likelihood of adverse side effects compared with previous techniques. As a result of improvements in imaging, most

notably transrectal ultrasound, there has been a resurgence of interest in brachytherapy—the implantation of permanent or temporary radioactive sources (palladium, iodine, or iridium) into the prostate. Brachytherapy can be combined with external beam radiation in patients with higher-grade or higher-volume disease or as monotherapy in those with low-grade or low-volume malignancies. The PSA may rise after brachytherapy because of prostate inflammation and necrosis. This transient elevation (PSA bounce) should not be mistaken for recurrence and may occur up to 20 months after treatment.

D. Surveillance

A beneficial impact of treating localized prostate cancer with respect to survival has not been conclusively demonstrated. Therefore, surveillance alone may be an appropriate form of management for selected patients with prostate cancer. Patients included in observational series are typically older with small volume, well-differentiated cancers. Many men with prostate cancer may be candidates for surveillance due to the significant migration to lower stage as well as lower grade, resulting from screening for prostate cancer using PSA testing. Depending on the age and health of the patient, some of these very low-volume, low-grade cancers may never become clinically relevant and can be monitored with serial PSA levels, rectal examinations, and periodic prostate biopsies to assess grade and extent of tumor. The goal of surveillance is to avoid treatment in men who never experience disease progression while recognizing and effectively treating men with evidence of progression. End points for intervention in patients on surveillance, particularly PSA changes, have not been clearly defined and surveillance regimens remain investigational.

E. Cryosurgery

Cryosurgery is a technique whereby liquid nitrogen is circulated through small hollow-core needles inserted into the prostate under ultrasound guidance. The freezing process results in tissue destruction. There has been a resurgence of interest in less invasive forms of therapy for localized prostate cancer as well as several recent technical innovations, including improved percutaneous techniques, expertise in transrectal ultrasound, improved cryotechnology, and better understanding of cryobiology. The positive biopsy rate after cryoablation ranges between 7% and 23%.

F. Locally and Regionally Advanced Disease

Prostate cancers associated with minimal degrees of capsular penetration are candidates for standard irradiation or surgery. Those with locally extensive cancers, including those with seminal vesicle and bladder neck invasion, are at increased risk for both local and distant relapse despite conventional therapy. Currently, a variety of investigational regimens are being tested in an effort to improve

cancer outcomes in such patients. Combination therapy (androgen deprivation combined with surgery or irradiation), newer forms of irradiation, and hormonal therapy alone are being tested, as is neoadjuvant and adjuvant chemotherapy. Neoadjuvant and adjuvant androgen deprivation therapy combined with external beam radiation therapy have demonstrated improved survival compared with external beam radiation therapy alone.

G. Metastatic Disease

Since death due to prostate carcinoma is almost invariably the result of failure to control metastatic disease, research has emphasized efforts to improve control of distant disease. It is well known that most prostate carcinomas are hormone dependent and approximately 70–80% of men with metastatic prostate carcinoma will respond to various forms of androgen deprivation. Androgen deprivation may be affected at several levels along the pituitary–gonadal axis using a variety of methods or agents (Table 39–8). Use of luteinizing hormone-releasing hormone (LHRH) agonists (leuprolide, goserelin) achieves androgen deprivation without orchiectomy or administration of diethylstilbestrol and is currently the most common method of reducing testosterone levels. A single LHRH antagonist (degarelix) is FDA approved and has no short-term testosterone “flare” associated with LHRH agonists. Because of its rapid onset of action, ketoconazole should be considered in patients with advanced prostate cancer who present with spinal cord compression, bilateral ureteral obstruction, or disseminated intravascular coagulation. Although testosterone is the major circulating androgen, the adrenal gland secretes the androgens dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione. Some investigators believe that suppressing both testicular and adrenal androgens allows for a better initial and longer response than methods that only inhibit production of testicular androgens. Complete androgen blockade can be achieved by combining an antiandrogen with use of an LHRH agonist/antagonist or orchiectomy. Nonsteroidal antiandrogen agents appear to act by competitively binding the receptor for dihydrotestosterone, the intracellular androgen responsible for prostate cell growth and development. A meta-analysis of trials comparing the use of either an LHRH agonist or orchiectomy alone with the use of either in combination with an antiandrogen agent shows little benefit of combination therapy. However, patients at risk for disease-related symptoms (bone pain, obstructive voiding symptoms) due to the initial elevation of serum testosterone that accompanies the use of an LHRH agonist should receive antiandrogens initially. Bisphosphonates can prevent osteoporosis associated with androgen deprivation, decrease bone pain from metastases, and reduce skeletal related events. Denosumab, a RANK ligand inhibitor, is approved for the prevention of skeletal-related events in patients with bone metastases from prostate cancer and also appears to delay the development of these metastases.

Docetaxel is the first cytotoxic chemotherapy agent to improve survival in patients with hormone-refractory

Table 39-8. Androgen deprivation for prostatic cancer.

Level	Agent	Dose	Sequelae
Pituitary, hypothalamus	Diethylstilbestrol	1-3 mg orally daily	Gynecomastia, hot flushes, thromboembolic disease, erectile dysfunction
	LHRH agonists Leuprolide Goserelin	Monthly or 3-monthly depot injection	Erectile dysfunction, hot flushes, gynecomastia, rarely anemia
	LHRH antagonist Degarelix	240 mg subcutaneously initial dose, then 80 mg subcutaneously monthly	Hot flushes, weight gain, erectile dysfunction, increased liver function tests
Adrenal	Ketoconazole	400 mg three times orally daily	Adrenal insufficiency, nausea, rash, ataxia
	Aminoglutethimide	250 mg four times orally daily	Adrenal insufficiency, nausea, rash, ataxia
	Corticosteroids Prednisone	20-40 mg orally daily	Gastrointestinal bleeding, fluid retention
	CYP17a1 inhibitor Abiraterone	500 mg orally daily	Weight gain, fluid retention, hypokalemia, hypertension
Testis	Orchiectomy		Gynecomastia, hot flushes, erectile dysfunction
Prostate cell	Antiandrogens Flutamide Bicalutamide	250 mg three times orally daily 50 mg orally daily	No erectile dysfunction when used alone; nausea, diarrhea

LHRH, luteinizing-hormone-releasing hormone.

prostate cancer. Current research is underway combining docetaxel with androgen deprivation therapy, radiation therapy, and surgery to determine whether combinations are effective in patients with high-risk prostate cancer. Immune therapies are also under investigation and have shown promise for patients with advanced prostate cancer. Sipuleucel-T, an autologous cellular immunotherapy, is FDA approved in asymptomatic or minimally symptomatic men with metastatic hormone-refractory prostate cancer. Other agents—cabazitaxel and abiraterone—are also approved for advanced prostate cancer after clinical trials have demonstrated improvements in survival in men having received prior docetaxel, and it is expected that MDV3100, cabozantinib, and alpharadin will be approved shortly.

► Prognosis

The likelihood of success of surveillance or treatment can be predicted using risk assessment tools that usually combine stage, grade, PSA level, and number and extent of positive prostate biopsies. Several tools are available on the Internet (eg, <http://mskcc.org/mskcc/html/5794.cfm>). One of the most widely used is the Kattan nomogram; it incorporates tumor stage, grade, and PSA level to predict the likelihood that a patient will be disease-free after radical prostatectomy or radiation therapy.

The University of California San Francisco CAPRA nomogram uses serum PSA, Gleason grade, clinical stage, percent positive biopsies, and patient age in a point system to risk stratify and predict the likelihood of PSA

recurrence 3 and 5 years after radical prostatectomy (Tables 39-9 and 39-10). The CAPRA has been validated on large multicenter and international radical prostatectomy cohorts.

Table 39-9. The UCSF Cancer of the Prostate Risk Assessment (CAPRA).

Variable	Level	Points
PSA (ng/mL)	0-6	0
	6.1-10	1
	10.1-20	2
	20.1-30	3
	> 30	4
Gleason grade	1-3/1-3	0
	1-3/4-5	1
	4-5/1-5	3
T-stage	T1 or T2	0
	T3a	1
% positive biopsies (biopsy cores positive divided by the number of biopsies obtained)	< 34%	0
	> 34%	1
Age	< 50 years	0
	> 50 years	1

6	54 (27-75)	34 (12-57)
7+	24 (9-43)	8 (0-28)

PSA, prostate-specific antigen.

The patterns of prostate cancer progression have been well defined. Small and well-differentiated cancers (Gleason grades 1 and 2) are usually confined within the prostate, whereas large-volume (> 4 mL) or poorly differentiated (Gleason grades 4 and 5) cancers are more often locally extensive or metastatic to regional lymph nodes or bone. Penetration of the prostate capsule by cancer is common and occurs along perineural spaces. Seminal vesicle invasion is associated with a high likelihood of regional or distant disease, and disease recurrence. Lymphatic metastases can be identified in the obturator and internal iliac lymph node chains. The axial skeleton, as mentioned previously, is the most common site of distant metastases.

▶ When to Refer

- All patients should be referred to an urologist. PSA remains integral in prostate cancer diagnosis. Low-risk disease may be managed by active surveillance, surgery, or radiation therapy.
- High-risk disease often requires multimodal treatment strategies.

BLADDER CANCER

ESSENTIALS OF DIAGNOSIS

- ▶ Gross or microscopic hematuria.
- ▶ Irritative voiding symptoms.
- ▶ Positive urinary cytology in most patients.
- ▶ Filling defect within bladder noted on imaging.

▶ General Considerations

Bladder cancer is the second most common urologic cancer; it occurs more commonly in men than women (3.1:1), and the mean age of patients at diagnosis is 73 years. Cigarette smoking and exposure to industrial dyes or solvents are risk factors for the disease and account for approximately 60% and 15% of new cases, respectively. Ninety-eight percent of primary bladder cancers are epithelial malignancies, with the majority being urothelial cell carcinomas (90%). Adenocarcinomas and squamous cell cancers account for approximately 2% and 7%, respectively, of all bladder cancers detected in the United States. The latter is often associated with schistosomiasis, vesical calculi, or prolonged catheter use.

▶ Clinical Findings

A. Symptoms and Signs

Hematuria—gross or microscopic, chronic or intermittent—is the presenting symptom in 85–90% of patients with bladder cancer (also see the section on Hematuria, in

Chapter 23). Irritative voiding symptoms (urinary frequency and urgency) occur in a small percentage of patients as a result of the location or size of the cancer. Most patients with bladder cancer do not have signs of the disease because of its superficial nature. Abdominal masses detected on bimanual examination may be present in patients with large-volume or deeply infiltrating cancers. Hepatomegaly or palpable lymphadenopathy may be present in patients with metastatic disease, and lymphedema of the lower extremities may be present as a result of locally advanced cancers or metastases to pelvic lymph nodes.

B. Laboratory Findings

Urinalysis reveals microscopic or gross hematuria in the majority of cases. On occasion, hematuria may be accompanied by pyuria. Azotemia may be present in a small number of cases associated with ureteral obstruction. Anemia may occasionally be due to chronic blood loss or to bone marrow metastases. Exfoliated cells from normal and abnormal urothelium can be readily detected in voided urine specimens. Cytology can be useful in detecting the disease at the time of initial presentation or to detect recurrence. Cytology is sensitive in detecting cancers of higher grade and stage (80–90%) but less so in detecting superficial or well-differentiated lesions (50%). There are numerous urinary tumor markers under investigation for screening, assessing recurrence, progression, prognosis or response to therapy; the NMP22 point-of-care assay for a specific urinary protein has shown utility in detecting recurrent tumors.

C. Imaging

Bladder cancers may be identified using ultrasound, CT, or MRI where masses within the bladder are noted. However, the presence of cancer is confirmed by cystoscopy and biopsy, with imaging primarily used to evaluate the upper urinary tract and stage more advanced lesions.

D. Cystourethroscopy and Biopsy

The diagnosis and staging of bladder cancers are made by cystoscopy and transurethral resection. If cystoscopy—performed usually under local anesthesia—confirms the presence of bladder cancer, the patient is scheduled for transurethral resection under general or regional anesthesia. Random bladder and, on occasion, prostate urethral biopsies are performed to detect occult disease elsewhere in the bladder and potentially identify patients at greater risk for tumor recurrence and progression.

► Pathology & Staging

Grading is based on cellular features: size, pleomorphism, mitotic rate, and hyperchromatism. Bladder cancer staging is based on the extent of bladder wall penetration and the presence of regional or distant metastases.

The natural history of bladder cancer is based on two separate but related processes: tumor recurrence within the bladder and progression to higher-stage disease. Both are correlated with tumor grade and stage.

► Treatment

Patients with superficial cancers (Ta, T1) are treated with complete transurethral resection and selective use of intravesical chemotherapy. In the subset of patients with large, high-grade, recurrent Ta lesions or T1 cancers and those with carcinoma in situ are good candidates for adjuvant intravesical therapy.

Patients with invasive (T2, T3) but still localized cancers are at risk for both nodal metastases and progression and require radical cystectomy, irradiation, or the combination of chemotherapy and selective surgery or irradiation due to the much higher risk of progression compared with patients with lower-stage lesions.

For patients with muscle invasive (T2 or greater) transitional cell carcinoma, neoadjuvant systemic chemotherapy prior to radical cystectomy is superior to radical cystectomy alone. This is particularly important for higher stage or bulky tumors in order to improve their surgical resectability.

A. Intravesical Chemotherapy

Immunotherapeutic or chemotherapeutic agents delivered directly into the bladder via a urethral catheter can reduce the likelihood of recurrence in those who have undergone complete transurethral resection. Most agents are administered weekly for 6–12 weeks. Efficacy may be increased by prolonging contact time to 2 hours. The use of maintenance therapy after the initial induction regimen is beneficial. Common agents include thiotepa, mitomycin, doxorubicin, and BCG, the last being the most effective agent when compared with the others with respect to reducing disease progression. Side effects of intravesical chemotherapy include irritative voiding symptoms and hemorrhagic cystitis. Patients in whom symptoms or infection develop from BCG may require antituberculous therapy.

B. Surgical Treatment

Although transurethral resection is the initial form of treatment for all bladder tumors since it is diagnostic, allows for proper staging, and controls superficial cancers, muscle-infiltrating cancers require more aggressive treatment. Partial cystectomy is indicated in selected patients with solitary lesions or those with cancers in a bladder diverticulum. Radical cystectomy entails removal of the bladder, prostate, seminal vesicles, and surrounding fat and peritoneal attachments in men and the uterus, cervix, urethra, anterior vaginal vault, and usually the ovaries in women. Bilateral pelvic lymph node dissection is performed in all patients.

Urinary diversion can be performed using a conduit of small or large bowel. However, continent forms of diversion have been developed that avoid the necessity of an external appliance and can be considered in a significant number of patients.

C. Radiotherapy

External beam radiotherapy delivered in fractions over a 6- to 8-week period is generally well tolerated, but approximately 10–15% of patients will develop bladder,

bowel, or rectal complications. Local recurrence is common after radiotherapy alone (30–70%) and is therefore combined with systemic chemotherapy in an effort to reduce the need for radical cystectomy or to treat patients who are poor candidates for radical cystectomy.

D. Chemotherapy

Metastatic disease is present in 15% of patients with newly diagnosed bladder cancer, and metastases develop within 2 years in up to 40% of patients who were believed to have localized disease at the time of cystectomy or definitive radiotherapy. Cisplatin-based combination chemotherapy results in partial or complete responses in 15–45% of patients (see Table 39–4).

Combination chemotherapy has been integrated into trials of surgery and radiotherapy. It has been used to decrease recurrence rates with both modalities and to attempt bladder preservation in those treated with radiation. Chemotherapy should be considered before surgery in those with bulky lesions or those suspected of having regional disease, and recent evidence suggests that neoadjuvant chemotherapy may benefit all patients with muscle-invasive disease prior to planned cystectomy. Chemoradiation is best suited for those with T2 or limited T3 disease without ureteral obstruction. Alternatively, chemotherapy has been used after cystectomy in patients at high risk for recurrence, such as those who have lymph node involvement or local invasion.

► Prognosis

The frequency of recurrence and progression are correlated with grade. Whereas progression may be noted in few grade I cancers (19–37%), it is common with poorly differentiated lesions (33–67%). Carcinoma in situ is most often found in association with papillary bladder cancers. Its presence identifies patients at increased risk for recurrence and progression.

At initial presentation, approximately 50–80% of bladder cancers are superficial: stage Ta, Tis, or T1. When properly treated, lymph node metastases and progression are uncommon in this population and survival is excellent at 81%. Five-year survival of patients with T2 and T3 disease ranges from 50% to 75% after radical cystectomy. Long-term survival for patients with metastatic disease at presentation is rare.

► When to Refer

- All patients should be referred to an urologist. Hematuria often deserves evaluation with upper urinary tract imaging and cystoscopy, particularly in a high-risk group (ie, older men).
- Histologic diagnosis and staging require endoscopic resection of tumor.

CANCERS OF THE URETER & RENAL PELVIS

Cancers of the renal pelvis and ureter are rare and occur more commonly in patients with bladder cancer, smokers, those with Balkan nephropathy, those exposed to Thorotrast (a contrast agent with radioactive thorium in use until the 1960s), or those with a long history of analgesic abuse. The majority are urothelial cell carcinomas. Gross or microscopic hematuria is present in most patients, and flank pain secondary to bleeding and obstruction occurs less commonly. Like primary bladder tumors, urinary cytology is often positive. The most common signs identified at the time of intravenous urography or CT include an intraluminal filling defect, unilateral nonvisualization of the collecting system, and hydronephrosis. Ureteral and renal pelvic tumors must be differentiated from calculi, blood clots, papillary necrosis, or inflammatory and infectious lesions. On occasion, upper urinary tract lesions are accessible for biopsy, fulguration, or resection using a ureteroscope. Treatment is based on the site, size, grade, depth of penetration, and number of tumors present. Most are excised with laparoscopic or open nephroureterectomy (renal pelvic and upper ureteral lesions) or segmental excision of the ureter (distal ureteral lesions). Endoscopic resection may be indicated in patients with limited renal function or focal, low-grade, cancers.

RENAL CELL CARCINOMA

ESSENTIALS OF DIAGNOSIS

- Gross or microscopic hematuria.
- Flank pain or mass in some patients.
- Systemic symptoms such as fever, weight loss may be prominent.
- Solid renal mass on imaging.

► General Considerations

Renal cell carcinoma accounts for 2.6% of all adult cancers. In the United States, approximately 60,000 cases of renal cell carcinoma are diagnosed and 12,500 deaths result

annually. Renal cell carcinoma has a peak incidence in the sixth decade of life and a male-to-female ratio of 2:1. It may be associated with a number of paraneoplastic syndromes (see below and Table 39–2).

The cause is unknown. Cigarette smoking is the only significant environmental risk factor that has been identified. Familial settings for renal cell carcinoma have been identified (von Hippel–Lindau syndrome, hereditary papillary renal cell carcinoma, hereditary leiomyoma-renal cell carcinoma, Birt-Hogg-Dube syndrome) as well as an association with dialysis-related acquired cystic disease and specific genetic aberrations (eg, Xp11.2 translocation), but sporadic tumors are far more common.

Renal cell carcinoma originates from the proximal tubule cells. Various histologic cell types are recognized (clear cell, papillary, chromophobe, collecting duct and sarcomatoid).

► Clinical Findings

A. Symptoms and Signs

Historically, 60% of patients presented with gross or microscopic hematuria. Flank pain or an abdominal mass was detected in approximately 30% of cases. The triad of flank pain, hematuria, and mass was found in only 10–15% of patients and is often a sign of advanced disease. Fever may be present as a paraneoplastic symptom (see Table 39–2). Symptoms of metastatic disease (cough, bone pain) occur in 20–30% of patients at presentation. Because of the widespread use of ultrasound and CT scanning, renal tumors are frequently detected incidentally in individuals with no urologic symptoms. There has been profound stage migration toward lower stages of disease over the past 10 years, likely due to the increased use of abdominal imaging. However, population mortality rates remain stable.

B. Laboratory Findings

Hematuria is present in 60% of patients. Erythrocytosis from increased erythropoietin production occurs in 5%, though anemia is more common; hypercalcemia may be present in up to 10% of patients. **Stauffer syndrome** is a reversible syndrome of hepatic dysfunction (with elevated liver function tests) in the absence of metastatic disease.

C. Imaging

Solid renal masses are often first identified by abdominal ultrasonography or CT. CT and MRI scanning are the most valuable imaging tests for renal cell carcinoma. It confirms the character of the mass and further stages the lesion with respect to regional lymph nodes, renal vein, or hepatic involvement. CT and MRI also provide valuable information regarding the contralateral kidney (function, bilaterality of neoplasm). Chest radiographs exclude pulmonary metastases, and bone scans should be performed for large tumors and in patients with bone pain or elevated alkaline phosphatase levels. MRI and duplex Doppler ultrasonography are excellent methods of assessing for the presence and extent of tumor thrombus within the renal vein or vena cava.

► Differential Diagnosis

Solid lesions of the kidney are renal cell carcinoma until proved otherwise. Other solid masses include angiomyolipomas (fat density usually visible by CT), urothelial cell cancers of the renal pelvis (more centrally located, involvement of the collecting system, positive urinary cytologic tests), adrenal tumors (superoanterior to the kidney) and oncocytomas (indistinguishable from renal cell carcinoma preoperatively), and renal abscesses.

► Treatment

Surgical resection is the primary treatment for localized renal cell carcinoma. Patients with a single kidney, bilateral lesions, or significant medical renal disease should be considered for partial nephrectomy. Patients with a normal contralateral kidney and good renal function but a small cancer are also candidates for partial nephrectomy, while radical nephrectomy is indicated in cases of larger tumors (> 7 cm) and those where partial nephrectomy is not technically feasible. The use of radiofrequency or cryosurgical ablation is being studied and likely yield equivalent short-term oncologic outcomes with reduced morbidity.

No effective chemotherapy is available for metastatic renal cell carcinoma. Vinblastine is the single most efficacious agent, with short-term partial response rates of 15%. Bevacizumab can prolong time to progression in those with metastatic disease (see Table 39–4). Biologic response modifiers have received much attention, including interferon- α and interleukin-2. Partial response rates of 15–20% and 15–35%, respectively, have been reported. Responders tend to have lower tumor burdens, metastatic disease confined to the lung, and a high performance status. Patients with metastatic kidney cancer and good performance status who have resectable primary tumors should undergo cytoreductive nephrectomy. Two randomized trials have shown a survival benefit of surgery followed by the use of systemic therapy—specifically, biologic response modifiers—compared with the use of systemic therapy alone.

Several targeted drugs, specifically VEGF, Raf-kinase, and mTOR inhibitors, are effective (40% response rates) in patients with advanced kidney cancer. The drugs are oral agents, well tolerated, and particularly active for clear cell carcinoma. The appropriate timing and combination of these agents, with and without surgery and cytokine therapy, remains to be determined.

► Prognosis

After radical or partial nephrectomy, tumors confined to the renal capsule (T1–T2) demonstrate 5-year disease-free survivals of 90–100%. Tumors extending beyond the renal capsule (T3 or T4) and node-positive tumors have 50–60% and 0–15% 5-year disease-free survival, respectively. One subgroup of patients with nonlocalized disease has reasonable long-term survival, namely, those with solitary resectable metastases. In this setting, radical nephrectomy with resection of the metastasis results in 5-year disease-free survival rates of 15–30%.

▶ When to Refer

- Patients with solid renal masses or complex cysts require further evaluation and should be referred to an urologist.
- Surgical excision of renal cell carcinoma remains the gold standard.
- Patients with metastatic disease should be referred to an oncologist.

OTHER PRIMARY TUMORS OF THE KIDNEY

Oncocytomas account for 3–5% of renal tumors, are usually benign, and are indistinguishable from renal cell carcinoma on preoperative imaging. These tumors are seen in other organs, including the adrenals, salivary glands, and thyroid and parathyroid glands.

Angiomyolipomas are rare benign tumors composed of fat, smooth muscle, and blood vessels. They are most commonly seen in patients with tuberous sclerosis (often multiple and bilateral) or in young to middle-aged women. CT scanning may identify the fat component, which is diagnostic for angiomyolipoma. Asymptomatic lesions < 5 cm in diameter usually do not require intervention; large lesions can spontaneously bleed. Acute bleeding can be treated by angiographic embolization or, in rare cases, nephrectomy. Lesions over 5 cm are often prophylactically treated with angioembolization to reduce the risk of bleeding.

SECONDARY TUMORS OF THE KIDNEY

The kidney is not an infrequent site for metastatic disease. Of the solid tumors, lung cancer is the most common (20%), followed by breast (10%), stomach (10%), and the contralateral kidney (10%). Lymphoma, both Hodgkin and non-Hodgkin, may also involve the kidney, although

it tends to appear as a diffusely infiltrative process resulting in renal enlargement rather than a discrete mass.

PRIMARY TUMORS OF THE TESTIS

ESSENTIALS OF DIAGNOSIS

- ▶ Most common neoplasm in men aged 20–35 years.
- ▶ Patient typically discovers a painless nodule.
- ▶ Orchiectomy necessary for diagnosis.

▶ General Considerations

Malignant tumors of the testis are rare, with approximately five to six cases per 100,000 males reported in the United States each year. Ninety to 95 percent of all primary testicular tumors are germ cell tumors and can be divided into two major categories: **nonseminomas**, including embryonal cell carcinoma (20%), teratoma (5%), choriocarcinoma (< 1%), and mixed cell types (40%); and **seminomas** (35%). The remainder of primary testicular tumors are nongerminal neoplasms (Leydig cell, Sertoli cell, gonadoblastoma). The lifetime probability of developing testicular cancer is 0.3% for an American male. For the purposes of this review, only germ cell tumors will be considered.

Approximately 5% of testicular tumors develop in a patient with a history of cryptorchidism, with seminoma being the most common. However, 5–10% of these tumors occur in the contralateral, normally descended testis. The relative risk of development of malignancy is highest for the intra-abdominal testis (1:20) and lower for the inguinal testis (1:80). Placement of the cryptorchid testis into the scrotum (orchidopexy) does not alter the malignant potential of the cryptorchid testis but does facilitate routine examination and tumor detection.

Testicular cancer is slightly more common on the right than the left, paralleling the increased incidence of cryptorchidism on the right side. One to 2 percent of primary testicular tumors are bilateral and up to 50% of these men have a history of unilateral or bilateral cryptorchidism. Primary bilateral testicular tumors may occur synchronously or asynchronously but tend to be of the same histology. Seminoma is the most common histologic finding in bilateral *primary* testicular tumors, while malignant lymphoma is the most common bilateral testicular tumor overall.

In animal models, exogenous estrogen administration during pregnancy has been associated with an increased development of testicular tumors with relative risk ranging from 2.8 to 5.3. Other acquired factors such as trauma and infection-related testicular atrophy have been associated with testicular tumors; however, a causal relationship has not been established.

▶ Clinical Findings

A. Symptoms and Signs

The most common symptom of testicular cancer is painless enlargement of the testis. Sensations of heaviness are

not unusual. Patients are usually the first to recognize an abnormality, yet the typical delay in seeking medical attention ranges from 3 to 6 months. Acute testicular pain resulting from intratesticular hemorrhage occurs in approximately 10% of cases. Ten percent of patients are asymptomatic at presentation, and 10% manifest symptoms relating to metastatic disease such as back pain (retroperitoneal metastases), cough (pulmonary metastases), or lower extremity edema (vena cava obstruction).

A discrete mass or diffuse testicular enlargement is noted in most cases. Secondary hydroceles may be present in 5–10% of cases. In advanced disease, supraclavicular adenopathy may be present, and abdominal examination may reveal a mass. Gynecomastia is seen in 5% of germ cell tumors.

B. Laboratory Findings

Several serum markers are important in the diagnosis and monitoring of testicular carcinoma, including human chorionic gonadotropin (hCG), α -fetoprotein, and lactate dehydrogenase. α -Fetoprotein is never elevated with pure seminomas, and while hCG is occasionally elevated in seminomas, levels tend to be lower than those seen with nonseminomas. Lactate dehydrogenase may be elevated with either type of tumor. Liver function tests may be elevated in the presence of hepatic metastases, and anemia may be present in advanced disease.

C. Imaging

Scrotal ultrasound can readily determine whether a mass is intratesticular or extratesticular. Once the diagnosis of testicular cancer has been established by inguinal orchiectomy, clinical staging of the disease is accomplished by chest, abdominal, and pelvic CT scanning.

► Staging

In a commonly used staging system for nonseminoma germ cell tumors, a stage A lesion is confined to the testis; stage B demonstrates regional lymph node involvement in the retroperitoneum; and stage C indicates distant metastasis. For seminoma, the M.D. Anderson system is commonly used. In this system, a stage I lesion is confined to the testis, a stage II lesion has spread to the retroperitoneal lymph nodes, and a stage III lesion has supradiaphragmatic nodal or visceral involvement.

► Differential Diagnosis

An incorrect diagnosis is made at the initial examination in up to 25% of patients with testicular tumors. Scrotal ultrasonography should be performed if any uncertainty exists with respect to the diagnosis. Although most intratesticular masses are malignant, a benign lesion—epidermoid cyst—may rarely be seen. Epidermoid cysts are usually very small benign nodules located just underneath the tunica albuginea; occasionally, however, they can be large.

► Treatment

Inguinal exploration with early vascular control of the spermatic cord structures is the initial intervention. If cancer

cannot be excluded by examination of the testis, radical orchiectomy is warranted. Scrotal approaches and open testicular biopsies should be avoided. Further therapy depends on the histology of the tumor as well as the clinical stage.

Up to 75% of clinical stage I **nonseminomas** are cured by orchiectomy alone. Selected patients who meet specific criteria may be offered surveillance after orchiectomy. These criteria are as follows: (1) tumor is confined within the tunica albuginea; (2) tumor does not demonstrate vascular invasion; (3) tumor markers normalize after orchiectomy; (4) radiographic imaging of the chest and abdomen shows no evidence of disease; and (5) the patient is reliable. Patients most likely to experience relapse on a surveillance regimen include those with predominantly embryonal cancer and those with vascular or lymphatic invasion identified in the orchiectomy specimen.

Stage I and IIa/b **seminomas** (retroperitoneal disease < 2 cm/2–5 cm in diameter) are treated by radical orchiectomy and retroperitoneal irradiation. Patients with clinical stage I disease may be candidates for surveillance or single-agent carboplatin. Seminomas of stage IIc (> 5 cm retroperitoneal involvement) and stage III receive primary chemotherapy (etoposide and cisplatin or cisplatin, etoposide, and bleomycin) (Table 39–4). Surgical resection of residual retroperitoneal masses is warranted if the mass is > 3 cm in diameter, under which circumstances 40% will harbor residual carcinoma.

Surveillance needs to be considered an active process both by the clinician and by the patient. Patients are followed monthly for the first 2 years and bimonthly in the third year. Tumor markers are obtained at each visit, and chest radiographs and CT scans are obtained every 3 months. Follow-up continues beyond the initial 3 years; however, 80% of relapses will occur within the first 2 years. With rare exceptions, patients who relapse can be cured by chemotherapy or surgery. Alternatives to surveillance for clinical stage I nonseminoma include adjuvant chemotherapy (bleomycin, etoposide, cisplatin) (see Table 39–4) or retroperitoneal lymph nodes dissection.

Patients with bulky retroperitoneal disease (> 5 cm nodes) or metastatic nonseminomas are treated with primary cisplatin-based combination chemotherapy following orchiectomy (etoposide and cisplatin or cisplatin, etoposide, and bleomycin). If tumor markers normalize and a residual mass > 1 cm persists on imaging studies, the mass is resected because 15–20% of the time it will harbor viable cancer and 40% of the time it will harbor teratoma. Even if patients have a complete response to chemotherapy, some clinicians advocate retroperitoneal lymphadenectomy since 10% of patients may harbor residual carcinoma and 10% may have teratoma in the retroperitoneum. If tumor markers fail to normalize following primary chemotherapy, salvage chemotherapy is required (cisplatin, etoposide, ifosfamide).

► Prognosis

The 5-year disease-free survival rate for patients with stage A **nonseminomas** (includes all treatments) ranges from 96% to 100%. For low-volume stage B disease, 90% 5-year

disease-free survival is expected. The 5-year disease-free survival rates for stage I and IIa **seminomas** (retroperitoneal disease < 10 cm in diameter) treated by radical orchiectomy and retroperitoneal irradiation are 98% and 92–94%, respectively. Ninety-five percent of patients with stage III disease attain a complete response following orchiectomy and chemotherapy. Patients with bulky retroperitoneal or disseminated disease treated with primary chemotherapy followed by surgery have a 5-year disease-free survival rate of 55–80%.

▶ When to Refer

Patients with solid masses of the testis should be referred to a urologist.

SECONDARY TUMORS OF THE TESTIS

Secondary tumors of the testis are rare. In men over the age of 50 years, lymphoma is the most common testis tumor, and overall it is the most common secondary neoplasm of the testis, accounting for 5% of all testicular tumors. It may be seen in three clinical settings: (1) late manifestation of widespread lymphoma, (2) the initial presentation of clinically occult disease, and (3) primary extranodal disease. Radical orchiectomy is indicated to make the diagnosis. Prognosis is related to the stage of disease.

Metastasis to the testis is rare. The most common primary site of origin is the prostate, followed by the lung, gastrointestinal tract, melanoma, and kidney.

CANCER COMPLICATIONS & EMERGENCIES

SPINAL CORD COMPRESSION

ESSENTIALS OF DIAGNOSIS

- ▶ Complication of metastatic solid tumor, lymphoma, or multiple myeloma.
- ▶ Back pain is most common presenting symptom.
- ▶ Prompt diagnosis is essential because once a severe neurologic deficit develops, it is often irreversible.
- ▶ Emergent treatment may prevent or potentially reverse paresis and urinary and bowel incontinence.

▶ General Considerations

Cancers that cause spinal cord compression most commonly metastasize to the vertebral bodies, resulting in physical damage to the spinal cord from edema, hemorrhage, and pressure-induced ischemia to the vasculature of the spinal cord. Persistent compression can result in irreversible changes to the myelin sheaths resulting in permanent neurologic impairment.

Prompt diagnosis and therapeutic intervention are essential, since the probability of reversing neurologic symptoms largely depends on the duration of symptoms. Patients who are treated promptly after symptoms appear may have partial or complete return of function and, depending on tumor sensitivity to specific treatment, may respond favorably to subsequent anticancer therapy.

▶ Clinical Findings

A. Symptoms and Signs

Back pain at the level of the tumor mass occurs in over 80% of cases and may be aggravated by lying down, weight bearing, sneezing, or coughing; it usually precedes the development of neurologic symptoms or signs. Since involvement is usually epidural, a mixture of nerve root and spinal cord symptoms often develops. Progressive weakness and sensory changes commonly occur. Bowel and bladder symptoms progressing to incontinence are late findings.

The initial findings of impending cord compression may be quite subtle, and there should be a high index of suspicion when back pain or weakness of the lower extremities develops in cancer patients.

B. Imaging

MRI is usually the initial imaging procedure of choice in a cancer patient with new-onset back pain. When there are neurologic findings suggesting spinal cord compression, an emergent MRI should be obtained; the MRI should include a survey of the entire spine in order to define all areas of tumor involvement for treatment planning purposes.

Bone radiographs, if done, may show evidence of vertebral body or pedicle destruction by the cancer. However, bone radiographs are neither sensitive nor specific and therefore are not helpful in diagnosis or treatment planning. If the back pain symptoms are nonspecific, bone scan imaging may be useful as a screening procedure.

► Treatment

Patients found to have epidural impingement of the spinal cord should be given corticosteroids immediately. The initial dexamethasone dose is 10–100 mg intravenously followed by 4–6 mg every 6 hours intravenously or orally. Patients without a known diagnosis of cancer should have emergent surgery to relieve the impingement and obtain a pathologic specimen. Patients with a single area of compression due to solid tumors are best treated with surgical decompression followed by radiation therapy. A randomized trial comparing surgery followed by radiation therapy with radiation therapy alone showed better outcomes (ie, improved ability to ambulate and improved bladder and bowel functions) in persons who had surgery followed by radiation therapy. If multiple vertebral body levels are involved with cancer, radiation therapy is the preferred treatment option. Corticosteroids are generally tapered toward the end of radiation therapy.

MALIGNANT EFFUSIONS

ESSENTIALS OF DIAGNOSIS

- Occur in pleural, pericardial, and peritoneal spaces.
- Caused by direct neoplastic involvement of serous surface or obstruction of lymphatic drainage.
- Half of undiagnosed effusions in patients not known to have cancer are malignant.

► General Considerations

The development of an effusion in the pleural, pericardial, or peritoneal space may be the initial finding in a patient with cancer, or an effusion may appear during the course of disease progression. Direct involvement of the serous surface with tumor is the most frequent initiating cause of the accumulation of fluid. The most common malignancies

causing pleural and pericardial effusions are lung and breast cancers; the most common malignancies associated with malignant ascites are ovarian, colorectal, stomach, and pancreatic cancers.

► Clinical Findings

A. Symptoms and Signs

Patients with pleural and pericardial effusions complain of shortness of breath and orthopnea. Patients with ascites complain of abdominal distention and discomfort. Cardiac tamponade causing pressure equalization in the chambers impairing both filling and cardiac output can be a life-threatening event. Signs of tamponade include tachycardia, pulsus paradoxus, and hypotension. Signs of pleural effusions include decreased breath sounds, egophony, and percussion dullness.

B. Laboratory Findings

Malignancy is confirmed as the cause of an effusion when analysis of the fluid specimen shows malignant cells in either the cytology or cell block specimen.

C. Imaging

The presence of effusions can be confirmed with radiographic studies or ultrasonography.

► Differential Diagnosis

The differential diagnosis of a malignant exudative pleural or pericardial effusion includes nonmalignant processes, such as infection, pulmonary embolism, congestive heart failure, and trauma. Malignant effusions are rarely transudative.

The differential diagnosis of malignant ascites includes similar benign processes, such as congestive heart failure and infections; cirrhosis and pancreatic disease also cause ascites.

Bloody effusions are usually due to cancer, but a bloody pleural effusion can also be due to pulmonary embolism, trauma and, occasionally, infection. Chylous pleural or ascitic fluid is generally associated with obstruction of lymphatic drainage as might occur in lymphomas.

► Treatment

In some cases, treatment of the underlying cancer with chemotherapy can cause regression of the effusions; however, not uncommonly, the presence of an effusion is an end-stage manifestation of the disease. In this situation, decisions regarding management are in large part dictated by the patient's symptoms and goals of care.

A. Pleural Effusion

A pleural effusion that is symptomatic may be managed initially with a **large volume thoracentesis**. With some patients, the effusion slowly reaccumulates, which allows

for periodic thoracentesis when the patient becomes symptomatic. However, in many patients, the effusion reaccumulates quickly, causing rapid return of symptoms of shortness of breath. For those patients, several options exist for management. **Chest tube drainage followed by pleurodesis** is the preferred option for patients with a reasonable life expectancy. The procedure involves placement of a chest tube that is connected to closed water seal drainage. After lung expansion is confirmed on a chest radiograph, a sclerosing agent (such as talc slurry or doxycycline) is injected into the catheter. Patients should be premedicated with analgesics and placed in a variety of positions in order to distribute the drug through the pleural spaces. Previously, injection of the sclerosing agent was done only after drainage had decreased to < 100 mL/d; but it is now clear that effective sclerosis can be achieved after 24 hours of drainage regardless of the amount of the residual fluid. Pleurodesis will not be successful if the lung cannot be reexpanded; these patients may be treated with the placement of a shunt or an indwelling catheter. Placement of an indwelling catheter that can be drained by a family member or a visiting nurse may also be preferable for patients with short life expectancies or for those who do not respond to pleurodesis.

B. Pericardial Effusion

Fluid may be removed by a needle aspiration or by placement of a catheter for more thorough drainage. As with pleural effusions, most pericardial effusions will reaccumulate. Management options for recurrent, symptomatic effusions include catheter drainage followed by sclerosis with such agents as doxycycline or bleomycin or by pericardiectomy.

C. Malignant Ascites

Patients with malignant ascites not responsive to chemotherapy are generally treated with repeated large volume paracenteses. As the frequency of drainage to maintain comfort can compromise the patient's quality of life, other alternatives include placement of a catheter or port so that the patient, family member, or visiting nurse can drain fluid as needed at home. Another option is placement of a peritoneovenous shunt; this can be considered for a select group of patients with life expectancy > 3 months and fluid that is nonviscous, nonbloody, and nonoculated.

HYPERCALCEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Usually symptomatic and severe (≥ 15 mg/dL [> 3.75 mmol/L]).
- ▶ Most common paraneoplastic endocrine syndrome; accounts for most inpatients with hypercalcemia.
- ▶ The neoplasm is clinically apparent in nearly all cases when hypercalcemia is detected.

▶ General Considerations

Hypercalcemia affects 20–30% of cancer patients at some point during their illness. The most common cancers causing hypercalcemia are myeloma, breast carcinoma, and non–small cell lung cancer. The presence of bone metastases is not an essential feature of the syndrome, since hypercalcemia can be caused by systemic effects of tumor-released proteins (see The Paraneoplastic Syndromes above).

▶ Clinical Findings

A. Symptoms and Signs

Symptoms and signs of hypercalcemia can be subtle; more severe symptoms occur with higher levels of hypercalcemia and with a rapid rate at which the calcium level rises. Early symptoms typically include anorexia, nausea, fatigue, constipation, and polyuria; later findings may include muscular weakness and hyporeflexia, confusion, psychosis, tremor, and lethargy.

B. Laboratory Findings

Symptoms and signs are caused by free calcium; as calcium is bound by protein in the serum, the measured serum calcium will underestimate the free or ionized calcium in patients with low albumin levels. In the setting of hypoalbuminemia, the corrected serum calcium should be calculated by one of several available formulas (eg, corrected calcium = measured calcium – measured albumin + 4). Alternatively, the free calcium can be measured. When the corrected serum calcium rises above 12 mg/dL (3 mmol/L), sudden death due to cardiac arrhythmia or asystole may occur. The presence of hypercalcemia does not invariably indicate a dismal prognosis, especially in patients with breast cancer, myeloma, or lymphoma.

In the absence of signs or symptoms of hypercalcemia, a laboratory finding of elevated serum calcium should be retested immediately to exclude the possibility of error.

C. ECG

Electrocardiography often shows a shortening of the QT interval.

▶ Treatment

Emergency management should begin with the initiation of intravenous fluids with 0.9% saline at 100–200 mL/h to

ensure rehydration with brisk urinary output of the often volume-depleted patient. If kidney function is normal or only marginally impaired, a bisphosphonate should be given. Choices include pamidronate, 60–90 mg intravenously over 2–4 hours, or zoledronic acid, 4 mg intravenously over several minutes. Zoledronic acid is more potent than pamidronate and has the advantage of a shorter administration time as well as a longer duration of effect but is more associated with the uncommon but serious side effect of osteonecrosis of the jaw. Once hypercalcemia is controlled, treatment directed at the cancer should be initiated if possible. Commonly, though, hypercalcemia occurs in patients with cancers that are unresponsive to treatment. In the event that the hypercalcemia becomes refractory to repeated doses of bisphosphonates, other agents that can help control hypercalcemia (at least temporarily) include gallium nitrate, calcitonin, and mithramycin; corticosteroids can be useful in patients with myeloma and lymphoma. Salmon calcitonin, 4–8 international units/kg given subcutaneously or intramuscularly every 12 hours, can be useful in patients with kidney disease; its onset of action is within hours but its hypocalcemic effect will wane in 2–3 days.

HYPERURICEMIA & TUMOR LYSIS SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Complication of treatment-associated tumor lysis of hematologic and rapidly proliferating malignancies.
- ▶ May be worsened by thiazide diuretics.
- ▶ Rapid increase in serum uric acid can cause acute urate nephropathy from uric acid crystallization.
- ▶ Reducing pre-chemotherapy serum uric acid is fundamental to preventing urate nephropathy.

▶ General Considerations

Tumor lysis syndrome (TLS) is seen most commonly following treatment of hematologic malignancies, such as acute lymphoblastic leukemia and Burkitt lymphoma. However, TLS can develop from any tumor highly sensitive to chemotherapy. TLS is caused by the massive release

of cellular material including nucleic acids, proteins, phosphorus, and potassium. If both the metabolism and excretion of these breakdown products are impaired, hyperuricemia, hyperphosphatemia, and hyperkalemia will develop abruptly. Acute kidney injury may then develop from the crystallization and deposition of uric acid and calcium phosphate within the renal tubules further exacerbating the hyperphosphatemia and hyperkalemia.

▶ Clinical Findings

Symptoms of hyperphosphatemia include nausea and vomiting as well as seizures. Also, with high levels of phosphorus, co-precipitation with calcium can cause renal tubule blockage further exacerbating the kidney injury. Hyperkalemia, due to release of intracellular potassium and impaired kidney excretion, can cause arrhythmias and sudden death.

▶ Treatment

Prevention is the most important factor in the management of TLS. Published guidelines for TLS management include aggressive hydration prior to initiation of chemotherapy as well as during and after completion of the chemotherapy. Administration of fluid helps keep urine flowing and facilitates excretion of uric acid and phosphorus. For the patients with moderate risk of developing TLS, for instance, those with intermediate grade lymphomas and acute leukemias, allopurinol (which blocks the enzyme xanthine oxidase and therefore the formation of uric acid from purine breakdown) should be given before starting chemotherapy at an oral dose of 100 mg/m² every 8 hours (maximum 800 mg/d) with dose reductions for impaired kidney function. For patients at high risk for developing TLS, for instance, patients with high-grade lymphomas or patients with acute leukemias and markedly elevated white blood cell counts (with acute myeloid leukemia, white blood cell count > 50,000/mcL [$> 50,000/10^9/L$]; with acute lymphoblastic leukemia, white blood cell count > 100,000/mcL [$> 100,000/10^9/L$]) or in whom hyperuricemia develops despite treatment with allopurinol, rasburicase 0.1–0.2 mg/kg/d is given intravenously for 1–7 days. Rasburicase is a recombinant urate oxidase that converts uric acid into the more soluble form resulting in rapid decline in uric acid levels. Rasburicase cannot be given to patients with known glucose 6-phosphate dehydrogenase (G6PD) deficiency nor can it be given to pregnant or lactating women. One of the mainstays of TLS management, systemic bicarbonate infusions to alkalinize the urine, is no longer routinely recommended. Laboratory values should be monitored following initiation of chemotherapy; elevated potassium or phosphorus levels need to be promptly managed.

▶ When to Refer

Should urinary output drop, creatinine level rise, or hyperphosphatemia persist, a nephrologist should be immediately consulted to evaluate the need for dialysis.

INFECTIONS

Chapter 30 provides a more detailed discussion of infections in the immunocompromised patient.

ESSENTIALS OF DIAGNOSIS

- ▶ In patients with neutropenia, infection is a medical emergency.
- ▶ The presence of fever, although sometimes attributable to other causes, must be assumed to be due to an infection.

▶ General Considerations

Many patients with disseminated neoplasms have increased susceptibility to infection. In some patients, this results from impaired defense mechanisms (eg, acute leukemia, Hodgkin disease, multiple myeloma, chronic lymphocytic leukemia); in others, it results from the myelosuppressive and immunosuppressive effects of cancer chemotherapy or a combination of these factors. Complicating impaired defense mechanisms are the frequent presence of indwelling catheters, impaired mucosal surfaces, and colonization with more virulent hospital-acquired pathogens.

The source of a neutropenic febrile episode is determined in about 30% of cases through blood, urine, or sputum cultures. The bacterial organisms accounting for the majority of infections in cancer patients include gram-negative bacteria (*Escherichia coli*, *Klebsiella*, *Pseudomonas*, *Enterobacter*) and gram-positive bacteria (coagulase-negative *Staphylococcus*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Corynebacterium*, and streptococci). There has been a trend over the last few decades of an increasing percentage of gram-positive organisms. The risk of bacterial infections rises when the neutrophil count is below 1000/mcL ($1.0 \times 10^9/L$); the risk dramatically increases when the count falls below 100/mcL ($0.1 \times 10^9/L$).

▶ Clinical Findings

A thorough physical examination should be performed. Routine DREs are generally avoided unless symptoms suggest a rectal abscess or prostatitis. If a rectal examination is necessary, antibiotics should be administered first. Appropriate cultures (eg, blood, sputum, urine and, if indicated, cerebrospinal fluid) should always be obtained before starting therapy. Two sets of blood cultures should be drawn; if the patient has an indwelling catheter, one of the cultures should be drawn from the line. A chest radiograph should also be obtained.

▶ Treatment

Empiric antibiotic therapy needs to be initiated immediately in the febrile, neutropenic patient. The choice of antibiotics depends on a number of different factors including the patient's clinical status and any localizing source of infection. If the patient is clinically well, monotherapy with an intravenous β -lactam with anti-*Pseudomonas* activity (cefepime, ceftazidime, imipenem/cilastatin, piperacillin/tazobactam) should be started (see Infections in the Immunocompromised Patient, Chapter 30). If the patient is clinically ill with hypotension or hypoxia, an aminoglycoside or fluoroquinolone should be added for "double" gram-negative bacteria coverage. If there is a strong suspicion of a gram-positive organism, such as from *S aureus* catheter infection, vancomycin can be given empirically. In some instances, patients may be treated with oral antibiotics and potentially in the outpatient setting. The Infectious Disease Society of America (IDSA) has published recommendations for antibiotic use in these low-risk patients. These patients must have an expected neutropenic timeframe of 7 days or less and not have comorbidities or signs of hemodynamic instability, gastrointestinal symptoms, altered mental status, pulmonary issues (an infiltrate, hypoxia, or underlying chronic obstructive pulmonary disease) and their liver and kidney function must not be impaired. If a patient is to be treated as an outpatient, he or she must also have good support at home and easy access to returning to the hospital if the clinical status worsens.

Antibiotics should be continued until the neutrophil count is rising and $> 500/mcL$ ($> 0.5 \times 10^9/L$) for at least 1 day and the patient has been afebrile for 2 days. If an organism is identified through the cultures, the antibiotics should be adjusted to the antibiotic sensitivities of the isolate; treatment should be continued for the appropriate period of time and at least until the neutrophil count recovers.

For the neutropenic patient who is persistently febrile despite broad-spectrum antibiotics, an empiric antifungal drug should be added (amphotericin B, caspofungin, itraconazole, voriconazole, or liposomal amphotericin B).

Freifeld AG et al. Clinical practice guideline for the use of antimicrobial agents in neutropenic patients with cancer: 2010 Update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2011 Feb 15;52(4):427–31. [PMID: 21205990]

PRIMARY CANCER TREATMENT

SYSTEMIC CANCER THERAPY

Detailed guidelines from the NCCN for cancer treatment can be found at www.nccn.org.

Use of cytotoxic drugs, hormones, antihormones, and biologic agents has become a highly specialized and increasingly effective means of treating cancer, with therapy usually administered by a medical oncologist. Selection of specific drugs or protocols for various types of cancer has traditionally been based on results of prior clinical trials; however, many patients have drug-resistant

tumors. Molecular mechanisms of drug resistance continue to be the subject of intense study. Described mechanisms of drug resistance include impaired membrane transport of drugs, enhanced drug metabolism, mutated target proteins, and blockage of apoptosis due to mutations in cell cycle -proteins. Cancer cells may initially be resistant to chemotherapy or acquire resistance when exposed to drugs.

TOXICITY & DOSE MODIFICATION OF CHEMOTHERAPEUTIC AGENTS

Use of chemotherapy to treat cancer is generally guided by results from clinical trials in individual tumor types. The complexity of treating cancer has increased over the last decade as more drugs, including those with novel mechanisms of action, have been approved by the Food and Drug Administration and introduced into general practice. Drug side effects and toxicities must be anticipated and carefully monitored. The short- and long-term toxicities of individual drugs are listed in Tables 39–11 and 39–12. Decisions on dose modifications for toxicities should be guided by the intent of therapy. In the palliative setting where the aim of therapy is to improve symptoms and quality of life, lowering doses to minimize toxicity is commonly done. However, when the goal of treatment is cure, dosing frequency and intensity should be maintained whenever possible. Cancer chemotherapy should be given and monitored by a medical oncologist or hematologist.

A complete blood count consisting of a differential count with particular attention to the absolute neutrophil count and platelet count as well as tests of liver and kidney function should be obtained before the initiation of chemotherapy. In patients with normal blood counts as well as normal liver and kidney function, drugs are started at their full dose. When the intent of chemotherapy is cure, including treatment in the adjuvant setting, every attempt should be made to schedule chemotherapy on time and at full dose. A complete blood count with differential should be checked at mid cycle to determine the nadir of the absolute neutrophil and platelet counts as well as immediately before the next cycle of chemotherapy is due.

Dose reductions may be necessary for patients with impaired kidney or liver function depending on the clearance mechanism of the drug. For patients receiving chemotherapy for palliation, bone marrow toxicity can be managed with dose reductions or delaying the next treatment cycle. A schema for dose modification is shown in Table 39–13.

1. Bone Marrow Toxicity

A. Neutropenia

Granulocyte colony-stimulating factor (G-CSF), given as either daily subcutaneous injections (filgrastim, 300 mcg or 480 mcg) or as a one-time dose (pegfilgrastim, 6 mg) beginning 24–72 hours after cytotoxic chemotherapy is completed, has been shown to reduce the duration and severity of granulocytopenia following cytotoxic chemotherapy

(Table 39–12). The American Society of Clinical Oncology and NCCN guidelines recommend primary prophylaxis with a G-CSF when there is 20% risk of febrile neutropenia or when the patient's age, medical history, and disease characteristics make the patient at high risk for complications related to myelosuppression.

B. Anemia

Erythropoiesis-stimulating agents (ESAs) ameliorate the anemia and associated symptoms caused by cancer chemotherapy but these drugs have untoward effects, including an increased risk of thromboembolism, and even more concerning, potentially decreased survival due to cancer-related deaths. These findings have prompted the US Food and Drug Administration and other organizations (American Society of Hematology, American Society of Clinical Oncology, and NCCN) to issue advisories and guidelines limiting their use. The NCCN recommendation that these drugs should not be used when the intent of chemotherapy is curative is based on evidence that survival can be affected by the administration of ESAs. Studies done in patients with potentially curable head and neck, breast, and cervical cancers have shown inferior outcomes when ESAs were used. It is important to point out that the target hemoglobin used in these studies was higher than is currently recommended. Nonetheless, ESAs cannot be currently recommended when the intent of therapy is cure. The alternative to managing symptomatic anemia in these patients receiving curative chemotherapy is administration of red blood cell transfusions.

When using ESAs, treatment should not be initiated until the hemoglobin is < 10 g/dL (< 100 g/L) with the medication held when the hemoglobin is > 12 g/dL (> 120 g/L). Epoetin alfa can be given subcutaneously as a weekly dose of 30,000–40,000 units with a target hemoglobin of 11–12 g/dL (110–120 g/L) (see Table 39–12). Darbepoetin alfa is given subcutaneously every 2–3 weeks at a dose of 200–300 mcg with the same target hemoglobin. Patients need to be iron replete to have maximum therapeutic effect. Uncontrolled hypertension is a contraindication to the use of ESAs; blood pressure must be controlled prior to initiation of this therapy. The FDA mandates that prescribing clinicians receive specific education on use of ESAs, and patients receiving ESAs must be provided written material describing the risks and benefits of the drug.

C. Thrombocytopenia

Drug management of chemotherapy-induced thrombocytopenia is more limited. The only available drug, oprelvekin or recombinant interleukin-11, has modest activity in improving thrombocytopenia associated with chemotherapy; however, the side effects of fluid retention, congestive heart failure, and arrhythmias have limited its use. Thrombopoietin, the protein that stimulates megakaryopoiesis in vivo, was isolated in 1994. Despite much work attempting to produce a clinically effective thrombopoietin agent for therapeutic use, no such drug is commercially available for this indication. Two drugs that activate the thrombopoietin receptor and are approved for use in

Table 39-11. Chemotherapeutic agents: Dosage and toxicity.

Chemotherapeutic Agent	Usual Adult Dosage	Acute Toxicity	Delayed Toxicity
Alkylating Agents—Nitrogen Mustards			
Bendamustine (Treanda)	100–120 mg/m ² intravenously every 3–4 weeks	Hypersensitivity reaction, nausea, vomiting, skin reaction	Myelosuppression, pyrexia, fatigue
Cyclophosphamide (Cytoxan)	500–1000 mg/m ² intravenously every 3 weeks; 100 mg/m ² /d orally for 14 days every 4 weeks	Nausea and vomiting	Myelosuppression, hemorrhagic cystitis, alopecia, cardiotoxicity with high-dose therapy, SIADH
Estramustine (Emcyt)	14 mg/kg/d orally in three or four divided doses	Nausea, vomiting, diarrhea	Gynecomastia, thromboembolism, edema
Ifosfamide (Ifex)	1200 mg/m ² daily for 5 days intravenously every 3 weeks	Nausea and vomiting	Myelosuppression, hemorrhagic cystitis, neurotoxicity, alopecia, SIADH
Mechlorethamine (nitrogen mustard, Mustargen)	0.4 mg/kg intravenously every 3–6 weeks; or 6 mg/m ² intravenously on days 1 and 8 every 4 weeks	Severe nausea and vomiting, severe vesicant	Myelosuppression, increased risk of secondary malignancies
Melphalan (Alkeran)	0.25 mg/kg/d or 8–10 mg/m ² /d orally for 4 days every 4–6 weeks; 16 mg/m ² intravenously every 2–4 weeks; 200 mg/m ² intravenously for bone marrow transplant	Nausea, vomiting, diarrhea, hypersensitivity (IV), mucositis (IV)	Myelosuppression, increased risk of secondary malignancies
Alkylating Agents—Platinum Analogs			
Carboplatin (Paraplatin)	Area under the curve (AUC)-based dosing use Calvert equation [Dose (mg) = AUC × (GFR + 25)] AUC = 2–7 mg/mL/min every 2–4 weeks; or 200–400 mg/m ² intravenously every 4 weeks	Nausea, vomiting, hypersensitivity reaction	Myelosuppression, electrolyte disturbances, peripheral neuropathy, nephrotoxicity (less common than with cisplatin)
Cisplatin (Platinol)	50–100 mg/m ² intravenously every 3–4 weeks; 20 mg/m ² /d intravenously for 5 days every 3 weeks	Severe nausea and vomiting	Nephrotoxicity, ototoxicity, peripheral neuropathy, myelosuppression, electrolyte disturbances
Oxaliplatin (Eloxatin)	85–130 mg/m ² intravenously every 2–3 weeks	Peripheral neuropathy triggered or exacerbated by cold, nausea, vomiting, diarrhea, rare anaphylactic reactions	Peripheral neuropathy, myelosuppression
Alkylating Agents—Triazines			
Dacarbazine (DTIC-Dome)	375 mg/m ² intravenously on day 1 and 15 every 4 weeks, 250 mg/m ² intravenously for 5 days	Severe nausea and vomiting, anorexia	Myelosuppression, photosensitivity, hepatotoxicity, flu-like syndrome
Procarbazine (Matulane)	60–100 mg/m ² orally for 14 days every 4 weeks	Nausea and vomiting	Myelosuppression; disulfiram-like reaction with alcohol; caution with tyramine-containing foods, tricyclic antidepressants, and sympathomimetic agents – MAO inhibition; increased risk of secondary malignancies
Temozolomide (Temodar)	75 mg/m ² orally daily during radiation for 42 days 150–200 mg/m ² orally for 5 days every 4 weeks	Nausea, vomiting, headache, constipation	Myelosuppression
Alkylating Agents—Miscellaneous			
Busulfan (Myleran)	1–8 mg daily orally	Nausea and vomiting	Myelosuppression, mucositis, hyper-pigmentation of skin, rare pulmonary fibrosis, hepatic veno-occlusive disease with high doses (> 16 mg/d in transplant patients)

(continued)

Table 39–11. Chemotherapeutic agents: Dosage and toxicity. (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Acute Toxicity	Delayed Toxicity
Chlorambucil (Leukeran)	0.1–0.2 mg/kg/d orally for 3–6 weeks; or 0.4 mg/kg pulse every 4 weeks	None	Myelosuppression, rare pulmonary toxicity, skin reaction, increased risk of secondary malignancies with prolonged use
Lomustine (CCNU)	100–130 mg/m ² orally every 6 weeks	Nausea and vomiting	Myelosuppression, pulmonary toxicity
Antimetabolites—Folate Antagonists			
Methotrexate (MTX; Trexall)	Intrathecal: 12 mg High dose: 1000–12,000 mg/m ² intravenously every 2–3 weeks	Nausea, vomiting, mucositis	Myelosuppression, nephrotoxicity, hepatotoxicity, neurotoxicity (with intrathecal administration and high-dose therapy), photosensitivity, pulmonary toxicity, caution multiple drug interactions which may enhance toxicities (avoid aspirin, penicillins, NSAIDs, omeprazole, TMP-SMZ)
Pemetrexed (Alimta)	500 mg/m ² intravenously every 3 weeks	Fatigue, nausea, vomiting, diarrhea, rash	Myelosuppression, mucositis Avoid NSAIDs which may decrease pemetrexed clearance and enhance toxicities
Pralatrexate (Folotyn)	30 mg/m ² intravenous bolus once weekly for 6 weeks in 7-week cycle	Nausea, mucositis	Myelosuppression, edema, fever, fatigue, liver function test abnormalities, renal impairment
Antimetabolites—Purine Analogs			
Cladribine (Leustatin)	0.14 mg/kg/d intravenously or subcutaneously daily for 5 days or 0.09 mg/kg/d intravenously via continuous infusion for 7 days	Mild nausea, fatigue, injection site reaction, rash	Myelosuppression, immunosuppression, fever
Clofarabine (Clolar)	52 mg/m ² intravenously daily for 5 days every 2–6 weeks (for patients < 21 years of age)	Nausea, vomiting, diarrhea, dermatitis, pruritus, headache, rigor	Myelosuppression, hepatotoxicity, nephrotoxicity, capillary leak syndrome, immunosuppression
Fludarabine (Fludara)	25 mg/m ² intravenously for 5 days every 4 weeks	Asthenia, fever, myalgias, rare hypersensitivity reaction	Myelosuppression, immunosuppression, neurotoxicity, visual disturbances
Mercaptopurine (6-MP; Purinethol)	Induction: 2.5–5 mg/kg/d orally Maintenance: 1.5–2.5 mg/kg/d orally	Diarrhea, hyperpigmentation of skin, rash	Myelosuppression, immunosuppression, hepatotoxicity, mucositis
Pentostatin (Nipent)	4 mg/m ² intravenously every other week	Nausea, vomiting, rash	Myelosuppression, immunosuppression, hepatotoxicity
Antimetabolites—Pyrimidine Analogs			
Azacitidine (Vidaza)	75 mg/m ² subcutaneously or intravenously for 7 days every 4 weeks, may increase to 100 mg/m ² after two cycles if no response	Injection site reaction, nausea, constipation, fever	Myelosuppression, hepatotoxicity, and nephrotoxicity (rare)
Capecitabine (Xeloda)	625–1250 mg/m ² orally twice a day for 14 days every 3 weeks	Nausea, vomiting, diarrhea	Hand-foot syndrome, mucositis, hyperbilirubinemia, myelosuppression
Cytarabine (Ara-C, Cytosar U)	Standard dose: 100 mg/m ² /d intravenously via continuous infusion for 7 days High dose: 1000–3000 mg/m ² intravenously every 12 hours on days 1, 3, 5	Nausea, vomiting, rash, flu-like syndrome	Myelosuppression High-dose therapy: neurotoxicity (cerebellar ataxia, lethargy, confusion), ocular toxicities (conjunctivitis and keratitis), hepatotoxicity, pancreatitis, pulmonary toxicity
Cytarabine Liposome (DepoCyt)	50 mg intrathecally every 14 or 28 days		Chemical arachnoiditis

(continued)

Table 39–11. Chemotherapeutic agents: Dosage and toxicity. (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Acute Toxicity	Delayed Toxicity
Decitabine (Dacogen)	15 mg/m ² intravenously every 8 hours for 3 days, repeat every 8 weeks	Nausea, fatigue, hyperglycemia	Myelosuppression
Fluorouracil (5-FU; Adrucil)	500–600 mg/m ² intravenous bolus weekly for 6 weeks, repeat every 8 weeks; in combination with oxaliplatin: 400 mg/m ² intravenous bolus followed immediately by 600 mg/m ² intravenously over 22 hours on days 1 and 2 or 400 mg/m ² intravenous bolus followed immediately by 2400 mg/m ² intravenously over 46 hours; 1000 mg/m ² intravenously via continuous infusion for 4–5 days every 3–4 weeks	Nausea, diarrhea	Myelosuppression (intravenous bolus), hand-foot syndrome, mucositis, neurotoxicity, ocular toxicity, photosensitivity, cardiotoxicity (rare)
Gemcitabine (Gemzar)	1000–1250 mg/m ² intravenously on days 1, 8, 15 every 4 weeks	Nausea, rash, flu-like symptoms, fever, diarrhea	Myelosuppression, edema, hepatotoxicity (rare), hemolytic uremic syndrome (rare), pulmonary toxicity (rare)
Antimicrotubules—Vinca Alkaloids			
Vinblastine (Velban)	6 mg/m ² intravenously on days 1 and 15 every 4 weeks; 0.11 mg/kg on days 1 and 2	Vesicant, bronchospasm and dyspnea (rare)	Myelosuppression, peripheral neuropathy, constipation, mucositis, alopecia, SIADH (rare)
Vincristine (Oncovin)	0.5–1.4 mg/m ² intravenously every 3 weeks; 0.4 mg/m ² intravenously via continuous infusion for 4 days; maximum single dose usually limited to 2 mg	Vesicant	Peripheral neuropathy, constipation, alopecia, SIADH (rare)
Vinorelbine (Navelbine)	30 mg/m ² intravenously on days 1 and 8 every 3 weeks	Vesicant, nausea, vomiting, bronchospasm and dyspnea (rare)	Myelosuppression, peripheral neuropathy, constipation, alopecia, SIADH (rare)
Antimicrotubules—Taxanes			
Cabazitaxel (Jevtana)	25 mg/m ² intravenously every 3 weeks	Hypersensitivity reaction, nausea, vomiting	Myelosuppression, peripheral neuropathy, fatigue, diarrhea, renal failure
Docetaxel (Taxotere)	60–100 mg/m ² intravenously every 3 weeks; 35–40 mg/m ² intravenously weekly for 3 weeks with 1 week rest	Hypersensitivity reaction, nausea, vomiting	Myelosuppression, peripheral neuropathy, alopecia, edema, fatigue, mucositis, diarrhea
Paclitaxel (Taxol)	135–175 mg/m ² intravenously every 3 weeks; 50–80 mg/m ² intravenously weekly	Hypersensitivity reaction, nausea, vomiting, bradycardia and hypotension during infusion	Myelosuppression, peripheral neuropathy, alopecia, mucositis, diarrhea, arthralgias/myalgias
Paclitaxel protein-bound (Abraxane)	260 mg/m ² intravenously every 3 weeks	Nausea, vomiting, diarrhea, hypersensitivity reaction (less than paclitaxel)	Myelosuppression, peripheral neuropathy, alopecia, mucositis, arthralgias/myalgias
Antimicrotubules—Epothilone			
Ixabepilone (Ixempra)	40 mg/m ² intravenously every 3 weeks	Hypersensitivity reaction, nausea, vomiting	Peripheral neuropathy, myelosuppression, alopecia, fatigue, mucositis, diarrhea, arthralgias/myalgias

(continued)

Table 39–11. Chemotherapeutic agents: Dosage and toxicity. (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Acute Toxicity	Delayed Toxicity
Enzyme Inhibitors—Anthracyclines			
Daunorubicin (Cerubidine)	30–60 mg/m ² intravenously for 3 days	Nausea, vomiting, mucositis, diarrhea, red/orange discoloration of urine, cardiotoxicity (ECG changes). All anthracyclines except for liposomal doxorubicin are potent vesicants.	Myelosuppression, cardiotoxicity (cardiomyopathy with congestive heart failure–dose related), alopecia. Liposomal Doxorubicin can also cause hand-foot syndrome
Liposomal Daunorubicin (Daunoxome)	40 mg/m ² intravenously every 2 weeks		
Doxorubicin (Adriamycin)	15–20 mg/m ² intravenously weekly; 45–60 mg/m ² intravenously every 3 weeks		
Liposomal Doxorubicin (Doxil)	20–50 mg/m ² intravenously every 3–4 weeks		
Epirubicin (Ellence)	35 mg/m ² intravenously every 2 weeks; 60–120 mg/m ² intravenously every 3–4 weeks	Liposomal daunorubicin and liposomal doxorubicin may cause infusion-related reactions	
Idarubicin (Idamycin)	12 mg/m ² intravenously for 3 days		
Enzyme Inhibitors—Topoisomerase Inhibitors			
Etoposide (Vepesid)	50–100 mg/m ² intravenously for 3–5 days every 3 weeks, oral dose is twice the intravenous dose	Nausea, vomiting, hypersensitivity reaction, fever, hypotension	Myelosuppression, alopecia, fatigue
Etoposide Phosphate (Etopophos)	100 mg/m ² intravenously for 3–5 days every 3 weeks		
Irinotecan (Camptosar)	60 mg/m ² intravenously on days 1, 8, and 15 every 4 weeks; 125 mg/m ² intravenously weekly for 4 weeks every 6 weeks; 180 mg/m ² intravenously every other week; 350 mg/m ² intravenously every 3 weeks	Diarrhea and cholinergic syndrome, nausea, vomiting	Myelosuppression, alopecia
Topotecan (Hycamtin)	1.5 mg/m ² intravenously for 5 days every 3 weeks; 2.3 mg/m ² orally for 5 days every 3 weeks	Nausea, vomiting, diarrhea	Myelosuppression, alopecia, asthenia
Targeted Therapy—Monoclonal Antibodies			
Alemtuzumab (Campath)	30 mg/m ² intravenously three times weekly	Infusion-related reaction, nausea, vomiting, hypotension	Myelosuppression, immunosuppression
Bevacizumab (Avastin)	5–15 mg/kg intravenously every 2–3 weeks	Infusion-related reaction	Arterial thromboembolism, wound healing complications, gastro-intestinal perforation or fistula, hemorrhage, hypertension, proteinuria
Brentuximab Vedotin (Adcetris)	1.8 mg/kg intravenously every 3 weeks	Infusion-related reaction, nausea, vomiting, diarrhea	Myelosuppression, peripheral neuropathy, tumor lysis syndrome, fatigue, rash
Cetuximab (Erbix)	Loading dose 400 mg/m ² intravenously followed by maintenance dose 250 mg/m ² intravenously weekly	Infusion-related reaction	Acneiform skin rash, hypomagnesemia, asthenia, paronychia inflammation, pulmonary toxicity (rare)
Ibritumomab tiuxetan (Zevalin)	0.4 mCi/kg intravenously on day 8	Infusion-related reaction	Myelosuppression, asthenia, infections, increased risk of secondary malignancies

(continued)

Table 39-11. Chemotherapeutic agents: Dosage and toxicity. (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Acute Toxicity	Delayed Toxicity
Ipilimumab (Yervoy)	3 mg/kg intravenously every 3 weeks for a total of four doses	Infusion-related reaction	Fatigue, diarrhea, colitis, pruritus, rash, hepatotoxicity, neuropathy, endocrinopathy
¹³¹ I Tositumomab (Bexxar)	450 mg intravenously	Infusion-related reaction	Myelosuppression, asthenia, infections, hypothyroidism, increased risk of secondary malignancies
Ofatumumab (Arzerra)	300 mg initial dose (Dose 1), followed 1 week later by 2000 mg weekly for 7 doses (Doses 2 through 8), followed 4 weeks later by 2000 mg every 4 weeks for 4 doses (Doses 9 through 12)	Infusion-related reaction, diarrhea, nausea	Neutropenia, infections, pyrexia, rash, fatigue
Panitumumab (Vectibix)	6 mg/kg intravenously every 2 weeks	Infusion-related reaction	Acneiform skin rash, hypomagnesemia, asthenia, paronychia inflammation, pulmonary toxicity (rare)
Rituximab (Rituxan)	375 mg/m ² intravenously weekly for 4 weeks, or every 3 weeks	Infusion-related reaction	Rare reactions: Hepatitis B reactivation, pulmonary toxicity, tumor lysis syndrome, Stevens-Johnson syndrome, progressive multifocal leukoencephalopathy, cardiac arrhythmias, bowel obstruction
Trastuzumab (Herceptin)	Loading dose 4 mg/kg intravenously followed by 2 mg/kg intravenously weekly; or loading dose 8 mg/kg followed by 6 mg/kg intravenously every 3 weeks	Infusion-related reaction, headache, diarrhea	Cardiotoxicity, pulmonary toxicity, myelosuppression in combination with chemotherapy
Targeted Therapy—mTOR Inhibitors			
Everolimus (Afinitor)	10 mg orally once daily	Mucositis, diarrhea, cough	Myelosuppression, fatigue, edema, hypercholesterolemia, hypertriglyceridemia, hyperglycemia, hypophosphatemia, immunosuppression, pneumonitis (rare)
Temsirolimus (Torisel)	25 mg intravenously weekly	Hypersensitivity reaction, rash, mucositis	Myelosuppression, edema, fatigue, mucositis, hyperglycemia, hyperlipemia, immunosuppression, nephrotoxicity, interstitial lung disease (rare), bowel perforation (rare), abnormal wound healing
Targeted Therapy—Tyrosine Kinase Inhibitors			
Crizotinib (Xalkori)	250 mg orally twice daily	Nausea, vomiting, diarrhea, constipation	Edema, pneumonitis, vision disorder, liver function test abnormalities, prolonged QT interval
Dasatinib (Sprycel)	70 mg orally twice daily; 100-140 mg orally once daily	Diarrhea, nausea, vomiting	Myelosuppression, fluid retention, fatigue, musculoskeletal pain, rash, cardiac dysfunction/congestive heart failure (rare), hemorrhage (rare)
Erlotinib (Tarceva)	100-150 mg orally once daily	Diarrhea	Acneiform skin rash, fatigue, anorexia, conjunctivitis, gastrointestinal hemorrhage (rare), pulmonary toxicity (rare)
Gefitinib (Iressa)	250 mg orally once daily	Diarrhea	Acneiform skin rash, asthenia, ocular toxicity, myelosuppression, hepatotoxicity (rare), pulmonary toxicity (rare)
Imatinib (Gleevec)	100-800 mg orally once daily	Nausea, vomiting, diarrhea	Myelosuppression, edema, myalgias, rash, congestive heart failure, left ventricular dysfunction (rare), hemorrhage (rare), hepatotoxicity (rare)

(continued)

Table 39-11. Chemotherapeutic agents: Dosage and toxicity. (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Acute Toxicity	Delayed Toxicity
Lapatinib (Tykerb)	1250 mg orally once daily in combination with capecitabine	Diarrhea, nausea, vomiting	Hand-foot syndrome, fatigue, hepatotoxicity (rare), left ventricular dysfunction (rare), prolonged QT interval (rare), interstitial lung disease (rare)
Nilotinib (Tasigna)	400 mg orally twice daily	Nausea, vomiting, headache, diarrhea	Edema, rash, arthralgia, fatigue, myelosuppression, electrolyte abnormalities, elevated serum lipase (rare), hepatotoxicity (rare), prolonged QT interval (rare)
Pazopanib (Votrient)	800 mg orally once daily	Nausea, vomiting, diarrhea	Hypertension, hair color changes, hepatotoxicity, hemorrhagic events, hypothyroidism
Sorafenib (Nexavar)	400 mg orally twice daily	Diarrhea and nausea	Hypertension, hand-foot syndrome, rash, fatigue, gastrointestinal perforation (rare), hemorrhage (rare), cardiac ischemia/infarction (rare)
Sunitinib (Sutent)	50 mg orally once daily for 4 weeks followed by 2 weeks rest.	Diarrhea and nausea	Hypertension, hand-foot syndrome, rash, yellow discoloration of skin, fatigue, hypothyroidism, mucositis, myelosuppression, left ventricular dysfunction (rare), prolonged QT interval (rare), hemorrhage (rare)
Vandetanib (Caprelsa)	300 mg orally once daily	Nausea and diarrhea	Acneiform skin rash, hypertension, fatigue, anorexia, abdominal pain, prolonged QT interval, interstitial lung disease (rare)
Vemurafenib (Zelboraf)	960 mg orally twice daily	Nausea, hypersensitivity reaction (rare)	Photosensitivity, rash, arthralgia, alopecia, fatigue, prolonged QT interval, cutaneous squamous cell carcinoma
Miscellaneous Agents			
Altretamine (Hexalen)	260 mg/m ² orally in 4 divided doses for 14-21 days every 4 weeks	Nausea, vomiting, diarrhea	Neurotoxicity, myelosuppression, flu-like syndrome
Arsenic Trioxide (Trisenox)	0.15 mg/kg intravenously daily	Nausea, dizziness	Edema, acute promyelocytic leukemia differentiation syndrome (fever, dyspnea, skin rash, fluid retention, pleural effusions), prolonged QT interval and complete atrioventricular block
Asparaginase (Elspar)	6000-10,000 units/m ² intravenously daily on days 17-28; 6000-10,000 units/m ² intramuscularly every 3 days for a total of 9 doses	Hypersensitivity reaction (requires test dose), nausea, vomiting	Coagulation abnormalities (hemorrhagic and/or thrombotic events), hepatotoxicity, pancreatitis, neurotoxicity
Bleomycin (Blenoxane)	10 units/m ² intravenously on days 1 and 15 every 4 weeks; 30 units on day 2, 9, and 16 every 3 weeks	Hypersensitivity reaction	Skin reaction (rash, hyperpigmentation of skin, striae), pulmonary fibrosis
Bortezomib (Velcade)	1.3 mg/m ² intravenous bolus on days 1, 4, 8, 11 followed by a 10 day rest every 3 weeks	Orthostatic hypotension, fever	Peripheral neuropathy, fatigue, myelosuppression, hemorrhage (rare), left ventricular dysfunction (rare), pulmonary toxicity (rare), reversible posterior leukoencephalopathy syndrome (rare), hepatotoxicity (rare)
Dactinomycin (Cosmegen)	15 mcg/kg intravenously daily for 5 days; 12 mcg/kg intravenously daily for 5 days; 1000 mcg/m ² intravenously	Vesicant, nausea, vomiting	Myelosuppression, mucositis, diarrhea, alopecia, hyperpigmentation of skin, hepatotoxicity, hepato-veno-occlusive disease (rare)
Denileukin diftitox (Ontak)	9 or 18 mcg/kg intravenously daily for 5 days every 3 weeks	Flu-like syndrome, hypersensitivity reaction, nausea, vomiting	Diarrhea, decreased visual acuity, fever, increased risk for infection, hypoalbuminemia, capillary leak syndrome (rare)
Hydroxyurea (Hydrea)	20-30 mg/kg orally once daily	Nausea	Myelosuppression, dermatopathy

(continued)

Table 39-11. Chemotherapeutic agents: Dosage and toxicity. (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Acute Toxicity	Delayed Toxicity
Lenalidomide (Revlimid)	5-25 mg orally once daily for 21 days every 4 weeks	Diarrhea, itching, rash	Myelosuppression, potential for birth defects, thromboembolic events, fatigue
Mitomycin (Mutamycin)	20 mg/m ² intravenously every 6-8 weeks; 20-40 mg intravesically weekly	Vesicant, local irritation (cystitis when given intravesically)	Myelosuppression, mucositis, hemolytic uremic syndrome (rare), pulmonary toxicity (rare)
Mitoxantrone (Novantrone)	12-14 mg/m ² intravenously every 3 weeks; induction chemotherapy for leukemia 12 mg/m ² intravenously for 2-3 days	Blue-green discoloration of urine, nausea, vomiting, diarrhea, intravenous irritant	Myelosuppression, cardiotoxicity, alopecia, mucositis, increased risk of secondary malignancies (rare)
Romidepsin (Istodax)	14 mg/m ² intravenously on days 1, 8, 15 of a 28-day cycle	Nausea, vomiting	Myelosuppression, fatigue, anorexia, ECG changes, QT prolongation
Sipuleucel-T (Provenge)	One dose (minimum of 50 million autologous CD54+ cells) intravenously every 2 weeks for three doses	Infusion-related reaction, nausea, vomiting	Fatigue, back pain, joint ache, headache, stroke
Thalidomide (Thalomid)	50-800 mg orally once daily	Sedation, constipation, fatigue	Potential for birth defects, thromboembolic events, peripheral neuropathy, edema
Tretinoin (All-Trans-Retinoic Acid, ATRA, Vesanoïd)	45 mg/m ² orally divided twice daily for 45-90 days or 30 days past complete remission		Headache, vitamin A toxicity, retinoic acid-acute promyelocytic leukemia syndrome, ototoxicity
Antiandrogens			
Bicalutamide (Casodex)	50 mg orally once daily	None	Hot flashes, decreased libido, erectile dysfunction, gynecomastia, breast tenderness, fatigue
Flutamide (Eulexin)	250 mg orally every 8 hours	Diarrhea, yellow-green discoloration of urine	Hot flashes, decreased libido, erectile dysfunction, gynecomastia, breast tenderness, hepatotoxicity (rare)
Nilutamide (Nilandron)	300 mg orally for 30 days then 150 mg orally once daily	Nausea	Visual disturbances (impaired adaptation to dark), hot flashes, decreased libido, erectile dysfunction, gynecomastia, breast tenderness, disulfiram reaction with alcohol, interstitial pneumonitis (rare), hepatotoxicity (rare)
Selective Estrogen Receptor Modulators			
Tamoxifen (Nolvadex)	20-40 mg orally once daily	None	Hot flashes, vaginal discharge or bleeding, menstrual irregularities, thromboembolic events (rare), endometrial hyperplasia, cataracts, hepatotoxicity, tumor flare
Toremifene (Fareston)	60 mg orally once daily	Nausea	Hot flashes, vaginal discharge, thromboembolic events (rare), tumor flare, endometrial hyperplasia, cataracts, hepatotoxicity
Aromatase Inhibitors			
Anastrozole (Arimidex)	1 mg orally once daily	Nausea	Hot flashes, peripheral edema, hypercholesterolemia, arthralgia/myalgia, headache, osteoporosis
Exemestane (Aromasin)	25 mg orally once daily		
Letrozole (Femara)	2.5 mg orally once daily		

(continued)

Table 39–11. Chemotherapeutic agents: Dosage and toxicity. (continued)

Chemotherapeutic Agent	Usual Adult Dosage	Acute Toxicity	Delayed Toxicity
Pure Estrogen Receptor Antagonist			
Fulvestrant (Faslodex)	250 mg intramuscularly once a month	Injection site reactions, nausea, diarrhea, constipation	Hot flashes, backache, headache
Progestins			
Megestrol acetate (Megace)	40–320 mg orally once daily or in divided doses (four times a day)	Nausea	Hot flashes, tumor flare, weight gain, hyperglycemia, thrombotic events (rare), adrenal insufficiency (rare)
LHRH Analogs			
Goserelin acetate (Zoladex)	3.6 mg subcutaneously once every month; 10.8 mg subcutaneously once every 3 months	Injection site discomfort	Hot flashes, tumor flare, decreased libido, erectile dysfunction, vaginal bleeding, thromboembolic events (rare), osteoporosis (rare)
Leuprolide (Lupron)	7.5 mg intramuscularly once every month; 22.5 mg intramuscularly once every 3 months; 30 mg intramuscularly once every 4 months	Injection site reaction	Hot flashes, tumor flare, edema, erectile dysfunction thromboembolic events (rare), osteoporosis
Triptorelin pamoate (Trelstar)	3.75 mg intramuscularly once every month; 11.25 mg intramuscularly once every 3 months	None	Hot flashes, tumor flare, skeletal pain, erectile dysfunction
LHRH Antagonist			
Degarelix (Firmagon)	Initial: 240 mg subcutaneously Maintenance: 80 mg subcutaneously every 28 days	Injection site reaction	Hot flashes, weight gain, LFT elevation
Adrenocorticosteroids			
Abiraterone (Zytiga)	1000 mg orally once daily	Diarrhea, edema	Adrenocortical insufficiency, hepatotoxicity, joint swelling, hypokalemia, hot flashes
Dexamethasone	40 mg orally once weekly or 40 mg orally on days 1–4, 9–12, 17–20	None	Hyperglycemia, weight gain, fluid retention, psychiatric symptoms
Ketoconazole	400 mg orally three times daily	Nausea and vomiting	Hepatotoxicity (rare)
Prednisone	5 mg orally twice a day; 100 mg orally daily for 5 days	None	Hyperglycemia, weight gain, gastritis, fluid retention, psychiatric symptoms
Biologic Response Modifiers			
Aldesleukin (IL-2, Proleukin)	600,000 international units/kg intravenously every 8 hours for 14 doses, repeat after 9 days rest	Hypotension, nausea, vomiting, diarrhea	Capillary leak syndrome (rare), impaired neutrophil function and increased risk of infection, lethargy or somnolence that may result in coma if therapy is not held
Interferon- α -2b (Intron A)	5 million international units subcutaneously 3 times a week; 2 million international units/m ² intramuscularly/subcutaneously three times a week; 20 million international units/m ² 5 days a week for 4 weeks then 10 million international units/m ² three times a week	Hypersensitivity reaction, injection site reaction, flu-like syndrome, nausea, vomiting, diarrhea	Myelosuppression, fatigue, anorexia, alopecia, depression, hyperthyroidism or hypothyroidism (rare), hepatotoxicity (rare), visual disturbances

GFR, glomerular filtration rate; LFT, liver function tests; LHRH, luteinizing hormone–releasing hormone; MAO, monoamine oxidase; NSAIDs, nonsteroidal anti-inflammatory drugs; SIADH, syndrome of inappropriate antidiuretic hormone; TMP-SMZ, trimethoprim-sulfamethoxazole.

Table 39–12. Supportive care agents: Dosage and toxicity.

Agent	Indication	Usual Dose	Acute Toxicity	Delayed Toxicity
Allopurinol (Xyloprim)	Prevent hyperuricemia from tumor lysis syndrome	300 mg orally once daily	None	Rash, Stevens-Johnson syndrome (rare), myelosuppression (rare)
Rasburicase (Elitek)	Prevent hyperuricemia from tumor lysis syndrome	0.1–0.2 mg/kg intravenously for pediatric patients; 3–6 mg intravenously once	Hypersensitivity reaction in patients with G6PD deficiency, nausea, vomiting, diarrhea, fever, headache	Rash
Mesna (Mesnex)	Prevent ifosfamide-induced hemorrhagic cystitis	20% of ifosfamide dose intravenously immediately before ifosfamide and at 4 hours and 8 hours after (total dose is 60% of ifosfamide dose); 100% of ifosfamide dose mixed with ifosfamide in same intravenous bag	Nausea and vomiting	Fatigue, hypotension
Leucovorin	Rescue after high-dose methotrexate; in combination with fluorouracil for colon cancer	10 mg/m ² intravenously or orally every 6 hours until serum methotrexate level is below 0.01 micromolar; 20 mg/m ² or 200–500 mg/m ² intravenously before fluorouracil	Nausea	None
Levoleucovorin (Fusilev)	Rescue after high-dose methotrexate in osteosarcoma	7.5 mg intravenously every 6 hours for 10 doses (to start 24 hours after the beginning of methotrexate infusion)	Nausea, vomiting	Stomatitis
Amifostine (Ethylol)	Prevent cisplatin nephropathy; prevent radiation-induced xerostomia	910 mg/m ² intravenously before cisplatin; 200 mg/m ² intravenously before radiation	Nausea, vomiting, hypotension, infusion-related reaction	Hypocalcemia
Dexrazoxane (ZIncard)	Prevent cardiomyopathy secondary to doxorubicin; anthracycline-induced injection site extravasation	10 times the doxorubicin dose intravenously before doxorubicin	Nausea	Myelosuppression
Palifermin (Kepivance)	Prevent mucositis following chemotherapy	60 mcg/kg/d intravenously for 3 days before and 3 days after chemotherapy	None	Edema, rash, pruritus, erythema, fever, enlargement or discoloration of tongue, altered taste sensation
Pilocarpine (Salagen)	Radiation-induced xerostomia	5 mg orally 1 hour before chemotherapy, then 5 mg once daily for 7 days; 5–10 mg orally three times a day	Flushing, sweating, nausea, dizziness, increased urinary frequency, rhinitis	None
Samarium (Quadramet)	Pain from bone metastasis	1 milliCurie/kg intravenously	Pain flare, diarrhea, hematuria	Myelosuppression, spinal cord compression
Strontium (Metastron)	Pain from bone metastasis	148 megabecquerels (4 milliCuries) intravenously; or 1.5–2.2 megabecquerels/kg (40–60 microcuries/kg)	Flushing, pain flare	Myelosuppression
Bone-Modifying Agents				
Denosumab (Xgeva)	Osteolytic bone metastasis	120 mg subcutaneously every 4 weeks	None	Hypocalcemia, hypophosphatemia, fatigue, nausea, osteonecrosis of the jaw

(continued)

Table 39-12. Supportive care agents: Dosage and toxicity. (continued)

Agent	Indication	Usual Dose	Acute Toxicity	Delayed Toxicity
Pamidronate (Aredia)	Osteolytic bone metastasis, hypercalcemia of malignancy	90 mg intravenously every 3-4 weeks; 60-90 mg intravenously, may repeat after 7 days	Injection site reaction	Electrolyte disturbances (hypocalcemia), anemia, arthralgia, bone pain, osteonecrosis of the jaw, nephrotoxicity
Zoledronic acid (Zometa)	Osteolytic bone metastasis, hypercalcemia of malignancy	4 mg intravenously every 3-4 weeks	Injection site reaction	Electrolyte disturbances (hypocalcemia), anemia, arthralgia, bone pain, osteonecrosis of the jaw, nephrotoxicity
Growth Factors				
Epoetin alfa (Epoen, Procrit)	Chemotherapy-induced anemia	40,000 units subcutaneously once weekly; 150 units/kg subcutaneously 3 times a week	Injection site reaction	Hypertension, thrombotic events, increased risk of tumor progression or recurrence, seizures, rash
Darbepoetin alfa (Aranesp)	Chemotherapy-induced anemia	2.25 mcg/kg subcutaneously weekly; 500 mcg subcutaneously every 3 weeks Alternative dosing: 200 mcg subcutaneously every 2 weeks or 300 mcg subcutaneously every 3 weeks	Injection site reaction	Hypertension, thrombotic events, increased risk of tumor progression or recurrence, seizures, rash
Filgrastim (Neupogen)	Febrile neutropenia prophylaxis	5-10 mcg/kg/d subcutaneously or intravenously once daily, treat past nadir	Injection site reaction	Bone pain, enlarged spleen, leukocytosis
Pegfilgrastim (Neulasta)	Febrile neutropenia prophylaxis	6 mg subcutaneously once per chemotherapy cycle	Injection site reaction	Bone pain, enlarged spleen, leukocytosis
Sargramostim (Leukine)	Myeloid reconstitution following bone marrow transplant, febrile neutropenia prophylaxis	250 mcg/m ² intravenously daily until the absolute neutrophil count is > 1500 cells/mcL for 3 consecutive days	Rash, pruritus, injection site reaction, dyspnea, fever	Bone pain, myalgia, fluid retention, supraventricular tachycardia, capillary leak syndrome (rare)
Oprelvekin (Neumega)	Chemotherapy-induced thrombocytopenia	50 mcg/kg subcutaneously every day for 14-21 days or until post-nadir platelet count is > 50,000/mcL	Nausea, vomiting, headache, dizziness, blurred vision, dyspnea, injection site reaction	Candidiasis, rash, fluid retention, arrhythmias, febrile neutropenia

G6PD, glucose 6-phosphate dehydrogenase.

Table 39-13. A common scheme for dose modification of cancer chemotherapeutic agents.

Granulocyte Count (cells/mcL)	Platelet Count (/mcL)	Suggested Drug Dosage (% of Full Dose)
> 2000	> 100,000	100%
1000-2000	75,000-100,000	50%
< 2000	< 50,000	0%

idiopathic thrombocytopenia, romiplostim and eltrombopag, may also benefit patients with chemotherapy-associated thrombocytopenia, although larger trials are needed to establish their use in this setting.

2. Chemotherapy-Induced Nausea & Vomiting

A number of cytotoxic anticancer drugs can induce nausea and vomiting, which can be the most anticipated and stressful side effects for patients. Chemotherapy-induced

nausea and vomiting is mediated in part by the stimulation of at least two central nervous system receptors, 5-hydroxytryptamine subtype 3 (5HT₃) and neurokinin subtype 1 (NK₁). Chemotherapy-induced nausea and vomiting can be acute, occurring within minutes to hours of chemotherapy administration, or delayed until the second day and lasting up to 7 days. Anticipatory nausea and vomiting may even occur before the administration of chemotherapy. Chemotherapy drugs or drug regimens are classified into high, moderate, low, and minimal likelihoods of causing emesis (90%, 30–90%, 10–30%, < 10%, respectively). Highly emetogenic chemotherapy drugs include cisplatin, carmustine, cyclophosphamide at doses over 1.5 g/m², dacarbazine, mechlorethamine, and streptozocin. Chemotherapy drugs that are moderately emetogenic include doxorubicin, daunomycin, idarubicin, epirubicin, cyclophosphamide, irinotecan, oxaliplatin, ifosfamide, cytarabine, and carboplatin. Drugs with low emetic potential include bortezomib, docetaxel, etoposide, fluorouracil, gemcitabine, methotrexate, mitomycin, mitoxantrone, paclitaxel, pemetrexed, temsirolimus, and topotecan. Drugs with minimal risk of emesis include bevacizumab, bleomycin, cladribine, fludarabine, vinblastine, vincristine, and vinorelbine.

By understanding the physiology of chemotherapy-induced nausea and vomiting, major advances have occurred with the development of highly effective antiemetic drugs. Antagonists to the 5HT₃-receptor include ondansetron, granisetron, dolasetron, tropisetron, and palonosetron. Each of these drugs has similar efficacy. Ondansetron can be given either intravenously (8 mg or 0.15 mg/kg) or orally (24 mg for highly emetogenic chemotherapy, 8 mg twice daily for moderately emetogenic chemotherapy). Doses of 8 mg can be repeated parenterally or orally every 8 hours. Dosing of granisetron is 1 mg or 0.01 mg/kg intravenously or 1–2 mg orally. Dolasetron is given 1.8 mg/kg or a fixed dose of 100 mg intravenously or 100 mg can be given orally. Tropisetron is given at a dose of 5 mg either orally or intravenously. Palonosetron, a long-acting 5HT₃ with high affinity for the 5HT₃-receptor given at a dose of 0.25 mg intravenously, is effective for not only acute but also delayed emesis. The efficacy of the 5HT₃-blockers is improved by adding 6–10 mg of either oral or intravenous dexamethasone.

Aprepitant is an antagonist to the NK₁ receptor. When given as a 125-mg oral dose followed by 80 mg on the second and third day with a 5HT₃-receptor antagonist (such as ondansetron or granisetron), the immediate and delayed protective effect for highly emetogenic chemotherapy is increased.

Standard therapy for highly emetogenic chemotherapy includes a 5HT₃-antagonist given on the first day and both dexamethasone and aprepitant given on the first day as well as the second and third days. Moderately emetogenic chemotherapy regimens are best managed with a two-drug regimen of a 5HT₃-antagonist and dexamethasone. Doses of the 5HT₃ may be given on days 2 and 3 to prevent delayed emesis.

Other adjunctive medications that may be helpful include lorazepam, 0.5–1.0 mg given orally every 6–8 hours,

and prochlorperazine, 5–10 mg orally or intravenously every 8 hours. Lorazepam, in addition to antianxiety effects, has an antiemetic effect. Prochlorperazine is generally sufficient to treat patients receiving low emetogenic chemotherapy. A suppository form of prochlorperazine, 25 mg, may be used for patients who are unable to swallow oral medications.

The importance of treating chemotherapy-induced nausea and vomiting expectantly and aggressively beginning with the first course of chemotherapy cannot be overemphasized. Patients being treated in the clinic setting should always be given antiemetics for home use with written instructions as well as contact numbers to call for advice.

3. Gastrointestinal Toxicity

Untoward effects of cancer chemotherapy include damage to the more rapidly growing cells of the body such as the mucosal lining from the mouth through the gastrointestinal tract. Oral symptoms range from mild mouth soreness to frank ulcerations in the mouth. Not uncommonly, mouth ulcerations will have superimposed candida or herpes simplex infections. In addition to receiving cytotoxic chemotherapy, a significant risk factor for development of oral mucositis is poor oral hygiene and existing caries or periodontal disease. Toxicity in the gastrointestinal tract usually manifests as diarrhea. Gastrointestinal symptoms can range from mild symptoms of loose stools to life-threatening diarrhea due to dehydration and electrolyte imbalances. Drugs most commonly associated with causing mucositis in the mouth and the gastrointestinal tract are cytarabine, 5-FU, and methotrexate.

Patients undergoing treatment for head and neck cancer with concurrent chemotherapy and radiation therapy have a very high risk of developing severe mucositis.

Preventive strategies for managing oral mucositis includes a pretreatment dental examination, particularly for all head and neck cancer patients and any cancer patient with poor dental hygiene who will be receiving chemotherapy. For patients receiving fluorouracil, simple measures such as ice chips in the mouth for 30 minutes during infusion can reduce the incidence and severity of mucositis. Once mucositis is encountered, superimposed fungal infections should be treated with topical anti-fungal medications (oral nystatin mouth suspensions, or clotrimazole troches) or systemic therapy (fluconazole 100–400 mg orally daily). Suspected herpetic infections can be treated with acyclovir (up to 800 mg orally five times daily) or valacyclovir (1 g orally twice daily). Mucositis may also be managed with mouthwashes; it is also important to provide adequate pain medication.

Newer strategies for prevention of oral mucositis include the recombinant keratinocyte growth factor inhibitor palifermin. Practice guidelines recommend prophylaxis with intravenous palifermin (60 mcg/kg/d) for patients receiving high-dose chemotherapy in order to reduce the incidence and duration of mucositis.

Diarrhea is most associated with fluorouracil, capecitabine, and irinotecan as well as the tyrosine kinase inhibitors

(sorafenib, sunitinib, imatinib, dasatinib) and epithelial growth factor inhibitors (cetuximab, panitumumab, and erlotinib). Mild to moderate diarrhea can be managed with oral antidiarrheal medication (loperamide, 4 mg initially followed by 2 mg every 2–4 hours until bowel movements are formed). Occasionally, the diarrhea will be overwhelming causing dehydration, electrolyte imbalances, and acute kidney injury. These patients require inpatient management with aggressive intravenous hydration and replacement of electrolytes.

4. Skin Toxicity

Dermatologic complications from cancer chemotherapy can include hyperpigmentation (liposomal doxorubicin, busulfan, hydroxyurea) alopecia, photosensitivity, nail changes, acral erythema, and generalized rashes. Acral erythema, otherwise known as hand-foot syndrome and most commonly associated with administration of fluorouracil, capecitabine, and liposomal doxorubicin, manifests as painful palms or soles accompanied by erythema, progressing to blistering desquamation and ulceration in its worst forms. Management can include attempts at prevention with oral pyridoxine, 200 mg daily, and applying cold packs to the extremities while the chemotherapy is being administered. Agents targeting the epidermal growth factor pathway can cause an acne like rash; interestingly, the development of the rash may identify those who will respond to the drug. Inhibitors of the tyrosine kinase pathway are also associated with a high incidence of dermatologic complications, such as rash and acral erythema.

5. Miscellaneous Drug-Specific Toxicities

The toxicities of individual drugs have been summarized in Tables 39–11 and 39–12; however, several of these warrant additional mention, since they occur with frequently administered agents, and special measures are often indicated.

A. Hemorrhagic Cystitis Induced by Cyclophosphamide or Ifosfamide

Metabolic products of cyclophosphamide that retain cytotoxic activity are excreted into the urine. Some patients appear to metabolize more of the drug to these active excretory products; if their urine is concentrated, severe bladder damage may result. Patients receiving cyclophosphamide must maintain a high fluid intake prior to and following the administration of the drug and be counseled to empty their bladders frequently. Early symptoms suggesting bladder toxicity include dysuria and increased frequency or urination. Should microscopic hematuria develop, it is advisable to stop the drug temporarily or switch to a different alkylating agent, to increase fluid intake, and to administer a urinary analgesic such as phenazopyridine. With severe cystitis, large segments of bladder mucosa may be shed, resulting in prolonged gross hematuria. Such patients should be observed for signs of urinary obstruction and may require cystoscopy for removal of obstructing blood clots. The cyclophosphamide analog ifosfamide can cause severe

hemorrhagic cystitis when used alone. However, when its use is followed by a series of doses of the neutralizing agent mesna, bladder toxicity can be prevented. Mesna can also be used for patients taking cyclophosphamide in whom cystitis develops.

B. Neuropathy Due to Vinca Alkaloids and Other Chemotherapy Drugs

Neuropathy is caused by a number of different chemotherapy drugs, the most common being vincristine. The peripheral neuropathy can be sensory, motor, autonomic, or a combination of these effects. In its mildest form, it consists of paresthesias of the fingers and toes. Occasionally, acute jaw or throat pain can develop after vincristine therapy. This may be a form of trigeminal neuralgia. With continued vincristine therapy, the paresthesias extend to the proximal interphalangeal joints, hyporeflexia appears in the lower extremities, and significant weakness can develop. Other drugs in the vinca alkaloid class as well as the taxane drugs (paclitaxel and docetaxel) and agents to treat myeloma (thalidomide and bortezomib) cause similar toxicity. The presence of neurologic symptoms is not in itself a reason to stop therapy; the severity of the symptoms must be balanced against the goals of therapy. Usually though, the presence of moderate to severe paresthesias or the detection of motor impairment would result in the decision to discontinue the drug.

Constipation is the most common symptom of autonomic neuropathy associated with the vinca alkaloids. Patients receiving these drugs should be started on stool softeners and mild cathartics when therapy is begun; otherwise, severe impaction may result from an atonic bowel.

More serious autonomic involvement can lead to acute intestinal obstruction with signs indistinguishable from those of an acute abdomen. Bladder neuropathies are uncommon but may be severe. These two complications are absolute contraindications to continued vincristine therapy.

C. Methotrexate Toxicity

Methotrexate, a folate antagonist, is a commonly used drug and a key component of regimens to treat patients with leptomeningeal disease, acute lymphoblastic leukemia, and sarcomas. The dose used in intrathecal therapy is 12 mg. Methotrexate is almost entirely eliminated by the kidney. The methotrexate toxicity affects cells with rapid turnover, including the bone marrow and mucosa resulting in myelosuppression and mucositis. Methotrexate can also damage the liver and kidney manifesting as elevated liver enzymes and creatinine. High-dose methotrexate, usually defined as a dose of 500 mg/m² or more given over 4–36 hours, would be lethal without “rescue” of the normal tissues. Leucovorin, a form of folate, will reverse the toxic effects of methotrexate and is given until serum methotrexate levels are in the safe range (< 0.05 mmol/L). It is crucial that high-dose methotrexate and leucovorin are given precisely according to protocol as deviations of the timing of methotrexate delivery or delay in rescue can result in patient death. Lower doses of methotrexate can be problematic in patients with kidney disease who cannot

clear the drug normally or with patients who have effusions. In the latter instance, methotrexate distributes itself in effusions and will leak out continuously, exposing normal tissue to small but cumulatively toxic amounts of the drug. If methotrexate is given to a patient who either has or develops kidney disease or to a patient with an effusion, prolonged rescue with leucovorin will be necessary.

Vigorous hydration and bicarbonate loading also appear to be important in preventing crystallization of high-dose methotrexate in the renal tubular epithelium and minimizing the possibility of nephrotoxicity. Daily monitoring of the serum creatinine is mandatory. Drugs impairing methotrexate excretion include aspirin, nonsteroidal anti-inflammatory drugs, amiodarone, omeprazole, penicillin, phenytoin, and sulfa compounds; these drugs should be stopped if possible before methotrexate administration.

D. Anthracycline Cardiotoxicity

A number of cancer chemotherapy drugs can cause cardiotoxicity. The most common class of drugs associated with cardiotoxicity is the anthracycline antibiotics, including doxorubicin, daunomycin, idarubicin, and epirubicin. They can produce acute (during administration), subacute (days to months following administration), and delayed (years following administration) cardiac toxicity. The most feared complication is the delayed development of congestive heart failure. Risk factors for this debilitating toxicity include the anthracycline cumulative dose, age over 70, previous or concurrent irradiation of the chest, preexisting cardiac disease, and concurrent administration of chemotherapy drugs such as trastuzumab. The problem is greatest with doxorubicin because this drug is the most commonly administered anthracycline due to its major role in the treatment of lymphomas, sarcomas, breast cancer, and certain other solid tumors. Patients receiving anthracyclines should have a baseline multiple-gated radio-nuclide cardiac scan (MUGA) to calculate the left ventricular ejection fraction (LVEF). If the LVEF is $> 50\%$, anthracyclines can be administered; if the LVEF is $< 30\%$, these drugs should not be given. For patients with intermediate cardiac function, anthracycline dosing, if necessary, should be cautiously done with LVEF monitoring between doses. Studies of left ventricular function and endomyocardial biopsies indicate that some changes in cardiac dynamics occur in most patients by the time they have received 300 mg/m^2 of doxorubicin. In general, patients should not receive a total dose of doxorubicin in excess of 450 mg/m^2 ; the dose should be lower if prior chest radiotherapy has been given. The appearance of a high resting pulse may herald the appearance of overt cardiac toxicity. Unfortunately, toxicity may be irreversible and frequently fatal at dosage levels above 550 mg/m^2 . At lower doses (eg, 350 mg/m^2 of doxorubicin), the symptoms and signs of cardiac failure generally respond well to medical therapy as well as the discontinuation of anthracycline. Laboratory studies suggest that cardiac toxicity may be due to a mechanism involving the formation of intracellular free radicals in cardiac muscle. The iron chelator dexrazoxane has been approved for use as a cardioprotectant for

patients receiving anthracyclines; however, some evidence suggests that the anthracycline anticancer effect may be compromised by the coadministration of dexrazoxane. In general, dexrazoxane should not be used when the goal of chemotherapy is for curative intent either in the settings of adjuvant or definitive treatment. Doxorubicin and daunomycin have been formulated as liposomal products; these drugs, approved for use in patients with Kaposi sarcoma and sometimes used in certain cancers as a substitute for conventional anthracyclines, appear to have minimal potential for cardiac toxicity.

E. Cisplatin Nephrotoxicity and Neurotoxicity

Cisplatin is effective in treating a wide range of malignancies, including testicular, bladder, lung, and ovarian cancers. Although nausea and vomiting are the side effects most commonly associated with cisplatin, the more serious side effects of nephrotoxicity and neurotoxicity must also be anticipated and aggressively managed. Patients must be vigorously hydrated prior, during, and after cisplatin administration. Both kidney function and electrolytes must be monitored. Low magnesium and potassium levels as well as hyponatremia can develop. The neurotoxicity is usually manifested as a peripheral neuropathy of mixed sensorimotor type and may be associated with painful paresthesias. Development of neuropathy typically occurs after cumulative doses of 300 mg/m^2 . Ototoxicity is a potentially serious manifestation of neurotoxicity and can progress to deafness. Amifostine, developed initially as a radioprotective agent and given intravenously at a dose of 910 mg/m^2 over 15 minutes prior to cisplatin, is used to protect against nephrotoxicity and neuropathy. Use of amifostine does not appear to compromise the antineoplastic effect of cisplatin. The second-generation platinum analog carboplatin is non-nephrotoxic, although it is myelosuppressive. In the setting of preexisting kidney disease or neuropathy, carboplatin is occasionally substituted for cisplatin.

F. Bleomycin Toxicity

Bleomycin is used for the treatment of testicular cancer, Hodgkin disease, and non-Hodgkin lymphoma. Bleomycin produces edema of the interphalangeal joints and hardening of the palmar and plantar skin. The more serious toxicities include an anaphylactic or serum sickness-like reaction and a serious or fatal pulmonary fibrotic reaction (seen especially in elderly patients receiving a total dose of over 300 units). If nonproductive cough, dyspnea, and pulmonary infiltrates develop, the drug is discontinued, and high-dose corticosteroids are instituted as well as empiric antibiotics pending cultures. Fever alone or with chills is an occasional complication of bleomycin treatment and is not an absolute contraindication to continued treatment. The fever may be avoided by intravenous premedication with hydrocortisone administration. Moreover, fever alone is not predictive of pulmonary toxicity. About 1% of patients (especially those with lymphoma) may have a severe or even fatal hypotensive reaction after the initial dose of bleomycin. In order to identify such patients, a test dose of 5 units of bleomycin is administered first with

adequate monitoring and emergency facilities available should they be needed. Patients exhibiting a hypotensive reaction should not receive further bleomycin therapy.

PROGNOSIS

A valuable sign of clinical improvement is the general well-being of the patient. Although this finding is a combination of subjective and objective factors and may be partly a placebo effect, it nonetheless serves as a sign of clinical improvement in assessing some of the objective observations listed above. Factors included in the

assessment of general well-being are improved appetite and weight gain and increased “performance status” (eg, ambulatory versus bedridden). Evaluation of factors such as activity status enables the clinician to judge whether the net effect of chemotherapy is worthwhile palliation (see Chapter 5).

Clinical Genetic Disorders

Reed E. Pyeritz, MD, PhD

ACUTE INTERMITTENT PORPHYRIA

 ESSENTIALS OF DIAGNOSIS

- ▶ Unexplained abdominal crisis, generally in young women.
- ▶ Acute peripheral or central nervous system dysfunction.
- ▶ Recurrent psychiatric illnesses.
- ▶ Hyponatremia.
- ▶ Porphobilinogen in the urine during an attack.

▶ General Considerations

Though there are several different types of porphyrias, the one with the most serious consequences and the one that usually presents in adulthood is acute intermittent porphyria (AIP), which is inherited as an autosomal dominant, though it remains clinically silent in most patients who carry a mutation in *HMBS*. Clinical illness usually develops in women. Symptoms begin in the teens or 20s, but onset can begin after menopause in rare cases. The disorder is caused by partial deficiency of porphobilinogen deaminase activity, leading to increased excretion of aminolevulinic acid and porphobilinogen in the urine. The diagnosis may be elusive if not specifically considered. The characteristic abdominal pain may be due to abnormalities in autonomic innervation in the gut. In contrast to other forms of porphyria, cutaneous photosensitivity is absent in AIP. Attacks are precipitated by numerous factors, including drugs and intercurrent infections. Harmful and relatively safe drugs for use in treatment are listed in Table 40–1. Hyponatremia may be seen, due in part to inappropriate release of antidiuretic hormone, although gastrointestinal loss of sodium in some patients may be a contributing factor.

▶ Clinical Findings

A. Symptoms and Signs

Patients show intermittent abdominal pain of varying severity, and in some instances it may so simulate acute

abdomen as to lead to exploratory laparotomy. Because the origin of the abdominal pain is neurologic, there is an absence of fever and leukocytosis. Complete recovery between attacks is usual. Any part of the nervous system may be involved, with evidence for autonomic and peripheral neuropathy. Peripheral neuropathy may be symmetric or asymmetric and mild or profound; in the latter instance, it can even lead to quadriplegia with respiratory paralysis. Other central nervous system manifestations include seizures, psychosis, and abnormalities of the basal ganglia. Hyponatremia may further cause or exacerbate central nervous system manifestations.

B. Laboratory Findings

Often there is profound hyponatremia. The diagnosis can be confirmed by demonstrating an increased amount of porphobilinogen in the urine during an acute attack. Freshly voided urine is of normal color but may turn dark upon standing in light and air.

Most families have a different mutation in the porphobilinogen deaminase gene causing AIP. Mutations can be detected and used for presymptomatic and prenatal diagnosis.

▶ Prevention

Avoidance of factors known to precipitate attacks of AIP—especially drugs—can reduce morbidity. Sulfonamides and barbiturates are the most common culprits; others are listed in Table 40–1 and on the Internet (www.drugs-porphyria.org). Starvation diets or prolonged fasting also cause attacks and so must be avoided. Hormonal changes during pregnancy can precipitate crises.

▶ Treatment

Treatment with a high-carbohydrate diet diminishes the number of attacks in some patients and is a reasonable empiric gesture considering its benignity. Acute attacks may be life-threatening and require prompt diagnosis, withdrawal of the inciting agent (if possible), and treatment with analgesics and intravenous glucose and hemeatin. A minimum of 300 g of carbohydrate per day should be provided orally or intravenously. Electrolyte balance

Table 40-1. Some of the “unsafe” and “probably safe” drugs used in the treatment of acute porphyrias.

Unsafe	Probably Safe
Alcohol	Acetaminophen
Alkylating agents	β-Adrenergic blockers
Barbiturates	Amitriptyline
Carbamazepine	Aspirin
Chloroquine	Atropine
Chlorpropamide	Chloral hydrate
Clonidine	Chlordiazepoxide
Dapsone	Corticosteroids
Ergots	Diazepam
Erythromycin	Digoxin
Estrogens, synthetic	Diphenhydramine
Food additives	Guanethidine
Glutethimide	Hyoscyne
Griseofulvin	Ibuprofen
Hydralazine	Imipramine
Ketamine	Insulin
Meprobamate	Lithium
Methyldopa	Naproxen
Metoclopramide	Nitrofurantoin
Nortriptyline	Opioid analgesics
Pentazocine	Penicillamine
Phenytoin	Penicillin and derivatives
Progestins	Phenothiazines
Pyrazinamide	Procaine
Rifampin	Streptomycin
Spironolactone	Succinylcholine
Succinimides	Tetracycline
Sulfonamides	Thiouracil
Theophylline	
Tolazamide	
Tolbutamide	
Valproic acid	

requires close attention. Hematin therapy should be undertaken with full recognition of adverse consequences, especially phlebitis and coagulopathy. The intravenous dosage is up to 4 mg/kg once or twice daily. Liver transplantation may provide an option for patients with disease poorly controlled by medical therapy.

► When to Refer

- For management of severe abdominal pain, seizures, or psychosis.
- For preventive management when a patient with porphyria contemplates pregnancy.
- For genetic counseling and molecular diagnosis.

► When to Admit

The patient should be hospitalized when he or she has an acute attack accompanied by mental status changes, seizure, or hyponatremia.

ALKAPTONURIA

ESSENTIALS OF DIAGNOSIS

- Ochronosis (gray-black discoloration of connective tissue, including the sclerae, ears, and cartilage).
- Characteristic radiologic changes in the spine, with radiodense intervertebral discs.
- Arthropathy.
- Urine darkens on standing.

► Clinical Findings

A. Symptoms and Signs

Alkaptonuria is caused by a recessively inherited deficiency of the enzyme homogentisic acid oxidase. This acid derives from metabolism of both phenylalanine and tyrosine and is present in large amounts in the urine throughout the patient's life. An oxidation product accumulates slowly in cartilage throughout the body, leading to degenerative joint disease of the spine and peripheral joints. Indeed, examination of patients in the third and fourth decades shows a slight darkish blue color below the skin in areas overlying cartilage, such as in the ears, a phenomenon called **ochronosis**. In some patients, a more severe hyperpigmentation can be seen in the sclera, conjunctiva, and cornea. Accumulation of metabolites in heart valves can lead to aortic or mitral stenosis. A predisposition to coronary artery disease may also be present. Although the syndrome causes considerable morbidity, life expectancy is reduced only modestly. Symptoms are more often attributable to spondylitis with back pain, leading to a clinical picture difficult to distinguish from that of ankylosing spondylitis, though on radiographic assessment the sacroiliac joints are not fused in alkaptonuria.

B. Laboratory Findings

The diagnosis is established by demonstrating homogentisic acid in the urine, which turns black spontaneously on exposure to the air; this reaction is particularly noteworthy if the urine is alkaline or when alkali is added to a specimen. Molecular analysis of the homogentisic acid oxidase gene (*HGD*) is available but not necessary for diagnosis.

► Prevention

Carrier screening and prenatal diagnosis are possible by testing for genetic mutations.

► Treatment

Treatment of the arthritis is similar to that for other arthropathies. Though, in theory, rigid dietary restriction might reduce accumulation of the pigment, this has not proved to be of practical benefit.

DOWN SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Typical craniofacial features (flat occiput, epicanthal folds, large tongue).
- ▶ Mental retardation.
- ▶ Congenital heart disease (eg, atrioventricular canal defects) in 50% of patients.
- ▶ Three copies of chromosome 21 (trisomy 21) or a chromosome rearrangement that results in three copies of a region of the long arm of chromosome 21.

► Clinical Findings

A. Symptoms and Signs

Down syndrome is usually diagnosed at birth on the basis of the typical craniofacial features, hypotonia, and single palmar crease. Several serious problems that may be evident at birth or may develop early in childhood include duodenal atresia, congenital heart disease (especially atrioventricular canal defects), and hematologic malignancy. The intestinal and cardiac anomalies usually respond to surgery. A transient neonatal leukemia generally responds to conservative management. The incidences of both acute lymphoblastic and myeloid leukemias are increased in childhood. Intelligence varies across a wide spectrum. Many people with Down syndrome do well in sheltered workshops and group homes, but few achieve full independence in adulthood. Other frequent complications include atlanto-axial instability, celiac disease, and hypothyroidism. An Alzheimer-like dementia usually becomes evident in the fourth or fifth decade. Patients with Down syndrome who survive childhood and who develop dementia have a reduced life expectancy; on average, they live to about age 55 years.

B. Laboratory Findings

Cytogenomic analysis should always be performed—even though most patients will have simple trisomy for chromosome 21—to detect unbalanced translocations; such patients may have a parent with a balanced translocation, and there

will be a substantial recurrence risk of Down syndrome in future offspring of that parent and potentially that parent's relatives.

► Prevention

Nearly 0.5% of all human conceptions are trisomic for chromosome 21. Because of increased fetal mortality, birth incidence of Down syndrome is 1 per 700 but varies from 1 per 1000 in young mothers to more than three times as frequent in women of advanced maternal age. The presence of a fetus with Down syndrome can be detected in many pregnancies in the first or early second trimester through screening maternal serum for α -fetoprotein and other biomarkers (“multiple marker screening”) and by detecting increased nuchal thickness and underdevelopment of the nasal bone on fetal ultrasound. The risk of bearing a child with Down syndrome increases exponentially with the age of the mother at conception and begins a marked rise after age 35. By age 45 years, the odds of having an affected child are as high as 1 in 40. The risk of other conditions associated with trisomy also increases, because of the predisposition of older oocytes to nondisjunction during meiosis. There is little risk of trisomy associated with increased paternal age. However, older men do have an increased risk of fathering a child with a new autosomal dominant condition. Because there are so many distinct conditions, though, the chance of fathering an offspring with any given one is extremely small.

► Treatment

Duodenal atresia should be treated surgically. Congenital heart disease should be treated as in any other patient. No medical treatment has been proven to affect the intellectual capacity.

► When to Refer

- For comprehensive evaluation of infants to investigate congenital heart disease, hematologic malignancy, and duodenal atresia.
- For genetic counseling of the parents.
- For signs of dementia in an adult patient.

► When to Admit

An affected young patient should be hospitalized when he or she has failure to thrive, regurgitation, breathlessness, or easy bruising.

FRAGILE X MENTAL RETARDATION

ESSENTIALS OF DIAGNOSIS

- ▶ Expanded trinucleotide repeat in the *FMR1* gene.
- ▶ Mental retardation and autism in males.
- ▶ Large testes after puberty.
- ▶ Learning disabilities or mental retardation in females.
- ▶ Premature ovarian failure.
- ▶ Late-onset tremor and ataxia in males and females with moderate trinucleotide repeat expansion (premutation carriers).

▶ Clinical Findings

A. Symptoms and Signs

This X-linked condition accounts for more cases of mental retardation in males than any condition except Down syndrome; about 1 in 5000 males is affected. The condition also affects intellectual function in females, although less severely and about 50% less frequently than in males. Affected (heterozygous) young women show no physical signs other than early menopause, but they may have learning difficulties or frank retardation. Affected males show macro-orchidism (enlarged testes) after puberty, large ears and a prominent jaw, a high-pitched voice, autistic characteristics, and mental retardation. Some males show evidence of a mild connective tissue defect, with joint hypermobility and mitral valve prolapse.

Women who are premutation carriers (55–200 CGG repeats) are at increased risk for premature ovarian failure and mild cognitive abnormalities. Male and female premutation carriers are at risk for mood and anxiety disorders and the development of tremor and ataxia beyond middle age (fragile-X tremor-ataxia syndrome, FXTAS). Changes in the cerebellar white matter may be evident on MRI before symptoms appear. Because of the relatively high prevalence of premutation carriers in the general population, older people in whom any of these behavioral or neurologic problems develop should undergo testing of the *FMR1* locus.

B. Laboratory Findings

The first marker for this condition was a small gap, or fragile site, evident near the tip of the long arm of the X chromosome. Subsequently, the condition was found to be due to expansion of a trinucleotide repeat (CGG) near a gene called *FMR1*. All individuals have some CGG repeats in

this location, but as the number increases beyond 52, the chances of further expansion during spermatogenesis or oogenesis increase.

Being born with one *FMR1* allele with 200 or more repeats results in mental retardation in most men, and in about 60% of women. The more repeats, the greater the likelihood that further expansion will occur during gameto-genesis; this results in anticipation, in which the disorder can worsen from one generation to the next.

▶ Prevention

DNA diagnosis for the number of repeats has supplanted cytogenetic analysis for both clinical and prenatal diagnosis. This should be done on any male or female who has unexplained mental retardation. Newborn screening based on hypermethylation of the *FMR1* gene is being considered as a means of early detection and intervention.

▶ Treatment

No specific treatments have been developed but several based on the mouse model are in development. Valproic acid may reduce symptoms of hyperactivity and attention deficit, but standard therapies should be tried first.

▶ When to Refer

- For otherwise unexplained mental retardation or learning difficulties in boys and girls.
- For otherwise unexplained tremor or ataxia in middle-aged individuals.
- For premature ovarian failure.
- For genetic counseling.

GAUCHER DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Deficiency of β -glucocerebrosidase.
- ▶ Anemia and thrombocytopenia.
- ▶ Hypersplenism.
- ▶ Pathologic fractures.

► Clinical Findings

A. Symptoms and Signs

Gaucher disease has an autosomal recessive pattern of inheritance. A deficiency of β -glucocerebrosidase causes an accumulation of sphingolipid within phagocytic cells throughout the body. Anemia and thrombocytopenia are common and may be symptomatic; both are due primarily to hypersplenism, but marrow infiltration with Gaucher cells may be a contributing factor. Cortical erosions of bones, especially the vertebrae and femur, are due to local infarctions, but the mechanism is unclear. Episodes of bone pain (termed “crises”) are reminiscent of those in sickle cell disease. A hip fracture in a patient with a palpable spleen—especially in a Jewish person of Eastern European origin—suggests the possibility of Gaucher disease.

Two uncommon forms of Gaucher disease, called type II and type III, involve neurologic accumulation of sphingolipid and a variety of neurologic problems. Type II is of infantile onset and has a poor prognosis. Heterozygotes for Gaucher disease are at increased risk for developing Parkinson disease.

B. Laboratory Findings

Bone marrow aspirates reveal typical Gaucher cells, which have an eccentric nucleus and periodic acid–Schiff (PAS)-positive inclusions, along with wrinkled cytoplasm and inclusion bodies of a fibrillar type. In addition, the serum acid phosphatase is elevated. Definitive diagnosis requires the demonstration of deficient glucocerebrosidase activity in leukocytes. Hundreds of mutations have been found to cause Gaucher disease and some are highly predictive of the neuronopathic forms. Thus, mutation detection, especially in a young person, is of potential value. Only four mutations in glucocerebrosidase account for more than 90% of the disease among Ashkenazi Jews, in whom the carrier frequency is 1:15.

► Prevention

Most clinical complications can be prevented by early institution of enzyme replacement therapy. Carrier screening, especially among Ashkenazi Jews, detects those couples at 25% risk of having an affected child. Prenatal diagnosis through mutation analysis is feasible.

► Treatment

For many years, treatment was supportive and included splenectomy for thrombocytopenia secondary to platelet sequestration. A recombinant form of the enzyme glucocerebrosidase (imiglucerase) for intravenous administration on a regular basis now permits a reduction in total body stores of glycolipid and improvement in orthopedic and hematologic manifestations. Unfortunately, the neurologic manifestations of types II and III have not improved with enzyme replacement therapy. The major drawback is the exceptional cost of imiglucerase, which can exceed \$100,000

per year for a severely affected patient. Early treatment of affected children normalizes growth and bone mineral density and improves liver and spleen size, anemia, and thrombocytopenia. Alternative or complementary therapies, including methods to reduce substrate and to provide a chaperone for a defective enzyme, are being developed. One approved medication, miglustat, does reduce the production of glucocerebroside in some patients, but can be poorly tolerated because of adverse effects.

DISORDERS OF HOMOCYSTEINE METABOLISM

ESSENTIALS OF DIAGNOSIS

- For homocystinuria, dislocated ocular lenses.
- Elevated homocysteine in the urine or plasma.

► General Considerations

Considerable evidence has accumulated to support the observation that patients with clinical and angiographic evidence of coronary artery disease tend to have higher levels of plasma homocysteine than persons without coronary artery disease. The relationship has been extended to cerebrovascular and peripheral vascular diseases. Although this effect was initially thought to be due at least in part to heterozygotes for cystathionine β -synthase deficiency (see below), there is little supporting evidence. Rather, an important factor leading to hyperhomocysteinemia is folate deficiency. Pyridoxine (vitamin B₆) and vitamin B₁₂ are also important in the metabolism of methionine, and deficiency of any of these vitamins can lead to accumulation of homocysteine. A number of genes influence utilization of these vitamins and can predispose to deficiency. For example, having one—and especially two—copies of an allele that causes thermolability of methylene tetrahydrofolate

reductase predisposes people to elevated fasting homocysteine levels. Both nutritional and most genetic deficiencies of these vitamins can be corrected by dietary supplementation of folic acid and, if serum levels are low, vitamins B₆ and B₁₂. In the United States, cereal grains are fortified with folic acid. However, therapy with B vitamins and folate lowers homocysteine levels significantly but does not reduce the risk of either venous thromboembolism or complications of coronary artery disease. The role of lowering homocysteine as primary prevention for sequelae of atherosclerosis has received little direct support in clinical trials. Hyperhomocysteinemia occurs with end-stage chronic kidney disease.

► Clinical Findings

A. Symptoms and Signs

Homocystinuria in its classic form is caused by cystathionine β-synthase deficiency and exhibits an autosomal recessive pattern of inheritance. This results in extreme elevations of plasma and urinary homocystine levels, a basis for diagnosis of this disorder. Homocystinuria is similar in certain superficial aspects to Marfan syndrome, since patients may have a similar body habitus and ectopia lentis is almost always present. However, mental retardation is often present in homocystinuria, and the cardiovascular events are those of repeated venous and arterial thromboses whose precise cause remains obscure. Life expectancy is reduced, especially in untreated and pyridoxine-unresponsive patients; myocardial infarction, stroke, and pulmonary embolism are the most common causes of death. This condition is diagnosed by newborn screening for hypermethioninemia; however, pyridoxine-responsive infants may not be detected. The diagnosis should be suspected in patients in the second and third decades of life who have arterial or venous thromboses without other risk factors.

B. Laboratory Findings

Although many mutations have been identified in the cystathionine β-synthase gene (*CBC*), amino acid analysis of plasma remains the most appropriate diagnostic test. Patients should be studied after they have been off folate or pyridoxine supplementation for at least 1 week. Relatively few laboratories currently provide highly reliable assays for homocysteine. Processing of the specimen is crucial to obtain accurate results. The plasma must be separated within 30 minutes; otherwise, blood cells release the amino acid and the measurement will then be artificially elevated.

► Prevention

About 50% of patients have a form of cystathionine β-synthase deficiency that improves biochemically and clinically through pharmacologic doses of pyridoxine (50–500 mg/d) and folate (5–10 mg/d). For these patients, treatment from infancy can prevent retardation and the other clinical problems. Patients who are pyridoxine non-responders must be treated with a dietary reduction in

methionine and supplementation of cysteine, also from infancy. The vitamin betaine is also useful in reducing plasma methionine levels by facilitating a metabolic pathway that bypasses the defective enzyme.

► Treatment

Patients with classic homocystinuria who have suffered venous thrombosis receive anticoagulation therapy, but there are no studies to support prophylactic use of warfarin or antiplatelet agents.

KLINFELTER SYNDROME

ESSENTIALS OF DIAGNOSIS

- Males with hypogonadism and small testes.
- 47,XXY karyotype.

► Clinical Findings

A. Symptoms and Signs

Boys with an extra X chromosome are normal in appearance before puberty; thereafter, they have disproportionately long legs and arms, a female escutcheon, gynecomastia, and small testes. Infertility is due to azoospermia; the seminiferous tubules are hyalinized. The diagnosis is often not made until a couple is evaluated for inability to conceive. Mental retardation is somewhat more common than in the general population. Many men with Klinefelter syndrome have learning problems. However, their intelligence usually tests within the broad range of normal. As adults, detailed psychometric testing may reveal a deficiency in executive skills. The risk of breast cancer and diabetes mellitus is much higher in men with Klinefelter syndrome than in 46,XY men.

B. Laboratory Findings

Low serum testosterone is common. The karyotype is typically 47,XXY.

► Prevention

Screening for cancer, especially of the breast, and for glucose intolerance are indicated.

► Treatment

Treatment with testosterone after puberty is advisable but will not restore fertility. However, men with Klinefelter syndrome have had mature sperm aspirated from their testes and injected into oocytes, resulting in fertilization. After the blastocysts have been implanted into the uterus of a partner, conception has resulted. However, men with Klinefelter syndrome do have an increased risk for aneuploidy in sperm, and therefore genomic analysis of a blastocyst should be considered before implantation.

MARFAN SYNDROME

ESSENTIALS OF DIAGNOSIS

- Disproportionately tall stature, thoracic deformity, and joint laxity or contractures.
- Ectopia lentis and myopia.
- Aortic dilation and dissection.
- Mitral valve prolapse.

► General Considerations

Marfan syndrome, a systemic connective tissue disease, has an autosomal dominant pattern of inheritance. It is characterized by abnormalities of the skeletal, ocular, and cardiovascular systems; spontaneous pneumothorax; dural ectasia; and striae atrophicae. Of most concern is disease of the ascending aorta, which begins as a dilated aortic root. Histology of the aorta shows diffuse medial degeneration. Mitral valve leaflets are also abnormal and mitral prolapse and regurgitation may be present, often

with elongated chordae tendineae, which on occasion may rupture.

► Clinical Findings

A. Symptoms and Signs

Affected patients are typically tall, with particularly long arms, legs, and digits (arachnodactyly). However, there can be wide variability in the clinical presentation. Commonly, scoliosis and anterior chest deformity, such as pectus excavatum, are found. Ectopia lentis is present in about half of patients; severe myopia is common and retinal detachment can occur. Mitral valve prolapse is seen in about 85% of patients. Aortic root dilation is common and leads to aortic regurgitation or dissection with rupture. To diagnose Marfan syndrome, people with an affected relative need features in at least two systems. People with no family history need features in the skeletal system, two other systems, and one of the major criteria of ectopia lentis, dilation of the aortic root, or aortic dissection. Patients with homocystinuria due to cystathionine synthase deficiency also have dislocated lenses; tall, disproportionate stature; and thoracic deformity. They tend to have below normal intelligence, stiff joints, and a predisposition to arterial and venous occlusive disease. Males with Klinefelter syndrome do not show the typical ocular or cardiovascular features of Marfan syndrome and are generally sporadic occurrences in the family.

B. Laboratory Findings

Mutations in the fibrillin gene (*FBN1*) on chromosome 15 cause Marfan syndrome. Nonetheless, no simple laboratory test is available to support the diagnosis in questionable cases because related conditions may also be due to defects in fibrillin. The nature of the *FBN1* mutation has little predictive value in terms of prognosis. The pathogenesis of Marfan syndrome involves aberrant regulation of transforming growth factor (TGF) β activity. Mutations in either of two receptors for TGF β (TGFBR1 and TGFBR2) can cause conditions that resemble Marfan syndrome in terms of aortic aneurysm and dissection and autosomal dominant inheritance.

► Prevention

There is prenatal and presymptomatic diagnosis for patients in whom the molecular defect in fibrillin has been found.

► Treatment

Children with Marfan syndrome require regular ophthalmologic surveillance to correct visual acuity and thus prevent amblyopia, and annual orthopedic consultation for diagnosis of scoliosis at an early enough stage so that bracing might delay progression. Patients of all ages require echocardiography at least annually to monitor aortic diameter and mitral valve function. Long-term

β -adrenergic blockade, titrated to individual tolerance but enough to produce a negative inotropic effect (atenolol, 1–2 mg/kg orally daily) retards the rate of aortic dilation. Several clinical trials comparing the effectiveness of atenolol and losartan, a drug that reduces activity of TGF β , are underway. Restriction from vigorous physical exertion protects from aortic dissection. Prophylactic replacement of the aortic root with a composite graft when the diameter reaches 45–50 mm in an adult (normal: < 40 mm) prolongs life. A procedure to reimplant the patient's native aortic valve and replace just the aneurysmal sinuses of Valsalva avoids the need for lifelong anticoagulation.

► Prognosis

People with Marfan syndrome who are untreated commonly die in the fourth or fifth decade from aortic dissection or congestive heart failure secondary to aortic regurgitation. However, because of earlier diagnosis, lifestyle modifications, β -adrenergic blockade, and prophylactic aortic surgery, life expectancy has increased by several decades in the past 25 years.

► When to Refer

- For detailed ophthalmologic examination.
- For at least annual cardiologic evaluation.
- For moderate scoliosis.
- For pregnancy in a woman with Marfan syndrome.
- For genetic counseling.

► When to Admit

Any patient with Marfan syndrome in whom severe or unusual chest pain develops should be hospitalized to exclude pneumothorax and aortic dissection.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

ESSENTIALS OF DIAGNOSIS

- Recurrent epistaxis.
- Mucocutaneous telangiectases.
- Visceral arteriovenous malformations (especially lung, liver, brain, bowel).

► Clinical Findings

A. Symptoms and Signs

Hereditary hemorrhagic telangiectasia (HHT), formerly termed “Osler-Weber-Rendu syndrome,” is an autosomal dominant disorder of development of the vasculature. Epistaxis may begin in childhood or later in adolescence. Punctate telangiectases of the lips, tongue, fingers, and skin generally appear in later childhood and adolescence. Arteriovenous malformations (AVMs) can occur at any age in the brain, lungs, and liver. Bleeding from the gastrointestinal tract is due to mucosal vascular malformations and usually is not a problem until mid-adult years or later. Pulmonary AVMs can cause hypoxemia (with peripheral cyanosis, dyspnea, and clubbing) and right-to-left shunting (with embolic stroke or brain abscess). The criteria for diagnosis require presence of three of the following four features: (1) recurrent epistaxis, (2) visceral AVMs, (3) mucocutaneous telangiectases, and (4) being the near relative of a clearly affected individual. Mutation analysis can be used for presymptomatic diagnosis or exclusion of the worry of HHT.

B. Laboratory Findings

MR or CT arteriography detects AVMs. Mutations in at least five genes can cause HHT. Three have been identified and molecular analysis to identify them is available; these mutations in *ENG*, *ALK1*, and *SMAD4* account for about 87% of families with HHT. When the familial mutation is known, molecular testing is far more cost effective than repeated screening of relatives who are at risk.

► Prevention

Embolization of pulmonary AVMs with wire coils or other occlusive devices reduces the risk of stroke and brain abscess. Treatment of brain AVMs reduces the risk of hemorrhagic stroke. All patients with HHT with evidence of a pulmonary shunt should practice routine endocarditis prophylaxis (see Table 33–6). All intravenous lines (except those for transfusion of red blood cells and radiographic contrast) should have an air-filter to prevent embolization of an air bubble. Prenatal diagnosis through mutation detection is possible.

▶ Treatment

All patients in whom the diagnosis of HHT is considered should have an MRI of the brain with contrast. A contrast echocardiogram will detect most pulmonary AVMs when “bubbles” appear on the left side of the heart after 3–6 cardiac cycles. A positive contrast echocardiogram should be followed by a high-resolution CT angiogram for localization of pulmonary AVMs. Patients who have AVMs with a feeding artery of 1–2 mm diameter or greater should undergo embolization. After successful embolization of all treatable pulmonary AVMs, the CT angiogram should be repeated in 3 years. A person with a negative contrast echocardiogram should have the test repeated every 5 years.

Sports Medicine & Outpatient Orthopedics

Anthony Luke, MD, MPH, & C. Benjamin Ma, MD

41

GENERAL APPROACH TO MUSCULOSKELETAL INJURIES

ESSENTIALS OF DIAGNOSIS

- ▶ History is most important in diagnosing musculoskeletal problems.
- ▶ The mechanism of injury can explain the pathology and symptoms.
- ▶ Determine whether the injury is traumatic or atraumatic, acute or chronic, high or low velocity (greater velocity suggests more structural damage), or whether any movement aggravates or relieves pain associated with the injury.

▶ General Considerations

Musculoskeletal problems account for about 10–20% of outpatient primary care clinical visits. Orthopedic problems can be classified as traumatic (ie, injury-related) or atraumatic (ie, degenerative or overuse syndromes) as well as acute or chronic. The mechanism of injury is usually the most helpful part of the history in determining the diagnosis.

The onset of symptoms should be elicited. With acute traumatic injuries, patients typically seek medical attention within 1–6 weeks of onset. The patient should describe the exact location of symptoms, which helps determine anatomic structures that may be damaged. If the patient is vague, the clinician can ask the patient to point with one finger only to the point of maximal tenderness.

▶ Clinical Findings

A. Symptoms and Signs

The chief musculoskeletal complaints are typically pain (most common), instability or dysfunction around the joints. Since symptoms and signs are often nonspecific, recognizing the expected combination of symptoms and

physical examination signs can help facilitate the clinical diagnosis. Patients may describe symptoms of “locking” or “catching,” suggesting internal derangement in joints. Symptoms of “instability” or “giving way” suggest ligamentous injury; however, these symptoms may also be due to pain causing muscular inhibition. Constitutional symptoms of fever or weight loss, swelling with no injury, or systemic illness suggest medical conditions (such as infection, cancer, or rheumatologic disease).

Initial evaluation should follow routine trauma guidelines to rule out serious joint injury. However, typical evaluations in the clinic follow the traditional components of the physical examination and should include inspection, palpation, and assessment of range of motion and neurovascular status.

Inspection includes observation of swelling, erythema, atrophy, deformity, and (surgical) scars (remembered by the mnemonic, “SEADS”). The patient should be asked to move joints of concern (see Table 41–1). If motion is asymmetric, the clinician should assess the passive range of motion for any physical limitation.

There are special tests to assess each joint. Typically, **provocative tests** recreate the mechanism of injury with the goal to reproduce the patient’s pain. **Stress tests** apply load to ligaments of concern. Typically, 10 to 15 pounds of force should be applied when performing stress tests. **Functional testing**, including simple tasks performed during activities of daily living, is useful to assess injury severity.

B. Imaging

Bony pathology can be assessed using standard radiographs, although there also may be characteristic soft tissue findings. However, CT scans are the most effective method for visualizing any bony pathology, including morphology of fractures. Nuclear bone scans are now less commonly used but are still valuable for identifying stress injuries, infection, malignancy, or multisite pathology. Positron emission tomography (PET) scans are useful in identifying metastatic malignant lesions. MRI provides excellent visualization of ligaments, cartilage, and soft tissues. Gadolinium contrast can be injected as an MRI arthrogram to increase sensitivity

of detecting certain internal derangements in joints such as labral injuries. Musculoskeletal ultrasound, where available, can be useful for identifying superficial tissue problems, including tendinopathies and synovial problems.

C. Special Tests

Arthrocentesis must be performed promptly to rule out an infection when acute knee pain with effusion and inflammation are present and the patient is unable to actively flex the joint. The joint fluid should be sent for cell count, crystal analysis, and culture. Arthrocentesis and joint fluid analysis demonstrating crystals can lead to the diagnosis of gout (negatively birefringent, needle-shaped crystals) or pseudogout (positively birefringent, rectangular-shaped crystals). In large, uncomfortable knee joint effusions, removal of excessive joint fluid may improve joint range of motion (flexion) and patient comfort. To avoid infecting the joint, arthrocentesis should not be performed when there is an active cellulitis or abscess overlying the joint. It is also contraindicated if there is a significant coagulopathy (INR > 3.0). Markers of inflammation such as complete blood cell count, erythrocyte sedimentation rate, and C-reactive protein, and rheumatologic tests are useful in evaluating for infectious, oncologic, or rheumatologic processes. Electrodiagnostic studies such as electromyography and nerve conduction studies are useful when there are neurologic concerns; they can also help with prognostication in chronic conditions.

► Treatment

While most outpatient musculoskeletal problems are best treated conservatively, the first consideration is whether there is an immediate surgical need. Surgical treatment is chosen when the outcome promises better health, restoration of function, and improved quality of life. During surgery, the musculoskeletal problem is usually repaired, removed, realigned, reconstructed, or replaced (eg, joint replacement).

If surgery is not immediately indicated, conservative treatment in the outpatient setting usually includes modification of activities, ice, compression, and elevation (remembered by the mnemonic, “MICE”). Controlling pain is an early concern for most patients. Commonly prescribed medications are analgesics (nonsteroidal anti-inflammatory drugs [NSAIDs], acetaminophen, or opioids). Other medications that may also be prescribed, albeit less commonly, are muscle relaxants or co-analgesics for neuropathic pain (which include the calcium channel α_2 - δ ligands [eg, gabapentin] or tricyclic antidepressants). Topical medications, such as capsaicin cream or patch, lidocaine patches, and NSAID patches, can help provide superficial local pain relief.

Immobilization by casting, slings, and braces is helpful to protect an injured limb. Crutches are useful to reduce weight bearing. Rehabilitation and physical therapy are frequently needed. Other modalities commonly used by patients include chiropractic manipulation, massage therapy, acupuncture, and osteopathy.

► When to Refer

Indications for *emergency* referral (immediate)

- Neurovascular injury.
- Fractures (open, unstable).
- Unreduced joint dislocation.
- Septic arthritis.

Indications for *urgent* referral (within 7 days)

- Fractures (closed, stable).
- Reduced joint dislocation.
- “Locked” joint (inability to fully extend a joint due to mechanical derangement, usually a loose body or torn cartilage).
- Tumor.

Indications for *early* orthopedic assessment (2–4 weeks)

- Motor weakness (neurologic).
- Constitutional symptoms (eg, fever not due to septic arthritis, weight loss).
- Multiple joint involvement.

Indications for *routine* orthopedic assessment (for further management)

- Failure of conservative treatment (persistent symptoms > 3 months).
- Persistent numbness and tingling in an extremity.

Ma L et al. Acute monoarthritis: what is the cause of my patient's painful swollen joint? CMAJ. 2009 Jan 6;180(1):59–65. [PMID: 19124791]

SHOULDER

1. Subacromial Impingement Syndrome

ESSENTIALS OF DIAGNOSIS

- Shoulder pain with overhead motion.
- Night pain with sleeping on shoulder.
- Pain with internal rotation.
- Numbness and pain radiation below the elbow are usually due to cervical spine disease.

► General Considerations

The chief complaints for shoulder problems are usually pain, instability, weakness, or loss of range of motion. With any shoulder problem, it is important to establish the patient's hand dominance, occupation, and recreational activities because shoulder injuries may present differently depending on the demands placed on the shoulder joint.

For example, baseball pitchers with impingement syndrome may complain of pain while throwing. Alternatively, elders with even full thickness rotator cuff tears may not complain of any pain because the demands on the joint are low.

The subacromial impingement syndrome describes a collection of diagnoses that cause mechanical inflammation in the subacromial space. Causes of impingement syndrome can be related to muscle strength imbalances, poor scapula control, rotator cuff tears, and subacromial bone spurs.

▶ Clinical Findings

A. Symptoms and Signs

Shoulder problems classically present with one or more of the following: pain with overhead activities, nocturnal pain with sleeping on the shoulder, or pain on internal rotation (eg, putting on a jacket or bra). On inspection, there may be appreciable atrophy in the supraspinatus or infraspinatus fossa. The patient with impingement syndrome can have mild scapula winging or “dyskinesis.” The patient often has a rolled-forward shoulder posture or head-forward posture. On palpation, the patient can have tenderness over the anterolateral shoulder at the edge of the greater tuberosity. The patient may lack full active range of motion (Table 41–1) but should have preserved passive range of motion. Impingement symptoms can be elicited with the Neer and Hawkins impingement signs (Table 41–1).

B. Imaging

The following four radiographic views should be ordered to evaluate subacromial impingement syndrome: the anteroposterior scapula, the anteroposterior acromioclavicular joint, the lateral scapula (scapular Y), and the axillary lateral. The anteroposterior scapula view can rule out glenohumeral joint arthritis. The anteroposterior acromioclavicular view evaluates the acromioclavicular joint for inferior spurs. The scapula Y view evaluates the acromial shape, and the axillary lateral view visualizes the glenohumeral joint as well and for the presence of os acromiale.

MRI of the shoulder may demonstrate full or partial thickness tears or tendinosis. Ultrasound evaluation may demonstrate thickening of the rotator cuff tendons and tendinosis. Tears may also be visualized, although it is more difficult to identify partial tears from small full thickness on ultrasound than on MRI.

▶ Treatment

A. Conservative

The first-line treatment for impingement syndrome is usually a conservative approach with education, activity modification, and physical therapy exercises. Impingement syndrome can be caused by muscle weakness or tear. Rotator cuff muscle strengthening can alleviate weakness or pain, unless the tendons are seriously compromised, which may cause more symptoms. Physical therapy is directed at rotator cuff muscle strengthening, scapula stabilization, and postural exercises. There is no strong

evidence supporting the effectiveness of ice and NSAID therapy. In a 2004 Cochrane review, corticosteroid injections produced slightly better relief of symptoms in the short-term when compared with placebo. Most patients respond well to conservative treatment.

B. Surgical

Procedures include arthroscopic acromioplasty with coracoacromial ligament release, bursectomy, or debridement or repair of rotator cuff tears.

▶ When to Refer

- Failure of conservative treatment over 3 months.
- Young and active patients with impingement due to full thickness rotator cuff tears.

Kuhn JE. Exercise in the treatment of rotator cuff impingement: a systematic review and a synthesized evidence-based rehabilitation protocol. *J Shoulder Elbow Surg.* 2009 Jan–Feb; 18(1):138–60. [PMID: 18835532]

2. Rotator Cuff Tears

ESSENTIALS OF DIAGNOSIS

- ▶ A common cause of shoulder impingement syndrome after age 40.
- ▶ Difficulty lifting the arm with limited active range of motion.
- ▶ Weakness with resisted strength testing suggests full thickness tears.

▶ General Considerations

Rotator cuff tears can be caused by acute injuries related to falls on an outstretched arm or to pulling on the shoulder. It can also be related to chronic repetitive injuries with overhead movement and lifting. Partial rotator cuff tears are one of the major reasons for impingement syndrome. Full thickness rotator cuff tears are usually more symptomatic and may require surgical treatment. The most commonly torn tendon is the supraspinatus.

▶ Clinical Findings

A. Symptoms and Signs

Most patients complain of weakness or pain with overhead movement. Night pain is also a common complaint. The clinical findings with rotator cuff tears include those of the impingement syndrome except that with full-thickness rotator cuff tears there may be more obvious weakness noted with light resistance testing of specific rotator cuff muscles. Supraspinatus tendon strength is tested with

Table 41-1. Shoulder examination.

Maneuver	Description
Inspection	Check the patient's posture and "SEADS" (swelling, erythema, atrophy, deformity, surgical scars).
Palpation	Include important landmarks: acromioclavicular (AC) joint, long head of biceps tendon, coracoid, and greater tuberosity (supraspinatus insertion).
Range of motion testing	Check range of motion actively (patient performs) and passively (clinician performs).
Flexion  <p>A line drawing of a person's upper body from the side, performing shoulder flexion. A vertical dashed line represents the midline. The arm is raised forward and upward. An arc indicates a 180-degree angle from the vertical to the arm's position. Another arc indicates a 150-degree angle from the vertical to the arm's position.</p>	Move the arm forward as high as possible in the sagittal plane .
External rotation  <p>A line drawing of a person's upper body from the front, performing shoulder external rotation. The arm is raised forward. A dashed line represents the midline. An arc indicates a 50-degree angle of external rotation. Another arc indicates a 70-degree angle from the midline to the arm's position.</p>	Check the patient's elbow touching their body so that external rotation occurs predominantly at the glenohumeral joint.

(continued)

Table 41-1. Shoulder examination. (continued)

Maneuver	Description
<p>Internal rotation</p> 	<p>The patient is asked to reach the thumbs as high as possible behind the spine on each side. The clinician can record the highest spinous process that the individual can reach on each side (iliac crest = L4, inferior angle of scapula = T8).</p>
<p>Rotator cuff strength testing</p> <p>Supraspinatus (open can) test</p> 	<p>Perform resisted shoulder abduction at 90 degrees with slight forward flexion to around 45 degrees to test for supraspinatus tendon strength ("open can" test), or with shoulder abduction at 30 degrees and flexion to 30 degrees ("empty can" test).</p>
<p>External rotation</p> 	<p>The patient resists by externally rotating the arms with elbows at his or her side.</p>

(continued)

Table 41-1. Shoulder examination. (continued)

Maneuver	Description
<p data-bbox="107 290 348 316">Internal rotation (lift off test)</p> 	<p data-bbox="820 290 1249 445">A positive “lift-off” test is the inability of the patient to hold his or her hand away from the body when reaching toward the small of the back. The clinician pushes the patient’s hand toward the back while the patient resists. A positive lift-off indicates subscapularis tendon insufficiency.</p>
<p data-bbox="107 733 248 788">Internal rotation (belly press test)</p> 	<p data-bbox="820 733 1259 838">A positive “belly-press” test is the inability to hold the elbow in front of the trunk while pressing down with the hand on the belly. A positive belly press test indicates subscapularis tendon insufficiency.</p>
Impingement tests	
<p data-bbox="107 1237 300 1264">Neer impingement sign</p> 	<p data-bbox="820 1237 1236 1366">Perform by having the clinician flex the shoulder maximally in an overhead position. The test is positive when pain is reproduced with full passive shoulder flexion. Sensitivity is 79%; specificity is 53%.</p>

(continued)

Table 41-1. Shoulder examination. (continued)

Maneuver	Description
<p>Hawkins impingement sign</p> 	<p>Perform with the shoulder forward flexed 90 degrees and the elbow flexed at 90 degrees. The shoulder is then maximally internally rotated to impinge the greater tuberosity on the undersurface of the acromion. The test is considered positive when the patient's pain is reproduced by this maneuver. Sensitivity is 79%; specificity is 59%.</p>
Stability tests	
<p>Apprehension test</p> 	<p>With persistent anterior instability or a recent dislocation, the patient feels pain or guards when the shoulder is abducted and externally rotated at 90 degrees. With posterior instability, the patient is apprehensive with the shoulder forward flexed and internally rotated to 90 degrees with a posteriorly directed force.</p>
<p>Load and shift test</p> 	<p>Perform to determine shoulder instability by manually translating the humeral head anteriorly and posteriorly in relation to the glenoid. However, this test can be difficult to perform when the patient is not relaxed.</p>

(continued)

Table 41-1. Shoulder examination. (continued)

Maneuver	Description
<p>O'Brien test</p> 	<p>Performed to rule out labral cartilage tears that often occur following a shoulder subluxation or dislocation. The test involves flexing the patient's arm to 90 degrees, fully internally rotating the arm so the thumb is facing down (palm down) and adducting the arm to 10 degrees. Once positioned properly, the clinician applies downward force and asks the patient to resist. The test is then repeated in the same position except that the patient has his arm fully supinated (palm up). A positive O'Brien test for labral tear is pain deep in the shoulder with palm down more than the palm up.</p> <p>The O'Brien test can also be used to identify AC joint pathology. The patient would typically complain equally of pain directly over the AC joint with the palm down or up.</p>

resisted shoulder abduction at 90 degrees with slight forward flexion to around 45 degrees ("open can" test) (Table 41-1). Infraspinatus/teres minor strength is tested with resisted shoulder external rotation with shoulder at 0 degrees abduction, elbow by side (Table 41-1). Subscapularis strength is tested with the "lift-off" or "belly-press" tests (Table 41-1). The affected patient usually also has positive Neer and Hawkins impingement tests.

B. Imaging

Recommended radiographs are very similar to impingement syndrome: anteroposterior scapula (glenohumeral), axillary lateral, supraspinatus outlet, and anteroposterior acromioclavicular joint views. The anteroposterior scapula view is useful in visualizing rotator cuff tears because degenerative changes can appear between the acromion and greater tuberosity of the shoulder. Axillary lateral views show superior elevation of the humeral head in relation to the center of the glenoid. Supraspinatus outlet views allow evaluation of the shape of the acromion. High-grade acromial spurs are associated with a higher incidence of rotator cuff tears. The anteroposterior acromioclavicular joint view evaluates for the presence of acromioclavicular

joint arthritis, which can mimic rotator cuff tears, and for spurs that can cause rotator cuff injuries.

MRI is the best method for visualizing rotator cuff tears. The MR arthrogram can show partial or small (< 1 cm) rotator cuff tears. For patients who cannot undergo MRI testing or when postoperative artifacts limit MRI evaluations, ultrasonography can be helpful.

► Treatment

Partial rotator cuff tears may heal with scarring. Most partial rotator cuff tears can be treated with physical therapy and scapular and rotator cuff muscle strengthening. Physical therapy can strengthen the remaining muscles to compensate for loss of strength. Physical therapy is also an option for older sedentary patients. On the contrary, **full-thickness rotator cuff tears** do not heal well and have a tendency to progress with time. Most young active patients with acute, full-thickness tears should be treated with operative fixation.

Subscapularis tendon injuries warrant different treatment. Full-thickness subscapularis tendon tears should undergo surgical repair as they usually lead to premature osteoarthritis of the shoulder.

► When to Refer

- Young and active patients with full thickness rotator cuff tears.
- Partial tears with > 50% involvement and with significant pain.
- Older and sedentary patients with full-thickness rotator cuff tears who have not responded to nonoperative treatment.
- Full thickness subscapularis tears.

3. Shoulder Dislocation & Instability

ESSENTIALS OF DIAGNOSIS

- Most dislocations (95%) are in the anterior direction.
- Pain and apprehension with an unstable shoulder that is abducted and externally rotated.
- Acute shoulder dislocations should be reduced as quickly as possible, using manual relocation techniques if necessary.

► General Considerations

The shoulder is a ball and socket joint, similar to the hip. However, the bony contours of the shoulder bones are much different than the hip. Overall, the joint has much less stability than the hip, allowing greater movement and action. Stabilizing the shoulder joint relies heavily on rotator cuff muscle strength and also scapular control. Ninety five percent of the shoulder dislocations/instability occur in the anterior direction. Dislocations usually are caused by a fall on an outstretched and abducted arm. Patients complain of pain and feeling of instability when the arm is in the abducted and externally rotated position. Posterior dislocations are usually caused by falls from a height, epileptic seizures, or electric shocks. Traumatic shoulder dislocation can lead to instability. The rate of repeated dislocation is directly related to the patient's age: patients age 21 years or younger have a 70–90% risk of redislocation, whereas patients age 40 years or older have a much lower rate (20–30%). Ninety percent of young active individuals who had traumatic shoulder dislocation have labral injuries often described as Bankart lesions when the anterior inferior labrum is torn,

which can lead to continued instability. Older patients (over age 55 years) are more likely to have rotator cuff tears or fractures following dislocation. Atraumatic shoulder dislocations are usually caused by intrinsic ligament laxity or repetitive microtrauma leading to joint instability. This is often seen in swimmers, gymnasts, and pitchers as well as other athletes involved in overhead and throwing sports.

► Clinical Findings

A. Symptoms and Signs

For acute traumatic dislocations, patients usually have an obvious deformity with the humeral head dislocated anteriorly. The patient holds the shoulder and arm in an externally rotated position. The patient complains of acute pain and deformity that are improved with manual relocation of the shoulder. Reductions are usually performed in the emergency department. Even after reduction, the patient will continue to have limited range of motion and pain especially following a first-time shoulder dislocation.

Patients with recurrent dislocations can have less pain with subsequent dislocations. Posterior dislocations can be easily missed because the patient usually holds the shoulder and arm in an internally rotated position, which makes the shoulder deformity less obvious. Patients complain of difficulty pushing open a door.

Atraumatic shoulder instability is usually well tolerated with activities of daily living. Patients usually complain of a “sliding” sensation during exercises or strenuous activities such as throwing. Such dislocations may be less symptomatic and can often undergo spontaneous reduction of the shoulder with pain resolving within days after onset. The clinical examination for shoulder instability includes the apprehension test (Table 41–1), the load and shift test (Table 41–1) and the O'Brien test (Table 41–1). Most patients with persistent shoulder instability have preserved range of motion.

B. Imaging

Radiographs for acute dislocations should include a standard trauma series of anteroposterior and axillary lateral scapula (glenohumeral) views to determine the relationship of the humerus and the glenoid and to rule out fractures. Orthogonal views are used to identify a posterior shoulder dislocation, which can be missed easily with one anteroposterior view of the shoulder. An axillary lateral view of the shoulder can be safely performed even in the acute setting of a patient with a painful shoulder dislocation. For chronic injuries or symptomatic instability, these recommended radiographic views are helpful to identify bony injuries and Hill-Sachs lesions (indented compression fractures at the posterior-superior part of the humeral head associated with anterior shoulder dislocation). MRI is commonly used to show soft tissue injuries to the labrum and to visualize associated rotator cuff tears. MRI arthrograms better identify labral tears and ligamentous structures.

► Treatment

For **acute dislocations**, the shoulder should be reduced as soon as possible. The Stimson procedure is the least

traumatic method and is quite effective. The patient lies prone with the dislocated arm hanging off the examination table with a weight applied to the wrist to provide traction for 20–30 minutes. Afterward, gentle medial mobilization can be applied manually to assist the reduction. The shoulder can also be reduced with axial “traction” on the arm with “counter-traction” along the trunk. The patient should be sedated and relaxed. The shoulder can then be gently internally and externally rotated to guide it back into the socket.

Initial treatment of acute shoulder dislocations should include sling immobilization for 2–4 weeks along with pendulum exercises. Early physical therapy can be used to maintain range of motion and strengthening of rotator cuff muscles. Patients can also modify their activities to avoid active and risky sports. For patients with a traumatic incident and unilateral shoulder dislocation, a Bankart lesion is commonly present (remembered by the mnemonic, “TUBS”) and surgical treatment is often required.

The treatment of **atraumatic shoulder instability** is different than traumatic shoulder instability. Patients with chronic, recurrent shoulder dislocations should be managed with physical therapy and a regular maintenance program, consisting of scapular stabilization and postural and rotator cuff strengthening exercises. Activities may need to be modified. In patients with an atraumatic, multidirectional, bilateral shoulder instability, rehabilitation is the mainstay for treatment; inferior capsular shift surgery is rarely required (remembered by the mnemonic, “AMBRI”).

▶ When to Refer

- Patients who are at risk for second dislocation, such as young patients, certain jobholders (eg, police officers, fire fighters, and rock climbers) to avoid recurrent dislocation or dislocation while at work.
- Patients who have not responded to conservative approach or who have chronic instability.

4. Adhesive Capsulitis (“Frozen Shoulder”)

ESSENTIALS OF DIAGNOSIS

- ▶ Very painful shoulder triggered by minimal or no trauma.
- ▶ Pain out of proportion to clinical findings during the inflammatory phase.
- ▶ Stiffness during the “freezing” phase and resolution during the “thawing” phase.

▶ General Considerations

Adhesive capsulitis (“frozen shoulder”) is seen commonly in patients 40- to 65-years-old. It is more commonly seen in women than men, especially in perimenopausal women or in patients with endocrine disorders, such as diabetes mellitus or thyroid disease. Adhesive capsulitis is a self-limiting but very debilitating disease.

▶ Clinical Findings

A. Symptoms and Signs

Patients usually present with a painful shoulder that has a limited range of motion with both passive and active movements. A useful clinical sign is limitation of movement of external rotation with the elbow by the side of the trunk (Table 41–1). Strength is usually normal but it can appear diminished when the patient is in pain.

There are three phases: the inflammatory phase, the “freezing” phase, and the “thawing” phase. During the **inflammatory phase**, which usually lasts 4–6 months, patients complain of a very painful shoulder without obvious clinical findings to suggest trauma, fracture, or rotator cuff tear. During the **“freezing” phase**, which also usually lasts 4–6 months, the shoulder becomes stiffer and stiffer even though the pain is improving. The **“thawing” phase** can take up to a year as the shoulder slowly regains its motion. The total duration of an idiopathic frozen shoulder is usually about 24 months; it can be much longer for patients who have trauma or an endocrinopathy.

B. Imaging

Standard anteroposterior, axillary, and lateral glenohumeral radiographs are useful to rule out glenohumeral arthritis, which can also present with limited active and passive range of motion. However, adhesive capsulitis is usually a clinical diagnosis, and it does not need an extensive diagnostic work-up.

▶ Treatment

Adhesive capsulitis is caused by acute inflammation of the capsule followed by scarring and remodeling. During the acute “freezing” phase, NSAIDs and physical therapy are recommended to maintain motion. There is also evidence of short-term benefit from intra-articular corticosteroid injection or oral prednisone. One study demonstrated improvement at 6 weeks but not 12 weeks following 30 mg of daily prednisone for 3 weeks. During the “freezing” phase, the shoulder is less painful but remains stiff. Anti-inflammatory medication is not as helpful during the “thawing” phase as it is during the “freezing” phase, and the shoulder symptoms usually resolve with time. Surgical treatments include manipulation under anesthesia and arthroscopic release.

▶ When to Refer

- When the patient does not respond after more than 6 months of conservative treatment.
- When there is no progress or worsening range of motion over 3 months.

SPINE PROBLEMS

1. Low Back Pain

ESSENTIALS OF DIAGNOSIS

- ▶ The cause of back pain may be categorized by pain on flexion versus pain on extension.
- ▶ Nerve root impingement is suspected when pain is leg-dominant rather than back-dominant.
- ▶ Alarming signs for serious spinal disease include unexplained weight loss, failure to improve with treatment, severe pain for more than 6 weeks, and night or rest pain.
- ▶ The cauda equina syndrome often presents with bowel or bladder symptoms (or both) and is an emergency.

▶ General Considerations

Low back pain is the most common cause of disability for patients under the age of 45 and is the second most common cause for primary care visits. The annual prevalence of low back pain is 15–45%, and the annual cost in the United States is over \$50 billion. Approximately 80% of episodes of low back pain resolve within 2 weeks and 90% resolve within 6 weeks. The exact cause of the low back pain is often difficult to diagnose; its cause is often multifactorial, although there are usually degenerative changes in the lumbar spine.

Alarming symptoms for back pain caused by cancer include unexplained weight loss, failure to improve with treatment, pain for more than 6 weeks, and pain at night or rest. History of cancer and age > 50 years are other risk factors for malignancy. Alarming symptoms for infection include fever, rest pain, recent infection (urinary tract infection, cellulitis, pneumonia), or history of immunocompromise or injection drug use. The **cauda equina syndrome** is suggested by urinary retention or incontinence, saddle anesthesia, decreased anal sphincter tone or fecal incontinence, bilateral lower extremity weakness, and progressive neurologic deficits. Risk factors for back pain due to vertebral fracture include use of corticosteroids, age > 70 years, history of osteoporosis, recent significant trauma, or very severe focal pain. Back pain may also be the presenting symptom in other serious medical problems, including abdominal aortic aneurysm, peptic ulcer disease, kidney stones, and pancreatitis.

▶ Clinical Findings

A. Symptoms and Signs

The physical examination is best done with the patient in the standing, sitting, supine, and then prone positions to avoid frequent repositioning of the patient. In the standing position, the patient's posture can be observed. Commonly encountered spinal asymmetries include scoliosis, thoracic kyphosis, and lumbar hyperlordosis. The active range of motion of the lumbar spine can be assessed. The common directions include flexion, rotation, and extension. The one-leg standing extension test assesses for pain as the patient stands on one leg while extending the spine. A positive test can be caused by pars interarticularis fractures (spondylolysis or spondylolisthesis) or facet joint arthritis, although sensitivity and specificity of the test is limited.

In the sitting position, the major muscles in the lower extremities are assessed for weakness by eliciting a resisted isometric contraction for approximately 5 seconds. It is important to compare the strength bilaterally to detect subtle muscle weakness, including hip flexors (L1–2 nerve roots), knee extensors or quadriceps (L3), ankle dorsiflexors (L4–L5), first toe extensor or extensor hallucis longus (L5), knee flexors or hamstrings (S1), ankle plantar-flexors or calf muscles (S1), and hip extensors (S1). Sensory testing to light touch is done next for the following areas: groin (L1 nerve root), thigh (L2), knee (L3), lateral shin and medial ankle (L4), first dorsal web space of the foot between first and second toes (L5), lateral foot (S1), back of the thigh (S2), and perianal area (S3, S4, S5). Knee (femoral nerve L2–4), ankle (deep peroneal nerve L4–L5), and Babinski (sciatic nerve L5–S1) reflexes can be checked with the patient sitting.

In the supine position, the hip should be evaluated for range of motion, focusing on internal rotation. The straight leg raise test puts traction and compression forces on the lower lumbar nerve roots (Table 41–2).

Finally, in the prone position, the clinician can carefully palpate each level of the spine and sacroiliac joints for tenderness. A rectal examination is required if the cauda equina syndrome is suspected. Superficial skin tenderness to a light touch over the lumbar spine, overreaction to maneuvers in the regular back examination, low back pain on axial loading of spine in standing, inconsistency in the straight leg raise test or on the neurologic examination suggest nonorthopedic causes for the pain or malingering.

B. Imaging

In the absence of alarming “red flag” symptoms suggesting infection, malignancy, or cauda equina syndrome, diagnostic imaging, including radiographs, is not typically recommended in the first 6 weeks. If done, radiographs of the lumbar spine should include anteroposterior and lateral views. Oblique views can be useful if the neuroforamina or lesions need to be visualized. MRI is the method of choice in the evaluation of symptoms not responding to conservative treatment or in the presence of red flags of serious conditions.

Table 41-2. Spine: back examination.

Maneuver	Description
Inspection	Check the patient's posture in the standing position. Assess for hyperlordosis, kyphosis, and scoliosis.
Palpation	Include important landmarks: spinous process, facet joints, paravertebral muscles, sacroiliac joints, and sacrum.
Range of motion testing	Check range of motion actively (patient performs) and passively (clinician performs) especially with flexion and extension of the spine. Rotation and lateral bending are also helpful to assess symmetric motion or any restrictions.
Neurologic examination	Check motor strength, reflexes and dermatomal sensation in the lower extremities.
Straight leg raise test	The patient lies supine and the clinician elevates the patient's leg. A positive test for sciatica pain is classically described as "electric shock"-like pain radiating down the posterior aspect of the leg from the low back. This can occur in the setting of a disk herniation or degenerative conditions causing neural foraminal stenosis. Cross-over pain, where sciatica symptoms occur down the opposite leg during a straight leg raise, usually indicates a large disk herniation.
Indirect straight leg raise test	The patient sits on the side of the exam table with the knees bent. The clinician extends the knee fully. A positive test for sciatica pain is classically described as "electric shock"-like pain radiating down the posterior aspect of the leg from the low back. Cross-over pain, where sciatica symptoms occur down the opposite leg during a straight leg raise, usually indicates a large disk herniation.

C. Special Tests

Electromyography or nerve conduction studies may be useful in assessing patients with possible nerve root symptoms lasting longer than 6 weeks; back pain may or may not also be present. These tests are usually not necessary if the diagnosis of radiculopathy is clear.

► Treatment

A. Conservative

Nonpharmacologic treatments are key in the management of low back pain. Education alone improves patient satisfaction with recovery and recurrence. Patients require information and reassurance when diagnostic procedures are not necessary. Discussion must include reviewing safe and effective methods of symptom control as well as how to decrease the risk of recurrence with proper lifting techniques, abdominal wall/core strengthening, weight loss, and smoking cessation. Strengthening and stabilization effectively reduce pain and functional limitation compared with usual care.

Physical therapy exercise programs can be tailored to the patient's symptoms and pathology. Spinal manipulation has short-term benefits if therapy is started within 6 weeks of onset of low back pain without radiculopathy. Heat and cold treatments have not shown any long-term benefits but may be used for symptomatic treatment. The efficacy of transcutaneous electrical nerve stimulation (TENS), back braces, physical agents, and acupuncture is unproven. Improvements in posture, core stability strengthening, physical conditioning, and modifications of activities to decrease physical strain are keys for ongoing management.

NSAIDs are effective in the early treatment of low back pain (see Chapter 20). There is limited evidence that muscle

relaxants can provide short-term relief; since these medications have addictive potential, they should be used with care. Muscle relaxants are best used if there is true muscle spasm that is painful rather than simply a protective response. Opioids may be necessary to alleviate pain immediately. Treatment of more chronic neuropathic pain with gabapentin and tricyclic antidepressants may be helpful.

B. Surgical

Surgical indications for back surgery include cauda equina syndrome, ongoing morbidity with no response to > 6 months of conservative treatment, cancer, infection, or severe spinal deformity. Prognosis is improved when there is an anatomic lesion that can be corrected and symptoms are neurologic. Spinal surgery has limitations. Patient selection is very important and the specific surgery recommended should have very clear indications. Patients should understand that surgery can improve their pain but is unlikely to cure it. Surgery is not generally indicated for radiographic abnormalities alone when the patient is asymptomatic. Depending on the surgery performed, possible complications include persistent pain; surgical site pain, especially if bone grafting is needed; infection; neurologic damage; non-union; cutaneous nerve damage; implant failure; deep venous thrombosis; and death.

► When to Refer

- Patients with the cauda equina syndrome.
- Patients with cancer, infection, or severe spinal deformity.
- Patients who have not responded to conservative treatment.

2. Spinal Stenosis

ESSENTIALS OF DIAGNOSIS

- ▶ Pain is usually worse with back extension and relieved by sitting.
- ▶ Occurs in older patients.
- ▶ May present with neurogenic claudication symptoms with walking.

▶ General Considerations

Osteoarthritis in the lumbar spine can cause narrowing of the spinal canal. A large disk herniation can also cause stenosis and compression of neural structures or the spinal artery resulting in “claudication” symptoms with ambulation. The condition usually affects patients aged 50 years or older.

▶ Clinical Findings

Patients report pain that worsens with extension. They describe reproducible single or bilateral leg symptoms that are worse after walking several minutes and that are relieved by sitting (termed “neurogenic claudication”). On examination, patients often exhibit limited extension of the lumbar spine, which may reproduce the symptoms radiating down the legs. A thorough neurovascular examination is recommended.

▶ Treatment

Flexion-based exercises as demonstrated by a physical therapist can help relieve symptoms. Spinal or facet joint corticosteroid injections can also reduce pain symptoms. Spinal decompression (widening the spinal canal or laminectomy), nerve root decompression (freeing a single nerve), and spinal fusion (joining the vertebra to eliminate motion and diminish pain from the arthritic joints) have not been shown to be superior to natural history, placebo treatment, or conservative management of degenerative lumbar disk disease (spondylosis). Some evidence suggests that instrumentation (adding surgical hardware to a spinal fusion) leads to a higher fusion rate, but there is no evidence that it makes any difference to clinical outcomes.

▶ When to Refer

- If a patient exhibits radicular or claudication symptoms > 12 weeks.
- MRI or CT confirmation of significant spinal stenosis.

Ammendolia C et al. Non-Operative Treatment for Lumbar Spinal Stenosis with Neurogenic Claudication: A Systematic Review. *Spine (Phila Pa 1976)*. 2012 May 1;37(10):E 609–E616.

3. Lumbar Disk Herniation

ESSENTIALS OF DIAGNOSIS

- ▶ Pain with back flexion or prolonged sitting.
- ▶ Radicular pain with compression of neural structures.
- ▶ Lower extremity numbness.
- ▶ Lower extremity weakness.

▶ General Considerations

Lumbar disk herniation is usually due to bending or heavy loading (eg, lifting) with the back in flexion, causing herniation or extrusion of disk contents (nucleus pulposus) into the spinal cord area. However, there may not be an inciting incident. Disk herniations usually occur from degenerative disk disease (desiccation of the annulus fibrosus) in patients between 30- and 50-years-old. The L5–S1 disk is affected in 90% of cases. Compression of neural structures, such as the sciatic nerve, causes radicular pain. Severe compression of the spinal cord can cause the cauda equina syndrome, a surgical emergency (see above).

▶ Clinical Findings

A. Symptoms and Signs

Discogenic pain typically is localized in the low back at the level of the affected disk and is worse with activity. “Sciatica” causes electric shock-like pain radiating down the posterior aspect of the leg often to below the knee. Symptoms usually worsen with back flexion such as bending or sitting for long periods (eg, driving). A significant disk herniation can cause numbness and weakness, including weakness with plantar flexion of the foot (L5/S1) or dorsiflexion of the toes (L4/L5). The cauda equina syndrome should be ruled out if the patient complains of perianal numbness or bowel or bladder incontinence.

B. Imaging

Plain radiographs are helpful to assess spinal alignment (scoliosis, lordosis), disk space narrowing, and osteoarthritis

changes. MRI is the best method to assess the level and morphology of the herniation and is recommended if surgery is planned.

► Treatment

For an acute exacerbation of pain symptoms, bed rest is appropriate for up to 48 hours. Otherwise, first-line treatments include modified activities; NSAIDs and other analgesics; and physical therapy, including core stabilization and McKenzie exercises. Epidural and transforaminal corticosteroid injections can be beneficial, especially in relieving acute radicular pain, although the benefit tends to last only 3 months. These injections may be effective in delaying surgery for chronic low back pain. Oral prednisone can reduce inflammation and is useful in reducing symptoms of acute sciatica; the initial dose is approximately 1 mg/kg once daily with tapering doses over 10 days. Co-analgesics for neuropathic pain, such as the calcium channel α_2 - δ ligands (ie, gabapentin, pregabalin) or tricyclic antidepressants, may be helpful (see Chapter 5).

A large, ongoing trial has shown that patients who underwent surgery for a lumbar disk herniation achieved greater improvement than conservatively treated patients in all primary and secondary outcomes except return to work status after 4 year follow-up.

► When to Refer

- Cauda equina syndrome.
- Progressive worsening of neurologic symptoms.
- Loss of motor function (sensory losses can be followed in the outpatient clinic).

4. Neck Pain

ESSENTIALS OF DIAGNOSIS

- Poor posture is often a factor for persistent neck pain.
- Degenerative disk disease is a typical underlying cause for neck pain.
- Cervical radiculopathy symptoms can be referred to the shoulder, arm, or upper back.
- Pain is usually worse with back extension and relieved by sitting.

► General Considerations

Most neck pain, especially in older patients, is due to mechanical degeneration involving the cervical disks, facet joints, and ligamentous structures and may occur in the setting of degenerative changes at other sites as well. Pain can also come from the supporting neck musculature, which often acts to protect the underlying neck structures. Posture is a very important factor, especially in younger patients. Many work-related neck symptoms are due to poor posture and repetitive motions over time. Acute injuries can also occur secondary to trauma. For example, whiplash occurs in 15–40% of motor vehicle accidents, with chronic pain developing in 5–7%. Neck fractures are serious traumatic injuries acutely and can lead to osteoarthritis in the long term. Ultimately, many degenerative conditions of the neck result in cervical canal stenosis or neural foraminal stenosis, sometimes affecting underlying neural structures. Cervical radiculopathy can cause neurologic symptoms in the upper extremities usually deriving from disease of the C5–C7 disks. Patients with neck pain may report associated headaches and shoulder pain. Thoracic outlet syndrome, in which there is mechanical compression of the brachial plexus and neurovascular structures with overhead positioning of the arm, should be considered in the differential diagnosis of neck pain.

► Clinical Findings

A. Symptoms and Signs

The patient's posture should be assessed, checking for shoulder rolled forward or head forward posture as well as scoliosis in the thoracolumbar spine. Patients with discogenic neck pain often complain of pain with flexion, which causes cervical disks to herniate posteriorly. Extension of the neck usually affects the neural foraminal and facet joints of the neck. Rotation and lateral flexion of the cervical spine should be measured both to the left and the right. A detailed neurovascular examination of the upper extremities should be performed, including sensory input to light touch and temperature; motor strength testing, especially the hand intrinsic muscles (thumb extension strength [C6], opponens strength (thumb to pinky) [C7], and finger abductors and adductors strength [C8–T1]); and upper extremity reflexes (biceps, triceps, brachioradialis). True cervical radiculopathy symptoms should match an expected dermatomal or myotomal distribution. The **Spurling test** involves asking the patient to rotate and extend the neck to one side (Table 41–3). The clinician can apply a gentle axial load to the neck. Reproduction of the cervical radiculopathy symptoms is a positive sign of nerve root compression. Palpation of the neck is best performed with the patient in the supine position where the clinician can palpate each level of the cervical spine with the muscles of the neck relaxed.

B. Imaging

Radiographs of the cervical spine can assist in determining the area of degenerative changes. Useful views include the anteroposterior and lateral view of the cervical spine. The

Table 41-3. Spine: neck examination.

Maneuver	Description
Inspection	Check the patient's posture in the standing position. Assess for cervical hyperlordosis, head forward posture, kyphosis, scoliosis, torticollis.
Palpation	Include important landmarks: spinous process, facet joints, paracervical muscles (sternocleidomastoid, scalene muscles).
Range of motion testing	Check range of motion in the cervical spine, especially with flexion and extension. Rotation and lateral bending are also helpful to assess symmetric motion or any restrictions. Pain and radicular symptoms can be exacerbated by range of motion testing.
Neurologic examination	Check motor strength, reflexes and dermatomal sensation in the upper (and lower if necessary) extremities.
Spurling test	Involves asking the patient to rotate and extend the neck to one side. The clinician can apply a gentle axial load to the neck. Reproduction of the cervical radiculopathy symptoms is a positive sign of nerve root compression.

odontoid view is usually added to rule out traumatic fractures and congenital abnormalities. Oblique views of the cervical spine can provide further information about arthritis changes and assess the neural foramina for narrowing.

CT scanning is the most useful method if bony abnormalities, such as fractures, are suspected. MRI is the best method to assess the cervical spine since the soft tissue structures (such as the disks, spinal cord, and nerve roots) can be evaluated. If the patient has signs of cervical radiculopathy with motor weakness, these more sensitive imaging modalities should be obtained urgently.

▶ Treatment

A course of neck stretching, strengthening and postural exercises in physical therapy have demonstrated benefit in relieving symptoms. Chiropractic manual manipulation and mobilization can provide short-term benefit for mechanical neck pain. Although the rate of complications is low (5–10/million manipulations), care should be taken whenever there are neurologic symptoms present. Specific patients may respond to use of home cervical traction. A soft cervical collar can be useful for short-term use (up to 1–2 weeks) in acute neck injuries. NSAIDs are commonly used and opioids may be needed in cases of severe neck pain. Muscle relaxants (eg, cyclobenzaprine 5–10 mg orally three times daily) can be used short-term if there is muscle spasm or as a sedative to aid in sleeping. Acute radicular symptoms can be treated with neuropathic medications (eg, gabapentin 300–1200 mg orally three times daily), and a short course of oral prednisone (5–10 days) can be considered (starting at 1 mg/kg). Cervical foraminal or

facet joint injections can also reduce symptoms. Surgeries are successful in reducing neurologic symptoms in 80–90% of cases but are still considered as treatments of last resort.

▶ When to Refer

- Patients with severe symptoms with motor weakness.
- Surgical decompression surgery if the symptoms are severe and there is identifiable, correctable pathology.

UPPER EXTREMITY

1. Lateral & Medial Epicondylitis

ESSENTIALS OF DIAGNOSIS

- ▶ Tenderness over the lateral or medial epicondyle.
- ▶ Diagnosis of tendinopathy is confirmed by pain with resisted strength testing and passive stretching of the affected tendon and muscle unit.
- ▶ Physical therapy and activity modification are more successful than anti-inflammatory treatments.

▶ General Considerations

Tendinopathy involving the wrist extensors, flexors, and pronators are very common complaints. The underlying mechanism is chronic repetitive overuse causing microtrauma at the tendon insertion, although acute injuries can occur as well if the tendon is strained due to excessive loading. The traditional term “epicondylitis” is a misnomer because histologically tendinosis or degeneration in the tendon is seen rather than acute inflammation. Therefore, these entities should be referred to as “tendinopathy” or “tendinosis.” Lateral epicondylitis involves the wrist extensors, especially the extensor carpi radialis brevis. This is usually caused by lifting with the wrist and the elbow extended. Medial epicondylitis involves the wrist flexors and most commonly the pronator teres tendon. Ulnar neuropathy and cervical radiculopathy should be considered in the differential diagnosis.

▶ Clinical Findings

A. Symptoms and Signs

For lateral epicondylitis, the patient describes pain with the arm and wrist extended. For example, common complaints include pain while shaking hands, lifting

objects, using a computer mouse, or hitting a backhand in tennis (“tennis elbow”). Medial epicondylitis presents with pain during motions in which the arm is repetitively pronated or the wrist is flexed. This is also known as “golfer’s elbow” due to the motion of turning the hands over during the golf swing. On examination, tenderness directly over the epicondyle is present, especially over the posterior aspect where the tendon insertion occurs. The proximal tendon and musculotendinous junction can also be sore. To confirm that the pain is due to tendinopathy, pain can be reproduced over the epicondyle with resisted wrist extension and third digit extension for lateral epicondylitis and resisted wrist pronation and wrist flexion for medial epicondylitis. The pain is also often reproduced with passive stretching of the affected muscle groups, which can be performed with the arm in extension. It is useful to check the ulnar nerve (located in a groove at the posteromedial elbow) for tenderness as well as to perform a Spurling test for cervical radiculopathy.

B. Imaging

Radiographs are often normal, although a small traction spur may be present in chronic cases (enthesopathy). Diagnostic investigations are usually unnecessary, unless the patient does not improve after up to 3 months of conservative treatment. At that point, a patient who demonstrates significant disability due to the pain should be assessed with an MRI or ultrasound. Ultrasound and MRI can visualize the tendon and confirm tendinosis or tears.

► Treatment

Treatment is usually conservative, including patient education regarding activity modification and management of symptoms. Ice and NSAIDs can help with pain. The most important steps are to begin a good stretching program followed by strengthening exercises. Counterforce elbow braces might provide some symptomatic relief, although there is no published evidence to support their use. If the patient has severe or long-standing symptoms, a course of physical therapy should be performed. Corticosteroid injection offers some short-term improvement. However, physical therapy and rehabilitative exercises are still the mainstays of treatment. Treatments such as extracorporeal shock wave therapy and injectable medications other than corticosteroids have not shown clear long-term benefit.

► When to Refer

Patients not responding to 6 months of conservative treatment should be referred for surgical debridement or repair of the tendon.

Bisset L et al. Mobilisation with movement and exercise, corticosteroid injection, or wait and see for tennis elbow: randomised trial. *BMJ*. 2006 Nov 4;333(7575):939. [PMID: 17012266]

Calfee RP et al. Management of lateral epicondylitis: current concepts. *J Am Acad Orthop Surg*. 2008 Jan;16(1):19–29. [PMID: 18180389]

2. Carpal Tunnel Syndrome

ESSENTIALS OF DIAGNOSIS

- Pain, burning, and tingling in the distribution of the median nerve.
- Initially, most bothersome during sleep.
- Late weakness or atrophy, especially of the thenar eminence.
- Can be caused by repetitive activities using the wrist.
- Commonly seen during pregnancy and in patients with diabetes mellitus or rheumatoid arthritis.

► General Considerations

An entrapment neuropathy, carpal tunnel syndrome is a painful disorder caused by compression of the median nerve between the carpal ligament and other structures within the carpal tunnel. The contents of the tunnel can be compressed by synovitis of the tendon sheaths or carpal joints, recent or malhealed fractures, tumors, tissue infiltration, and occasionally congenital syndromes (eg, mucopolysaccharidoses). Even though no anatomic lesion is apparent, flattening or even circumferential constriction of the median nerve may be observed during operative section of the overlying carpal ligament. The disorder may occur in fluid retention of pregnancy, in individuals with a history of repetitive use of the hands, or following injuries of the wrists. There is a familial type of carpal tunnel syndrome in which no etiologic factor can be identified. Carpal tunnel syndrome can also be a feature of many systemic diseases, such as rheumatoid arthritis and other rheumatic disorders (inflammatory tenosynovitis), myxedema, amyloidosis, sarcoidosis, leukemia, acromegaly, and hyperparathyroidism.

► Clinical Findings

A. Symptoms and Signs

The initial symptoms are pain, burning, and tingling in the distribution of the median nerve (the palmar surfaces of the thumb, the index and long fingers, and the radial half of the ring finger). Aching pain may radiate proximally into the forearm and occasionally proximally to the shoulder and over the neck and chest. Pain is exacerbated by manual activity, particularly by extremes of volar flexion or dorsiflexion of the wrist. It is most bothersome at night. Impairment of sensation in the median nerve distribution may or may not be demonstrable. Subtle disparity between the affected and opposite sides can be shown by testing for two-point discrimination or by requiring the patient to identify different textures of cloth by rubbing them between the tips of the thumb and the index finger. A Tinel or Phalen sign may be positive. A **Tinel sign** is tingling or shock-like pain on volar wrist percussion (Table 41–4). The **Phalen sign** is pain or paresthesia in the distribution of the

Table 41-4. Wrist examination.

Maneuver	Description
Inspection	Examine for the alignment of the wrist and fingers SEADS
Palpation	Include important landmarks: scaphoid “snuff box,” distal radius, scapholunate ligament, hook of hamate, ulnar joint line, distal radioulnar joint
Range of motion testing	Check range of motion actively (patient performs) and passively (clinician performs) especially with flexion and extension of the wrist. Ulnar and radial deviation and circumduction of the wrist can be screened.
Neurovascular examination	Check motor strength and dermatomal sensation in the fingers in the radial (thumb), median (3rd finger) and ulnar distribution (5th finger). Check capillary refill to digits as well as radial pulse.
Tinel sign	Tingling or shock-like pain on volar wrist percussion. The carpal compression test, in which numbness and tingling are induced by the direct application of pressure over the carpal tunnel, may be more sensitive and specific than the Tinel and Phalen tests.
Phalen sign	Pain or paresthesia in the distribution of the median nerve when the patient flexes both wrists to 90 degrees for 60 seconds.
Carpel compression test	Performed by applying direct application of pressure over the carpal tunnel.

SEADS, swelling, erythema, atrophy, deformity, and (surgical) scars.

median nerve when the patient flexes both wrists to 90 degrees for 60 seconds (Table 41-4). The **carpal compression test**, in which numbness and tingling are induced by the direct application of pressure over the carpal tunnel, may be more sensitive and specific than the Tinel and Phalen tests (Table 41-4). Muscle weakness or atrophy, especially of the thenar eminence, can appear later than sensory disturbances as compression of the nerve worsens.

B. Imaging

Ultrasound can demonstrate flattening of the median nerve beneath the flexor retinaculum. Sensitivity of ultrasound for carpal tunnel syndrome is variable but estimated between 54% and 98%.

C. Special Tests

Electromyography and nerve conduction studies show evidence of sensory conduction delay before motor delay, which can occur in severe cases. This syndrome should be differentiated from other cervicobrachial pain syndromes,

from compression syndromes of the median nerve in the forearm or arm, and from mononeuritis multiplex. When left-sided, it may be confused with angina pectoris.

► Treatment

Treatment is directed toward relief of pressure on the median nerve. When a causative lesion is discovered, it should be treated appropriately. Otherwise, patients in whom carpal tunnel syndrome is suspected should modify their hand activities and have the affected wrist splinted in the neutral position for up to 3 months. Oral corticosteroids or NSAIDs can also be tried. Carpal tunnel release surgery can be beneficial if the patient has a positive electrodiagnostic test, at least moderate symptoms, high clinical probability, unsuccessful nonoperative treatment, and symptoms lasting longer than 12 months.

► When to Refer

- If symptoms persist > 3 months despite conservative treatment, including the use of a wrist splint.
- If thenar muscle (eg, abductor pollicis brevis) weakness or atrophy develops.

HIP

1. Hip Fractures

ESSENTIALS OF DIAGNOSIS

- Internal rotation of the hip is the best provocative diagnostic maneuver.
- Hip fractures should be surgically repaired as soon as possible (within 24 hours).
- Delayed treatment of hip fractures in the elderly leads to increased complications and mortality.

► General Considerations

Approximately 4% of the 7.9 million fractures that occur each year in the United States are hip fractures. There is a high mortality rate among elderly patients following hip fracture, with death occurring in 8–9% within 30 days and in approximately 25–30% within 1 year. Osteoporosis, female sex, height > 5-foot 8-inches, and age over 50 years are risk factors for hip fracture. Hip fractures usually occur after a fall. High velocity trauma is needed in younger patients. Stress fractures can occur in athletes or individuals with

poor bone mineral density following repetitive loading activities.

► Clinical Findings

A. Symptoms and Signs

Patients typically report pain in the groin, though pain radiating to the lateral hip, buttock, or knee can also commonly occur. If a displaced fracture is present, the patient will not be able to bear weight and the leg may be externally rotated. Gentle logrolling of the leg with the patient supine helps rule out a fracture. Examination of the hip demonstrates pain with deep palpation in the area of the femoral triangle (similar to palpating the femoral artery). Provided the patient can tolerate it, the clinician can, with the patient supine, flex the hip to 90 degrees with the knee flexed to 90 degrees. The leg can then be internally and externally rotated to assess the range of motion on both sides. Pain with internal rotation of the hip is the most sensitive test to identify intra-articular hip pathology. Hip flexion, extension, abduction, and adduction strength can be tested.

Patients with hip stress fractures have less pain on physical examination than described previously but typically have pain with weight bearing. The Trendelenburg test can be performed to examine for weakness or instability of the hip abductors, primarily the gluteus medius muscle (Table 41–5). Another functional test is asking the patient to hop or jump during the examination. If the patient has a compatible clinical history of pain and is unable or unwilling to hop, then a stress fracture should be ruled out. The back should be carefully examined in

patients with hip complaints, including examining for signs for sciatica.

Following displaced hip fractures, a thorough medical evaluation and treatment should be pursued to maximize the patients' ability to undergo operative intervention. Patients who are unable to get up by themselves may have been immobile for hours or even days following their falls. Thus, clinicians must exclude rhabdomyolysis, hypothermia, deep venous thrombosis, pulmonary embolism, and other conditions that can occur with prolonged immobilization. Delay of operative intervention leads to an increased risk of perioperative morbidity and mortality.

B. Imaging

Useful radiographic views of the hip include anteroposterior views of the pelvis and bilateral hips and frog-leg lateral views of the painful hip. A CT scan or MRI may be necessary to identify the hip fracture pattern or to evaluate non-displaced fractures. Hip fractures are generally described by location, including femoral neck, intertrochanteric, or subtrochanteric.

► Treatment

Almost all patients with a hip fracture will require surgery and may need to be admitted to hospital for pain control while they await surgery. Surgery is recommended within the first 24 hours because studies have shown that delaying surgery 48 hours results in at least twice the rate of major and minor medical complications, including pneumonia, decubitus ulcers, and deep venous thrombosis.

Stress fractures in active patients require a period of protected weight-bearing and a gradual return to activities, although it may take 4–6 months before a return to normal activities. Femoral neck fractures are commonly treated with hemiarthroplasty or total hip replacement. This allows the patient to begin weight-bearing immediately postoperatively. Peritrochanteric hip fractures are treated with open reduction internal fixation, where plate and screw construct or intramedullary devices are used. The choice of implant will depend on the fracture pattern. Since fracture fixation requires the fracture to proceed to union, the patient may need to have protected weight-bearing during the early postoperative period. Dislocation, periprosthetic fracture, and avascular necrosis of the hip are common complications after surgery.

Patients should be mobilized as soon as possible postoperatively to avoid pulmonary complications and decubitus ulcers. Supervised physical therapy and rehabilitation is important for the patient to regain as much function as possible. Unfortunately, most patients following hip fractures will lose some degree of independence.

► Prevention

Bone density screening can identify patients at risk for osteopenia or osteoporosis, and treatment can be planned accordingly. Nutrition (calcium and vitamin D intake) and bone health (bone densitometry, serum calcium and 25-OH vitamin D levels) should be reviewed with the

Table 41–5. Hip examination.

Maneuver	Description
Inspection	Examine for the alignment of the lower extremity, consider lumbar spine exam
Palpation	Include important landmarks: ASIS and AIIIS (proximal quadriceps muscle insertions), greater trochanter (gluteal tendon insertions and bursa), anterior femoral triangle (hip joint and hip flexion insertion), ischial tuberosity (hamstring tendon insertion), sacroiliac joints
Range of motion testing	Check range of motion passively (clinician performs) especially internal and external rotation of the hip
Hip strength testing	Test resisted hip flexion, extension, abduction and adduction strength manually
Trendelenburg test	The patient balances first on one leg, raising the non-standing knee toward the chest. The clinician can stand behind the patient and observe for dropping of the pelvis and buttock on the non-stance side.

AIIIS, anterior inferior iliac spine; ASIS, anterior superior iliac spine.

patient (see Chapter 26). For patients with decreased mobility, systemic anticoagulation with low-molecular-weight heparin or warfarin should be considered to avoid deep venous thrombosis (see Table 14–13). Fall prevention exercise programs are available for elderly patients at risk for falls and hip fractures. Hip protectors are uncomfortable and have less use in preventing fractures.

► When to Refer

All patients in whom hip fracture is suspected.

Forte ML et al. Ninety-day mortality after intertrochanteric hip fracture: does provider volume matter? *J Bone Joint Surg Am.* 2010 Apr;92(4):799–806. [PMID: 20360501]

Lowe JA et al. Optimal treatment of femoral neck fractures according to patient's physiologic age: an evidence-based review. *Orthop Clin North Am.* 2010 Apr;41(2):157–66. [PMID: 20399355]

2. Osteoarthritis

ESSENTIALS OF DIAGNOSIS

- Pain deep in the groin on the affected side.
- Swelling.
- Degeneration of joint cartilage.
- Loss of active and passive range of motion in severe osteoarthritis.

► General Considerations

In the United States, the prevalence of osteoarthritis will grow as the number of persons over age 65 years doubles to more than 70 million by 2030. Cartilage loss and osteoarthritis symptoms are preceded by damage to the collagen-proteoglycan matrix. The etiology of osteoarthritis is often multifactorial, including previous trauma, prior high-impact activities, genetic factors, obesity, and rheumatologic or metabolic conditions.

► Clinical Findings

A. Symptoms and Signs

Osteoarthritis usually causes pain in the affected joint with loading of the joint or at the extremes of motion. Mechanical symptoms—such as swelling, grinding, catching, and locking—suggest internal derangement, which is indicated by damaged cartilage or bone fragments that affect the smooth range of motion expected at an articular joint. Pain can also produce the sensation of “buckling” or “giving way” due to muscle inhibition. As the joint degeneration becomes more advanced, the patient loses active range of motion and may lose passive range of motion as well.

Patients complain of pain deep in the groin on the affected side and have problems with weight-bearing activities such as walking, climbing stairs, and getting up

from a chair. They may limp and develop a lurch during their gait, leaning toward the affected side as the walk to reduce pressure on the hip.

B. Imaging

Weight-bearing radiographs of the affected hip are preferred for evaluation of hip osteoarthritis. To reduce radiation exposure, obtain an anteroposterior weight-bearing radiograph of the pelvis with a lateral view of the symptomatic hip. Joint space narrowing and sclerosis suggest early osteoarthritis, while osteophytes near the femoral head or acetabulum and subchondral bone cysts are more advanced changes.

► Treatment

A. Conservative

Changes in the articular cartilage are irreversible. Therefore, a cure for the diseased joint is not possible, although symptoms or structural issues can be addressed to try to maintain activity level. Conservative treatment for patients with osteoarthritis includes activity modification, therapeutic exercises, weight loss, and use of assistive devices (such as a cane). Lifestyle modifications also include proper footwear and avoidance of high impact activities.

Analgesics may be effective in some cases. Corticosteroid injections can be considered for short-term relief of pain; however, hip injections are best performed under fluoroscopic, ultrasound, or CT guidance to ensure accurate injection in the joint. Use of viscosupplementation in the hip has been studied with modest improvements; however, it remains an off-label use at this time.

B. Surgical

Two published randomized trials demonstrate that arthroscopy does not improve outcomes at 1 year over placebo or routine conservative treatment of osteoarthritis. Arthroscopic surgery is indicated in patients with osteoarthritis if, rather than pain, they have mechanical symptoms and internal derangement symptoms that can be removed as the main complaint. Such surgical treatments are useful to restore range of motion by removing osteophytes, cartilage fragments, or loose bodies.

Joint replacement surgeries are effective and cost-effective for patients with significant symptoms and functional limitations, providing improvements in pain, function, and quality of life. Minimally invasive surgeries and computer-assisted navigation during operation are being investigated as methods to improve techniques (eg, accurate placement of the hardware implant) and to reduce complication rates.

Hip resurfacing surgery is a newer joint replacement technique. Rather than use a traditional artificial joint implant of the whole neck and femur, only the femoral head is removed and replaced. Concerns following resurfacing surgery include the risk of femoral neck fracture and collapse of the head. The cumulative survival rate of this implant at 10 years from recent studies is estimated to be 94%. Evidence so far suggests that hip resurfacing is

comparable to total hip replacement and is a viable alternative for younger patients.

► When to Refer

Patients with sufficient disability, limited benefit from conservative therapy, and evidence of severe osteoarthritis can be referred for joint replacement surgery.

KNEE

1. Knee Pain

ESSENTIALS OF DIAGNOSIS

- ▶ Effusion can occur with intra-articular pathology, such as osteoarthritis, and meniscus and cruciate ligament tears.
- ▶ Acute knee swelling (hemarthrosis) within 2 hours may indicate ligament injuries or patellar dislocation or fracture.

► General Considerations

The knee is the largest joint in the body and is susceptible to injury from trauma, inflammation, infection, and degenerative changes. The knee is a hinge joint. The joint line exists between the femoral condyles and tibial plateaus. Separating and cushioning these bony surfaces is the lateral and medial meniscal cartilage, which functions as a shock absorber during weight bearing, protecting the articular cartilage. The patella is a large sesamoid bone anterior to the joint. It is embedded in the quadriceps tendon, and it articulates with the trochlear groove of the femur. Poor patellar tracking in the trochlear groove is a common source of knee pain especially when the cause is atraumatic in nature. The knee is stabilized by the collateral ligaments against varus (lateral collateral ligament) and valgus (medial collateral ligament) stresses. The tibia is limited in its anterior movement by the anterior cruciate ligament (ACL) and in its posterior movement by the posterior cruciate ligament (PCL). The bursae of the knee are located between the skin and bony prominences. They are sac-like structures with a synovial lining. They act to decrease friction of tendons and muscles as they move over adjacent bony structures. Excessive external pressure or friction can lead to swelling and pain of the bursae. The prepatellar bursae (located between the skin and patella), and the pes

anserine bursa (which is medial and inferior to the patella, just below the tibial plateau) are most commonly affected. Joint fluid, when excessive due to synovitis or trauma, can track posteriorly through a potential space, resulting in a popliteal cyst (also called a Baker cyst). Other structures that are susceptible to overuse injury and may cause knee pain following repetitive activity include the patellofemoral joint and the iliotibial band. Osteoarthritis of the knees is common after 50 years of age and can develop due to previous trauma, aging, activities, alignment issues, and genetic predisposition.

► Clinical Findings

A. Symptoms and Signs

Evaluation of knee pain should begin with general questions regarding duration and rapidity of symptom onset and the mechanism of injury or aggravating symptoms. Overuse or degenerative problems can occur with stress or compression from sports, hobbies, or occupation. A history of trauma, previous orthopedic problems with, or surgery to, the affected knee should also be specifically queried. Symptoms of infection (fever, recent bacterial infections, risk factors for sexually transmitted infections [such as gonorrhea] or other bacterial infections [such as staphylococcal infection]) should always be elicited.

Common symptom complaints include the following:

1. Presence of grinding, clicking, or popping with bending, may be indicative of osteoarthritis or the patellofemoral syndrome.
2. “Locking” or “catching” when walking suggests an internal derangement, such as meniscal injury or a loose body in the knee.
3. Intra-articular swelling of the knee or an effusion indicates an internal derangement or a synovial pathology. Large swelling may cause a popliteal (Baker) cyst. Acute swelling within minutes to hours suggests a hemarthrosis, most likely due to an ACL injury, fracture or patellar dislocation, especially if trauma is involved.
4. Lateral “snapping” with flexion and extension of the knee may indicate inflammation of the iliotibial band.
5. Pain that is worsened with bending and walking downstairs suggests issues with the patellofemoral joint, usually degenerative such as chondromalacia of the patella or osteoarthritis.
6. Pain that occurs when rising after prolonged sitting suggests a problem with tracking of the patella.

A careful history, coupled with a physical examination that includes observation, palpation and range of motion testing, as well as specific tests for particular anatomic structures is frequently sufficient to establish a diagnosis. When there is a knee joint effusion caused by increased fluid in the intra-articular space, physical examination will demonstrate swelling in the hollow or dimple around the patella and distention of the suprapatellar space.

Table 41–6 shows the differential diagnosis of knee pain, and Table 41–7 outlines possible diagnoses based on the location of pain.

Table 41-6. Differential diagnosis of knee pain.

Mechanical dysfunction or disruption
Internal derangement of the knee: injury to the menisci or ligaments
Degenerative changes caused by osteoarthritis
Dynamic dysfunction or misalignment of the patella
Fracture as a result of trauma
Intra-articular inflammation or increased pressure
Internal derangement of the knee: injury to the menisci or ligaments
Inflammation or infection of the knee joint
Ruptured popliteal (Baker) cyst
Peri-articular inflammation
Internal derangement of the knee: injury to the menisci or ligaments
Prepatellar or anserine bursitis
Ligamentous sprain

B. Laboratory Findings

Laboratory testing of aspirated joint fluid, when indicated, can lead to a definitive diagnosis in most patients.

C. Imaging

Knee pain is evaluated with plain (weight-bearing) radiographs and MRI most commonly, but CT and ultrasound are sometimes useful.

An acute hemarthrosis represents bloody swelling that usually occurs within the first 1–2 hours following trauma. In situations where the trauma may be activity-related and

not a result of a fall or collision, the differential diagnosis most commonly includes ACL tear (responsible for almost 50% of hemarthrosis in children and > 70% in adults), fracture (patella, tibial plateau, femoral supracondylar, growth plate [physeal]), and patellar dislocation. Meniscal tears are unlikely to cause large hemarthrosis.

2. Anterior Cruciate Ligament Injury

ESSENTIALS OF DIAGNOSIS

- ▶ An injury involving an audible pop when the knee buckles.
- ▶ Acute swelling immediately (or within 4 hours).
- ▶ Instability occurs with lateral movement activities and going down stairs.

▶ General Considerations

The anterior cruciate ligament (ACL) connects the posterior aspect of the lateral femoral condyle to the anterior aspect of the tibia. Its main function is to control anterior translation of the tibia on the femur. It also provides rotational stability of the tibia on the femur. ACL tears are common with sporting injuries. They can result from both contact (valgus blow to the knee) and non-contact (jumping, pivoting, and deceleration) activities. The patient usually falls down following the injury, has acute swelling and difficulty with weight-bearing, and complains of instability. ACL injuries are common in skiing, soccer, football, and basketball among young adolescents and middle-age patients. Pre-pubertal and older patients usually sustain fractures instead of ligamentous injuries.

▶ Clinical Findings

A. Symptoms and Signs

Acute ACL injuries usually lead to acute swelling of the knee, causing difficulty with motion. After the swelling has resolved, the patient can walk with a “stiff-knee” gait or quadriceps avoidance gait because of the instability. More importantly, patients describe symptoms of instability while performing side-to-side maneuvers or descending stairs. Stability tests assess the amount of laxity of the knee while performing side-to-side maneuvers or descending stairs. The **Lachman test** (84–87% sensitivity and 93% specificity) is performed with the patient lying supine and the knee flexed to 20–30 degrees (Table 41-8). The clinician grasps the distal femur from the lateral side and the proximal tibia with the other hand on the medial side. With the knee in neutral position, stabilize the femur, and pull the tibia anteriorly using a similar force to lifting a 10- to 15-pound weight. Excessive anterior translation of the tibia compared with the other side indicates injury to the ACL. The **anterior drawer test** (48% sensitivity and 87% specificity) is performed with the patient lying supine and the knee flexed to 90 degrees (Table 41-8). The clinician

Table 41-7. Location of common causes of knee pain.

Medial knee pain
Medial compartment osteoarthritis
Medial collateral ligament strain
Medial meniscal injury
Anserine bursitis (pain over the proximal medial tibial plateau)
Anterior knee pain
Patellofemoral syndrome (often bilateral)
Osteoarthritis
Prepatellar bursitis (associated with swelling anterior to the patella)
“Jumper’s knee” (pain at the inferior pole of the patella)
Septic arthritis
Gout or other inflammatory disorder
Lateral knee pain
Lateral meniscal injury
Iliotibial band syndrome (pain superficially along the distal iliotibial band near lateral femoral condyle or lateral tibial insertion)
Lateral collateral ligament sprain (rare)
Posterior knee pain
Popliteal (Baker) cyst
Osteoarthritis
Meniscal tears
Hamstring or calf tendinopathy

Table 41-8. Knee examination.

Maneuver	Description
Inspection	Examine for the alignment of the lower extremities (varus, valgus, knee recurvatum), ankle eversion and foot pronation, gait, SEADS.
Palpation	Include important landmarks: patellofemoral joint, medial and lateral joint lines (especially posterior aspects), pes anserine bursa, distal iliotibial band and Gerdy tubercle (iliotibial band insertion).
Range of motion testing 	Check range of motion actively (patient performs) and passively (clinician performs), especially with flexion and extension of the knee normally 0–10 degrees of extension and 120–150 degrees of flexion.
Knee strength testing	Test resisted knee extension and knee flexion strength manually.
Ligament stress tests	
Lachman test 	Performed with the patient lying supine, and the knee flexed to 20–30 degrees. The examiner grasps the distal femur from the lateral side, and the proximal tibia with the other hand on the medial side. With the knee in neutral position, stabilize the femur, and pull the tibia anteriorly using a similar force to lifting a 10–15 pound weight. Excessive anterior translation of the tibia compared with the other side indicates injury to the anterior cruciate ligament.
Anterior drawer 	Performed with the patient lying supine and the knee flexed to 90 degrees. The clinician stabilizes the patient's foot by sitting on it and grasps the proximal tibia with both hands around the calf and pulls anteriorly. A positive test finds anterior cruciate ligament laxity compared with the unaffected side.

(continued)

Table 41-8. Knee examination. (continued)

Maneuver	Description
<p data-bbox="107 290 193 314">Pivot shift</p> 	<p data-bbox="834 290 1266 469">Used to determine the amount of rotational laxity of the knee. The patient is examined while lying supine with the knee in full extension. It is then slowly flexed while applying internal rotation and a valgus stress. The clinician feels for a subluxation at 20-40 degrees of knee flexion. The patient must remain very relaxed to have a positive test.</p>
<p data-bbox="107 1157 214 1181">Valgus stress</p> 	<p data-bbox="834 1157 1256 1387">Performed with the patient supine. The clinician should stand on the outside of the patient's knee. With one hand, the clinician should hold the ankle while the other hand is supporting the leg at the level of the knee joint. A valgus stress is applied at the ankle to determine pain and laxity of the medial collateral ligament. The test should be performed at both 30 degrees and at 0 degrees of knee extension.</p>

(continued)

Table 41-8. Knee examination. (continued)

Maneuver	Description
<p>Varus stress</p> 	<p>The patient is again placed supine. For the right knee, the clinician should be standing on the right side of the patient. The left hand of the examiner should be holding the ankle while the right hand is supporting the lateral thigh. A varus stress is applied at the ankle to determine pain and laxity of the lateral collateral ligament. The test should be performed at both 30 degrees and at 0 degrees of knee flexion.</p>
<p>The sag sign</p>	<p>The patient is placed supine and both hips and knees are flexed up to 90 degrees. Because of gravity, the posterior cruciate ligament-injured knee will have an obvious set-off at the anterior tibia which is "sagging" posteriorly.</p>
<p>Posterior drawer</p>	<p>The patient is placed supine with the knee flexed at 90 degrees (see Anterior drawer figure above). In a normal knee, the anterior tibia should be positioned about 10 mm anterior to the femoral condyle. The clinician can grasp the proximal tibia with both hands and push the tibia posteriorly. The movement, indicating laxity and possible tear of the posterior cruciate ligament, is compared with the uninjured knee.</p>
<p>Meniscal signs</p>	
<p>McMurray test</p>	<p>Performed with the patient lying in supine. The clinician flexes the knee until the patient reports pain. For this test to be valid, it must be flexed pain-free beyond 90 degrees. The clinician externally rotates the patient's foot and then extends the knee while palpating the medial knee for "click" in the medial compartment of the knee or pain reproducing pain from a meniscus injury. To test the lateral meniscus, the same maneuver is repeated while rotating the foot internally (53% sensitivity and 59-97% specificity).</p>

(continued)

Table 41-8. Knee examination. (continued)

Maneuver	Description
<p>Modified McMurray</p> 	<p>Performed with the hip flexed to 90 degrees. The knee is then flexed maximally with internally or externally rotation of the lower leg. The knee can then be rotated with the lower leg in internal or external rotation to capture the torn meniscus underneath the condyles. A positive test is pain over the joint line while the knee is being flexed and internally or externally rotated.</p>
<p>Thessaly test</p> 	<p>Performed with the patient standing on one leg with knee slightly flexed. The patient is asked to twist the knee while standing on one leg. Pain can be elicited during twisting motion.</p>
<p>Patellofemoral joint test</p> <p>Apprehension sign</p>	<p>Suggests instability of the patellofemoral joint and is positive when the patient becomes apprehensive when the patella is deviated laterally.</p>

SEADS, swelling, erythema, atrophy, deformity, and (surgical) scars.

stabilizes the patient's foot by sitting on it and grasps the proximal tibia with both hands around the calf and pulls anteriorly. A positive test finds ACL laxity compared with the unaffected side. The **pivot shift** test is used to determine the amount of rotational laxity of the knee (Table 41–8). The patient is examined while lying supine with the knee in full extension. It is then slowly flexed while applying internal rotation and a valgus stress. The clinician feels for a subluxation at 20–40 degrees of knee flexion. The patient must remain very relaxed to have a positive test.

B. Imaging

Plain radiographs are usually negative in ACL tears but are useful to rule out fractures. A small avulsion injury can sometimes be seen over the lateral compartment of the knee. This is called a “segond” fracture and is pathognomonic of an ACL injury. MRI is the best method to diagnose ACL tears. It has > 95% sensitivity and specificity for ACL tears. MRI also allows evaluation of other associated structures, such as menisci and cartilages.

▶ Treatment

Most young and active patients will require surgical reconstruction of the ACL. Common surgical techniques use the patient's own tissues, usually the patellar or hamstring tendons (autograft) or a cadaver graft (allograft) to arthroscopically reconstruct the torn ACL. Different patients groups experienced improved results with specific surgical graft choices. Recovery from surgery usually requires 6 months.

Nonoperative treatments are usually reserved for older patients or those with a very sedentary lifestyle. Physical therapy can focus on hamstring strengthening and core stability. An ACL brace can help stability. Longitudinal studies have demonstrated that nonoperative management of an ACL tear can lead to a higher incidence of meniscus tears.

▶ When to Refer

- Almost all ACL tears should be referred to an orthopedic surgeon for evaluation.
- Individuals with instability in the setting of a chronic ACL tear (> 6 months) should be considered for surgical reconstruction.
- Patients with an ACL tear and associated meniscus or articular injuries may benefit from surgery to address the other injuries.

3. Collateral Ligament Injury

ESSENTIALS OF DIAGNOSIS

- ▶ Caused by a valgus or varus blow or stress to the knee.
- ▶ Pain and instability in the affected area.
- ▶ Limited range of motion.

▶ General Considerations

The medial collateral ligament (MCL) is the most commonly injured ligament in the knee. It is usually injured with a valgus stress to the partially flexed knee. It can also occur with a blow to the lateral leg. The MCL is commonly injured with acute ACL injuries. The lateral collateral ligament (LCL) is less commonly injured, but this can occur with a medial blow to the knee. Since both collateral ligaments are extra-articular, injuries to these ligaments may not lead to any intra-articular effusion. Affected patients may have difficulty walking initially, but this can improve when the swelling decreases.

▶ Clinical Findings

A. Symptoms and Signs

The main clinical findings for patients with collateral ligament injuries are pain along the course of the ligaments. The patient may have limited range of motion due to pain, especially during the first 2 weeks following the injury. The best tests to assess the collateral ligaments are the varus and valgus stress tests. The sensitivity of the tests is as high as 86–96%.

The **valgus stress test** is performed with the patient supine (Table 41–8). The clinician should stand on the outside of the patient's knee. With one hand, the clinician should hold the ankle while the other hand is supporting the leg at the level of the knee joint. A valgus stress is applied at the ankle to determine pain and laxity of the MCL. The test should be performed at both 30 degrees and at 0 degrees of knee extension.

For the **varus stress test**, the patient is again placed supine (Table 41–8). For the right knee, the clinician should be standing on the right side of the patient. The clinician's left hand should be holding the ankle while the right hand is supporting the lateral thigh. A varus stress is applied at the ankle to determine pain and laxity of the LCL. The test should be performed at both 30 degrees and at 0 degrees of knee flexion.

The test results can be graded from 1–3. Grade 1 is when the patient has pain with varus/valgus stress test but no instability. With grade 2 injuries, the patient has pain, and the knee shows instability at 30 degrees of knee flexion. In grade 3 injuries, the patient has marked instability but not much pain. The knee is often unstable at both 30 degrees and 0 degrees of knee flexion.

B. Imaging

Radiographs are usually nondiagnostic except for avulsion injuries. However, radiographs should be used to rule out fractures that can occur with collateral ligament injuries. Isolated MCL injuries usually do not require evaluation by MRI, but MRI should be used to evaluate possible associated cruciate ligament injuries. LCL or posterolateral corner injuries should have MRI evaluation to exclude associated injuries and to determine their significance.

► Treatment

The majority of MCL injuries can be treated with protected weight-bearing and physical therapy. For grade 1 and 2 injuries, the patient can usually bear weight as tolerated with full range of motion. A hinged knee brace can be given to patients with grade 2 MCL tears to provide stability. Early physical therapy is recommended to protect range of motion and muscle strength. Grade 3 MCL injuries require long leg braces to provide stability. Patients can weight-bear but only with the knee locked in extension with a brace. The motion can then be increased with the brace unlocked. Grade 3 injuries can take up to 6–8 weeks to heal. MCL injuries rarely need surgery. LCL injuries usually require surgical repair or reconstruction.

► When to Refer

- Symptomatic instability with chronic MCL tears or acute MCL tears with other ligamentous injuries.
- LCL or posterolateral corner injuries require urgent surgical repair or reconstruction (within 1 week).

Pacheco RJ et al. Posterolateral corner injuries of the knee: a serious injury commonly missed. *J Bone Joint Surg Br.* 2011 Feb;93(2):194–7. [PMID: 21282758]

Phisitkul P et al. MCL injuries of the knee: current concepts review. *Iowa Orthop J.* 2006;26:77–90. [PMID: 16789454]

4. Posterior Cruciate Ligament Injury

ESSENTIALS OF DIAGNOSIS

- Usually follows an anterior trauma to the tibia, such as a dashboard injury during a motor vehicle accident.
- The knee may freely dislocate and reduce.
- One-third of multi-ligament injuries involving the PCL have neurovascular injuries.

► General Considerations

The posterior cruciate ligament (PCL) is the strongest ligament in the knee. PCL injuries usually represent significant trauma and are highly associated with multi-ligament injuries and knee dislocations. More than 70–90% of PCL

injuries have associated injuries to the posterolateral corner, MCL, and ACL. There should be high suspicion for neurovascular injuries and a thorough neurovascular examination of the limb should be performed.

► Clinical Findings

A. Symptoms and Signs

Most patients with acute injuries have difficulty with ambulation. Patients with chronic PCL injuries can ambulate without gross instability but may complain of subjective “looseness” and often report pain and dysfunction, especially with bending. Clinical examinations of PCL injuries include the “**sag sign**” (Table 41–8). The patient is placed supine and both hips and knees are flexed up to 90 degrees. Because of gravity, the PCL-injured knee will have an obvious set-off at the anterior tibia which is “sagging” posteriorly. The PCL ligament can also be examined using the **posterior drawer test** (90% sensitivity and 99% specificity) (Table 41–8). The patient is placed supine with the knee flexed at 90 degrees. In a normal knee, the anterior tibia should be positioned about 10 mm anterior to the femoral condyle. The clinician can grasp the proximal tibia with both hands and push the tibia posteriorly. The movement, indicating laxity and possible tear of the PCL, is compared with the uninjured knee. A PCL injury is sometimes mistaken for an ACL injury during the anterior drawer test since the tibia is subluxed posteriorly in a sagged position and can be abnormally translated forward, yielding a false-positive test for an ACL injury. Pain, swelling, pallor, and numbness in the affected extremity may suggest a knee dislocation with possible injury to the popliteal artery.

B. Imaging

Radiographs are often nondiagnostic but are required to diagnose any fractures. MRI is used to diagnose PCL and other associated injuries.

► Treatment

Isolated PCL injuries can be treated nonoperatively. Acute injuries are usually immobilized using a knee brace with the knee extension; the patient uses crutches for ambulation. Physical therapy can help achieve increased range of motion and improved ambulation. Many PCL injuries are associated with other injuries and may require operative reconstruction. Neurovascular injuries occur in up to one-third of all knee dislocations or PCL injuries.

► When to Refer

- The patient should be seen urgently within 1–2 weeks.
- If the lateral knee is also unstable with varus stress testing, the patient should be assessed for a posterolateral corner injury, which may require an urgent surgical reconstruction.
- Isolated PCL tears may require surgery if the tear is complete (grade 3) and the patient is symptomatic.

Hammoud S et al. Outcomes of posterior cruciate ligament treatment: a review of the evidence. *Sports Med Arthrosc.* 2010 Dec;18(4):280–91. [PMID: 21079509]

5. Meniscus Injuries

ESSENTIALS OF DIAGNOSIS

- ▶ Patient may or may not report an injury.
- ▶ Joint line pain and pain with deep squatting are the most sensitive signs.
- ▶ Difficulty with knee extension suggests an internal derangement that should be evaluated urgently with MRI.

▶ General Considerations

The menisci act as shock absorbers within the knee. Injuries to a meniscus can lead to pain, clicking, and locking sensation. Most meniscus injuries occur with acute injuries (usually in younger patients) or repeated microtrauma, such as squatting or twisting (usually in older patients).

▶ Clinical Findings

A. Symptoms and Signs

The patient may have an antalgic (painful) gait and difficulty with squatting. He or she may complain of catching or locking of the meniscal fragment. Physical findings can include effusion or joint line tenderness. Patients can usually point out the area of maximal tenderness along the joint line. Swelling usually occurs during the first 24 hours after the injury or later. Meniscus tears rarely lead to the immediate swelling that is commonly seen with fractures and ligament tears. Meniscus tears are commonly seen in arthritic knees. However, it is often unclear whether the pain is coming from the meniscus tear or the arthritis.

Provocative tests, including the **McMurray test**, the **modified McMurray test**, and the **Thessaly test**, can be performed to confirm the diagnosis (Table 41–8). Most symptomatic meniscus tears cause pain with deep squatting and when waddling (performing a “duck walk”).

B. Imaging

Radiographs are usually normal but may show joint space narrowing, early osteoarthritis changes, or loose bodies. MRI of the knee is the best diagnostic tool for meniscal injuries (93% sensitivity and 95% specificity). High signal through the meniscus (bright on T2 images) represents a meniscal tear.

▶ Treatment

Conservative treatment can be used for degenerative tears in older patients. The treatment is similar for patients with

mild knee osteoarthritis, including analgesics and physical therapy for strengthening and core stability. Acute tears in young and active patients can be best treated arthroscopically with meniscus repair or debridement. Recent randomized controlled studies have demonstrated no benefit with arthroscopic meniscectomy in patients with advanced osteoarthritis.

▶ When to Refer

- If the patient has symptoms of internal derangement suspected as meniscus injury. The patient should receive an MRI to confirm the injury.
- If the patient cannot extend the knee due to a mechanical block, the patient should be evaluated as soon as possible. Certain shaped tears on MRI, such as bucket handle tears, are amenable to meniscal repair surgery.

McDermott I. Meniscal tears, repairs and replacement: their relevance to osteoarthritis of the knee. *Br J Sports Med.* 2011 Apr;45(4):292–7. [PMID: 21297172]

6. Patellofemoral Pain

ESSENTIALS OF DIAGNOSIS

- ▶ Pain experienced with bending activities (kneeling, squatting, climbing stairs).
- ▶ Lateral deviation or tilting of the patella in relation to the femoral groove.

▶ General Considerations

Patellofemoral pain, also known as anterior knee pain or “runner’s knee,” describes any pain involving the patellofemoral joint. The pain affects any or all of the anterior knee structures, including the medial and lateral aspects of the patella as well as the quadriceps and patellar tendon insertions. The patella engages the femoral trochlear groove with approximately 30 degrees of knee flexion. Forces on the patellofemoral joint increase up to three times body weight as the knee flexes to 90 degrees (eg, climbing stairs), and five times body weight when going into full knee flexion (eg, squatting). Abnormal patellar tracking during flexion can lead to abnormal articular cartilage wear and pain. When the patient has ligamentous hyperlaxity, the patella can sublux out of the groove, usually laterally. Patellofemoral pain is also associated with muscle strength and flexibility imbalances as well as altered hip and ankle biomechanics.

▶ Clinical Findings

A. Symptoms and Signs

Patients usually complain of pain in the anterior knee with bending movements and less commonly in full extension.

Pain from this condition is localized under the kneecap but can sometimes be referred to the posterior knee or over the medial or lateral inferior patella. Symptoms may begin after a trauma or after repetitive physical activity, such as running and jumping. When maltracking, palpable and sometimes audible crepitus can occur.

Intra-articular swelling usually does not occur unless there are articular cartilage defects or if osteoarthritis changes develop. On physical examination, it is important to palpate the articular surfaces of the patella. For example, the clinician can use one hand to move the patella laterally, and use the fingertips of the other hand to palpate the lateral undersurface of patella. Patellar mobility can be assessed by medially and laterally deviating the patella (deviation by one-quarter of the diameter of the kneecap is consider normal; greater than one-half the diameter suggests excessive mobility). The **apprehension sign** suggests instability of the patellofemoral joint and is positive when the patient becomes apprehensive when the patella is deviated laterally (Table 41–8). The **patellar grind test** is performed by grasping the knee superior to the patella and pushing it downward with the patient supine and the knee extended, pushing the patella inferiorly. The patient is asked to contract the quadriceps muscle to oppose this downward translation, with reproduction of pain or grinding being the positive sign for chondromalacia of the patella. There are two common presentations: (1) Patients whose ligaments and patella are too loose (hypermobility); (2) and patients who have soft tissues that are too tight leading to excessive pressure on the joint.

Evaluation of the quadriceps strength and hip stabilizers can be accomplished by having the patient perform a one-leg squat without support. Patients who are weak may display poor balance, with dropping of the pelvis (similar to a positive hip Trendelenburg sign) or excessive internal rotation of the knee medially. Normally, with a one-leg squat, the knee should align over the second metatarsal ray of the foot.

B. Imaging

Diagnostic imaging has limited use in younger patients and is more helpful in older patients to assess for osteoarthritis or to evaluate patients who do not respond to conservative treatment. Radiographs may show lateral deviation or tilting of the patella in relation to the femoral groove. MRI may show thinning of the articular cartilage but is not clinically necessary, except prior to surgery or to exclude other pathology.

► Treatment

A. Conservative

For symptomatic relief, use of local modalities such as ice and anti-inflammatory medications can be beneficial. If the patient has signs of patellar hypermobility, physical therapy exercises are useful to strengthen the quadriceps (especially the vastus medialis obliquus muscle) to help stabilize the patella and improve tracking. Support for the patellofemoral joint can be provided by use of a patellar

stabilizer brace or special taping techniques (McConnell taping). Correcting lower extremity alignment (with appropriate footwear or over-the-counter orthotics) can help improve symptoms, especially if the patient has pronation or high arched feet. If the patient demonstrates tight peripatellar soft tissues, special focus should be put on stretching the hamstrings, iliotibial band, quadriceps, calves and hip flexors. Strengthening exercises should include the quadriceps and hip abductors.

B. Surgical

Surgery is rarely needed and is considered a last resort for patellofemoral pain. Procedures performed include lateral release or patellar realignment surgery.

van Linschoten R et al. Supervised exercise therapy versus usual care for patellofemoral pain syndrome: an open label randomised controlled trial. *BMJ.* 2009 Oct 20;339:b4074. [PMID: 19843565]

7. Osteoarthritis

ESSENTIALS OF DIAGNOSIS

- Degeneration of joint cartilage.
- Pain with bending or twisting activities.
- Swelling.
- Loss of active and passive range of motion in severe osteoarthritis.

► General Considerations

In the United States, the prevalence of osteoarthritis will grow as the number of persons over age 65 years doubles to more than 70 million by 2030. The incidence of knee osteoarthritis in the United States is 240 per 100,000 person-years.

Cartilage loss and osteoarthritis symptoms are preceded by damage to the collagen-proteoglycan matrix. The etiology of osteoarthritis is often multifactorial including previous trauma, prior high-impact activities, genetic factors, obesity, and rheumatologic or metabolic conditions.

► Clinical Findings

A. Symptoms and Signs

Osteoarthritis usually causes pain in the affected joint with loading of the joint or at the extremes of motion.

Mechanical symptoms—such as swelling, grinding, catching, and locking—suggest internal derangement, which is indicated by damaged cartilage or bone fragments that affect the smooth range of motion expected at an articular joint. Pain can also produce the sensation of “buckling” or “giving way” due to muscle inhibition. As the joint degeneration becomes more advanced, the patient loses active range of motion and may lose passive range of motion as well.

As the condition worsens, patients with knee osteoarthritis have an increasingly limited ability to walk. Symptoms include pain with bending or twisting activities, and going up and down stairs. Swelling, limping, and pain while sleeping are common complaints with osteoarthritis, especially as it progresses.

B. Imaging

The most commonly recommended radiographs include bilateral weight-bearing 45-degree bent knee posteroanterior, lateral, and patellofemoral joint views (Merchant view). Radiographic findings include diminished width of the articular cartilage causing joint space narrowing, subchondral sclerosis, presence of osteophytes, and cystic changes in the subchondral bone. MRI of the knee is most likely unnecessary unless other pathology is suspected, including ischemic osteonecrosis of the knee.

► Treatment

A. Conservative

Changes in the articular cartilage are irreversible. Therefore, a cure for the diseased joint is not possible, although symptoms or structural issues can be addressed to try to maintain activity level. Conservative treatment for all patients with osteoarthritis includes activity modification, therapeutic exercises, and weight loss. Lifestyle modifications also include proper footwear and avoidance of high impact activities.

Use of a cane in the hand opposite to the affected side is mechanically advantageous. Knee sleeves or braces provide some improvement in subjective pain symptoms most likely due to improvements in neuromuscular function. If patients have unicompartmental osteoarthritis in the medial or lateral compartment, joint unloader braces are available to offload the degenerative compartment. Cushioning footwear and appropriate orthotics or shoe adjustments are useful for reducing impact to the lower extremities.

The initial drugs of choice for the treatment of pain in knee osteoarthritis are oral acetaminophen and topical capsaicin. If a traditional NSAID is indicated, the choice should be based on cost, side-effect profile, and compliance. The cyclooxygenase (COX)-2 inhibitor, celecoxib, is no more effective than traditional NSAIDs; it may offer short-term, but probably not long-term, advantage in preventing gastrointestinal complications. Due to its cost and potential cardiovascular risk, celecoxib should be reserved for carefully selected patients. The role of topical NSAIDs are being considered in the

osteoarthritis treatment algorithm, as they do avoid many of the traditional NSAID complications. Opioids can be used appropriately in patients with severe osteoarthritis (see Chapter 5). Glucosamine and chondroitin sulfate are supplements that have been widely used and marketed for osteoarthritis. Evidence for their effectiveness in slowing or reversing cartilage loss is limited and any effect present appears to be small. Despite some initial promise, the best-controlled studies indicate these supplements are ineffective as analgesics in osteoarthritis. However, they have minimal side effects and may be appropriate if the patient experiences subjective benefit.

Knee joint corticosteroid injections are options to help reduce pain and inflammation and can provide short-term pain relief, usually lasting about 6–12 weeks. Viscosupplementation by injections of hyaluronic acid-based products improves synovial fluid viscosity by increasing the molecular weight and quantity of hyaluronic acid beyond that naturally synthesized by the synovium. Laboratory studies also demonstrate that hyaluronic acid injections decrease inflammatory cytokines and free radicals. A review of five meta-analysis studies of viscosupplementation demonstrates a modest benefit. Studies also demonstrate more prolonged effects of viscosupplementation products compared with corticosteroid injection with symptom improvement for > 6 months in some patients with mild knee osteoarthritis.

B. Surgical

Two published randomized trials demonstrate that arthroscopy does not improve outcomes at 1 year over placebo or routine conservative treatment of osteoarthritis. Arthroscopic surgery is indicated in patients with osteoarthritis if, rather than pain, they have mechanical symptoms and internal derangement symptoms. Such surgical treatments are useful to restore range of motion by removing osteophytes, cartilage fragments, or loose bodies.

Joint replacement surgeries are effective and cost-effective for patients with significant symptoms or functional limitations, providing improvements in pain, function, and quality of life. Minimally invasive surgeries and computer-assisted navigation during operation are being investigated as methods to improve techniques (eg, accurate placement of the hardware implant) and to reduce complication rates.

Knee realignment surgery, such as high tibial osteotomy or partial knee replacement surgery, is indicated in patients younger than age 60 with unicompartmental osteoarthritis, who would benefit from delaying total knee replacement. Knee joint replacement surgery has been very successful in improving outcomes for patient with end-stage osteoarthritis. Recent long-term series describe > 95% survival rate of the implant at 15 years.

► When to Refer

Patients with sufficient disability, limited benefit from conservative therapy, and evidence of severe osteoarthritis can be referred for joint replacement surgery.

ANKLE INJURIES

1. Inversion Ankle Sprains

ESSENTIALS OF DIAGNOSIS

- ▶ Localized pain and swelling.
- ▶ The majority of ankle injuries involve inversion injuries affecting the lateral ligaments.
- ▶ Consider chronic ankle instability or associated injuries if pain persists for > 3 months following an ankle sprain.

▶ General Considerations

Ankle sprains are the most common sports injuries seen in outpatient clinics. Patients usually report “turning the ankle” during a fall or after landing on an irregular surface such as a hole or an opponent’s foot. The most common mechanism of injury is an inversion and plantarflexion sprain, which injures the anterior talofibular ligament (ATF) ligament rather than the calcaneofibular ligament (CF) ligament. Other injuries that can occur with inversion ankle injuries are listed in (Table 41–9).

▶ Clinical Findings

A. Symptoms and Signs

The usual symptoms following a sprain include localized pain and swelling over the lateral aspect of the ankle, difficulty weight bearing, and limping. The patient’s ankle may feel unstable. On examination, there may be swelling or bruising over the lateral aspect of the ankle. The anterior, inferior aspect below the lateral malleolus is most often the point of maximal tenderness consistent with ATF and CF ligament injuries. The swelling may limit motion of the ankle. Special stress tests for the ankle include the **anterior drawer test** (Table 41–10) and **subtalar tilt test** (Table 41–10). In order to grade the severity of ankle sprains, no laxity on stress tests is considered a grade 1 injury, laxity of the ATF ligament on anterior drawer testing but a negative tilt test is a grade 2 injury, and both positive drawer and tilt tests signify a grade 3 injury.

Table 41–9. Injuries associated with ankle sprains.

Ligaments
Subtalar joint sprain
Sinus tarsi syndrome
Syndesmotic sprain
Deltoid sprain
Lisfranc injury
Tendons
Posterior tibial tendon strain
Peroneal tendon subluxation
Bones
Osteochondral talus injury
Lateral talar process fracture
Posterior impingement (os trigonum)
Fracture at the base of the fifth metatarsal
Jones fracture
Salter fracture (fibula)
Ankle fractures

B. Imaging

Routine ankle radiographic views include the anteroposterior, lateral, and oblique (mortise) views. Less common views requested include the calcaneal view and subtalar view. Ottawa Ankle Rules are clinical prediction rules to the need for radiographs and have a 97% sensitivity and 99% negative predictive value. If the patient is unable to bear weight immediately in the office setting or emergency department for four steps, then the clinician should check for (1) bony tenderness at the posterior edge of the medial or lateral malleolus and (2) bony tenderness over the navicular (medial midfoot) or at the base of the fifth metatarsal. If either malleoli demonstrates pain or deformity, then ankle radiographs should be obtained. If the foot has bony tenderness, obtain foot radiographs. An MRI is helpful when considering the associated injuries.

▶ Treatment

Immediate treatment of an ankle sprain follows the MICE mnemonic: *modified activities, ice, compression, and elevation*. Subsequent treatment involves protected weight bearing with crutches and use of an ankle stabilizer brace, especially for grade 2 and 3 injuries. Early motion is essential, and patients should be encouraged to do home exercises or physical therapy. Proprioception and balance exercises (eg, “wobble board”) are useful to restore function to the ankle and prevent future ankle sprains. Regular use of an ankle support with activities can reduce the risk of lateral ankle sprains. Chronic instability can develop after acute ankle sprain in 10–20% of people and may require surgical stabilization with ligament reconstruction surgery.

▶ When to Refer

- Ankle fractures.
- Recurrent ankle sprains or signs of chronic ligamentous ankle instability.

Table 41–10. Ankle examination.

Maneuver	Description
Inspection	Examine for the alignment of the ankle. (SEADS)
Palpation	Include important landmarks: Ottawa Ankle Rules (medial and lateral malleolus, base of fifth metatarsal and navicular area), anterior tibiofibular ligament, posterior talus; tendons (Achilles, peroneals, posterior tibialis, flexor hallucis longus).
Range of motion testing	Check range of motion actively (patient performs) and passively (clinician performs), especially with flexion and extension of the spine. Rotation and lateral bending are also helpful to assess symmetric motion or any restrictions.
Ankle strength testing	Test resisted ankle dorsiflexion, plantarflexion, inversion and eversion strength manually.
Ankle anterior drawer	The clinician keeps the foot and ankle in the neutral position with the patient sitting, then uses one hand to fix the tibia and the other to hold the patient's heel and draw the ankle forward. Normally, there may be approximately 3 mm of translation until an endpoint is felt. A positive test includes increased translation of one foot compared to the other with loss of the endpoint of the anterior talofibular ligament.
Subtalar tilt test	Performed with the foot in the neutral position with the patient sitting. The clinician uses one hand to fix the tibia and the other to hold and invert the calcaneus. Normal inversion at the subtalar joint is approximately 30 degrees. A positive test consists of increased subtalar joint inversion greater than 10 degrees on the affected side with loss of endpoint for the calcaneofibular ligament.
External rotation stress test	Performed when the clinician fixes the tibia with one hand and grasps the foot in the other with the ankle in the neutral position and then dorsiflexes and externally rotates the ankle, reproducing the patient's pain.

SEADS, swelling, erythema, atrophy, deformity, and (surgical) scars.

- No response after more than 3 months of conservative treatment.
- Suspicion of associated injuries.

2. Eversion (“High”) Ankle Sprains

ESSENTIALS OF DIAGNOSIS

- ▶ Severe and prolonged pain.
- ▶ Limited range of motion.
- ▶ Mild swelling.
- ▶ Difficulty with weight bearing.

▶ General Considerations

A syndesmotic injury or “high ankle” sprain involves the anterior *tibio*fibular ligament in the anterolateral aspect of the ankle, superior to the anterior *talof*ibular (ATF) ligament. The injury mechanism often involves the foot being turned out or externally rotated and everted (eg, when being tackled). This injury is commonly missed or misdiagnosed as an ATF ligament sprain on initial visit.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms of a high ankle sprain include severe and prolonged pain over the anterior ankle at the anterior tibiofibular ligament, worse with weight bearing. This is often more painful than the typical ankle sprain. The point of maximal tenderness involves the anterior tibiofibular ligament, which is higher than the ATF ligament. It is also important to palpate the proximal fibula to rule out any proximal syndesmotic ligament injury and associated fracture known as a “maisonneuve fracture.” There is often some mild swelling in this area, and the patient may or may not have an ankle effusion. The patient usually has limited range of motion in all directions. The **external rotation stress test** reproduces the mechanism of injury (Table 41–10). (**Note:** The patient's foot should have an intact neurovascular examination before undertaking this test.)

B. Imaging

Radiographs of the ankle should include the anteroposterior, mortise, and lateral views. The mortise view may demonstrate loss of the normal overlap between the tibia and fibula, which should be at least 1–2 mm. Asymmetry in the joint space around the tibiotalar joint suggests disruption of the syndesmotic ligaments. If there is proximal tenderness in the lower leg especially around the fibula, an anteroposterior and lateral view of the tibia and fibula should be obtained to rule out a proximal fibula fracture. MRI is the best method to visualize injury to the tibiofibular ligament and to assess status of the other ligaments and the articular cartilage.

► Treatment

Whereas most ankle sprains are treated with early motion and weight bearing, treatment for a high ankle sprain should be conservative with a cast or walking boot for 4–6 weeks. Thereafter, protected weight bearing with crutches is recommended until the patient can walk pain-free. Physical therapy can start early to regain range of motion and maintain strength with limited weight-bearing initially.

► When to Refer

If there is widening of the joint space and asymmetry at the tibiotalar joint, the patient should be referred urgently to a

foot and ankle surgeon. Severe or prolonged persistent cases that do not heal may require internal fixation to avoid chronic instability at the tibiofibular joint.

Women's Health Issues

Megan McNamara, MD, MSc, &
Judith Walsh, MD, MPH

The field of women's health encompasses more than the reproductive health issues commonly addressed by obstetricians and gynecologists; it evaluates diseases and conditions only seen or experienced in women or experienced by women in ways different than men, as well as the evidence-based prevention and treatment of risk factors and diseases in women. Hence, all primary care providers, including internists and family physicians, should be well versed in women's health issues.

PREVENTIVE HEALTH CARE

Prevention of disease can be **primary** (preventing disease before it happens as well as identifying and modifying risk factors), **secondary** (identifying early disease), or **tertiary** (treating complications of the disease or limiting the impact of established disease). Important areas for primary prevention include encouraging women to exercise regularly to reduce the risk of coronary heart disease (CHD) and breast cancer as well as counseling women to discontinue smoking to reduce the risk of cardiac and lung diseases. Cancer screening in women focuses on secondary prevention, so that disease is detected early when prompt treatment improves outcome.

CARDIOVASCULAR DISEASE PREVENTION

Although cardiovascular disease is the leading cause of death in women, they are often more concerned about developing breast cancer (see below) than about developing heart disease. While some heart disease risk factors such as age and family history are not modifiable, as with men, other risk factors such as hypertension, hyperlipidemia, smoking, obesity, and diabetes are potentially modifiable. The Framingham risk calculator (<http://hp2010.nhlbihin.net/atp/iii/calculator.asp?usertype=prof>) can be used to estimate a woman's 10-year risk of CHD based on her age, smoking status, blood pressure, and cholesterol levels.

▶ Modifiable Risk Factors

A. Hypertension

Hypertension is a risk factor for CHD and stroke in both men and women. Approximately 70–80% of women over age 70 have hypertension. A woman with high blood pressure is at lower risk for CHD than a similar aged man. For many young and otherwise healthy women, drug treatment can be deferred, since their absolute risk of CHD in the next 10 years is likely to be low. When pharmacotherapy is started, the choice of medication is similar to those used in men (see Chapter 11).

B. Hyperlipidemia

Hyperlipidemia is a CHD risk factor in both men and women, but low levels of high-density lipoprotein (HDL) is more predictive of CHD risk in women. Elevated cholesterol is defined as a total cholesterol > 240 mg/dL (> 7.2 mmol/L) or low-density lipoprotein (LDL) cholesterol > 160 mg/dL (> 4.8 mmol/L). Borderline cholesterol is defined as a total cholesterol between 200 mg/dL and 240 mg/dL (6 mmol/L and 7.2 mmol/L) or an LDL cholesterol of 130–159 mg/dL (3.9–4.77 mmol/L). Ideal cholesterol is defined as a total cholesterol < 200 mg/dL (< 6 mmol/L) or an LDL < 130 mg/dL (< 3.9 mmol/L) and an HDL cholesterol > 50 mg/dL (> 1.5 mmol/L).

The US Preventive Services Task Force (USPSTF) recommends screening all women aged 45 and older for hyperlipidemia, whereas the National Cholesterol Education Program (NCEP) recommends screening all individuals aged 20 and over. Before screening a woman for hyperlipidemia, an important consideration is whether or not treatment recommendations will change based on the results. Since therapeutic lifestyle changes are recommended for all women, the question is at what point should medication treatment be considered.

There is clear evidence that medication treatment of hyperlipidemia reduces CHD events in women who already have CHD, but when lipid-lowering medications are used

in women who do not already have CHD, the evidence of benefit is less clear. Decisions about when to initiate medication treatment should include an assessment of an individual's absolute risk of CHD in the next 10 years. Medication treatment should be targeted toward women with CHD and high-risk women who are most likely to benefit. The NCEP recommends different thresholds at which to initiate medication therapy based on individual CHD risk. For example, for a woman with known CHD, lipid-lowering medication is initiated at an LDL cholesterol of > 130 mg/dL, whereas for a woman with 0–1 risk factor, medication therapy is not initiated until the LDL cholesterol measures > 190 mg/dL.

C. Diabetes

Diabetes is a CHD risk factor in both men and women. Studies have reached conflicting conclusions about the effect of tight control of diabetes on CHD outcomes in both men and women, although lipid lowering is clearly associated with a reduction in CHD events in diabetic women. All women should focus on primary prevention of diabetes with avoidance of obesity and maintenance of regular exercise.

D. Obesity

Obesity has been established as an independent risk factor for CHD in women. It is not known whether or not weight loss will decrease CHD risk. Since most obese women who lose weight gain it back, the overall goal should be ongoing avoidance of weight gain above normal weight.

E. Predictive Biomarkers and Clinical Tests

The use of high-sensitivity C-reactive protein (hsCRP) has increased in recent years. CRP is an inflammatory biomarker that has been shown to predict cardiovascular events. However, there is currently no evidence that screening for hsCRP improves cardiac outcomes. It has been suggested that measuring hsCRP may be useful in women for whom it would change treatment outcomes, but there is currently no evidence to support this. The USPSTF recently published guidelines outlining the use of nontraditional risk factors in the evaluation of CHD. The risk factors included in the recommendation were hsCRP, ankle-brachial index, leukocyte count, fasting blood glucose, periodontal disease, carotid intima media thickness, coronary artery calcification score, electron beam CT, homocysteine, and lipoprotein (a). The USPSTF concluded that there is insufficient evidence to balance the benefits and harms of screening asymptomatic men and women with no history of CHD to predict CHD events and did not recommend routine screening.

▶ Therapeutic Options for Reducing Risk Factors

A. Aspirin

Aspirin is clearly useful for secondary prevention of CHD in women. Among women who do not have CHD,

aspirin reduces the risk of stroke, whereas in men, it reduces the risk of CHD. Before starting an aspirin regimen to reduce the risk of the stroke, women should be assessed for their risk of gastrointestinal bleeding, which is the most common adverse side effect of aspirin use. The USPSTF recommends aspirin in women aged 55–79 years when the potential benefit of a reduction in ischemic strokes outweighs the potential harms of a gastrointestinal hemorrhage. For healthy or at-risk women, 81 mg/d or 100 mg every other day is the suggested dose. For high-risk women, a dose of 75–325 mg/d is recommended.

B. Exercise

Exercise has been associated with a reduction in all causes of cardiovascular mortality. Women often want to know how much exercise is necessary for health benefits. Studies have shown that walking 2.5–3 hours a week is associated with a reduction in cardiovascular disease. The Centers for Disease Control and Prevention and the American College of Sports Medicine recommend that all women accumulate at least 30 minutes a day of moderate intensity physical activity on most if not all days of the week. The Institute of Medicine recommends an hour a day for the goal of maintaining health and ideal body weight.

CANCER PREVENTION

1. Breast Cancer

► Risk Factors & Risk Assessment

Breast cancer is the most commonly detected cancer in women and the second leading cause of cancer death. Breast cancer risk is increased with age and with a family history of breast cancer. Women who drink more than two alcoholic drinks per day are at increased risk for breast cancer, and exercise is associated with a decreased risk of breast cancer. Dietary intake has not been conclusively associated with breast cancer risk.

Various models have been used to predict a woman's risk for breast cancer. The National Cancer Institute has developed the Breast Cancer Risk Assessment Tool, which is based on the Gail Model, and calculates the woman's risk of developing breast cancer in the next 5 years by considering the following factors: (1) the woman's age, (2) age at which she had her first menstrual period, (3) age at delivery of first live child, (3) number of first-degree relatives with breast cancer, (4) history of any breast biopsies, and (5) history of atypical hyperplasia. The model has been validated in white women and has been evaluated in black women and found to be relatively accurate, although it may underestimate the risk in black women with a history of previous breast biopsies. It has yet to be validated in women of other ethnicities.

► Primary Prevention

In addition to lifestyle modifications, such as exercise and moderation of alcohol intake, chemoprevention of breast cancer is an option for some women. The selective estrogen receptor modifiers (SERMS) tamoxifen and raloxifene have both been shown to reduce invasive breast cancer in high-risk women. However, there are risks associated with SERM treatment. Tamoxifen is associated with an increased risk of endometrial cancer and deep venous thrombosis (DVT). Although raloxifene is not associated with an increased risk of endometrial cancer, the risk of DVT remains. The USPSTF recommends that clinicians discuss chemoprevention with women at high risk for breast cancer and at low risk for the adverse effects of chemoprevention. Clinicians should inform patients of the potential benefits and harms of chemoprevention. Breast cancer risk increases with age, but the risk of adverse effects does as well. Since the clinical trials of tamoxifen and raloxifene for breast cancer prevention used a 1.66% 5-year risk, this risk level is often used as a guide for treatment.

► Breast Cancer Screening

Traditional breast cancer screening modalities include screening mammography, clinical breast examination, and breast self-examination. Teaching women to do routine breast self-examination has not been shown to reduce breast cancer mortality. The USPSTF recommends against teaching women to do breast self-examination. The American Cancer Society states that it is acceptable not to do it, but that if women are performing

breast self-examination, it is important to ensure that they are doing it correctly. The combination of breast examination done by a clinician and mammography is associated with a decrease in breast cancer mortality, but there is insufficient evidence to recommend clinical breast examination alone.

Mammography reduces breast cancer mortality in women aged 50–74 years and routine mammographic screening is recommended for women in this age group. For women aged 40–49 years, screening has been more controversial. Recent guidelines published by the USPSTF recommend that clinicians not routinely order mammography among 40- to 49-year-old women but rather that they individualize the decision to begin screening, since the number needed to invite to screen to prevent one breast cancer death is much higher in younger women and the number of false-positive and false-negative test results are much higher. Since women over age 75 have not been included in clinical trials and since the likelihood of comorbid diseases limiting life expectancy increases, routine screening of women in this age group is not recommended, but rather the decision making should be individualized.

Hubbard et al. Cumulative probability of false-positive recall or biopsy recommendation after 10 years of screening mammography: a cohort study. *Ann Intern Med.* 2011 Oct 18; 155(8):481–92. [PMID: 22007042]

2. Colorectal Cancer

Colorectal cancer is the third leading cause of cancer death in both men and women. In 2010, an estimated 9% of cancer deaths in women were caused by colorectal cancer. Since the risk of colorectal cancer increases with age, all women should be screened for colorectal cancer starting at the age of 50. The USPSTF recommends routine screening in men and women age 50–75, individualized decision making about screening in individuals aged 76–85, and no screening after the age of 85. Details of the screening options and suggested screening intervals are described in Chapter 1.

[PMID: 18384785]

U.S. Preventive Services Task Force. Screening for Colorectal Cancer: U.S. Preventive Services Task Force recommendation statement. *Ann Intern Med.* 2008 Nov 4;149(9):627–37. [PMID: 18838716]

3. Cervical Cancer

In contrast to most other cancers for which routine screening is recommended, the incidence of cervical cancer is higher in younger women and decreases with age. The major risk factor for cervical cancer is exposure to the human papillomavirus (HPV). Primary prevention of cervical cancer includes avoidance of smoking, postponing sexual debut, and limiting the number of sexual partners. Condom use may also be protective.

► Primary Prevention

A quadrivalent HPV vaccine that includes capsid proteins against four HPV types (6, 11, 16, and 18) has been approved for use in girls and women aged 9–26 years to prevent disease associated with these HPV types. A bivalent vaccine (Cervarix) is also available. The published studies, which are based on interim results, show a high degree of efficacy of prevention of vaccine-associated genital warts, persistent infections, and cervical intraepithelial neoplasia. Protection has not been shown against strains that are not in the vaccine or strains that were present before vaccination. The Advisory Committee on Immunization Practices (ACIP) recommends routine vaccination for girls aged 11 or 12 up to age 26, whereas the American Cancer Society recommends the vaccine for girls aged 11–18 but states that there is insufficient evidence to recommend for or against routine vaccination for women aged 19–26. The ACIP also recommends that all 11- and 12-year-old boys get vaccinated against HPV. Unanswered questions about the vaccine include the long-term effects and the length of protection. Receipt of vaccine should not change cervical cancer screening intervals in women.

► Secondary Prevention

An important focus of cervical cancer prevention is screening using the Papanicolaou smear. Cervical cancer screening is the biggest success in the history of cancer screening. Cervical cancer mortality has been reduced by about 70% with routine cervical cancer screening. One of the reasons that screening has been so successful is that there is a long preclinical phase where early changes can be detected and treated so as to avoid the development of cancer. In a 2012 update, the US Preventive Services Task Force (USPSTF) recommends screening for cervical cancer in women age 21 to 65 years with cytology (Papanicolaou smear) every 3 years or, for women age 30 to 65 years who want to lengthen the screening interval, screening with a combination of cytology and HPV testing every 5 years. Screening may be done with either liquid-based or conventional cytology. The USPSTF recommends against screening for cervical cancer with HPV testing, alone or in combination with cytology, in women younger than age 30 years. The USPSTF recommends against screening for cervical cancer in women older than age 65 years who have had adequate prior screening and are not otherwise at high risk for cervical cancer. Women with risk factors that place them at higher risk for cervical intraepithelial neoplasia may require more frequent screening. Guidelines from the American

College of Obstetricians and Gynecologists (ACOG) state screening should start at age 21 regardless of the onset of sexual activity. ACOG recommends screening every 2 years in women aged 21–29 and every 3 years in women aged 30 and older who have had at least three normal smears. All organizations agree that older women (over age 65 or 70) can stop screening.

Testing for high-risk HPV types is routinely used for the evaluation of abnormal Papanicolaou smears, but their use in routine screening is controversial. Since the prevalence of exposure to high risk HPV types is very high, the potential utility of HPV testing would be finding no evidence of HPV. ACOG and the American Cancer Society recommend co-testing with high risk HPV types as an option, and then rescreening in 3 years if the HPV testing is negative. The USPSTF concludes that the evidence is insufficient to assess the balance of benefits and harms of HPV testing, alone or in combination with cytology for screening for cervical cancer in women aged 30 and older. Given that women with a normal Papanicolaou smear can be rescreened in 3 years, it is not clear what high risk HPV testing for primary screening adds. However, given that the vast majority of cervical cancers occur in women who have never been screened, or who have not been screened in the past 5 years, efforts for cervical cancer prevention should primarily focus on those women.

American College of Obstetricians and Gynecologists. ACOG Practice Bulletin no. 109: Cervical cytology screening. *Obstet Gynecol.* 2009 Dec;114(6):1409–20. [PMID: 20134296]

U.S. Preventive Services Task Force. Screening for cervical cancer: U.S. Preventive Services Task Force recommendation statement. <http://www.uspreventiveservicestaskforce.org/uspstf11/cervcancer/cervcancers.htm>

4. Lung Cancer

Although lung cancer is not typically considered a “women’s cancer,” it is the leading cause of cancer mortality in both men and women. Primary prevention of lung cancer should be a high priority with encouragement of tobacco cessation among women who smoke. The use of chest radiographs and sputum cytology for cancer screening have not been shown to reduce lung cancer mortality. The National Lung Screening Trial (NLST) compared screening with low-dose CT to screening with chest radiography. High-risk participants (either current or former smokers) received either annual CT or chest radiography for 3 years and were then monitored for 6.5 years. There was a significant reduction in both lung cancer mortality and total mortality with CT screening. However, there were a very large number of false-positive test results, many of which led to additional testing. The USPSTF does not currently recommend any of these modalities for lung cancer screening, although many organizations are in the midst of reassessing their recommendations for lung cancer screening based on the results of the NLST.

National Lung Screening Trial Research Team; Aberle DR et al. Reduced lung-cancer mortality with low-dose computed tomographic screening. *N Engl Med.* 2011 Aug 4;365(5):395–409. [PMID: 21714641]

U.S. Preventive Services Task Force. Lung cancer screening: recommendation statement. *Ann Intern Med.* 2004 May 4;140(9):738–9. [PMID: 15126258]

5. Ovarian Cancer

Ovarian cancer is a relatively rare but dreaded cancer, with a lifetime incidence of about 1.2% in women with no family history of ovarian cancer. Because it is often detected late, treatment options may be limited.

Many of the risk factors for ovarian cancer such as age and family history are not modifiable, but there are protective factors, including having more than one full-term pregnancy, breast-feeding, and oral contraceptive use. Women at high-risk for ovarian cancer should consider the use of oral contraceptives for as long as it is feasible.

Although screening for ovarian cancer with either the serum marker CA-125 or with transvaginal ultrasound is theoretically appealing, the rarity of the disease limits their use and leads to many false-positive test results. The Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial, where women were screened for ovarian cancer with annual CA-125 and transvaginal ultrasound and monitored for 12.4 years, resulted in no reduction in ovarian cancer mortality. In addition, there were a large number of false-positive test results, some leading to surgical follow-up and resultant surgical complications. The USPSTF does not recommend screening for ovarian cancer.

Buys SS et al. Effect of screening on ovarian cancer mortality: the Prostate, Lung, Colorectal and Ovarian (PLCO) Cancer Screening Randomized Controlled Trial. *JAMA.* 2011 Jun 8;305(22):2295–303. [PMID: 21642681]

U.S. Preventive Services Task Force. Screening for ovarian cancer: recommendation statement. *Am Fam Physician.* 2005 Feb 15;71(4):759–62. [PMID: 15756773]

OSTEOPOROSIS PREVENTION

Osteoporotic fractures are increasing as the population ages. Age and female sex are major risk factors for osteoporotic fractures. Hip and vertebral fractures are associated with premature mortality. Osteoporosis risk can be assessed by measuring bone mineral density (BMD). Normal BMD is no lower than 1.0 standard deviation below the mean for young adult women (t score). Osteopenia is defined as BMD between 1.0 and 2.5 standard deviations below the mean for young adults (t score of –1.0 to –2.5) and osteoporosis is defined as a BMD more than 2.5 standard deviations below the young adult mean (t score < –2.5).

The World Health Organization has developed a fracture risk assessment tool (FRAX, available at <http://www.shef.ac.uk/FRAX/index.jsp>) that can predict a woman's 10-year risk of having any osteoporotic fracture and the 10-year risk of hip fracture. Risk factors used in the FRAX tool include age, gender, personal history of fracture,

parental history of hip fracture, low body mass index, use of oral corticosteroids, secondary osteoporosis, current smoking, and alcohol intake of three or more drinks per day. It can be used with or without BMD. The FRAX tool is particularly helpful in determining which women with osteopenia are most likely to benefit from treatment. Based on the World Health Organization algorithm adopted for the United States, treatment is recommended when there is a 10-year risk of hip fracture $\geq 3\%$ or a 10-year risk of a major osteoporotic fracture $\geq 20\%$.

► Primary Prevention

Although calcium supplementation is routinely recommended, evidence from the Women's Health Initiative showed that calcium supplementation did not reduce fracture risk in healthy postmenopausal women. Calcium appears to be necessary but not sufficient for fracture prevention. Recommended calcium intake for women younger than 50 years is 1000 mg/day and for women aged 51 and over, it is 1200 mg/day. Calcium can be given as either calcium citrate or calcium carbonate and should be given with vitamin D. Regular weight bearing exercise has also been associated with an increase in bone density although the effect is lost when the exercise is not continued.

Increasing evidence suggests that vitamin D supplementation is associated with a reduction in fracture risk. Vitamin D can be given as either D₂ or D₃ formulations. Recommendations are that women aged 70 and younger should consume 600 international units of vitamin D per day, whereas women aged 71 and older should consume 800 international units per day. Individuals with vitamin D deficiency (25-OH vitamin D < 20 mg/mL) may require higher doses, although most recommendations for vitamin D supplementation are based on achieving a serum 25-OH vitamin D concentration of a particular level, rather than on a clinical outcome. Whether or not women should be routinely screened for vitamin D deficiency remains an ongoing question. However, given the association of vitamin D and fractures, checking a 25-OH vitamin D level in women with osteoporosis is reasonable.

► Bone Mineral Density Screening

The biggest risk factor for developing osteoporosis is increasing age. Although many women expect to be screened around the time of menopause, routine BMD screening is not recommended until the age of 65. The National Osteoporosis Foundation recommends screening all women age 65 and older and screening younger postmenopausal women if there is a concern based on their risk-factor profile, if they have had a fracture, or if they are discontinuing hormone therapy. The USPSTF recommends screening women aged 65 and older and only screening women aged 60–64 who are at increased risk.

Treatment is generally recommended in women who have a t score < –2.5, who have already had a fracture or who have a t score in the osteopenic range but are at high risk for fracture. Treatment options for osteoporosis are described in Chapter 26.

PREVENTION OF SEXUALLY TRANSMITTED INFECTIONS

Many sexually transmitted infections are asymptomatic in women and some can lead to significant consequences. Primary prevention of sexually transmitted infections includes postponing sexual debut, limiting number of sexual partners, and regular condom use.

The USPSTF and the Centers for Disease Control and Prevention recommend annual screening for *Chlamydia trachomatis* and gonorrhea in sexually active women age 25 and younger. Screening should continue in women over age 25 and in women who have high-risk sexual behaviors. The Centers for Disease Control and Prevention recommends screening all women for HIV, whereas the USPSTF recommends focusing screening efforts on high-risk individuals. All patients who have a sexually transmitted infection or who seek testing for a sexually transmitted infection should be offered HIV testing.

Meyers D et al. U.S. Preventive Services Task Force recommendations for STI screening. *Am Fam Physician.* 2008 Mar 15; 77(6):819–24. [PMID: 18386598]

DEPRESSION SCREENING

Since depression is approximately two times more common in women than in men, clinicians should be alert to symptoms suggesting depression in women. Symptoms include depressed mood, loss of interest in activities, sleep disturbance, change in appetite or weight, psychomotor retardation, difficulty concentrating, feelings of worthlessness, and thoughts of suicide. Low energy or fatigue is a particularly common symptom in women.

There are several clinical surveys for depression screening. The two question screen appears to be effective. Patients are asked “Over the past 2 weeks, have you felt down, depressed or hopeless?” and “Over the past 2 weeks, have you felt little interest or pleasure in doing things?”

There is no evidence to suggest that any particular screening tool is superior. A positive screening test should lead to more extensive evaluation.

The USPSTF recommends screening for depression if staff-assisted depression care supports are in place to ensure accurate diagnosis, effective treatment, and follow-up. If these supports are not in place, screening is not recommended.

SPECIFIC ISSUES & CONDITIONS

INTIMATE PARTNER VIOLENCE

Intimate partner violence (IPV) is a pattern of abusive behavior by a person who is in some type of intimate relationship with the victim. The abuse can be physical, sexual, or emotional and can include economic deprivation. Although anyone can be a victim of IPV, women are much more likely than men to be victims. Regardless of the type of abuse, the goal of the abuser is to gain control over the victim. IPV is common but is often not diagnosed, in part because patients try to hide the abuse.

The prevalence estimate of IPV varies depending on the setting. Rates are higher when measured in emergency departments than when measured in the general population. In a randomized controlled trial of IPV screening in emergency departments, the prevalence over 12-months ranged from 4% to 18%.

Risk factors for abuse include being young (under age 35 years); being pregnant; being single, divorced, or separated; alcohol or drug abuse in the victim or the partner; smoking; and being poor.

Evaluation

Since patients often do not volunteer that they have been abused, clinicians must be alert to clues that suggest abuse, including an explanation of the injuries that do not fit with what is being seen; frequent visits to the emergency department; and somatic complaint such as chronic headache, abdominal pain, and fatigue. The patient may be vague about some of her symptoms and may avoid eye contact. If the abusing partner is present, he or she may answer all the questions or may decline to leave the room. It is critical that the patient have the opportunity to speak with the clinician alone. The patient's description of the events should be carefully detailed in case there are any subsequent legal issues.

Physical examination often reveals injuries in the central area of the body. There may be injuries on the forearms as well if the patient tried to defend herself. As with any situation of expected abuse, bruises that are in various stages of healing may be an important clue. All physical examination findings should be well documented.

In addition to the physical consequences, abuse can have psychological consequences. Posttraumatic stress disorder, depression, anxiety, and alcohol or other substance abuse can develop in victims. Somatization is also very common among victims.

Several instruments have been developed to screen for IPV. These include the HITS (Hurt, Insult, Threaten, Screamed at) tool, the Women Abuse Screening tool (WAST), the Partner Violence Screen (PVS), the Abuse Assessment Screen (AAS), and the Women's Experience with Battering (WEB) scale. A systematic review of these screening tools showed that most tools only had been evaluated in a relatively small number of studies and the sensitivities and specificities varied widely within and between the tools.

Inclusion of one question in the context of the medical history, "Have you ever been hit, kicked, punched or otherwise hurt by someone within the past year? If so, by whom?" has been shown to increase identification of IPV.

Many studies have addressed how the questions about IPV are asked. In one randomized trial, women preferred written questionnaires over face to face interviewing.

Screening for IPV (in contrast to asking questions when IPV is suspected) has been advocated by many experts, although there is currently no evidence that it improves outcomes. In a randomized controlled trial conducted in emergency departments and other clinical sites, women in the screened group were assessed for IPV and if the screen was positive, the information was given to the clinician before the visit. At 18-month follow-up, there was no difference in recurrence of IPV among women in the screened compared with the non-screened groups. There were also no differences in quality of life, although there were no adverse effects of screening.

The USPSTF has concluded that there is insufficient evidence to recommend for or against universal screening for IPV, since there is currently no evidence that screening improves outcomes. However, clinicians should remain on high alert for clues to IPV among patients.

▶ Interventions for IPV

Interventions can include encouraging the woman to leave the abusive situation, ensuring that she has a safe place to go, and counseling so that she can adequately assess her risk of danger and create a plan for safety. There is no evidence that treatment of the abuser changes abuser behavior.

▶ When to Refer

- Victims should be referred to social services so that they can provide information on local resources. There is a national domestic violence hotline (1-800-799-SAFE) that can provide information on local resources.
- In general, mandatory reporting of IPV or suspicion of it in adult women who are competent is not required in

most states. However, mandatory reporting by physicians is required in California, Colorado, Kentucky, Mississippi, Ohio and Rhode Island.

EATING DISORDERS

Eating disorders are common in women. Anorexia nervosa and bulimia nervosa are described in detail in Chapter 29. The female athlete triad, disordered eating in diabetics, and binge eating disorders are other eating disorders that should be considered in appropriate women.

1. Female Athlete Triad

ESSENTIALS OF DIAGNOSIS

- ▶ Disordered eating.
- ▶ Menstrual disorders.
- ▶ Low BMD.

▶ General Considerations

Female athletes who participate in sports and activities valuing thinness are at increased risk for developing the female athlete triad. The definition of the triad includes disordered eating (a spectrum of abnormal patterns of eating, including bingeing; purging; food restriction; prolonged fasting; and the use of diet pills, diuretics, or laxatives), menstrual disorders, and low BMD. Half of all athletes with amenorrhea have bone density at least 1.0 standard deviation below the mean. The bone density is decreased even in those areas subjected to stress during exercise. The diagnosis is made when the individual meets the three criteria of the triad.

▶ Clinical Findings

A. Symptoms and Signs

Individuals with the female athlete triad display some pattern of disordered eating and have some menstrual irregularities. Many women have amenorrhea but others have irregular menses. Typically, the patient has concerns about weight and body image. A history of stress fractures should also raise the clinician's concern.

B. Laboratory Findings

Depending on the severity of the symptoms and whether or not the patient is bingeing and purging, the laboratory

abnormalities can be similar to those seen in anorexia nervosa or bulimia nervosa. BMD, if measured, is decreased.

► Differential Diagnosis

The main differential diagnoses include anorexia nervosa, bulimia nervosa as well as endocrine disorders such as hyperthyroidism and diabetes mellitus.

► Treatment

Little evidence is currently available about treatment of the female athlete triad. Strategies such as counseling, cognitive behavior therapy, and possibly exercise restriction may be helpful. A multidisciplinary approach, including consultation with a nutritionist and communication with the coach and trainers, may enable common goal setting. The desire to participate in sports and the lure of a performance enhancing diet may motivate some patients to pursue treatment.

Bonci CM et al. National Athletic Trainers' Association position statement: preventing, detecting and managing disordered eating in athletes. *J Athl Train.* 2008 Jan-Mar;43(1):80-108. [PMID: 18335017]

Nattiv A et al. American College of Sports Medicine position stand. The female athlete triad. *Med Sci Sports Exerc.* 2007 Oct;39(10):1867-82. [PMID: 17909417]

2. Disordered Eating in Diabetics

ESSENTIALS OF DIAGNOSIS

- Binge eating.
- Purging with laxatives or vomiting.
- Insulin omission.
- Taking less insulin than prescribed to lose weight.

► General Considerations

Eating disturbances have been estimated to be present in up to one-third of young women with diabetes. Eating disorders are more common in adolescents with diabetes than in their non-diabetic peers. Mortality is particularly high in individuals with both diabetes and eating disorders.

For diabetes, the dietary regimen emphasizes intense meal timing and consistency. In addition, the hunger associated with hypoglycemia encourages binge eating. Finally, weight gain is often associated with good glycemic control. Diabetics with disordered eating have been shown to have an increased risk of retinopathy. Given the emphasis that young women often place on body weight, maintaining optimal diabetes control is a particular challenge. The diagnosis is typically made in a diabetic who has worsening diabetic control, when other causes of worsening control have been ruled out.

► Clinical Findings

A. Symptoms and Signs

Diabetics may report polydipsia, polyuria, or weight loss. In addition, upon questioning, they may report disturbed

eating patterns. Other symptoms associated with eating disorders, such as disturbance of body image and menstrual irregularities, may also be present.

B. Laboratory Findings

The main laboratory finding will be a trend of increasing levels of hemoglobin A_{1c}.

► Differential Diagnosis

The main differential diagnosis includes looking for other causes of worsening glycemic control such as underlying infection or metabolic disease such as hyperthyroidism.

► Treatment

There is currently no evidence to support any particular strategies for the treatment of disordered eating in diabetic patients. Proposed strategies for at risk diabetic patients include nutritional counseling to promote healthy eating instead of dietary restraint, regular (instead of fixed) meal and snack times, less intensive insulin therapy to reduce weight gain, and family counseling to improve communication.

No studies have evaluated the optimal treatment of diabetic patients with established eating disorders. Presumably, strategies that are effective for patients without diabetes, such as cognitive behavioral therapy and medications, will be effective. In addition, diabetic management strategies that do not require the patient to constantly think about food may be beneficial.

Gobel-Fabbri AE et al. Disturbed eating behaviors and eating disorders in type 1 diabetes: clinical significance and treatment recommendations. *Curr Diab Rep.* 2009 Apr;9(2):133-9. [PMID: 19323958]

3. Binge Eating Disorder

ESSENTIALS OF DIAGNOSIS

- Binge eating disorder consists of episodes of eating a large amount of food in a discreet period of time with a sense of lack of control.
- Binge episodes characterized by at least three of the following:
 - Eating large amounts of food when not feeling hungry.
 - Eating more rapidly than normal.
 - Eating until feeling uncomfortably full.
 - Eating alone because of embarrassment about the amount of food consumed.
 - Feeling disgusted, depressed, or guilty after eating.
- Episodes occur at least two times a week for at least 6 months.
- No compensatory behavior (purging, fasting, or excessive exercise) after eating.

► General Considerations

Binge eating disorder is more common than either anorexia nervosa or bulimia nervosa, but it is currently not recognized as a psychiatric diagnosis. Currently, the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) has criteria that are considered research criteria. Individuals who meet these criteria are defined as having eating disorder, not otherwise specified.

Binge eating disorder is much more common in women and is associated with obesity, although not all individuals with binge eating disorder are obese. Obesity-related complications are likely to occur, and the disorder may be more common in weight cycling patients.

► Clinical Findings

The patient may present with weight gain or may describe disordered eating patterns and binge eating episodes. There are no specific laboratory findings for binge eating disorder.

► Differential Diagnosis

The main differential diagnosis includes other psychiatric and eating disorders. Other diagnostic possibilities include hypothyroidism and Prader-Willi syndrome.

► Treatment

Treatment goals focus on decreasing the patient's binge eating episodes and may include weight loss and treatment of other psychiatric comorbidities. As in bulimia nervosa, cognitive behavioral therapy is the mainstay of treatment. Interpersonal therapy has also been shown to be effective. Pharmacotherapy with selective serotonin reuptake inhibitors is also helpful, but does not appear to be better than cognitive behavioral therapy.

SEXUALITY & SEXUAL HEALTH

Sexual health is defined by the World Health Organization as a state of physical, emotional, mental, and social well-being in relation to sexuality. Healthy sexual functioning therefore depends on a complex interplay of physical, psychological, and societal factors. In the United States, sexual dysfunction is common, with more than 44% of surveyed women reporting a sexual problem and 12% experiencing distress from the problem. Six female sexual disorders have been identified in the DSM-IV and include hypoactive sexual desire disorder (HSDD), sexual aversion disorder, female sexual arousal disorder, female orgasmic

disorder, dyspareunia, and vaginismus; these are discussed in detail in Chapters 18 and 25. Notably, HSDD is most prevalent in middle-aged women. Several psychological and biological risk factors can contribute to female sexual dysfunction, including poor mental health, relationship difficulties, and hormonal changes that are associated with aging. In contrast, positive feelings about the partner and the relationship can be “protective.” Physicians should routinely assess patients' sexual health during office visits; even a brief assessment provides patients with reassurance that this is an important topic. Providers can broach the subject using a broad question, such as “What concerns or questions do you have about your sexual functioning?” and then follow-up with more specific questions, including “Do you have difficulty with desire, arousal, or orgasm?” and “If you are not currently sexual, are there any particular problems that are contributing to your lack of sexual behavior?” Patient concerns can then be delineated more fully during the complete sexual assessment, which encompasses details about medical, surgical, and psychiatric problems, as well as medications and reproductive history. Treatment options depend on the diagnosed disorder and can include psychosexual and hormonal therapy (see Chapter 18).

CHRONIC PELVIC PAIN

ESSENTIALS OF DIAGNOSIS

- Noncyclic pain.
- Duration of 6 months or more.
- Localized to anatomic pelvis, anterior abdominal wall at or below the umbilicus, the lumbosacral back, or buttocks.
- Associated with functional disability.

► General Considerations

Chronic pelvic pain is defined as noncyclic pain lasting at least 6 months that localizes to one of the following areas: the anatomic pelvis, the anterior abdominal wall at or below the umbilicus, the lumbosacral back, or the buttocks. It must be of sufficient severity to cause functional disability or necessitate medical care. Endometriosis is diagnosed in up to two-thirds of women with chronic pelvic pain; other common etiologies include postoperative pelvic adhesions, pelvic varices, interstitial cystitis (IC), and

irritable bowel syndrome (IBS). Musculoskeletal disorders such as fibromyalgia and levator ani syndrome have also been linked to chronic pelvic pain. Women with a history of physical and sexual abuse, pelvic inflammatory disease, abdominopelvic surgery, or difficult obstetric deliveries are at increased risk for developing chronic pelvic pain.

► Clinical Findings

A. Symptoms and Signs

Certain features of the history and physical examination can provide clues to the underlying diagnosis. Patients should be asked about the location, quality, and intensity of their pain as well as the relationship with the menstrual cycle, sexual activity, urination, and defecation. Endometriosis, IC, and IBS may all worsen with hormonal changes, resulting in more pain during menses. Dysmenorrhea and dyspareunia are often experienced by patients with endometriosis, whereas dysuria, urgency, and frequency in association with pelvic pain are characteristic of IC. Pain related to pelvic varices is usually postural, worsening with prolonged standing and improving with leg elevation. Patients with IBS often report abdominal pain, distention, and diarrhea or constipation. The physical examination, including the pelvic examination, is usually quite painful in the patient with chronic pelvic pain and should be done carefully. A single-digit internal vaginal examination should be done to localize the exact area of pain and to assess for trigger points along the pelvic floor muscles, which may indicate a musculoskeletal etiology for the pain. Tenderness with palpation of the anterior vaginal wall is consistent with IC, whereas discomfort with palpation of the cervix is suggestive of endometriosis or chronic pelvic infection. Women with pelvic congestion related to varices may have significant uterine tenderness. The external genitalia should also be examined carefully to identify areas of vulvar discomfort because vulvodynia often coexists in patients with chronic pelvic pain. Notably, the absence of physical examination findings does not rule out significant pathology.

B. Laboratory Findings

Laboratory studies are useful if the history and physical examination do not identify an underlying cause for the pelvic pain. Laboratory tests can include a complete blood count, serum chemistry, erythrocyte sedimentation rate, urine microscopy and culture, and vaginal swabs for detecting chlamydia and gonorrhea.

C. Diagnostic Testing and Imaging

Pelvic ultrasonography is useful for investigating any abnormalities detected on physical examination, for screening patients in whom pelvic varices are suspected, and for providing reassurance to the patient if the ultrasound is normal. Additional testing may be done to confirm a suspected diagnosis. Patients with IC often have a positive intravesical potassium chloride test or abnormalities detected on cystoscopy. Laparoscopy may be helpful for diagnosing endometriosis or pelvic adhesions, although

40% of diagnostic laparoscopies are normal in patients with chronic pelvic pain.

► Differential Diagnosis

Chronic pelvic pain is frequently a manifestation of another disease, as noted above. The history, physical examination, and diagnostic testing should be directed toward identifying patients with the most common “benign” underlying conditions, including endometriosis, pelvic adhesions, pelvic varices, IC, and IBS. Clinicians should be aware that patients frequently have more than one diagnosis contributing to the chronic pelvic pain syndrome. Less common but serious causes of chronic pelvic pain should also be considered in the differential diagnosis, including bladder malignancy, colon cancer, endometrial cancer, and inflammatory bowel disease. Accordingly, symptoms such as unexplained weight loss, hematochezia, and abnormal vaginal bleeding should be investigated thoroughly. Many patients have no clear pathologic basis for their symptoms, and are thus diagnosed with idiopathic chronic pelvic pain.

► Treatment

A. Medical Treatment

Medical treatment may focus on managing the chronic pain, the underlying condition, or both. Analgesics are commonly used, and nonsteroidal anti-inflammatory drugs (NSAIDs), such as diclofenac and naproxen, are typically helpful. However, patients and clinicians should be cautious about long-term use of these medications because long-term NSAID therapy can be associated with significant gastric toxicity. Antidepressants (eg, amitriptyline) and antiseizure medications (eg, gabapentin) (see Table 5–5), which have demonstrated efficacy in the treatment of other pain syndromes, may also be useful for chronic pelvic pain. Opioid therapy improves pain but not functional or psychological outcomes and should generally be avoided.

Hormonal therapies are used primarily for treating gynecologic sources of chronic pelvic pain. Women with endometriosis often benefit from treatment with combined oral contraceptive pills, which suppress ovulation and reduce dysmenorrhea. Gonadotropin-releasing hormone (GnRH) agonists and progestins improve pain associated with endometriosis and pelvic varices. The decrease in BMD associated with GnRH agonist treatment can be mitigated with estrogen or progesterone add-back therapy. Patients in whom endometriosis is suspected may also be treated with GnRH agonist therapy; improvement in symptoms may allow such patients to avoid laparoscopy.

Medical therapies directed at the treatment of nongynecologic sources of chronic pelvic pain, including IC and IBS, are discussed in Chapters 15 and 23. Notably, pelvic pain associated with IC and IBS frequently varies with the menstrual cycle, and GnRH agonist therapy may be helpful for treatment in these disorders as well.

Physical therapy and injection of identified trigger points provide significant pain relief in patients with musculoskeletal sources of pain. Sacral nerve stimulation has been used in patients with IC but may also be effective in up to 60% of women with chronic pelvic pain but without urinary symptoms. Psychological evaluation and treatment should also be strongly considered in all patients, both to improve treatment outcomes (particularly in patients with pelvic varices) as well as to address a history of sexual or physical abuse.

B. Surgical Treatment

Surgical treatment of chronic pelvic pain requires referral to a gynecologist. Surgical therapies that treat the pain itself include presacral neurectomy and laparoscopic uterosacral nerve ablation. These denervating interventions are typically used in the treatment of patients with severe dysmenorrhea. Condition-specific surgical treatments include adhesiolysis in patients with pelvic adhesions and laparoscopic surgical destruction of implants in patients with endometriosis. Importantly, the efficacy of adhesiolysis in the treatment of chronic pelvic pain is controversial. Hysterectomy can be effective for relieving chronic pelvic pain and may also result in improved psychological and sexual outcomes.

► Prognosis

Cohort studies provide some information on the prognosis of women who undergo hysterectomy as definitive treatment for chronic pelvic pain. In a comparative study of women with chronic pelvic pain, abnormal uterine bleeding, or leiomyomas, women who had a hysterectomy experienced significant improvement in symptoms compared with those treated medically after 1 year. However, among younger patients with chronic pelvic pain who do not have obvious anatomic pathology, the benefits of surgery are less clear, and up to 40% of patients may still have persistent pain after hysterectomy.

► When to Refer

Patients should be referred to a gynecologist for diagnostic or therapeutic surgical procedures, if the underlying diagnosis is unclear, or if the provider feels uncomfortable managing side effects associated with medical treatments (ie, GnRH agonist therapy).

MASTALGIA

ESSENTIALS OF DIAGNOSIS

- ▶ Infection, malignancy, and extramammary conditions can cause breast pain.
- ▶ Benign mastalgia is diagnosed once other causes of breast pain have been excluded and is characterized as cyclical or noncyclical.
- ▶ Abnormal physical examination findings, such as a breast mass or skin abnormalities, should prompt radiographic imaging.

► General Considerations

Breast pain, or mastalgia, is categorized as cyclical, noncyclical, or extramammary. Although minor breast discomfort is commonly associated with the normal menstrual cycle, women with cyclical mastalgia typically have moderate to severe pain that can last more than 5 days. Cyclical mastalgia can be diagnosed only in reproductive-age women who experience breast pain as a result of the hormonally-mediated proliferation in breast tissue that occurs with ovulation. In contrast, noncyclical mastalgia has no relationship to the menstrual cycle and can occur in premenopausal or postmenopausal women. Causes of noncyclical mastalgia include large breast size (with stretching of Cooper ligaments), medications, pregnancy, thrombophlebitis, or inflammatory breast cancer. Extramammary mastalgia is caused by pain that is referred from other anatomic locations, including the chest wall, heart, gallbladder, or spine. Trauma or previous surgery may also produce extramammary pain.

► Clinical Findings

A. Symptoms and Signs

Cyclical mastalgia is often described as a deep, heavy, aching pain, which is typically diffuse and bilateral and is clearly associated with the menstrual cycle. Conversely, noncyclical pain, which may be constant or intermittent, is often well localized and can involve one or both breasts. Chest wall pain, a frequent cause of extramammary mastalgia, typically causes unilateral, burning pain that may be either localized or diffuse. Malignancy-associated mastalgia is often severe, progressive, and unilateral.

Breast cancer may be associated with mastalgia, and thus a careful physical examination is essential in all women who report breast pain. Large, pendulous breasts may be observed in women who have noncyclical pain caused by stretching of Cooper ligaments. Chest wall pain is usually related to inflammation or injury to the pectoralis major muscle; it may be reproduced by palpation or by having the patient place her hand on her hip and push inward. Any palpable breast mass must be evaluated further with radiologic imaging.

B. Imaging

An ultrasound or mammogram or both should be obtained in women who have a palpable breast mass. Clinicians should also ensure that patients with mastalgia are up to date on routine screening mammography, as appropriate for their age and personal risk factors.

► Differential Diagnosis

Malignancy must be ruled out in all patients with mastalgia, and this is usually accomplished through a careful history, physical examination, and diagnostic imaging in patients with clinical abnormalities, such as a palpable breast mass. Extramammary causes of breast pain include chest wall pain, spinal or gallbladder disease, and myocardial ischemia. Cyclical and noncyclical mastalgia are easily differentiated by assessing the temporal relationship between the patient's pain and her menstrual cycle.

► Treatment

Women with cyclical mastalgia who have a normal physical examination and are up to date on routine mammographic screening should be reassured about the benign nature of their symptoms and monitored closely. Cyclical and noncyclical mastalgia often improve with use of a supportive bra. Although there is conflicting evidence regarding the benefit of vitamin E, some experts advocate its use (at a dose of 2000–3000 mg daily) for women with cyclical breast pain. Topical NSAIDs, such as diclofenac gel, improve localized breast pain.

Women who experience severe and persistent cyclical mastalgia despite adherence to conservative measures may be offered hormonal treatment. Commonly used hormonal therapies for cyclical mastalgia include danazol, bromocriptine, and tamoxifen. Danazol, a synthetic androgen that inhibits ovulation, is the only medication that has been approved by the Food and Drug Administration (FDA) for the treatment of cyclical mastalgia. However, side effects associated with treatment are common and include weight gain, menstrual irregularities, voice deepening, and hot flashes. Similarly, in a study of patients with cyclical mastalgia who were treated with bromocriptine, 40% of patients experienced adverse reactions, including nausea, dizziness, and headache. Tamoxifen therapy is tolerated well by most women, and many experts recommend it as first-line therapy for the treatment of cyclical mastalgia. Patients treated with tamoxifen should be counseled about the possibility of hot flashes and menstrual irregularities (experienced by up to 10% of women), as well as the risk for more serious adverse events, such as thromboembolic disease and endometrial cancer.

► Prognosis

Symptoms of cyclical and noncyclical mastalgia improve without pharmacologic treatment in most women. In addition, most women with cyclical mastalgia have resolution of their pain with menopause. Observational studies examining the association between cyclical mastalgia

and the subsequent development of breast cancer have produced conflicting results. Two case-control studies suggested an increased risk of breast cancer, while a third observational study suggested a decreased risk. Based on this evidence, guidelines indicate that all women with mastalgia should have an individual assessment of their breast cancer risk, and that this should guide subsequent management.

Women in whom mastalgia develops while receiving hormone replacement therapy may have an increased risk of breast cancer. In a recent analysis of data from the Women's Health Initiative, women in whom new-onset breast tenderness developed after initiating treatment with conjugated equine estrogen plus medroxyprogesterone had a 48% higher risk of developing breast cancer compared with those who did not experience breast pain. Thus, women in whom mastalgia develops in the setting of hormone-replacement therapy should have a thorough discussion with their clinician regarding the risks and benefits of continued treatment as well as screening and preventative strategies for breast cancer.

► When to Refer

Patients with mastalgia and a palpable breast mass should be referred to a breast surgeon, even if the results of diagnostic imaging are normal.

THE PALPABLE BREAST MASS

ESSENTIALS OF DIAGNOSIS

- Diagnostic imaging is essential for any women with a palpable dominant breast mass, regardless of her age.
- Ultrasound is the initial test of choice for women under the age of 30; diagnostic mammography with or without ultrasonography is performed initially in women over the age of 30.

► General Considerations

Palpable breast masses may be detected by a patient on a breast self-examination, or may be identified by the provider during a routine physical examination. Approximately 10% of breast masses are malignant, and thus a thorough work-up of any palpable breast mass is essential, regardless of age and personal risk factors for breast cancer.

Common benign causes of palpable breast masses include fibrocystic condition, cysts, and fibroadenomas (see also Chapter 17).

► Clinical Findings

A. Symptoms and Signs

Clinicians should ask patients about temporal changes in the mass shape and size, as well as associated symptoms, including pain, skin thickening, and nipple discharge. A patient's personal risk for breast cancer should be assessed, including age, previous breast biopsies, family history, and age at menarche and first pregnancy.

The location of the mass should be described using the clock-face position and distance from the nipple, as this aids the radiologist in the diagnostic evaluation. Examiners should also note the size, site, mobility, and texture of the mass, as well as areas of skin dimpling, retraction, or erythema. Benign masses are typically mobile with well-defined margins; conversely, malignant lesions may be fixed and have indistinct borders. Some women may have areas of indeterminate thickening in the absence of a discrete and well-defined palpable mass; if this finding is asymmetric it should be evaluated further with diagnostic imaging.

B. Diagnostic Tests and Imaging

As noted above, all women with a dominant palpable breast mass require diagnostic imaging. Approved imaging techniques include diagnostic mammography and ultrasonography. Diagnostic mammography consists of the standard views that are used in screening mammography, plus additional views, such as spot-compression and magnification, to better delineate the area of concern. The breast ultrasound is the most sensitive test for distinguishing a cystic from a solid lesion, and also provides detailed information regarding the shape, borders, and acoustic properties of an identified mass. In addition, ultrasonography can be used to guide the biopsy of suspicious lesions.

Women over the age of 30 with a palpable breast mass should initially be evaluated with diagnostic mammography. Features of a benign lesion include a round shape with well-circumscribed borders; a suspicious finding may have an irregular shape with spiculated margins. Ultrasonography may be coupled with diagnostic mammography if the mass is mammographically occult or has concerning mammographic features. For women under the age of 30, ultrasonography is the initial diagnostic test of choice because the dense breast tissue found in younger women limits the sensitivity of mammography. Abnormal findings on ultrasound include posterior acoustic shadowing, microlobulations, and a spiculated margin. A mass which has a thin, echogenic capsule, an ellipsoid shape, and homogenous echogenicity is more likely to be benign.

In women who are pregnant, ultrasonography is the initial diagnostic test of choice; the sensitivity of mammography is limited by the loss of contrasting fatty tissue in the breast during pregnancy. Fine-needle aspiration (FNA) biopsy does not have the same accuracy in pregnant women as a result of the increased cellularity of the breast tissue, and breast biopsy may be technically difficult

because of increased breast vascularity. Surgical consultation should be obtained to evaluate persistent areas of concern that are identified on clinical breast examination and ultrasound.

► Differential Diagnosis

The differential diagnosis of palpable masses includes benign etiologies, such as cysts, fibroadenomas, fibrocystic condition, lymph nodes, galactoceles, lipomas, and hematomas. Breast cancer, including ductal carcinoma in situ, invasive lobular carcinoma, and invasive ductal carcinoma, can also initially present with a palpable breast mass. Certain history and physical examination features may be suggestive of a particular diagnosis. Cysts are fluid-filled structures that are commonly found in women aged 35–50 years; acute enlargement of the cysts may cause abrupt and severe pain. Fibroadenomas are typically diagnosed in reproductive age women between the ages of 15 and 35 years and present as firm, nontender, and mobile masses on physical examination. Fibrocystic condition describes a pathologic diagnosis that may be accompanied by clinical symptoms and signs, including cyclical pain that is bilateral and poorly localized as well as tender, multifocal nodules. These fibrocystic changes, which include macrocysts, microcysts, fibrosis, and ductal hyperplasia, are most common among premenopausal women.

► Treatment

Management of the palpable breast mass depends on the results of diagnostic imaging. If ultrasonography or mammography suggests that the mass is related to a simple cyst, fine-needle aspiration (FNA) may be offered to symptomatic women to relieve associated pain. Characteristics of the aspirated fluid guides further work-up. If benign fluid, which is typically yellow, straw-colored, green, or brown, is aspirated and the mass resolves, the patient can be monitored expectantly. Conversely, if bloody fluid is aspirated, or if the mass persists after aspiration, further intervention with either core biopsy or excision may be indicated. A complex cyst should always be aspirated because there is a small chance (0.4%) that it may be malignant.

Core-needle biopsy, which provides a sample of tissue for histologic diagnosis, is typically used to evaluate breast masses that have a *suspicious* appearance on diagnostic imaging. Ultrasonography, mammography, or MRI may be used to guide the biopsy, thereby resulting in few complications and minimal trauma to the breast tissue. Excisional biopsy may be necessary if the mass is not amenable to core-needle biopsy (because of location or imaging characteristics) or if additional tissue is needed to confirm a benign diagnosis.

Women who have palpable masses that are associated with *normal* ultrasound or mammographic imaging should be referred to a breast surgeon, with consideration given to performing a diagnostic core-needle biopsy. Benign biopsy results are reassuring but require close clinical follow-up for at least 1–2 years.

The radiologist may categorize certain breast masses as *probably benign* after review of ultrasound or mammographic

images. In rare cases, these masses may be associated with malignancy, and so two diagnostic options may be considered. The patient may opt to forgo biopsy at that time and have imaging performed again in 6 months. Alternatively, diagnostic core excisional biopsy may be performed immediately (after consultation with a breast surgeon) if there are worrisome findings on physical examination or if there is a high clinical suspicion for malignancy. All masses categorized as probably benign require follow-up imaging at 6-month intervals for at least 2 years.

The "triple test," which is composed of the findings on physical examination, the results of diagnostic imaging, and the pathologic diagnosis obtained from FNA or core-needle biopsy, helps clinicians determine the likelihood that a palpable breast mass is malignant. In all cases, the results of each of these tests should be concordant. For example, the diagnostic imaging should identify the palpable area of concern, and if benign features are noted, the results of the FNA biopsy or core-needle biopsy should confirm a benign diagnosis, such as a fibroadenoma. If the results of any of the tests are discordant, further evaluation is warranted. Thus, if the results of FNA biopsy or core-needle biopsy suggest a benign diagnosis, but the radiographic imaging indicates a suspicious lesion, it may be appropriate to repeat the biopsy or perform an excisional biopsy. Similarly, if there is a palpable breast mass that is not identified on radiographic imaging, referral to a breast surgeon is necessary to document resolution or persistence of the mass. If the mass is persistent, the surgeon may elect to perform a biopsy to obtain a definitive diagnosis.

► Prognosis

In general, the benign causes of a palpable breast mass have a favorable prognosis. Many women with breast pain and palpable masses due to fibrocystic condition have spontaneous resolution or have improvement in their symptoms with menopause. Benign simple cysts that are asymptomatic may be followed clinically, and symptomatic cysts should resolve with aspiration.

Certain pathologic diagnoses increase the risk of breast cancer, including papillary lesions, radial scars, atypical ductal or lobular hyperplasia, and lobular carcinoma in situ. FNA biopsy or core-needle biopsy results that indicate one of these diagnoses necessitate referral to a breast surgeon for further evaluation and management.

► When to Refer

- Women with a palpable breast mass should be referred to a breast surgeon in the following situations:
 - If diagnostic imaging indicates that the mass has *suspicious* features.
 - If the mass persists and diagnostic imaging is *normal*.
 - If the mass is categorized as *probably benign* on diagnostic imaging, but there are worrisome features on physical examination or there is a high clinical suspicion for malignancy.
 - If diagnostic imaging demonstrates a complex cyst, or aspiration of a simple cyst reveals a bloody aspirate.

- If the biopsy demonstrates a lesion with an increased risk of breast cancer (papillary lesions, radial scars, atypical hyperplasia, lobular carcinoma in situ).
- If the biopsy results are discordant with the physical examination and radiographic findings.
- It may also be prudent to refer pregnant women with a palpable breast mass to a breast surgeon, because of the limitations noted above with radiographic imaging and biopsy.

NIPPLE DISCHARGE

Nipple discharge is a common breast complaint but is rarely indicative of malignancy. In one retrospective study, invasive breast cancer was subsequently diagnosed in only 5% of women in whom nipple discharge was the presenting symptom. Nipple discharge that comes from multiple ducts, is bilateral, and is produced only with squeezing is considered physiologic, and no further work-up is necessary. Milky discharge that is bilateral and spontaneous is consistent with galactorrhea caused by an elevated prolactin level. Investigation should focus on identifying the underlying causes of the hyperprolactinemia, including pregnancy, pituitary tumors, and certain medications. Women who have bloody discharge or persistent spontaneous unilateral discharge from a single duct, should be referred for mammography and surgical consultation. These features are suggestive of a pathologic diagnosis, such as papilloma, duct ectasia, or malignancy. In addition, the presence of a palpable breast mass in association with the nipple discharge significantly increases the likelihood of underlying malignancy. Surgical excision of the involved duct is the gold standard for diagnosis. See also Chapter 17.

FEMALE PATTERN HAIR LOSS

Androgenetic alopecia, also known as female pattern hair loss, is the most common cause of alopecia in women; up to 50% of females will be affected in their lifetime. This type of alopecia is mediated by the effects of androgen on the hair follicle and is characterized by shortening of the anagen (growth) phase and follicle miniaturization. Clinically, presenting signs include diffuse thinning over the central scalp and a prominent midline part; the frontal

hairline is typically preserved. Although serum androgen levels are typically normal, androgen excess disorders can present with female pattern hair loss. If irregular menses, hirsutism, or acne accompany the female pattern hair loss, the patient should be evaluated for an underlying hyperandrogenic condition with measurements of total and free testosterone, prolactin, and dehydroepiandrosterone.

Topical minoxidil is currently the only medication that has been approved by the FDA for the treatment of female pattern hair loss. Randomized trials have confirmed the efficacy of this therapy, compared with placebo, for inducing minimal to moderate hair regrowth in the majority of treated women (NNT = 8). In patients with suspected female pattern hair loss, minoxidil 2% is applied directly onto the scalp twice daily while symptoms persist. The most common side effect of minoxidil is facial hypertrichosis, which can affect 3–5% of women, but this typically resolves after 1 year of treatment. In women who have excess androgen levels, the addition of spironolactone (an anti-androgen) to minoxidil treatment may result in additional clinical benefit. Similarly, an oral contraceptive pill containing drospirone, which is a spironolactone analogue, is an appropriate choice in women desiring hormonal contraception.

TREATMENT OF VARICOSE VEINS

Varicose veins result from weakness in the vein wall and may involve obstruction to, or reversal of, normal blood flow. Approximately 30–40% of women are affected, and the clinical presentation ranges from asymptomatic to severe, with lower extremity pain, swelling, and nocturnal cramps. Medical complications can include venous ulceration, abnormal skin pigmentation, and eczema.

Treatment may be considered to relieve symptoms or for cosmetic purposes. Conservative therapy is generally recommended for asymptomatic patients or those who experience only mild to moderate discomfort. The principle behind conservative therapy is to limit disease progression: weight loss and physical exercise will improve circulation, and avoidance of prolonged standing will reduce the pressure on affected valves. Compression stockings improve venous hemodynamics and reduce symptoms of pain and swelling.

Invasive therapy may be indicated to treat patients with more severe symptoms, or those who desire significant cosmetic results. The gold standard for treating varicose veins is surgical ligation and vein stripping. If the greater saphenous vein is involved, both ligation and stripping are typically performed; smaller saphenous veins may be treated only with ligation. Surgical techniques are effective in the short-term, but recurrence is common, ranging from 30% to 50% after 5 years. Moreover, patients who receive surgical therapy are exposed to the risks of general

or epidural anesthesia and may experience postoperative pain and neurologic damage.

Minimally invasive techniques for treating varicose veins have been increasing in popularity and are often associated with faster recovery times and fewer complications when compared with surgical treatment. Currently available therapies include ultrasound-guided foam sclerotherapy (UGFS), radiofrequency ablation (RFA), and endovenous laser ablation (EVLA). Sclerotherapy is usually done in the ambulatory setting and involves injecting a chemical through a catheter into the abnormal vein to induce scarring and collapse. UGFS mixes air or gas with the sclerosing substance to produce foam, which allows for coverage of a larger surface area. Injection sclerotherapy is most beneficial for small and medium-size veins; rare complications include embolization of foam to the brain or retina. RFA and EVLA both use the principles of thermolysis to selectively induce vessel-wall damage and collapse. Laser (EVLA) or radiofrequency (RFA) energy is used to generate a heated fiber, which is inserted into the abnormal vein and slowly advanced along its length. Endothelial and vessel wall damage results, with contraction of the vein wall and ultimate collapse of the entire vessel. A minority of patients may experience local bruising, tenderness, or paresthesias as a result of these procedures.

Meta-analysis evaluating the efficacy of each of these techniques compared with surgical intervention demonstrated that success rates, as measured by complete obliteration of the vessel at 5 years, were highest for EVLA and RFA (95.4% and 79.9%, respectively) and were similar for UGFS and surgery (73.5% and 75.7% respectively). Moreover, the efficacy of RFA, UGFS, and surgery declined substantially over time, but remained relatively constant for EVLA. The authors of this study concluded that EVLA was the most effective of the minimally invasive techniques and was associated with fewer side effects and faster improvement in health-related quality of life when compared with surgical therapy. However, more studies that directly compare these methods to each other are needed.

AGE-RELATED FACIAL CHANGES

Minimally invasive aesthetic procedures are now commonly used to treat mild to moderate age-related changes in the face. These procedures are generally safe and are associated with high rates of patient satisfaction. In 2008, more than 80% of aesthetic plastic surgery treatments involved minimally invasive techniques. Thus, primary care clinicians should be familiar with the efficacy and safety of these treatment modalities in order to best counsel their patients.

Visible signs of aging in the face result from loss of subcutaneous fat, gravitational changes, and alterations in skin elasticity. Various areas of the face respond differently to each of these changes and at different times. In the upper one-third of the face, hyperdynamic wrinkles, manifested as frown lines, crow's feet, and horizontal forehead lines, typically develop as a result of repetitive muscle contraction. Conversely, volume changes are more prominent in the mid-face, as gravitational descent of the malar fat pad and volume loss leads to deepening of the nasolabial folds. Changes in the lower one-third of the face are characterized both by hyperdynamic changes resulting in deep furrows and lines, as well as flattening and loss of fullness in the lips.

Clostridium botulinum is an organism that produces potent neurotoxins with various serotypes, ranging from A to G. These serotypes vary in both their mechanism of action and clinical use, and only serotype A is used for cosmetic purposes. Botox and Dysport are two formulations of botulinum serotype A that the FDA has approved for treating hyperactivity of the glabellar muscles, which produces frown lines. Both of these products work by inhibiting the release of acetylcholine at the neuromuscular junction, thereby resulting in a chemical denervation and an overall relaxation of hyperdynamic facial muscles. Botox and Dysport are also commonly used off-label to treat horizontal frown lines and crow's feet, as the restriction of muscular movement in these areas also reduces the appearance of fine wrinkles. The onset of action of these treatments is immediate, and results typically last 3–4 months. In one study, only 5% of studied patients who had been treated with Botox experienced adverse effects, the most common of which was local bruising.

Whereas Botox and Dysport are the treatments of choice in the upper one-third of the face to treat fine wrinkles, dermal fillers are commonly used in the mid- and lower face to restore volume and fullness. Several filler substances are currently used, including collagen, hydroxylapatite,

hyaluronic acid, and injectable poly-L-lactic acid. Among these, hyaluronic acid fillers have become increasingly popular and have been approved by the FDA for treatment of nasolabial folds. They are also frequently used off-label to volumize and shape the lips. Several formulations are currently available, and they differ in their degree of cross-linking, gel hardness, and ability to resist dilution. Clinically, these differences result in various degrees of longevity, with the effects of Restylane and Perlane lasting approximately 6 months, and the effects of Juvederm Ultra and Juvederm Ultra Plus lasting approximately 12 months. The effects of injection are immediately apparent, and complications are typically mild and local, including bruising, redness, and swelling. If necessary, the injection of hyaluronidase can reverse any significant adverse effects. Notably, the clinical improvement associated with hyaluronic acid injections seems to be closely associated with the expertise of the practitioner.

Combination therapy with botulinum toxin and hyaluronic acid is now commonly being used to achieve more satisfying cosmetic results. However, serious complications can result from the injection of hyaluronic acids in the upper face, including skin necrosis, which occurs when the injection inadvertently involves a blood vessel. A thorough knowledge of the anatomy in this area is essential for avoiding this adverse event. Similarly, only experienced practitioners should use botulinum toxin in the lower face, to avoid the drooling, speech problems, and mouth incompetence that result from over-injection or misplaced treatment.

Appendix: Therapeutic Drug Monitoring, Pharmacogenetic Testing, & Laboratory Reference Intervals

C. Diana Nicoll, MD, PhD, MPA
 Chuanyi Mark Lu, MD, PhD

Table 1. Therapeutic drug monitoring.¹

Drug	Effective Concentrations	Half-Life (hours)	Dosage Adjustments	Comments
Amikacin	Conventional dosing: Peak: 20-30 mg/L; trough: < 10 mg/L High dose once daily: Peak: 60 mg/L; trough: undetectable	2-3; ↑ in uremia	↓ in renal dysfunction	Concomitant kanamycin or tobramycin therapy may give falsely elevated amikacin results by immunoassay.
Amitriptyline	95-250 ng/mL	9-25		Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted therapeutic reference interval for effective concentration.
Carbamazepine	4-12 mg/L	10-15		Induces its own metabolism. Metabolite 10,11-epoxide exhibits 13% cross-reactivity by immunoassay. Adverse reactions: skin reactions, myelosuppression.
Cyclosporine	100-300 mcg/L (ng/mL) whole blood	6-12	↓ in renal dysfunction, liver disease	Cyclosporine is lipid-soluble (20% bound to leukocytes; 40% to erythrocytes; 40% in plasma, highly bound to lipoproteins); the binding is temperature-dependent in vitro and concentration-dependent in vivo. HPLC and LC-tandem mass spectrometry methods are highly specific for parent drug and considered as the gold standard assays. Monoclonal fluorescence polarization immunoassay (FPIA) and monoclonal chemiluminescence immunoassay also measure cyclosporine reliably; polyclonal immunoassays are less specific due to cross-reaction with drug metabolites. Anticonvulsants and rifampin increase metabolism. Erythromycin, ketoconazole, and calcium channel blockers decrease metabolism. The main adverse reaction is concentration-related nephrotoxicity.
Desipramine	100-250 ng/mL	13-23		Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted therapeutic reference interval for effective concentration.

(continued)

Table 1. Therapeutic drug monitoring.¹ (continued)

Drug	Effective Concentrations	Half-Life (hours)	Dosage Adjustments	Comments
Digoxin	CHF: 0.5-0.9 ng/mL Atrial fibrillation: 0.5-2 ng/mL	42; ↑ in uremia, CHF	↓ in renal dysfunction, CHF, hypothyroidism ↑ in hyperthyroidism	Bioavailability of digoxin tablets is 50-90%. Specimen must not be drawn within 4 hours of an intravenous dose or 6 hours of an oral dose. Dialysis does not remove a significant amount. Hypokalemia potentiates toxicity. Digitalis toxicity is a clinical and <i>not</i> a laboratory diagnosis. Digibind (digoxin-specific antibody) therapy of digoxin overdose can interfere with measurement of digoxin levels depending on the digoxin assay. Elimination reduced by amiodarone, quinidine, and verapamil.
Ethosuximide	40-100 mg/L	Child: 30 Adult: 50		Levels used primarily to assess clinical response and compli- ance. Toxicity is rare and does not correlate well with plasma concentrations.
Gentamicin	Conventional dosing: Peak: 4-8 mg/L; trough: < 2 mg/L High dose once daily: Peak: 20 mg/L; trough: undetectable	2-3; ↑ in uremia (7.3 during dialysis)	↓ in renal dysfunction	Draw peak specimen (conventional dosing) 30 minutes after end of 30- to 60-min infusion. Draw trough just before next dose. In uremic patients, some penicillins (eg, carbenicillin, ticarcillin, piperacillin) may decrease gentamicin half-life from 46 hours to 22 hours, posing a risk of reduced antibacterial efficacy. The main adverse reactions are CNS, otic, and renal toxicities.
Imipramine	180-350 ng/mL	10-16		Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted therapeutic reference interval for effective concentration.
Lidocaine	1-5 mg/L	1.8; × in uremia, CHF; ↑ in cirrhosis	↓ in CHF, liver disease	Levels increased with cimetidine therapy. CNS toxicity common in the elderly.
Lithium	0.5-1.5 mmol/L	22; ↑ in uremia	↓ in renal dysfunction	Thiazides and loop diuretics may increase serum lithium levels.
Methotrexate		3-10 low dose; 8-15 high dose; ↑ in uremia	↓ in renal dysfunction	Therapeutic concentrations depend on the treatment protocol (low versus high dose) and time of specimen collection. 7-Hydroxymethotrexate cross-reacts 1.5% in immunoassay. To minimize toxicity, leucovorin or glucarpidase should be continued if methotrexate level is > 0.1 mcmol/L at 48 hours after start of therapy. Methotrexate > 1 mcmol/L at > 48 hours requires an increase in rescue therapy.
Nortriptyline	50-140 ng/mL	18-44		Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted therapeutic reference interval for effective concentration.
Phenobarbital	10-40 mg/L	Child: 37-73 Adult: 53-140; ↑ in cirrhosis	↓ in liver disease	Metabolized primarily by the hepatic microsomal enzyme system. Many drug-drug interactions.
Phenytoin	10-20 mg/L; 5-10 mg/L in uremia and severe hypoalbuminemia	Dose/concentration- dependent		Drug metabolite cross-reacts in immunoassays; the cross- reactivity may be of significance only in the presence of advanced chronic kidney disease. Metabolism is capacity-limited. Increase dose cautiously when level approaches therapeutic reference interval, since new steady-state level may be disproportionately higher. Drug is very highly protein-bound; protein binding is decreased in uremia and hypoalbuminemia. Free drug level (pharmacologically active fraction) may be indicated in certain clinical circumstances.

(continued)

Table 1. Therapeutic drug monitoring.¹ (continued)

Drug	Effective Concentrations	Half-Life (hours)	Dosage Adjustments	Comments
Sirolimus	Trough: 4–12 ng/mL when used in combination with cyclosporine A; 12–20 ng/mL if used alone	62	↓ in liver dysfunction and with drugs inhibiting CYP3A4 activity	Sirolimus is an immunosuppressant used in combination with cyclosporine and corticosteroids for prophylaxis of organ rejection after kidney transplantation. It has also been used in liver and heart transplantation. When used in combination with cyclosporine, careful monitoring of kidney function is required. Once the initial dose titration is complete, monitoring sirolimus trough concentrations weekly for the first month and every 2 weeks for the second month appears to be appropriate. The optimal time for specimen collection is 24 h after the previous dose or 0.5 to 1 h prior to the next dose (trough level).
Tacrolimus	Trough: 8–12 ng/mL	8.7–11.3	↓ in liver dysfunction and with drugs inhibiting CYP3A4 activity	Tacrolimus is used for prophylaxis of organ rejection in adult patients undergoing liver or kidney transplantation and in pediatric patients undergoing liver transplantation. It has also been used to prevent rejection in heart, small bowel, and allogeneic bone marrow transplant patients and to treat autoimmune diseases. Antacid or sucralfate administration should be separated from tacrolimus by at least 2 h. The optimal time for specimen collection is 12 h after the previous dose or 0.5 to 1 h prior to the next dose (trough level).
Theophylline	5–15 mg/L	9	↓ in CHF, cirrhosis, and with cimetidine	Caffeine cross-reacts 10%. Elimination is increased 1.5–2 times in smokers. 1,3-Dimethyl uric acid metabolite increased in uremia and, because of cross-reactivity, may cause an apparent slight increase in serum theophylline.
Tobramycin	Conventional dosing: Peak: 5–10 mg/L; trough: < 2 mg/L High dose once daily: Peak: 20 mg/L; trough: undetectable	2–3; ↑ in uremia	↓ in renal dysfunction	Tobramycin, kanamycin, and amikacin may cross-react in immunoassay. Some antibiotics may decrease tobramycin half-life in uremic patients, causing reduced antibacterial efficacy.
Valproic acid	50–100 mg/L	Child: 6–8 Adult: 10–12		Significant fraction of the drug is protein-bound in vivo (concentration-dependent). Decreased binding in uremia and cirrhosis.
Vancomycin	Trough: 10–20 mg/L	6; ↑ in uremia	↓ in renal dysfunction	Ototoxicity in uremic patients may lead to irreversible deafness. Keep peak level < 40–50 mg/L to avoid severe toxicity.

¹Serum from a plain red-top tube is typically used for therapeutic drug monitoring except for cyclosporine, which requires whole blood sample in a lavender (EDTA) tube. In general, the specimen should be drawn just before the next dose (trough).

↑, increased; ↓, decreased; CYP, cytochrome P450; HPLC, high performance liquid chromatography; CHF, congestive heart failure; CNS, central nervous system.

Modified, with permission, from Nicoll D et al. *Pocket Guide to Diagnostic Tests*, 6th ed. McGraw-Hill, 2012.

Table 2. Selected pharmacogenetic tests: clinical relevance.¹

Pharmacogenetic Biomarker	Selected Variants (mutant allele, enzyme activity)	Allele Frequency	Drugs	Clinical Relevance
Cytochrome P450 (CYP) 2C9 variants	2C9*2 (430C>T, ↓) 2C9*3 (1075A>C, ↓↓)	2C9*2 and 2C9*3 are present in 9–20% of whites, 1–3% of blacks, and < 1% of Asians	Warfarin (Coumadin)	Hepatic CYP2C9 is responsible for the metabolic inactivation and clearance of the anticoagulant warfarin. Patients carrying 2C9*2 or 2C9*3 (or both) (heterozygote, homozygote or compound heterozygote) require reduced maintenance dose to reach a therapeutic INR. While INR remains the standard for monitoring warfarin therapy, CYP2C9 genotyping can be an important aid to dosing strategy for warfarin-naïve patients, particularly whites.
CYP 2C19 variants	2C19*2(681G>A, none) 2C19*3(636G>A, none) 2C19*4(1A>G, none) 2C19*5(1297C>T, none)	The mutant variants are present in 12–25% of Asians, and 2–7% of whites and blacks	Clopidogrel (Plavix)	Clopidogrel, an antiplatelet drug, must be metabolized in the liver by CYP isoenzymes, principally CYP 2C19, to become active. When treated with clopidogrel at recommended dosages, patients with CYP 2C19 variants have more cardiovascular events than do patients with normal CYP 2C19 function. Alternative drug or intervention strategies should be considered for patients with 2C19 variants. CYP 2C19*17 carrier status (25% of whites) is associated with increased enzyme activity and an increased risk of bleeding.
HLA-B*1502 allele	HLA-B*1502	10–15% of Asians; 1–2% of whites	Carbamazepine (Tegretol, Eptol)	Carbamazepine is associated with serious or even fatal idiosyncratic skin reactions, eg, Stevens-Johnson syndrome and toxic epidermal necrolysis. The reactions are significantly more common in patients who carry the HLA-B*1502 allele. This allele occurs almost exclusively in patients with ancestry across broad areas of Asia, including South Asian Indians. HLA-B*1502 genotyping may be useful for risk stratification in patients of Asian descent. Patients carrying the HLA-B*1502 allele should not be given carbamazepine unless the expected benefit clearly outweighs the increased risk of serious skin reactions.
HLA-B*5701 allele	HLA-B*5701	6–8% of whites and selected Indians; 1–2% of blacks and Asians	Abacavir (Ziagen)	Abacavir is a nucleoside analog reverse transcriptase inhibitor used for HIV treatment. The major treatment-limiting toxicity for abacavir use is drug hypersensitivity, occurring in 5–8% of recipients within 6 weeks of commencing therapy. There is an established association between carriage of the HLA-B*5701 allele and abacavir hypersensitivity reactions. HLA-B*5701-positive patients should not be prescribed abacavir or an abacavir-containing regimen.

(continued)

Table 2. Selected pharmacogenetic tests: clinical relevance.¹ (continued)

Pharmacogenetic Biomarker	Selected Variants (mutant allele, enzyme activity)	Allele Frequency	Drugs	Clinical Relevance
Thiopurine methyltransferase (TPMT) variants	TPMT*2 (238G>C, ↓) TPMT*3A (460G>A and 719A>G, ↓↓) TPMT*3B (460G>A, ↓) TPMT*3C (719A>G, ↓)	About 10–12% of whites and blacks have reduced enzyme activity because they are heterozygous for one of the mutant alleles. About 1 in 300 whites is homozygous for a mutant allele.	Azathioprine (AZA), 6-mercaptopurine (6-MP)	AZA is a prodrug that is metabolized to 6-MP, which is then further metabolized to active 6-thioguanine (6-TG) and inactive 6-methylmercaptopurine (6-MMP) through hypoxanthine phosphoribosyltransferase and TPMT, respectively. Variation in the TPMT gene can result in functional inactivation of the enzyme and an increased risk of life-threatening, 6-TG associated myelosuppression. TPMT genotyping before instituting AZA or 6-MP can help prevent toxicity by identifying individuals with low or absent TPMT enzyme activity. Patients with homozygous or compound heterozygous mutant alleles (“poor metabolizers”) should not be given AZA or 6-MP, while heterozygotes with a single mutant allele should be treated with lower doses.
Uridine diphosphoglucuronosyltransferase 1A1 (UGT 1A1) variants	UGT1A1*28 (7 TA repeats in promoter, ↓)	Homozygosity in 9–23% of whites, blacks and Indians, and in 1–2% of eastern Asians.	Irinotecan (Camptosar)	Irinotecan is used in the treatment of metastatic colorectal cancer. It is metabolized to active SN-38, a topoisomerase I inhibitor. SN-38 is further glucuronidated to inactive SN-38G by UGT1A1 and excreted. Heterozygous and homozygous UGT1A1*28 genotypes show a 25% and 70% decrease in enzyme activity, respectively. The presence of the UGT1A1*28 allele is a risk factor for the development of adverse drug reactions (eg, neutropenia, severe diarrhea). Testing for the allele can prevent drug toxicity at high doses of irinotecan.
Vitamin K epoxide reductase complex (VKORC1) variants	VKORC1 (–1639G>A)	The homozygous (–1639G>A) allele (–1639AA genotype) is present in approximately 15% of whites and 80% of Chinese.	Warfarin (Coumadin)	The primary therapeutic target of the anticoagulant warfarin is VKOR. Polymorphisms in the VKOR encoding gene (VKORC1) explain about 30% of the phenotypic variability in drug effect. Patients carrying the VKORC1 (–1639G>A) allele require a lower warfarin maintenance dose to reach a therapeutic INR.
<i>BRAF</i> gene	<i>BRAF</i> V600E mutation	40–60% of advanced melanomas	Vemurafenib (Zelboraf)	Activating mutations in <i>BRAF</i> (a serine-threonine protein kinase) are present in 40–60% of advanced melanomas. Most, with (80–90%) of the mutations are the substitution of glutamic acid for valine at amino acid 600 (V600E mutation), and this is associated with a more aggressive clinical course. Vemurafenib, a potent inhibitor of the mutant <i>BRAF</i> , has a high level of therapeutic activity against advanced melanomas containing the V600E mutation.

¹Testing of these genetic biomarkers prior to instituting drug therapy is now recommended per US Food and Drug Administration-approved drug labels. Note, however, that these tests are not yet mandated as standard practice.

↓, decreased; ↓↓, markedly decreased; >, single wild-type to variant nucleotide switch at the specific gene location; CYP, cytochrome P450 oxidase.

Current metric units × Conversion factor = SI units SI units ÷ Conversion factor = Current metric units					
Test	Specimen	Conventional Units	Conversion Factor	SI Units ²	Collection ³
<i>JAK2</i> mutations (V617F or exon 12/13 mutation), qualitative	Whole blood	Negative (Positive: myeloproliferative neoplasms, ie, polycythemia vera, essential thrombocythemia, and primary myelofibrosis)			Lavender
Kappa and lambda free light chains, quantitative	Serum	Free kappa: 0.57–2.63 mg/dL Free lambda: 0.33–1.94 mg/dL Free kappa/lambda ratio: 0.26–1.65	0.01	5.7–26.3 × 10 ⁻³ g/L 3.3–19.4 × 10 ⁻³ g/L	SST, red
Ketone bodies	Serum or plasma	Qualitative: Negative Quantitative: <10 mg/dL	10.0	< 100 mg/L	SST, PPT (green)
Lactate dehydrogenase (LDH)	Serum or plasma	88–230 units/L (laboratory-specific)	0.02	1.46–3.82 mckat/L (laboratory-specific)	SST, PPT (green)
Lactic acid (lactate)	Venous blood	0.5–2.0 mEq/L	1.00	0.5–2.0 mmol/L	Gray (iced)
LDL cholesterol (calculated or direct)	Serum or plasma	Desirable: < 130 mg/dL (< 99 mg/dL for patients with CHD); Borderline: 130–159 mg/dL; High risk: ≥ 160 mg/dL	0.0259	< 3.37 mmol/L (< 2.57 mmol/L); 3.38–4.13 mmol/L; > 4.16 mmol/L	SST, PPT (green)
Lead (Pb)	Whole blood	Child: < 25 mcg/dL Adult: < 40 mcg/dL	0.0483	Child: < 1.21 mcmol/L Adult: < 1.93 mcmol/L	Dark blue (trace metal free)
Leukocyte (white blood cell) count, total (WBC count)	Whole blood	4.8–10.8 × 10 ³ /mcl Panic: < 1.5 × 10 ³ /mcl	1.00	4.8–10.8 × 10 ⁹ /L	Lavender
Lipase	Serum	0–160 units/L (laboratory-specific)	0.02	0–2.66 mckat/L (laboratory-specific)	SST
Luteinizing hormone (LH)	Serum or plasma	Female: Follicular phase 1–18 mU/mL Luteal phase 0.4–20 mU/mL Midcycle 24–105 mU/mL Postmenopausal 15–62 mU/mL Male: 1–10 mU/mL (laboratory-specific)	1.00	Female: 1–18 units/L 0.4–20 units/L 24–105 units/L 15–62 units/L Male: 1–10 units/L (laboratory-specific)	SST, PPT
Lymphocyte count	Whole blood	0.8–3.5 × 10 ³ /mcl	1.00	0.8–3.5 × 10 ⁹ /L	Lavender
Magnesium (Mg ²⁺)	Serum or plasma	1.8–3.0 mg/dL Panic: < 0.5 or > 4.5 mg/dL	0.411	0.75–1.25 mmol/L	SST, PPT (green)
Mean corpuscular hemoglobin (MCH)	Whole blood	27–34 pg			Lavender
Mean corpuscular hemoglobin concentration (MCHC)	Whole blood	31–36 g/dL	10.00	310–360 g/L	Lavender
Mean corpuscular volume (MCV)	Whole blood	80–100 fL			Lavender
Metanephrines, free	Plasma	Normetanephrine: < 0.9 nmol/L Metanephrine: < 0.5 nmol/L			Lavender

(continued)

Table 3. Reference intervals for commonly used tests.^{1,2} (continued)

Current metric units × Conversion factor = SI units SI units ÷ Conversion factor = Current metric units					
Test	Specimen	Conventional Units	Conversion Factor	SI Units ²	Collection ³
Metanephrines	Urine	0.3–0.9 mg/24 h	5.46	1.6–4.9 mcmol/24 h	Urine bottle containing hydrochloric acid
Methemoglobin (MetHb)	Whole blood	< 1% of total hemoglobin	0.01	< 0.01 fraction of total hemoglobin	Blood gas syringe, lavender, or green
Methylmalonic acid	Serum or plasma	0–0.05 mg/L	8.475	0–0.4 mcmol/L	SST, PPT (green)
Monocyte count	Whole blood	0.2–0.8 × 10 ³ /mCL	1.00	0.2–0.8 × 10 ⁹ /L	Lavender
Neutrophil count	Whole blood	2.2–8.6 × 10 ³ /mCL	1.00	2.2–8.6 × 10 ⁹ /L	Lavender
Osmolality	Serum or plasma	275–293 mosm/kg H ₂ O Panic: < 240 or > 320 mosm/kg H ₂ O	1.00	275–293 mmol/kg H ₂ O	SST, PPT
	Urine	Random: 100–900 mosm/kg H ₂ O	1.00	Random: 100–900 mmol/kg H ₂ O	Urine container
Osteocalcin	Serum or plasma	Child or adolescent (age 7–17 years): 25–300 ng/mL	1.00	Child or adolescent (age 7–17 years): 25–300 mcg/L	SST, PPT (green)
		Adult: 10–15 ng/mL		Adult: 10–15 mcg/L	
Oxygen, partial pressure (P _{O₂})	Whole blood	83–108 mm Hg	0.13	11.04–14.36 kPa	Heparinized syringe (iced)
Pancreatic elastase, fecal	Formed stool	> 200 mcg/g			Leak-proof container (freeze immediately)
Parathyroid hormone (PTH), intact	Serum or plasma	Intact PTH: 11–54 pg/mL (laboratory-specific)	0.11	Intact PTH: 1.2–5.7 pmol/L (laboratory-specific)	Red, SST, PPT
Partial thromboplastin time, activated (PTT)	Plasma	25–35 seconds (reference interval varies) Panic: ≥ 60 seconds			Blue
pH	Whole blood	Arterial: 7.35–7.45 Venous: 7.31–7.41			Heparinized syringe (iced)
Phosphorus	Serum or plasma	2.5–4.5 mg/dL Panic: < 1.0 mg/dL	0.323	0.8–1.45 mmol/L	SST, PPT (green)
Plasminogen	Plasma	70–113% (activity)	1.00	70–113%	Blue
Platelet count (Plt)	Whole blood	150–450 × 10 ³ /mCL Panic: < 25 × 10 ³ /mCL	1.0	150–450 × 10 ⁹ /L Panic: < 25 × 10 ⁹ /L	Lavender
Platelet-associated IgG	Plasma or serum	Negative			Lavender, PPT, SST
Platelet function test (PFA-100 closure time) (CEPI: collagen/epinephrine cartridge; CADP: collagen/ADP cartridge)	Whole blood	CEPI: 70–170 seconds (laboratory-specific) CADP: 50–110 seconds (laboratory-specific)	1.0	CEPI: 70–170 seconds CADP: 50–110 seconds	Blue
Porphobilinogen (PBG)	Urine	Negative			Protect from light

(continued)

Table 3. Reference intervals for commonly used tests.^{1,2} (continued)

Current metric units × Conversion factor = SI units SI units ÷ Conversion factor = Current metric units					
Test	Specimen	Conventional Units	Conversion Factor	SI Units ²	Collection ³
Potassium (K ⁺)	Serum or plasma	3.5–5.0 mEq/L Panic: < 3.0 or > 6.0 mEq/L	1.00	3.5–5.0 mmol/L	SST, PPT (green)
Procalcitonin	Serum or plasma	< 0.10 ng/mL	1.00	< 0.10 mcg/L	SST, PPT (green)
Prolactin (PRL)	Serum or plasma	< 20 ng/mL	1.00	< 20 mcg/L	SST, PPT (green)
Prostate-specific antigen (PSA)	Serum or plasma	0–4 ng/mL	1.00	0–4 mcg/L	SST, PPT
Protein C	Plasma	71–176% (functional) 60–150% (antigenic)			Blue
Protein electrophoresis	Serum	Adult: Albumin: 3.3–4.7 g/dL α_1 : 0.1–0.4 g/dL α_2 : 0.3–0.9 g/dL β_2 : 0.7–1.5 g/dL γ : 0.5–1.4 g/dL (polyclonal)	10.00	33–47 g/L 1–4 g/L 3–9 g/L 7–15 g/L 5–14 g/L (polyclonal)	SST, red
Protein S (antigen)	Plasma	76–178%			Blue
Protein, total	Serum or plasma	6.0–8.0 g/dL	10.00	60–80 g/L	SST, PPT (green)
Prothrombin time (PT)	Plasma	11–15 seconds Panic: ≥ 30 seconds (laboratory-specific)			Blue
Red blood cell count	Whole blood	4.7–6.1 × 10 ⁶ /mL (male) 3.5–5.5 × 10 ⁶ /mL (female)	1.00	4.7–6.1 × 10 ¹² /L 3.5–5.5 × 10 ¹² /L	Lavender
Renin activity	Plasma	High-sodium diet (75–150 mEq Na ⁺ /d): Supine: 0.2–2.3 ng/mL/h Standing: 1.3–4.0 ng/mL/h Low-sodium diet (30–75 mEq Na ⁺ /d): Standing: 4.0–7.7 ng/mL/h			Lavender
Reticulocyte count	Whole blood	33–137 × 10 ³ /mL	1.00	33–137 × 10 ⁹ /L	Lavender
Russell viper venom clotting time (dilute) (RVVT)	Plasma	24–37 seconds			Blue
Salicylate (aspirin)	Serum	200–300 mg/L Panic: > 350 mg/L	0.00724	1.45–2.17 mmol/L Panic: > 2.53 mmol/L	Red
Sodium (Na ⁺)	Serum or plasma	135–145 mEq/L Panic: < 125 or > 155 mEq/L	1.00	135–145 mmol/L Panic: < 125 or > 155 mmol/L	SST, PPT (green)
Somatostatin	Plasma	< 25 pg/mL (laboratory-specific)	0.611	< 15.28 pmol/L (laboratory-specific)	Lavender, PPT (white)
Testosterone	Serum or plasma	Male: 175–781 ng/dL Female: 10–75 ng/dL	0.0347	Male: 6–27 nmol/L Female: 0.3–2.6 nmol/L	SST, PPT (green)
Thyroglobulin	Serum or plasma	3–42 ng/mL	1.00	3–42 mcg/L	SST, PPT (green)
Thyroid-stimulating hormone (TSH)	Serum or plasma	0.4–4 mIU/mL	1.00	0.4–4 mU/L	SST, PPT (green)

(continued)

Table 3. Reference intervals for commonly used tests.^{1,2} (continued)

Current metric units × Conversion factor = SI units SI units ÷ Conversion factor = Current metric units					
Test	Specimen	Conventional Units	Conversion Factor	SI Units ²	Collection ³
Thyroid-stimulating antibody, Thyroid stimulating hormone receptor antibody (TSH-R Ab [stim])	Serum	< 130% of basal activity; based on cAMP generation in thyroid cell tissue culture			
Thyroxine, free (FT ₄)	Serum or plasma	0.7-1.86 ng/dL	12.87	9-24 pmol/L (varies with method)	SST, PPT (green)
Thyroxine (T ₄), total	Serum or plasma	5-11 mcg/dL	12.87	64-142 nmol/L	SST, PPT (green)
Transferrin	Serum or plasma	190-375 mg/dL	0.01	1.9-3.75 g/L	SST, PPT (green)
Transferrin receptor, soluble (sTfR)	Serum or plasma	2.2-5 mg/L (male) 1.9-4.4 mg/L (female) (laboratory-specific)			SST, PPT (green)
Triglycerides	Serum or plasma	< 165 mg/dL	0.0113	< 1.8 mmol/L	SST, PPT (green) (fasting)
Triiodothyronine (T ₃), total	Serum	95-190 ng/dL	0.0154	1.5-2.9 nmol/L	Red
Troponin-I (cTnI)	Plasma	< 0.1 ng/mL (method-dependent)	1.0	< 0.1 mcg/L (method-dependent)	Lavender
Uric acid	Serum or plasma	Male: 2.4-7.4 mg/dL Female: 1.4-5.8 mg/dL	59.48	Male: 140-440 mcmol/L Female: 80-350 mcmol/L	SST, PPT (green)
Vanillylmandelic acid (VMA)	Urine	2-7 mg/24 h	5.05	10-35 mcmol/d	Urine bottle containing hydrochloric acid
Vitamin B ₁₂	Serum or plasma	170-820 pg/mL	0.738	125-600 pmol/L	SST, PPT (green)
Vitamin D, 25-hydroxy (25[OH]D)	Serum or plasma	20-50 ng/mL	2.496	50-125 nmol/L	SST, PPT (green)
Vitamin D, 1,25-dihydroxy (1,25[OH] ₂ D)	Serum or plasma	20-76 pg/mL	2.6	48-182 pmol/L	SST, PPT (green)
von Willebrand factor (vWF)	Plasma	50-180% (activity and antigen)			Blue
White blood cell count	Whole blood	4.8-10.8 × 10 ³ /mCL	1.00	4.8-10.8 × 10 ⁹ /L	Lavender

¹The reference intervals given here in conventional units and in SI units are from several large medical centers. Always use the reference intervals provided by your clinical laboratory, since intervals may be method-dependent.

[PMID: 3789557]; Systeme Internationale (SI) conversion factors for selected laboratory components. *JAMA Author Instructions.* 2001 Sep 28. http://jama.ama-assn.org/site/misc/auinst_si.xhtml; and Stein K. Journal adopts use of conventional and SI units. *J Am Diet Assoc.* 2005 Aug;105(8):1186-7. [PMID: 16182628]

³See Table 4 for commonly used blood specimen collection tubes.

Table 4. Commonly used blood specimen collection tubes.

Tube	Tube Contents	Typical Use
Lavender or Pink	K ₂ EDTA	Complete blood count; blood banking (plasma); molecular testing
Gold SST	Clot activator and gel for serum separation	Serum chemistry tests
White PPT	K ₂ EDTA and gel for plasma separation	Molecular testing (plasma-based)
Red	None	Blood banking (serum); therapeutic drug monitoring
Blue	Na citrate	Coagulation studies
Gray	Inhibitor of glycolysis (sodium fluoride)	Lactic acid; glucose
Green PPT, light green PPT	Sodium heparin or lithium heparin (green PPT, without gel; light green PPT, with gel for plasma separation)	Plasma chemistry tests (light green PPT); chromosome analysis (sodium heparin) (green PPT)
Yellow	Acid citrate dextrose (ACD) Sodium polyanethol sulfonate (SPS)	ACD: HLA typing; blood banking (plasma); flow cytometry immunophenotyping SPS: blood culture (microbiology)
Dark Blue	Clot activator (trace metal free)	Trace metals (eg, lead, mercury, arsenic)
Orange RST	Thrombin and gel for serum separation	Serum chemistry tests

EDTA, ethylenediamine tetraacetic acid; PPT, plasma preparation tube; RST, rapid serum tube; SST, serum separator tube.

Index

NOTE: Page numbers in **boldface** type indicate a major discussion. A *t* following a page number indicates tabular material, and *f* following a page number indicates a figure. Drugs are listed under their generic names. When a drug trade name is listed, the reader is referred to the generic name.

- A3243G mutation, in diabetes mellitus, 1195
- A antigen, in compatibility testing, 534
- A-C ventilation. *See* Assist-control (A-C) ventilation
- A cells, pancreatic, 1171
