McGraw-Hill eBooks are available at special quantity discounts to use as premiums and sales promotions, or for use in corporate training programs. To contact a representative please e-mail us at bulksales@mcgraw-hill.com.

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each medication they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used medications.

TERMS OF USE

This is a copyrighted work and The McGraw-Hill Companies, Inc. ("McGraw-Hill") and its licensors reserve all rights in and to the work. Use of this work is subject to these terms. Except as permitted under the Copyright Act of 1976 and the right to store and retrieve one copy of the work, you may not decompile, disassemble, reverse engineer, reproduce, modify, create derivative works based upon, transmit, distribute, disseminate, sell, publish or sublicense the work or any part of it without McGraw-Hill's prior consent. You may use the work for your own noncommercial and personal use; any other use of the work is strictly prohibited. Your right to use the work may be terminated if you fail to comply with these terms.

THE WORK IS PROVIDED "AS IS." MCGRAW-HILL AND ITS LICENSORS MAKE NO GUARANTEES OR WARRANTIES AS TO THE ACCURACY, ADEQUACY OR COMPLETENESS OF OR RESULTS TO BE OBTAINED FROM USING THE WORK, INCLUDING ANY INFORMATION THAT CAN BE ACCESSED THROUGH THE WORK VIA HYPERLINK OR OTHERWISE, AND EXPRESSLY DISCLAIM ANY WARRANTY, EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO IMPLIED WARRANTIES OF MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE. McGraw-Hill and its licensors do not warrant or guarantee that the functions contained in the work will meet your requirements or that its operation will be uninterrupted or error free. Neither McGraw-Hill nor its licensors shall be liable to you or anyone else for any inaccuracy, error or omission, regardless of cause, in the work or for any damages resulting therefrom. McGraw-Hill has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

Contents

Authors	xi	Depression	63
Preface	xvii	Delirium	64
1. Disease Prevention & Health Promotion	1	Immobility	65
<i>Michael Pignone, MD, MPH, & René Salazar, MD</i>		Falls & Gait Disorders	65
Prevention of Infectious Diseases	3	Urinary Incontinence	67
Prevention of Cardiovascular Disease	5	Undernutrition & Frailty	69
Prevention of Osteoporosis	11	Pressure Ulcers	70
Prevention of Physical Inactivity	12	Pharmacotherapy & Polypharmacy	71
Prevention of Overweight & Obesity	13	Vision Impairment	72
Cancer Prevention	15	Hearing Impairment	72
Prevention of Injuries & Violence	17	Elder Mistreatment & Self Neglect	72
Prevention of Substance Abuse: Alcohol & Illicit Drugs	18		
2. Common Symptoms	21	5. Palliative Care & Pain Management	74
<i>Ralph Gonzales, MD, MSPH, & Paul L. Nadler, MD</i>		<i>Michael W. Rabow, MD, & Steven Z. Pantilat, MD</i>	
Cough	21	Definition & Scope of Palliative Care	74
Dyspnea	24	Pain Management	74
Hemoptysis	26	Principles of Pain Management	74
Chest Pain	28	Pain at the End of Life	75
Palpitations	30	Pharmacologic Pain Management Strategies	76
Lower Extremity Edema	33	Nonpharmacologic Treatments	85
Fever & Hyperthermia	35	Palliation of Other Common Symptoms	85
Involuntary Weight Loss	37	Dyspnea	85
Fatigue & Chronic Fatigue Syndrome	38	Nausea & Vomiting	86
Acute Headache	40	Constipation	86
Dysuria	43	Fatigue	86
		Delirium & Agitation	86
		End-of-Life Care	87
		Tasks after Death	92
3. Preoperative Evaluation & Perioperative Management	46	6. Dermatologic Disorders	94
<i>Hugo Q. Cheng, MD</i>		<i>Timothy G. Berger, MD</i>	
Evaluation of the Asymptomatic Patient	46	Principles of Dermatologic Therapy	94
Cardiac Risk Assessment & Reduction	46	Common Dermatoses	100
Pulmonary Evaluation in Non-Lung Resection Surgery	50	Pigmented Lesions	100
Evaluation of the Patient with Liver Disease	51	Scaling Disorders	103
Preoperative Hematologic Evaluation	52	Vesicular Dermatoses	118
Neurologic Evaluation	53	Weeping or Crusted Lesions	123
Management of Endocrine Diseases	54	Pustular Disorders	125
Kidney Disease	55	Erythemas	132
Antibiotic Prophylaxis of Surgical Site Infections	55	Blistering Diseases	138
		Papules	139
		Violaceous to Purple Papules & Nodules	143
		Pruritus (Itching)	145
		Inflammatory Nodules	150
		Epidermal Inclusion Cyst	152
		Photodermatitis	152
		Ulcers	153
		Miscellaneous Dermatologic Disorders	155
4. Geriatric Disorders	57	Pigmentary Disorders	155
<i>C. Bree Johnston, MD, MPH, G. Michael Harper, MD, & C. Seth Landefeld, MD</i>		Baldness (Alopecia)	156
General Principles of Geriatric Care	57	Nail Disorders	157
Assessment of the Older Adult	57	Dermatitis Medicamentosa (Drug Eruption)	158
Management of Common Geriatric Problems	59		
Dementia	59		

7. Disorders of the Eyes & Lids 162*Paul Riordan-Eva, FRCOphth*

Refractive Errors	162
Disorders of the Lids & Lacrimal Apparatus	163
Conjunctivitis	164
Pinguecula & Pterygium	167
Corneal Ulcer	167
Acute Angle-Closure Glaucoma	174
Chronic Glaucoma	175
Uveitis	177
Cataract	179
Retinal Detachment	179
Vitreous Hemorrhage	180
Age-Related Macular Degeneration	180
Central & Branch Retinal Vein Occlusions	181
Central & Branch Retinal Artery Occlusions	183
Transient Monocular Blindness	184
Retinal Disorders Associated with Systemic Diseases	185
Ischemic Optic Neuropathy	187
Optic Neuritis	188
Optic Disk Swelling	189
Ocular Motor Palsies	190
Dysthyroid Eye Disease	191
Orbital Cellulitis	191
Ocular Trauma	192
Ultraviolet Keratitis (Actinic Keratitis)	194
Chemical Conjunctivitis & Keratitis	194
Treatment of Ocular Disorders	194
Precautions in Management of Ocular Disorders	194
Adverse Ocular Effects of Systemic Drugs	195

8. Ear, Nose & Throat Disorders 198*Lawrence R. Lustig, MD, & Joshua S. Schindler, MD*

Diseases of the Ear	198
Diseases of the Nose & Paranasal Sinuses	213
Diseases of the Oral Cavity & Pharynx	224
Diseases of the Salivary Gland	232
Diseases of the Larynx	233
Tracheostomy & Cricothyrotomy	238
Foreign Bodies in the Upper Aerodigestive Tract	238
Diseases Presenting as Neck Masses	239

9. Pulmonary Disorders 242*Mark S. Chesnutt, MD, Thomas J. Prendergast, MD, & Emmanuel T. Tavan, MD*

Disorders of the Airways	242
Pulmonary Infections	270
Pulmonary Neoplasms	289
Interstitial Lung Disease (Diffuse Parenchymal Lung Disease)	292
Disorders of the Pulmonary Circulation	297
Environmental & Occupational Lung Disorders	307
Pleural Diseases	313
Disorders of Control of Ventilation	317
Acute Respiratory Failure	319
Acute Respiratory Distress Syndrome	322

10. Heart Disease 324*Thomas M. Bashore, MD, Christopher B. Granger, MD, Patrick Hranitzky, MD, & Manesh R. Patel, MD*

Congenital Heart Disease	324
Valvular Heart Disease	333
Coronary Heart Disease (Atherosclerotic CAD, Ischemic Heart Disease)	350
Disorders of Rate & Rhythm	376
Bradycardias & Conduction Disturbances	394
Congestive Heart Failure	398
Myocarditis & the Cardiomyopathies	409
Rheumatic Fever	417
Diseases of the Pericardium	419
Pulmonary Hypertension & Pulmonary Heart Disease	423
Neoplastic Diseases of the Heart	426
Cardiac Involvement in Miscellaneous Systemic Diseases	427
Traumatic Heart Disease	428
Risk of Surgery in the Cardiac Patient	429
Heart Disease & Pregnancy	429
Cardiovascular Screening of Athletes	431

11. Systemic Hypertension 433*Michael Sutters, MD, MRCP (UK)*

How Is Blood Pressure Measured and Hypertension Diagnosed?	433
Prehypertension	434
Approach to Hypertension	435
Drug Therapy: Current Antihypertensive Agents	444
Resistant Hypertension	459
Hypertensive Urgencies & Emergencies	460

12. Blood Vessel & Lymphatic Disorders 464*Joseph H. Rapp, MD, Christopher D. Owens, MD, MSc, & Meshell D. Johnson, MD*

Atherosclerotic Peripheral Vascular Disease	464
Nonatherosclerotic Vascular Disease	471
Arterial Aneurysms	472
Venous Diseases	478
Diseases of the Lymphatic Channels	483
Shock	485

13. Blood Disorders 490*Lloyd E. Damon, MD, Charalambos Andreadis, MD, & Charles A. Linker, MD*

Anemias	490
Neutropenia	509
Leukemias & Other Myeloproliferative Neoplasms	511
Lymphomas	524
Stem Cell Transplantation	532
Blood Transfusions	534

14. Disorders of Hemostasis, Thrombosis, & Antithrombotic Therapy 538*Patrick F. Fogarty, MD, & Tracy Minichiello, MD*

Platelet Disorders	538
Disorders of Coagulation	549
Antithrombotic Therapy	554

15. Gastrointestinal Disorders 564*Kenneth R. McQuaid, MD*

Symptoms & Signs of Gastrointestinal Disease	564
Diseases of the Peritoneum	587
Diseases of the Esophagus	591
Diseases of the Stomach & Duodenum	607
Diseases of the Small Intestine	621
Diseases of the Colon & Rectum	632
Anorectal Diseases	657

16. Liver, Biliary Tract, & Pancreas Disorders 662*Lawrence S. Friedman, MD*

Jaundice & Evaluation of Abnormal Liver	
Biochemical Tests	662
Diseases of the Liver	665
Diseases of the Biliary Tract	702
Diseases of the Pancreas	711

17. Breast Disorders 718*Armando E. Giuliano, MD, & Sara A. Hurvitz, MD*

Benign Breast Disorders	718
Fibrocystic Condition	718
Fibroadenoma of the Breast	719
Nipple Discharge	720
Fat Necrosis	720
Breast Abscess	721
Disorders of the Augmented Breast	721
Carcinoma of the Female Breast	722
Carcinoma of the Male Breast	745

18. Gynecologic Disorders 747*H. Trent MacKay, MD, MPH, & Jason Woo, MD, MPH, FACOG*

Abnormal Premenopausal Bleeding	747
Postmenopausal Vaginal Bleeding	749
Premenstrual Syndrome	
(Premenstrual Tension)	749
Dysmenorrhea	750
Vaginitis	751
Cervical Polyps	753
Bartholin Duct Cysts & Abscesses	753
Cervical Intraepithelial Neoplasia (CIN)	
(Dysplasia of the Cervix)	754
Carcinoma of the Cervix	756
Leiomyoma of the Uterus (Fibroid Tumor)	757
Carcinoma of the Endometrium	759
Carcinoma of the Vulva	759

Endometriosis	760
Pelvic Organ Prolapse	762
Pelvic Inflammatory Disease	
(Salpingitis, Endometritis)	762
Ovarian Cancer & Ovarian Tumors	764
Polycystic Ovary Syndrome	765
Female Sexual Dysfunction	766
Infertility	768
Contraception	770
Rape	777
Menopausal Syndrome	779

19. Obstetrics & Obstetric Disorders 781*Vanessa L. Rogers, MD, & Kevin C. Worley, MD*

Diagnosis of Pregnancy	781
Essentials of Prenatal Care	782
Nutrition in Pregnancy	785
Prevention of Rhesus Alloimmunization	785
Lactation	786
Travel & Immunizations during Pregnancy	786
Obstetric Complications of the	
First & Second Trimesters	787
Vomiting of Pregnancy (Morning Sickness) & Hyperemesis Gravidarum (Pernicious Vomiting of Pregnancy)	787
Spontaneous Abortion	788
Recurrent (Habitual) Abortion	789
Ectopic Pregnancy	790
Gestational Trophoblastic Disease (Hydatidiform Mole & Choriocarcinoma)	791
Obstetric Complications of the Second & Third Trimesters	792
Preeclampsia-Eclampsia	792
Acute Fatty Liver of Pregnancy	795
Preterm Labor	796
Third-Trimester Bleeding	797
Obstetric Complications of the Peripartum Period	797
Puerperal Mastitis	797
Chorioamnionitis & Metritis	798
Medical Conditions Complicating Pregnancy	798
Anemia	798
Antiphospholipid Syndrome	799
Thyroid Disease	800
Diabetes Mellitus	800
Chronic Hypertensive Disease	802
Heart Disease	802
Asthma	803
Seizure Disorders	803
Infectious Conditions Complicating Pregnancy	803
Urinary Tract Infection	803
Group B Streptococcal Infection	804
Varicella	804
Tuberculosis	805
HIV/AIDS during Pregnancy	805
Maternal Hepatitis B & C Carrier State	806
Herpes Genitalis	806

25. Psychiatric Disorders 1038*Stuart J. Eisendrath, MD, & Jonathan E. Lichtmacher, MD*

Common Psychiatric Disorders	1038
Substance Use Disorders (Drug Dependency, Drug Abuse)	1079
Delirium & Other Cognitive Disorders (Formerly: Organic Brain Syndrome)	1087
Psychiatric Problems Associated with Hospitalization & Illness	1089

26. Endocrine Disorders 1093*Paul A. Fitzgerald, MD*

Diseases of the Hypothalamus & Pituitary Gland	1093
Diseases of the Thyroid Gland	1105
Diseases of the Parathyroids	1135
Metabolic Bone Disease	1144
Diseases of the Adrenal Cortex	1154
Pheochromocytoma & Paraganglioma	1166
Pancreatic & Duodenal Neuroendocrine Tumors	1171
Diseases of the Testes & Male Breast	1173
Amenorrhea & Menopause	1179
Multiple Endocrine Neoplasia	1188
Clinical Use of Corticosteroids	1190

27. Diabetes Mellitus & Hypoglycemia 1192*Umesh Masharani, MB, BS, MRCP (UK)*

Diabetes Mellitus	1192
Diabetic Coma	1231
The Hypoglycemic States	1238

28. Lipid Disorders 1245*Robert B. Baron, MD, MS*

Lipoproteins & Atherogenesis	1245
Lipid Fractions & the Risk of Coronary Heart Disease	1246
Therapeutic Effects of Lowering Cholesterol	1246
Secondary Conditions that Affect Lipid Metabolism	1247
Clinical Presentations	1247
Screening for High Blood Cholesterol	1248
Treatment of High Low-Density Lipoprotein Cholesterol	1252
High Blood Triglycerides	1255

29. Nutritional Disorders 1257*Robert B. Baron, MD, MS*

Protein-Energy Malnutrition	1257
Obesity	1258
Eating Disorders	1262
Disorders of Vitamin Metabolism	1264
Diet Therapy	1268
Nutritional Support	1270

30. Common Problems in Infectious Diseases & Antimicrobial Therapy 1276*Peter V. Chin-Hong, MD, & B. Joseph Guglielmo, PharmD*

Common Problems in Infectious Diseases	1276
Fever of Unknown Origin	1276
Infections in the Immunocompromised Patient	1278
Health Care-Associated Infections	1282
Infections of the Central Nervous System	1285
Animal & Human Bite Wounds	1288
Sexually Transmitted Diseases	1290
Infections in Drug Users	1292
Acute Infectious Diarrhea	1293
Infectious Diseases in the Returning Traveler	1296
Traveler's Diarrhea	1297
Antimicrobial Therapy	1298
Selected Principles of Antimicrobial Therapy	1298
Hypersensitivity Tests & Desensitization	1305
Immunization Against Infectious Diseases	1307
Recommended Immunization of Infants, Children, & Adolescents	1307
Recommended Immunization for Adults	1307
Recommended Immunization for Travelers	1314
Vaccine Safety	1316

31. HIV Infection & AIDS 1319*Andrew R. Zolopa, MD, & Mitchell H. Katz, MD*

Epidemiology	1319
Etiology	1322
Pathogenesis	1322
Pathophysiology	1322
Clinical Findings	1322
Differential Diagnosis	1324
Complications	1324
Prevention	1333
Treatment	1336
Course & Prognosis	1349
When to Refer	1349
When to Admit	1349

32. Viral & Rickettsial Infections 1350*Wayne X. Shandera, MD, & Ingrid L. Roig, MD*

Viral Diseases	1350
Human Herpesviruses	1350
Major Vaccine-Preventable Viral Infections	1367
Other Neurotropic Viruses	1376
Other Systemic Viral Diseases	1384
Common Viral Respiratory Infections	1393
Adenovirus Infections	1401
Other Exanthematous Viral Infections	1402
Viruses & Gastroenteritis	1404
Enteroviruses that Produce Several Syndromes	1405
Rickettsial Diseases	1408
Typhus Group	1408

Spotted Fevers	1412	Coccidioidomycosis	1532
Other Rickettsial & Rickettsial-Like Diseases	1414	Pneumocystosis (<i>Pneumocystis jiroveci</i> Pneumonia)	1533
Kawasaki Disease	1417	Cryptococcosis	1535
33. Bacterial & Chlamydial Infections	1419	Aspergillosis	1537
<i>Brian S. Schwartz, MD</i>		Mucormycosis	1538
Infections Caused by Gram-Positive Bacteria	1419	Blastomycosis	1538
Infective Endocarditis	1435	Paracoccidioidomycosis (South American Blastomycosis)	1539
Infections Caused by Gram-Negative Bacteria	1440	Sporotrichosis	1539
Actinomycosis	1456	<i>Penicillium marneffe</i> Infections	1540
Nocardiosis	1457	Chromoblastomycosis (Chromomycosis)	1540
Infections Caused by Mycobacteria	1458	Mycetoma (Maduromycosis & Actinomycetoma)	1540
Infections Caused by Chlamydiae	1461	Other Opportunistic Mold Infections	1540
34. Spirochetal Infections	1464	Antifungal Therapy	1541
<i>Susan S. Philip, MD, MPH</i>		37. Disorders Related to Environmental Factors	1543
Syphilis	1464	<i>Jacqueline A. Nemer, MD, FACEP</i>	
Non-Sexually Transmitted Treponematoses	1474	Cold & Heat	1543
Selected Spirochetal Diseases	1475	Thermal Burns	1549
Relapsing Fever	1475	Electrical Injury	1552
Rat-Bite Fever	1476	Radiation Exposure	1553
Leptospirosis	1477	Near Drowning	1555
Lyme Disease (Lyme Borreliosis)	1478	Environmental Disorders Related to Altitude	1557
35. Protozoal & Helminthic Infections	1484	38. Poisoning	1562
<i>Philip J. Rosenthal, MD</i>		<i>Kent R. Olson, MD</i>	
Protozoal Infections	1484	Initial Evaluation: Poisoning or Overdose	1562
African Trypanosomiasis (Sleeping Sickness)	1484	The Symptomatic Patient	1562
American Trypanosomiasis (Chagas Disease)	1486	Antidotes & Other Treatment	1566
Leishmaniasis	1487	Diagnosis of Poisoning	1568
Malaria	1490	Selected Poisonings	1570
Babesiosis	1499	39. Cancer	1593
Toxoplasmosis	1500	<i>Patricia A. Cornett, MD, & Tiffany O. Dea, PharmD</i>	
Amebiasis	1503	Etiology	1593
Infections with Pathogenic Free-Living Amebas	1505	Modifiable Risk Factors	1593
Coccidiosis (Cryptosporidiosis, Isosporiasis, Cyclosporiasis, Sarcocystosis) & Microsporidiosis	1506	Staging	1594
Giardiasis	1509	The Paraneoplastic Syndromes	1594
Other Intestinal Flagellate Infections	1510	Types of Cancer	1595
Trichomoniasis	1510	Lung Cancer	1595
Helminthic Infections	1511	Hepatobiliary Cancers	1603
Trematode (Fluke) Infections	1511	Alimentary Tract Cancers	1612
Liver, Lung, & Intestinal Flukes	1512	Cancers of the Genitourinary Tract	1630
Cestode Infections	1514	Cancer Complications & Emergencies	1644
Intestinal Nematode (Roundworm) Infections	1517	Primary Cancer Treatment	1648
Invasive Nematode (Roundworm) Infections	1520	Systemic Cancer Therapy	1648
Filariasis	1524	Toxicity & Dose Modification of Chemotherapeutic Agents	1649
36. Mycotic Infections	1529	Prognosis	1663
<i>Samuel A. Shelburne, MD, PhD, & Richard J. Hamill, MD</i>		40. Clinical Genetic Disorders	1664
Candidiasis	1529	<i>Reed E. Pyeritz, MD, PhD</i>	
Histoplasmosis	1531	Acute Intermittent Porphyria	1664
		Alkaptonuria	1665

Down Syndrome	1666	Ankle Injuries	1703
Fragile X Mental Retardation	1667	Inversion Ankle Sprains	1703
Gaucher Disease	1667	Eversion (“High”) Ankle Sprains	1704
Disorders of Homocysteine Metabolism	1668		
Klinefelter Syndrome	1669	42. Women’s Health Issues	1706
Marfan Syndrome	1670	<i>Megan McNamara, MD, MSc, & Judith Walsh, MD, MPH</i>	
Hereditary Hemorrhagic Telangiectasia	1671	Preventive Health Care	1706
		Cardiovascular Disease Prevention	1706
41. Sports Medicine & Outpatient Orthopedics	1673	Cancer Prevention	1708
<i>Anthony Luke, MD, MPH, & C. Benjamin Ma, MD</i>		Osteoporosis Prevention	1710
General Approach to Musculoskeletal Injuries	1673	Prevention of Sexually Transmitted Infections	1711
Shoulder	1674	Depression Screening	1711
Subacromial Impingement Syndrome	1674	Specific Issues & Conditions	1711
Rotator Cuff Tears	1675	Intimate Partner Violence	1711
Shoulder Dislocation & Instability	1681	Eating Disorders	1712
Adhesive Capsulitis (“Frozen Shoulder”)	1682	Sexuality & Sexual Health	1714
Spine Problems	1683	Chronic Pelvic Pain	1714
Low Back Pain	1683	Mastalgia	1716
Spinal Stenosis	1685	The Palpable Breast Mass	1717
Lumbar Disk Herniation	1685	Nipple Discharge	1719
Neck Pain	1686	Female Pattern Hair Loss	1719
Upper Extremity	1687	Treatment of Varicose Veins	1720
Lateral & Medial Epicondylitis	1687	Age-Related Facial Changes	1720
Carpal Tunnel Syndrome	1688		
Hip	1689	Appendix: Therapeutic Drug Monitoring, Pharmacogenetic Testing, & Laboratory Reference Intervals	1722
Hip Fractures	1689	<i>C. Diana Nicoll, MD, PhD, MPA, & Chuanyi Mark Lu, MD, PhD</i>	
Osteoarthritis	1691	Index	1737
Knee	1692		
Knee Pain	1692		
Anterior Cruciate Ligament Injury	1693		
Collateral Ligament Injury	1698		
Posterior Cruciate Ligament Injury	1699		
Meniscus Injuries	1700		
Patellofemoral Pain	1700		
Osteoarthritis	1701		

ONLINE-ONLY CHAPTERS

www.AccessMedicine.com/CMDT

Anti-infective Chemotherapeutic & Antibiotic Agents

B. Joseph Guglielmo, PharmD

Penicillins	Alternative Drugs in Tuberculosis Treatment
Cephalosporins	Rifamycins
Other β -Lactam Drugs	Sulfonamides & Antifolate Drugs
Erythromycin Group (Macrolides)	Sulfones Used in the Treatment of Leprosy
Ketolides	Specialized Drugs Used Against Bacteria
Tetracycline Group	Streptogramins
Glycylcyclines	Oxazolidinones
Chloramphenicol	Daptomycin
Aminoglycosides	Telavancin
Polymyxins	Quinolones
Antituberculous Drugs	Pentamidine & Atovaquone
	Urinary Antiseptics
	Antifungal Drugs
	Antiviral Chemotherapy

Basic Genetics

Reed E. Pyeritz, MD, PhD

- Introduction to Medical Genetics
 - Genes & Chromosomes
 - Mutation
 - Genes in Individuals
 - Genes in Families
 - Disorders of Multifactorial Causation
 - Chromosomal Aberrations
- The Techniques of Medical Genetics
 - Family History & Pedigree Analysis
 - Cytogenetics & Cytogenomics
 - Biochemical Genetics
 - DNA Analysis
 - Prenatal Diagnosis
 - Neoplasia: Cytogenomic & DNA Analysis

Diagnostic Testing & Medical Decision Making

C. Diana Nicoll, MD, PhD, MPA, Michael Pignone, MD, MPH, & Chuanyi Mark Lu, MD, PhD

- Benefits, Costs, & Risks
- Performance of Diagnostic Tests
- Test Characteristics
- Use of Tests in Diagnosis & Management
- Odds-Likelihood Ratios

Information Technology in Patient Care

Russ Cucina, MD, MS

- Patient Confidentiality & Information Technology
- Clinical Uses of E-mail
- Electronic Health Records
- Computerized Provider Order Entry
- Clinical Decision Support Systems
- Social Media & Websites in Clinical Practice
- Mobile Computing for Clinicians
- Telemedicine

Complementary & Alternative Medicine

Kevin Barrows, MD

- Botanical Medicines
- Dietary Supplements
- Acupuncture
- Mind-Body Medicine

Preface

Current Medical Diagnosis & Treatment 2013 (CMDT 2013) is the 52nd edition of this single-source reference for practitioners in both hospital and ambulatory settings. The book emphasizes the practical features of clinical diagnosis and patient management in all fields of internal medicine and in specialties of interest to primary care practitioners and to subspecialists who provide general care.

INTENDED AUDIENCE FOR *CMDT*

House officers, medical students, and all other health professions students will find the descriptions of diagnostic and therapeutic modalities, with citations to the current literature, of everyday usefulness in patient care.

Internists, family physicians, hospitalists, nurse practitioners, physicians' assistants, and all primary care providers will appreciate *CMDT* as a ready reference and refresher text. Physicians in other specialties, pharmacists, and dentists will find the book a useful basic medical reference text. Nurses, nurse-practitioners, and physicians' assistants will welcome the format and scope of the book as a means of referencing medical diagnosis and treatment.

Patients and their family members who seek information about the nature of specific diseases and their diagnosis and treatment may also find this book to be a valuable resource.

NEW IN THIS EDITION OF *CMDT*

- Addition of a new chapter on Women's Health Issues
- Expanded use of photos in chapters
- Updated CDC recommendations for adult and adolescent immunizations, including Tdap to prevent pertussis
- New algorithm for diagnosis and assessment of hypertension, and new sections on treatment of hypertension in the elderly and on treatment of hypertensive emergency
- Recommendations for anticoagulation and antiplatelet therapy for acute coronary syndromes
- New risk assessment model for deep venous thrombosis and new therapy for its prevention following hip or knee replacement
- Update on use of the thrombopoietin receptor agonists, eltrombopag and romiplostim
- Thoroughly updated breast cancer treatment options
- Updated guidelines for percutaneous coronary intervention, for coronary artery angiography and stent placement and for diagnosis of myocardial infarction by high-sensitivity troponin assay
- New antiarrhythmic and anticoagulant treatments of atrial fibrillation and use of CHADS₂ and CHADS-VASC scores to determine appropriateness of such anticoagulation
- Update on new percutaneous technique for PDA closure and newer interventional approaches to aortic, mitral, and pulmonary valve replacement
- Inclusion of new questionnaire methods to detect alcohol dependence, obstructive sleep apnea, cognitive dysfunction, and confusion
- New lung cancer screening recommendations
- Review of benefits of screening mammography, prostate specific antigen testing, and transvaginal ultrasound and serum CA-125 testing
- Update on cervical screening recommendations from the US Preventive Services Task Force
- Updated section on treating menopause
- Updated CDC guidelines for the treatment of sexually transmitted infections
- Information on new medications to lower serum uric acid
- Stepwise approach to assessing surgical risk in cardiac patients undergoing noncardiac surgery and update on postoperative myocardial infarction
- New classification of pulmonary hypertension and revised treatment options algorithm
- New drug treatment (ivacaftor) for cystic fibrosis
- FDA approval for belimumab to treat patients with active antibody-positive systemic lupus erythematosus
- FDA approval for a single rapid treponemal test for syphilis and data on sensitivity by stage of several other new tests for syphilis
- New therapeutic approach for patients with hypertrophic cardiomyopathy

- Information on mistreatment and self-neglect and on advance financial planning for elders
- Review of utility of antiretroviral medication therapy pre- and post-HIV exposure
- Strategies aimed at preventing preterm birth in high-risk women
- Information regarding a new recombinant hepatitis E vaccine and new ACIP recommendation of HPV vaccination of young males
- Extensive revision of the section on rhabdomyolysis
- Updated recommendations for inferior vena cava filter placement, tracking, and removal
- Updated rules for discontinuing hepatitis C treatment
- Updates on measuring liver stiffness for estimating degree of liver fibrosis without the need for liver biopsy
- Update on best techniques for detection of small hepatic carcinomas in patients eligible for resection
- New section on peripheral artery aneurysms
- Revised recommendations for tuberculosis screening and guidelines for a new assay to detect *Mycobacterium tuberculosis*
- Information about atypical hemolytic uremic syndrome and its treatment with eculizumab
- Update on management of factor inhibitors in hemophilia
- Information on when a laboratory work-up for thrombophilia is indicated
- Substantial revision of the following chapters: Viral & Rickettsial Infections, Disorders Related to Environmental Factors, and Blood Disorders

OUTSTANDING FEATURES OF CMDT

- Medical advances up to time of annual publication
- Detailed presentation of all primary care topics, including gynecology, obstetrics, dermatology, ophthalmology, otolaryngology, psychiatry, neurology, toxicology, urology, geriatrics, orthopedics, preventive medicine, and palliative care
- Concise format, facilitating efficient use in any practice setting
- More than 1000 diseases and disorders
- Annual update on HIV infection and AIDS
- Specific disease prevention information
- Easy access to medication dosages, with trade names indexed and costs updated in each edition
- Recent references, with unique identifiers (PubMed, PMID numbers) for rapid downloading of article abstracts and, in some instances, full-text reference articles
- ICD-9 codes listed on the inside covers

CMDT Online (www.AccessMedicine.com) provides full electronic access to *CMDT 2013* plus expanded basic science information and five additional chapters. The five online-only chapters (Anti-infective Chemotherapeutic & Antibiotic Agents, Basic Genetics, Diagnostic Testing & Medical Decision Making, Information Technology in Patient Care, and Complementary & Alternative Medicine) are available at www.AccessMedicine.com/CMDT. CMDT Online is updated throughout the year and includes an expanded, dedicated Media Gallery as well as links to related Web sites. Subscribers also receive access to *Diagnosaurus* with 1000+ differential diagnoses, *Pocket Guide to Diagnostic Tests*, *Quick Answers*, and *CURRENT Practice Guidelines in Primary Care*.

ACKNOWLEDGMENTS

We wish to thank our associate authors for participating once again in the annual updating of this important book. We are especially grateful to Shruti Patel, MD, who is leaving *CMDT* this year. We have all benefited from her clinical wisdom and commitment.

Many students and physicians also have contributed useful suggestions to this and previous editions, and we are grateful. We continue to welcome comments and recommendations for future editions in writing or via electronic mail. The editors' and authors' institutional and e-mail addresses are given in the Authors section.

From inability to let alone; from too much zeal for the new and contempt for what is old; from putting knowledge before wisdom, and science before art and cleverness before common sense; from treating patients as cases; and from making the cure of the disease more grievous than the endurance of the same, Good Lord, deliver us.

—Sir Robert Hutchison

& René Salazar, MD

1

GENERAL APPROACH TO THE PATIENT

The medical interview serves several functions. It is used to collect information to assist in diagnosis (the “history” of the present illness), to assess and communicate prognosis, to establish a therapeutic relationship, and to reach agreement with the patient about further diagnostic procedures and therapeutic options. It also serves as an opportunity to influence patient behavior, such as in motivational discussions about smoking cessation or medication adherence. Interviewing techniques that avoid domination by the clinician increase patient involvement in care and patient satisfaction. Effective clinician-patient communication and increased patient involvement can improve health outcomes.

▶ Patient Adherence

For many illnesses, treatment depends on difficult fundamental behavioral changes, including alterations in diet, taking up exercise, giving up smoking, cutting down drinking, and adhering to medication regimens that are often complex. Adherence is a problem in every practice; up to 50% of patients fail to achieve full adherence, and one-third never take their medicines. Many patients with medical problems, even those with access to care, do not seek appropriate care or may drop out of care prematurely. Adherence rates for short-term, self-administered therapies are higher than for long-term therapies and are inversely correlated with the number of interventions, their complexity and cost, and the patient’s perception of overmedication.

As an example, in HIV-infected patients, adherence to antiretroviral therapy is a crucial determinant of treatment success. Studies have unequivocally demonstrated a close relationship between patient adherence and plasma HIV RNA levels, CD4 cell counts, and mortality. Adherence levels of > 95% are needed to maintain virologic suppression. However, studies show that over 60% of patients are < 90% adherent and that adherence tends to decrease over time.

Patient reasons for nonadherence include simple forgetfulness, being away from home, being busy, and changes in daily routine. Other reasons include psychiatric disorders (depression or substance abuse), uncertainty about the

effectiveness of treatment, lack of knowledge about the consequences of poor adherence, regimen complexity, and treatment side effects.

Patients seem better able to take prescribed medications than to adhere to recommendations to change their diet, exercise habits, or alcohol intake or to perform various self-care activities (such as monitoring blood glucose levels at home). A 2008 review on the effectiveness of interventions to improve medication adherence found that for short-term regimens, adherence to medications can be improved by giving clear instructions. Writing out advice to patients, including changes in medication, may be helpful. Because low functional health literacy is common (almost half of English-speaking US patients are unable to read and understand standard health education materials), other forms of communication—such as illustrated simple text, videotapes, or oral instructions—may be more effective. For non-English-speaking patients, clinicians and health care delivery systems can work to provide culturally and linguistically appropriate health services.

To help improve adherence to long-term regimens, clinicians can work with patients to reach agreement on the goals for therapy, provide information about the regimen, ensure understanding by using the “teach-back” method, counsel about the importance of adherence and how to organize medication-taking, reinforce self-monitoring, provide more convenient care, prescribe a simple dosage regimen for all medications (preferably one or two doses daily), suggest ways to help in remembering to take doses (time of day, mealtime, alarms) and to keep appointments, and provide ways to simplify dosing (medication boxes). Single-unit doses supplied in foil wrappers can increase adherence but should be avoided for patients who have difficulty opening them. Medication boxes with compartments (eg, Medisets) that are filled weekly are useful. Microelectronic devices can provide feedback to show patients whether they have taken doses as scheduled or to notify patients within a day if doses are skipped. Reminders, including cell phone text messages, are another effective means of encouraging adherence. The clinician can also enlist social support from family and friends, recruit an adherence monitor, provide a more convenient care environment, and provide rewards and recognition

for the patient's efforts to follow the regimen. Collaborative programs that utilize pharmacists to help ensure adherence have also been shown to be effective.

Adherence is also improved when a trusting doctor-patient relationship has been established and when patients actively participate in their care. Clinicians can improve patient adherence by inquiring specifically about the behaviors in question. When asked, many patients admit to incomplete adherence with medication regimens, with advice about giving up cigarettes, or with engaging only in "safer sex" practices. Although difficult, sufficient time must be made available for communication of health messages.

Medication adherence can be assessed generally with a single question: "In the past month, how often did you take your medications as the doctor prescribed?" Other ways of assessing medication adherence include pill counts and refill records; monitoring serum, urine, or saliva levels of drugs or metabolites; watching for appointment nonattendance and treatment nonresponse; and assessing predictable drug effects such as weight changes with diuretics or bradycardia from β -blockers. In some conditions, even partial adherence, as with drug treatment of hypertension and diabetes mellitus, improves outcomes compared with nonadherence; in other cases, such as HIV antiretroviral therapy or treatment of tuberculosis, partial adherence may be worse than complete nonadherence.

▶ Guiding Principles of Care

Ethical decisions are often called for in medical practice, at both the "micro" level of the individual patient-clinician relationship and at the "macro" level of the allocation of resources. Ethical principles that guide the successful approach to diagnosis and treatment are honesty, beneficence, justice, avoidance of conflict of interest, and the pledge to do no harm. Increasingly, Western medicine involves patients in important decisions about medical care, including how far to proceed with treatment of patients who have terminal illnesses (see Chapter 5).

The clinician's role does not end with diagnosis and treatment. The importance of the empathic clinician in helping patients and their families bear the burden of serious illness and death cannot be overemphasized. "To cure sometimes, to relieve often, and to comfort always" is a French saying as apt today as it was five centuries ago—as is Francis Peabody's admonition: "The secret of the care of the patient is in caring for the patient." Training to improve mindfulness and enhance patient-centered communication increases patient satisfaction and may also improve clinician satisfaction.

HEALTH MAINTENANCE & DISEASE PREVENTION

Preventive medicine can be categorized as primary, secondary, or tertiary. Primary prevention aims to remove or reduce disease risk factors (eg, immunization, giving up or not starting smoking). Secondary prevention techniques promote early detection of disease or precursor states (eg, routine cervical Papanicolaou screening to detect carcinoma or dysplasia of the cervix). Tertiary prevention measures are aimed at limiting the impact of established disease (eg, partial mastectomy and radiation therapy to remove and control localized breast cancer). Tables 1-1 and 1-2 give leading causes of death in the United States and estimates of deaths from preventable causes.

Many effective preventive services are underutilized, and few adults receive all of the most strongly recommended services. The three highest-ranking services in terms of potential health benefits and cost-effectiveness include discussing aspirin use with high-risk adults, tobacco-use screening and brief interventions, and immunizing children. Other high-ranking services with data with substantial room for improvement in utilization are screening adults aged 50 and older for colorectal cancer, immunizing adults aged 65 and older against pneumococcal disease, and screening young women for *Chlamydia*.

Several methods, including the use of provider or patient reminder systems, reorganization of care environments, and possibly provision of financial incentives, can increase utilization of preventive services, but such methods have not been widely adopted.

Danaei G et al. The preventable causes of death in the United States: comparative risk assessment of dietary, lifestyle, and metabolic risk factors. *PLoS Med*. 2009 Apr 28;6(4):e1000058. [PMID: 19399161]

Table 1-2. Deaths from all causes attributable to common preventable risk factors. (Numbers given in the thousands.)

Risk Factor	Male (95% CI)	Female (95% CI)	Both Sexes (95% CI)
Tobacco smoking	248 (226-269)	219 (196-244)	467 (436-500)
High blood pressure	164 (153-175)	231 (213-249)	395 (372-414)
Overweight-obesity (high BMI)	114 (95-128)	102 (80-119)	216 (188-237)
Physical inactivity	88 (72-105)	103 (80-128)	191 (164-222)
High blood glucose	102 (80-122)	89 (69-108)	190 (163-217)
High LDL cholesterol	60 (42-70)	53 (44-59)	113 (94-124)
High dietary salt (sodium)	49 (46-51)	54 (50-57)	102 (97-107)
Low dietary omega-3 fatty acids (seafood)	45 (37-52)	39 (31-47)	84 (72-96)
High dietary trans fatty acids	46 (33-58)	35 (23-46)	82 (63-97)
Alcohol use	45 (32-49)	20 (17-22)	64 (51-69)
Low intake of fruits and vegetables	33 (23-45)	24 (15-36)	58 (44-74)
Low dietary polyunsaturated fatty acids (in replacement of saturated fatty acids)	9 (6-12)	6 (3-9)	15 (11-20)

BMI, body mass index; CI, confidence interval; LDL, low-density lipoprotein.

Note: Numbers of deaths cannot be summed across categories.

PREVENTION OF INFECTIOUS DISEASES

Much of the decline in the incidence and fatality rates of infectious diseases is attributable to public health measures—especially immunization, improved sanitation, and better nutrition.

Immunization remains the best means of preventing many infectious diseases. Recommended immunization schedules for children and adolescents can be found online at <http://www.cdc.gov/vaccines/recs/schedules/child-schedule.htm> and the schedule for adults is outlined in Table 30-7. Substantial vaccine-preventable morbidity and mortality continue to occur among adults from vaccine-preventable diseases, such as hepatitis A, hepatitis B, influenza, and pneumococcal infections. For example, in adults in the United States, there are an estimated 50,000–70,000 deaths annually from influenza, hepatitis B, and invasive pneumococcal disease. Strategies to enhance vaccinations include increasing community demand for vaccinations; enhancing access to vaccination services; and provider- or system-based interventions, such as reminder systems.

Evidence suggests annual **influenza vaccination** is safe and effective with potential benefit in all age groups, and the Advisory Committee on Immunization Practices (ACIP) recommends routine influenza vaccination for all persons aged 6 months and older, including all adults.

When vaccine supply is limited, certain groups should be given priority, such as adults 50 years and older, individuals with chronic illness or immunosuppression, and pregnant women. An alternative high-dose inactivated vaccine for adults 65 years and older is available. This inactivated trivalent vaccine contains 60 mcg of hemagglutinin antigen per influenza vaccine virus strain (Fluzone High-Dose [Sanofi Pasteur]). Adults 65 years and older can receive either the standard dose or high-dose vaccine, whereas those younger than 65 years should receive a standard-dose preparation.

Increasing reports of **pertussis** among US adolescents, adults, and their infant contacts have stimulated vaccine development for older age groups. A safe and effective tetanus-diphtheria 5-component acellular pertussis vaccine (Tdap) is available for use in adolescents and in adults younger than 65 years. Compared with DTaP, which is used in children under the age of 7, Tdap has a reduced dose of the diphtheria and pertussis vaccines. The ACIP recommends routine use of a single dose of Tdap for adults aged 19–64 years to replace the next booster dose of tetanus and diphtheria toxoids vaccine (Td). Due to increasing reports of pertussis in the United States, clinicians may choose to give Tdap to persons aged 65 years and older despite limited published data on the safety and efficacy of the vaccine in this age group.

Both **hepatitis A vaccine** and immune globulin provide protection against hepatitis A; however, administration of immune globulin may provide a modest benefit over vaccination in some settings. A recombinant protein **hepatitis E vaccine** has been developed that has proven safe and efficacious in preventing hepatitis E among high-risk populations.

Human papillomavirus (HPV) virus-like particle (VLP) vaccines have demonstrated effectiveness in preventing persistent HPV infections, and thus may impact the rate of cervical intraepithelial neoplasia (CIN) II–III. The American Academy of Pediatrics (AAP) recommends routine HPV vaccination for girls aged 11–12 years. The AAP also recommends that all unvaccinated girls and women ages 13–26 years receive the HPV vaccine. It is estimated that routine use of HPV vaccination of females at 11 to 12 years of age and catch-up vaccination of females at age 13–16 (with vaccination of girls age 9 and 10 at the discretion of the physician) could prevent 95% to 100% of CIN and adenocarcinoma in situ, 99% of genital warts and approximately 70% of cervical cancer cases worldwide; thus, the role of HPV testing will need redefinition. In October 2011, the ACIP approved recommendations for routine vaccination of males 11 or 12 years of age with three doses of HPV4 (quadrivalent vaccine). Vaccination of males with HPV may lead to indirect protection of women by reducing transmission of HPV. Despite the effectiveness of the vaccine, rates of immunization are low. Interventions addressing personal beliefs and system barriers to vaccinations may help address the slow adoption of this vaccine.

Persons traveling to countries where infections are endemic should take precautions described in Chapter 30. Immunization registries—confidential, population-based, computerized information systems that collect vaccination data about all residents of a geographic area—can be used to increase and sustain high vaccination coverage.

Skin testing for **tuberculosis** (see Table 9–16) and treating selected patients reduce the risk of reactivation tuberculosis. Two blood tests, which are not confounded by prior BCG (bacille Calmette-Guérin) vaccination, have been developed to detect tuberculosis infection by measuring in vitro T-cell interferon-gamma release in response to two antigens (the enzyme-linked immunospot [ELISpot], [T-SPOT.TB] and the other, a quantitative ELISA [QuantIFERON-TBGold] test). These T-cell-based assays have an excellent specificity that is higher than tuberculin skin testing in BCG-vaccinated populations. The rate of tuberculosis in the United States has been declining since 1992. In 2009, the US tuberculosis rate was 3.8 cases per 100,000 population, a decrease of 11.4% from the 2008 rate (4.2 per 100,000). This represents the greatest single-year decrease ever recorded and was the lowest recorded rate since national tuberculosis surveillance began in 1953.

The Advisory Council for the Elimination of Tuberculosis has called for a renewed commitment to eliminating tuberculosis in the United States, and the Institute of Medicine has published a detailed plan for achieving that goal. Patients with HIV infection are at an especially high risk for tuberculosis, and tuberculosis preventive therapy in the era of HIV will require further work to overcome implementation barriers and to identify optimal duration of preventive therapy and treatment approach for individuals receiving highly active antiretroviral therapy (HAART).

Treatment of tuberculosis poses a risk of hepatotoxicity and thus requires close monitoring of liver transaminases.

Alanine aminotransferase (ALT) monitoring during the treatment of latent tuberculosis infection is recommended for certain individuals (preexisting liver disease, pregnancy, chronic alcohol consumption). ALT should be monitored in HIV-infected patients during treatment of tuberculosis disease and should be considered in patients over the age of 35. Symptomatic patients with an ALT elevation three times the upper limit of normal (ULN) or asymptomatic patients with an elevation five times the ULN should be treated with a modified or alternative regimen.

In 2010, the Centers for Disease Control and Prevention (CDC) updated guidelines for the prevention and treatment of sexually transmitted diseases. Highlights of these guidelines include updated treatments for bacterial vaginosis and genital warts as well as antibiotic-resistant *Neisseria gonorrhoeae*, the prevalence of which has risen.

HIV infection is a major infectious disease problem in the world, and it affects 850,000–950,000 persons in the United States. Since sexual contact is a common mode of transmission, primary prevention relies on eliminating unsafe sexual behavior by promoting abstinence, later onset of first sexual activity, decreased number of partners, and use of latex condoms. Appropriately used, condoms can reduce the rate of HIV transmission by nearly 70%. In one study, couples with one infected partner who used condoms inconsistently had a considerable risk of infection: the rate of seroconversion was estimated to be 13% after 24 months. No seroconversions were noted with consistent condom use. Unfortunately, as many as one-third of HIV-positive persons continue unprotected sexual practices after learning that they are HIV-infected. Preexposure prophylaxis with antiretroviral drugs in men who have sex with men could have a major impact on preventing HIV infection, and studies evaluating the impact in other groups are underway. Postexposure prophylaxis is widely used after occupational and nonoccupational contact, and it has been estimated to reduce the risk of transmission by approximately 80%.

With regard to secondary prevention, many HIV-infected persons in the United States receive the diagnosis at advanced stages of immunosuppression, and almost all will progress to AIDS if untreated. On the other hand, HAART substantially reduces the risk of clinical progression or death in patients with advanced immunosuppression. Screening tests for HIV are extremely (> 99%) accurate. While the benefits of HIV screening appear to outweigh its harms, current screening is generally based on individual patient risk factors. Such screening can identify persons at risk for AIDS but misses a substantial proportion of those infected. Nonetheless, the yield from screening higher prevalence populations is substantially greater than that from screening the general population, and more widespread screening of the population remains controversial.

In immunocompromised patients, live vaccines are contraindicated but many killed or component vaccines are safe and recommended. *Asymptomatic* HIV-infected patients have not shown adverse consequences when given live MMR and influenza vaccinations as well as tetanus, hepatitis B,

H influenzae type b and pneumococcal vaccinations—all should be given. However, if poliomyelitis immunization is required, the inactivated poliomyelitis vaccine is indicated. In *symptomatic* HIV-infected patients, live virus vaccines such as MMR should generally be avoided, but annual influenza vaccination is safe.

Whenever possible, immunizations should be completed before procedures that require or induce immunosuppression (organ transplantation or chemotherapy), or that reduce immunogenic responses (splenectomy). However, if this is not possible, the patient may mount only a partial immune response, yet even this partial response can be beneficial. Patients who undergo allogeneic bone marrow transplantation lose preexisting immunities and should be revaccinated. In many situations, family members should also be vaccinated to protect the immunocompromised patient, although oral live polio vaccine should be avoided because of the risk of infecting the patient.

Herpes zoster, caused by reactivation from previous varicella zoster virus (VZV) infection, affects many older adults and people with immune system dysfunction. Whites are at higher risk than other ethnic groups and the incidence in adults age 65 and older may be higher than previously described. It can cause postherpetic neuralgia, a potentially debilitating chronic pain syndrome. A varicella vaccine is available for the prevention of herpes zoster. Several clinical trials have shown that this vaccine (Zostavax) is safe, elevates VZV-specific cell-mediated immunity, and significantly reduces the incidence of herpes zoster and postherpetic neuralgia in persons older than 60 years. In one randomized, double-blind, placebo-controlled trial among more than 38,000 older adults, the vaccine reduced the incidence of postherpetic neuralgia by 66% and the incidence of herpes zoster by 51%. The ACIP recommends routine zoster vaccination, administered as a one-time subcutaneous dose (0.65 mL), of all persons aged 60 years or older. Persons who report a previous episode of zoster can be vaccinated; however, the vaccine is contraindicated in immunocompromised (primary or acquired) individuals. The durability of vaccine response and whether any booster vaccination is needed are still uncertain. The cost effectiveness of the vaccine varies substantially, and the patient's age should be considered in vaccine recommendations. One study reported a cost-effectiveness exceeding \$100,000 per quality-adjusted life year saved. Despite its availability, uptake of the vaccine remains low at 2–7% nationally. Financial barriers (cost, limited knowledge of reimbursement) have had a significant impact on its underutilization.

Methicillin-resistant *Staphylococcus aureus* (MRSA), previously recognized as a nosocomial pathogen, has emerged as a common cause of staphylococcal infection in the outpatient setting; it accounts for more than 50% of outpatient staphylococcal infections. Community-acquired (CA)-MRSA strains affect healthy individuals, and the burden of disease can range from a furuncle to more severe life-threatening infections. Treatment of CA-MRSA is different from nosocomial MRSA because CA-MRSA strains typically retain susceptibility to antibiotics that are ineffective in treating nosocomial strains.

PREVENTION OF CARDIOVASCULAR DISEASE

Cardiovascular diseases, including coronary heart disease (CHD) and stroke, represent two of the most important causes of morbidity and mortality in developed countries. Several risk factors increase the risk for coronary disease and stroke. These risk factors can be divided into those that are modifiable (eg, lipid disorders, hypertension, cigarette smoking) and those that are not (eg, gender, age, family history of early coronary disease). Impressive

declines in age-specific mortality rates from heart disease and stroke have been achieved in all age groups in North America during the past two decades, in large part through improvement of modifiable risk factors: reductions in cigarette smoking, improvements in lipid levels, and more aggressive detection and treatment of hypertension. This section considers the role of screening for cardiovascular risk and the use of effective therapies to reduce such risk. Key recommendations for cardiovascular prevention are shown in Table 1–3.

Kahn R et al. The impact of prevention on reducing the burden of cardiovascular disease. *Circulation*. 2008 Jul 29;118(5):576–85. [PMID: 18606915]

▶ Abdominal Aortic Aneurysm

One-time screening for abdominal aortic aneurysm (AAA) by ultrasonography in men aged 65–75 years is associated with a significant reduction in AAA-related mortality (odds ratio, 0.56 [95% CI, 0.44 to 0.72]). With long-term (7–15 years) follow-up, the reduction in AAA-related mortality is sustained, and screening appears to produce a reduction in all-cause mortality (OR = 0.94, 95% CI 0.92, 0.97). Women do not appear to benefit from screening, and most of the benefit in men appears to accrue among current or former smokers. Recent analyses suggest that screening men aged 65 years and older is highly cost-effective.

Lindholt JS et al. Long-term benefit and cost-effectiveness analysis of screening for abdominal aortic aneurysms from a randomized controlled trial. *Br J Surg*. 2010 Jun;97(6):826–34. [PMID: 20473995]

▶ Cigarette Smoking

Cigarette smoking remains the most important cause of preventable morbidity and early mortality. In 2000, there were an estimated 4.8 million premature deaths in the world attributable to smoking, 2.4 million in developing countries and 2 million in industrialized countries. More than three-quarters (3.8 million) of these deaths were in men. The leading causes of death from smoking were cardiovascular diseases (1.7 million deaths), chronic obstructive pulmonary disease (COPD) (1 million deaths), and lung cancer (0.9 million deaths). Cigarettes are responsible for one in every four deaths in the United States. Fortunately, US smoking rates are declining. Currently, 20% of US adults and 21.6% of adolescents in 12th grade are smokers.

Nicotine is highly addictive, raises brain levels of dopamine, and produces withdrawal symptoms on discontinuation.

Smokers die 5–8 years earlier than never-smokers. They have twice the risk of fatal heart disease, 10 times the risk of lung cancer, and several times the risk of cancers of the mouth, throat, esophagus, pancreas, kidney, bladder, and cervix; a twofold to threefold higher incidence of stroke and peptic ulcers (which heal less well than in non-smokers); a twofold to fourfold greater risk of fractures of the hip, wrist, and vertebrae; four times the risk of invasive pneumococcal disease; and a twofold increase in cataracts.

In the United States, over 90% of cases of COPD occur among current or former smokers. Both active smoking and passive smoking are associated with deterioration of the elastic properties of the aorta (increasing the risk of aortic aneurysm) and with progression of carotid artery atherosclerosis. Smoking has also been associated with increased risks of leukemia, of colon and prostate cancers, of breast cancer among postmenopausal women who are slow acetylators of *N*-acetyltransferase-2 enzymes, osteoporosis, and Alzheimer disease. In cancers of the head and neck, lung, esophagus, and bladder, smoking is linked to mutations of the *P53* gene, the most common genetic change in human cancer. Patients with head and neck cancer who continue to smoke during radiation therapy have lower rates of response than those who do not smoke. Olfaction and taste are impaired in smokers, and facial wrinkles are increased. Heavy smokers have a 2.5 greater risk of age-related macular degeneration.

The children of smokers have lower birth weights, are more likely to be mentally retarded, have more frequent respiratory infections and less efficient pulmonary function, have a higher incidence of chronic ear infections than children of nonsmokers, and are more likely to become smokers themselves.

In addition, exposure to environmental tobacco smoke has been shown to increase the risk of cervical cancer, lung cancer, invasive pneumococcal disease, and heart disease; to promote endothelial damage and platelet aggregation; and to increase urinary excretion of tobacco-specific lung carcinogens. The incidence of breast cancer may be increased as well. Of approximately 450,000 smoking-related deaths in the United States annually, as many as 53,000 are attributable to environmental tobacco smoke. Annual costs of smoking-related health care is approximately \$96 billion per year in the United States, with another \$97 billion in productivity losses.

Smoking cessation reduces the risks of death and of myocardial infarction in people with coronary artery disease; reduces the rate of death and acute myocardial infarction in patients who have undergone percutaneous coronary revascularization; lessens the risk of stroke; slows the rate of progression of carotid atherosclerosis; and is associated with improvement of COPD symptoms. On average, women smokers who quit smoking by age 35 add about 3 years to their life expectancy, and men add more than 2 years to theirs. Smoking cessation can increase life expectancy even for those who stop after the age of 65.

Although tobacco use constitutes the most serious common medical problem, it is undertreated. Almost 40% of smokers attempt to quit each year, but only 4%

Table 1-3. Expert recommendations for cardiovascular prevention methods: US Preventive Services Task Force (USPSTF).¹

Prevention Method	Recommendation
Screening for abdominal aortic aneurysm	<p>Recommends one-time screening for abdominal aortic aneurysm (AAA) by ultrasonography in men aged 65 to 75 who have ever smoked. (B)</p> <p>No recommendation for or against screening for AAA in men aged 65 to 75 who have never smoked. (C)</p> <p>Recommends against routine screening for AAA in women. (D)</p>
Aspirin use	<p>Recommends the use of aspirin for men age 45 to 79 years when the potential benefit due to a reduction in myocardial infarctions outweighs the potential harm due to an increase in gastrointestinal hemorrhage. (A)</p> <p>Recommends the use of aspirin for women age 55 to 79 years when the potential benefit of a reduction in ischemic strokes outweighs the potential harm of an increase in gastrointestinal hemorrhage. (A)</p> <p>Current evidence is insufficient to assess the balance of benefits and harms of aspirin for cardiovascular disease prevention in men and women 80 years or older. (I)</p> <p>Recommends against the use of aspirin for stroke prevention in women younger than 55 years and for myocardial infarction prevention in men younger than 45. (D)</p>
Blood pressure screening	Recommends screening for high blood pressure in adults aged 18 and older. (A)
Serum lipid screening	<p>Strongly recommends screening men aged 35 and older for lipid disorders. (A)</p> <p>Recommends screening men aged 20 to 35 for lipid disorders if they are at increased risk for coronary heart disease. (B)</p> <p>Strongly recommends screening women aged 45 and older for lipid disorders if they are at increased risk for coronary heart disease. (A)</p> <p>Recommends screening women aged 20 to 45 for lipid disorders if they are at increased risk for coronary heart disease. (B)</p> <p>No recommendation for or against routine screening for lipid disorders in men aged 20 to 35, or in women aged 20 and older who are not at increased risk for coronary heart disease. (C)</p>
Counseling about healthy diet	<p>Evidence is insufficient to recommend for or against routine behavioral counseling to promote a healthy diet in unselected patients in primary care settings. (I)</p> <p>Recommends intensive behavioral dietary counseling for adult patients with hyperlipidemia and other known risk factors for cardiovascular and diet-related chronic disease. Intensive counseling can be delivered by primary care clinicians or by referral to other specialists, such as nutritionists or dietitians. (B)</p>
Screening for diabetes mellitus	<p>Recommends screening for type 2 diabetes mellitus in asymptomatic adults with sustained blood pressure (either treated or untreated) > 135/80 mm Hg. (B)</p> <p>Current evidence is insufficient to assess the balance of benefits and harms of screening for type 2 diabetes in asymptomatic adults with blood pressure of 135/80 mm Hg or lower. (I)</p>
Counseling to promote physical activity	Evidence is insufficient to recommend for or against behavioral counseling in primary care settings to promote physical activity. (I)
Screening for smoking and counseling to promote cessation	Recommends that clinicians ask all adults about tobacco use and provide tobacco cessation interventions for those who use tobacco products. (A)

Recommendation A: The USPSTF strongly recommends that clinicians routinely provide the service to eligible patients. (The USPSTF found good evidence that the service improves important health outcomes and concludes that benefits substantially outweigh harms.)

Recommendation B: The USPSTF recommends that clinicians routinely provide the service to eligible patients. (The USPSTF found at least fair evidence that the service improves important health outcomes and concludes that benefits substantially outweigh harms.)

Recommendation C: The USPSTF makes no recommendation for or against routine provision of the service.

Recommendation D: The USPSTF recommends against routinely providing the service to asymptomatic patients. (The USPSTF found at least fair evidence that the service is ineffective or that harms outweigh benefits.)

Recommendation I: The USPSTF concludes that the evidence is insufficient to recommend for or against routinely providing the service. <http://www.uspreventiveservicestaskforce.org/3rduspstf/ratings.htm>

are successful. Persons whose clinicians advise them to quit are 1.6 times as likely to attempt quitting. Over 70% of smokers see a physician each year, but only 20% of them receive any medical quitting advice or assistance.

Factors associated with successful cessation include having a rule against smoking in the home, being older, and having greater education. Several effective interventions are available to promote smoking cessation, including counseling, pharmacotherapy, and combinations of the two. The five steps for helping smokers quit are summarized in Table 1–4.

Common elements of supportive smoking cessation treatments are reviewed in Table 1–5. A system should be implemented to identify smokers, and advice to quit should be tailored to the patient's level of readiness to change. Pharmacotherapy to reduce cigarette consumption is ineffective in smokers who are unwilling or not ready to quit. Conversely, all patients trying to quit should be offered pharmacotherapy except those with medical contraindications, women who are pregnant or breast-feeding, and adolescents. Weight gain occurs in most patients (80%) following smoking cessation. For many, it averages 2 kg, but for others (10–15%) major weight gain—over 13 kg—may occur. Planning for the possibility of weight gain, and means of mitigating it, may help with maintenance of cessation.

Several pharmacologic therapies have been shown to be effective in promoting cessation. Nicotine replacement therapy doubles the chance of successful quitting. The nicotine patch, gum, and lozenges are available over-the-counter, and nicotine nasal spray and inhalers by prescription. The sustained-release antidepressant drug bupropion (150–300 mg/d orally) is an effective smoking cessation agent and is associated with minimal weight gain, although seizures are a contraindication. It acts by boosting brain levels of dopamine and norepinephrine, mimicking the effect of nicotine. More recently, varenicline, a partial nicotinic acetylcholine-receptor agonist, has been shown to improve cessation rates; however, its adverse effects, particularly its effects on mood, are not completely understood and warrant careful consideration. No single pharmacotherapy is clearly more effective than others, so patient preferences and data on adverse effects should be taken into account in selecting a treatment.

Clinicians should not show disapproval of patients who failed to stop smoking or who are not ready to make a quit attempt. Thoughtful advice that emphasizes the benefits of cessation and recognizes common barriers to success can increase motivation to quit and quit rates. An intercurrent illness such as acute bronchitis or acute myocardial infarction may motivate even the most addicted smoker to quit.

Individualized or group counseling is very cost-effective, even more so than treating hypertension. Smoking cessation counseling by telephone (“quitlines”) has proved effective, and a recent trial showed a text messaging-based intervention to be effective. An additional strategy is to recommend that any smoking take place out of doors to limit the effects of passive smoke on housemates and coworkers. This can lead to smoking reduction and quitting.

The clinician's role in smoking cessation is summarized in Table 1–4. Public policies, including higher cigarette taxes and more restrictive public smoking laws, have also been shown to encourage cessation, as have financial incentives directed to patients.

► Lipid Disorders

Higher low-density lipoprotein (LDL) cholesterol concentrations and lower high-density lipoprotein (HDL) levels are associated with an increased risk of CHD. Cholesterol lowering therapy reduces the relative risk of CHD events, with the degree of reduction proportional to the reduction in LDL cholesterol achieved. The absolute benefits of screening for—and treating—abnormal lipid levels depend on the presence and number of other cardiovascular risk factors, including hypertension, diabetes, smoking, age, and gender. If other risk factors are present, cardiovascular risk is higher and the benefits of therapy are greater. Patients with known cardiovascular disease are at higher risk and have larger benefits from reduction in LDL cholesterol.

Evidence for the effectiveness of statin-type drugs is better than for the other classes of lipid-lowering agents or dietary changes specifically for improving lipid levels. Multiple large randomized, placebo-controlled trials have demonstrated important reductions in total mortality, major coronary events, and strokes with lowering levels of LDL cholesterol by statin therapy for patients with known cardiovascular disease. Statins also reduce cardiovascular events for patients with diabetes mellitus. For patients with

Table 1-4. Actions and strategies for the primary care clinician to help patients quit smoking.

Action	Strategies for Implementation
Step 1. Ask—Systematically Identify All Tobacco Users at Every Visit	
Implement an officewide system that ensures that for every patient at every clinic visit, tobacco-use status is queried and documented ¹	Expand the vital signs to include tobacco use. Data should be collected by the health care team. The action should be implemented using preprinted progress note paper that includes the expanded vital signs, a vital signs stamp or, for computerized records, an item assessing tobacco-use status. Alternatives to the vital signs stamp are to place tobacco-use status stickers on all patients' charts or to indicate smoking status using computerized reminder systems.
Step 2. Advise—Strongly Urge All Smokers to Quit	
In a clear, strong, and personalized manner, urge every smoker to quit	Advice should be Clear: "I think it is important for you to quit smoking now, and I will help you. Cutting down while you are ill is not enough." Strong: "As your clinician, I need you to know that quitting smoking is the most important thing you can do to protect your current and future health." Personalized: Tie smoking to current health or illness and/or the social and economic costs of tobacco use, motivational level/readiness to quit, and the impact of smoking on children and others in the household. Encourage clinic staff to reinforce the cessation message and support the patient's quit attempt.
Step 3. Attempt—Identify Smokers Willing to Make a Quit Attempt	
Ask every smoker if he or she is willing to make a quit attempt at this time	If the patient is willing to make a quit attempt at this time, provide assistance (see step 4). If the patient prefers a more intensive treatment or the clinician believes more intensive treatment is appropriate, refer the patient to interventions administered by a smoking cessation specialist and follow up with him or her regarding quitting (see step 5). If the patient clearly states he or she is not willing to make a quit attempt at this time, provide a motivational intervention.
Step 4. Assist—Aid the Patient in Quitting	
A. Help the patient with a quit plan	Set a quit date. Ideally, the quit date should be within 2 weeks, taking patient preference into account. Help the patient prepare for quitting. The patient must: Inform family, friends, and coworkers of quitting and request understanding and support. Prepare the environment by removing cigarettes from it. Prior to quitting, the patient should avoid smoking in places where he or she spends a lot of time (eg, home, car). Review previous quit attempts. What helped? What led to relapse? Anticipate challenges to the planned quit attempt, particularly during the critical first few weeks.
B. Encourage nicotine replacement therapy except in special circumstances	Encourage the use of the nicotine patch or nicotine gum therapy for smoking cessation
C. Give key advice on successful quitting	Abstinence: Total abstinence is essential. Not even a single puff after the quit date. Alcohol: Drinking alcohol is highly associated with relapse. Those who stop smoking should review their alcohol use and consider limiting or abstaining from alcohol use during the quit process. Other smokers in the household: The presence of other smokers in the household, particularly a spouse, is associated with lower success rates. Patients should consider quitting with their significant others and/or developing specific plans to maintain abstinence in a household where others still smoke.
D. Provide supplementary materials	Source: Federal agencies, including the National Cancer Institute and the Agency for Health Care Policy and Research; nonprofit agencies (American Cancer Society, American Lung Association, American Heart Association); or local or state health departments. Selection concerns: The material must be culturally, racially, educationally, and age appropriate for the patient. Location: Readily available in every clinic office.

(continued)

Table 1-4. Actions and strategies for the primary care clinician to help patients quit smoking. (continued)

Action	Strategies for Implementation
Step 5. Arrange—Schedule Follow-Up Contact	
Schedule follow-up contact, either in person or via telephone	<p>Timing: Follow-up contact should occur soon after the quit date, preferably during the first week. A second follow-up contact is recommended within the first month. Schedule further follow-up contacts as indicated.</p> <p>Actions during follow-up: Congratulate success. If smoking occurred, review the circumstances and elicit recommitment to total abstinence. Remind the patient that a lapse can be used as a learning experience and is not a sign of failure. Identify the problems already encountered and anticipate challenges in the immediate future. Assess nicotine replacement therapy use and problems. Consider referral to a more intense or specialized program.</p>

Repeated assessment is not necessary in the case of the adult who has never smoked or not smoked for many years and for whom the information is clearly documented in the medical record.

no previous history of cardiovascular events or diabetes, a meta-analysis showed important reductions of cardiovascular events. The JUPITER trial suggested that statins reduce coronary events relatively similarly for both men and women.

Table 1-5. Common elements of supportive smoking treatments.

Component	Examples
Encouragement of the patient in the quit attempt	Note that effective cessation treatments are now available. Note that half the people who have ever smoked have now quit. Communicate belief in the patient's ability to quit.
Communication of caring and concern	Ask how the patient feels about quitting. Directly express concern and a willingness to help. Be open to the patient's expression of fears of quitting, difficulties experienced, and ambivalent feelings.
Encouragement of the patient to talk about the quitting process	Ask about: Reasons that the patient wants to quit. Difficulties encountered while quitting. Success the patient has achieved. Concerns or worries about quitting.
Provision of basic information about smoking and successful quitting	Inform the patient about: The nature and time course of withdrawal. The addictive nature of smoking. The fact that any smoking (even a single puff) increases the likelihood of full relapse.

▶ Hypertension

Over 43 million adults in the United States have hypertension, but 31% are unaware of their elevated blood pressure; 17% are aware but untreated; 29% are being treated but have not controlled their blood pressure (still greater than 140/90 mm Hg); and only 23% are well controlled. In every adult age group, higher values of systolic and diastolic blood pressure carry greater risks of stroke and congestive heart failure. Systolic blood pressure is a better predictor of morbid events than diastolic blood pressure. Home monitoring is better correlated with target organ damage than clinic-based values. Clinicians can apply specific blood pressure criteria, such as those of the Joint National Committee, along with consideration of the patient's cardiovascular risk and personal values, to decide at what levels treatment should be considered in individual cases. Table 11-1 presents a classification of hypertension based on blood pressures.

Primary prevention of hypertension can be accomplished by strategies aimed at both the general population and special high-risk populations. The latter include persons with high-normal blood pressure or a family history of hypertension, blacks, and individuals with various behavioral risk factors such as physical inactivity; excessive consumption of salt, alcohol, or calories; and deficient

intake of potassium. Effective interventions for primary prevention of hypertension include reduced sodium and alcohol consumption, weight loss, and regular exercise. Potassium supplementation lowers blood pressure modestly, and a diet high in fresh fruits and vegetables and low in fat, red meats, and sugar-containing beverages also reduces blood pressure. Interventions of unproven efficacy include pill supplementation of potassium, calcium, magnesium, fish oil, or fiber; macronutrient alteration; and stress management.

Improved identification and treatment of hypertension is a major cause of the recent decline in stroke deaths as well as the reduction in incidence of heart failure-related hospitalizations. Because hypertension is usually asymptomatic, screening is strongly recommended to identify patients for treatment. Despite strong recommendations in favor of screening and treatment, hypertension control remains suboptimal. An intervention that included patient education and provider education was more effective than provider education alone in achieving control of hypertension, suggesting the benefits of patient participation; another trial found that home monitoring combined with telephone-based nurse support was more effective than home monitoring alone for blood pressure control. Pharmacologic management of hypertension is discussed in Chapter 11.

► Chemoprevention

As discussed in Chapters 10 and 24, regular use of low-dose aspirin (81–325 mg) can reduce the incidence of myocardial infarction in men. Low-dose aspirin reduces stroke but not myocardial infarction in middle-aged women. Based on its ability to prevent cardiovascular events, aspirin use appears cost-effective for men and women who are at increased cardiovascular risk, which can be defined as 10-year risk over 10%. Results from a meta-analysis suggest that aspirin may also reduce the risk of death from several common types of cancer.

Nonsteroidal anti-inflammatory drugs may reduce the incidence of colorectal adenomas and polyps but may also increase heart disease and gastrointestinal bleeding, and thus are not recommended for colon cancer prevention in average risk patients.

Antioxidant vitamin (vitamin E, vitamin C, and beta-carotene) supplementation produced no significant reductions in the 5-year incidence of—or mortality from—vascular disease, cancer, or other major outcomes in high-risk individuals with coronary artery disease, other occlusive arterial disease, or diabetes mellitus. More recently, a large prospective cohort study found modestly increased risk of mortality with several common dietary supplements.

PREVENTION OF OSTEOPOROSIS

Osteoporosis, characterized by low bone mineral density, is common and associated with an increased risk of fracture. The lifetime risk of an osteoporotic fracture is approximately 50% for women and 30% for men. Osteoporotic fractures can cause significant pain and disability. As such, research has focused on means of preventing osteoporosis and related fractures. Primary prevention strategies include calcium supplementation, vitamin D supplementation, and exercise programs. A 2007 systematic review and meta-analysis found that calcium supplementation of 1200 mg per day or more (with or without vitamin D) could decrease fracture risk for adults (mainly women were studied) over age 50. Vitamin D supplements alone do not appear to reduce fracture risk.

Screening for osteoporosis on the basis of low bone mineral density is also recommended for women over age 60, based on indirect evidence that screening can identify women with low bone mineral density and that treatment of women with low bone density with bisphosphonates is effective in reducing fractures. However, real-world adherence to pharmacologic therapy for osteoporosis is low: one-third to one-half of patients do not take their medication as directed. The effectiveness of screening for osteoporosis in younger women and in men has not been established. Concern has been raised that bisphosphonates may increase the risk of certain types of fractures and osteonecrosis of the jaw, making consideration of the benefits and risks of therapy important when considering screening.

PREVENTION OF PHYSICAL INACTIVITY

Lack of sufficient physical activity is the second most important contributor to preventable deaths, trailing only tobacco use. A sedentary lifestyle has been linked to 28% of deaths from leading chronic diseases. The US Department of Health and Human Services and the CDC recommends that adults and older adults engage in 150 minutes of moderate-intensity (such as brisk walking) or 75 minutes of vigorous-intensity aerobic activity (such as jogging or running) or an equivalent mix of moderate- and vigorous-intensity aerobic activity each week. In addition to the activity recommendations, the CDC recommends activities to strengthen all major muscle groups (abdomen, arms, back, chest, hips, legs, and shoulders) at least twice a week.

Patients who engage in regular moderate to vigorous exercise have a lower risk of myocardial infarction, stroke, hypertension, hyperlipidemia, type 2 diabetes mellitus, diverticular disease, and osteoporosis. Evidence supports the recommended guidelines of 30 minutes of moderate physical activity on most days of the week in both the primary and secondary prevention of CHD.

In older nonsmoking men, walking 2 miles or more per day is associated with an almost 50% lower age-related mortality. Diet and increased physical activity have been shown to prevent the onset of diabetes, which has reached epidemic proportions in the United States. In sedentary individuals with dyslipidemia, high amounts of high-intensity exercise produce significant beneficial effects on serum lipoprotein profiles. Physical activity is associated with a lower risk of colon cancer (although not rectal cancer) in men and women and of breast and reproductive organ cancer in women. Finally, weight-bearing exercise (especially resistance and high-impact activities) increases bone mineral content and retards development of osteoporosis in women and contributes to a reduced risk of falls in older persons. Resistance training has been shown to enhance muscular strength, functional capacity, and quality of life in men and women with and without CHD and is endorsed by the American Heart Association.

Exercise may also confer benefits on those with chronic illness. Men and women with chronic symptomatic osteoarthritis of one or both knees benefited from a supervised walking program, with improved self-reported functional status and decreased pain and use of pain medication. Exercise produces sustained lowering of both systolic and diastolic blood pressure in patients with mild hypertension. Physical activity reduces depression and anxiety;

improves adaptation to stress; improves sleep quality; and enhances mood, self-esteem, and overall performance.

In longitudinal cohort studies, individuals who report higher levels of leisure time physical activity are less likely to gain weight. Conversely, individuals who are overweight are less likely to stay active. However, at least 60 minutes of daily moderate-intensity physical activity may be necessary to maximize weight loss and prevent significant weight regain. Moreover, adequate levels of physical activity appear to be important for the prevention of weight gain and the development of obesity. Physical activity also appears to have an independent effect on health-related outcomes such as development of type 2 diabetes mellitus in patients with impaired glucose tolerance when compared with body weight, suggesting that adequate levels of activity may counteract the negative influence of body weight on health outcomes.

Only about 20% of adults in the United States are active at the moderate level—and only 8% currently exercise at the more vigorous level—recommended for health benefits. Instead, 60% report irregular or no leisure time physical activity.

Increased activity increases the risk of musculoskeletal injuries, which can be minimized by proper warm-up and stretching and by gradual rather than sudden increase in activity. In insulin-requiring diabetic patients who undertake vigorous exercise, the need for insulin is reduced; hypoglycemia may be a consequence. Physical exertion can rarely trigger the onset of acute myocardial infarction, particularly in persons who are habitually sedentary. Other potential complications of exercise include angina pectoris, arrhythmias, sudden death, and asthma.

The value of routine electrocardiography stress testing prior to initiation of an exercise program in middle-aged or older adults remains controversial. Patients with ischemic heart disease or other cardiovascular disease require medically supervised, graded exercise programs. Medically supervised exercise prolongs life in patients with congestive heart failure. Exercise should not be prescribed for patients with decompensated congestive heart failure, complex ventricular arrhythmias, unstable angina pectoris, hemodynamically significant aortic stenosis, or significant aortic aneurysm. Five- to 10-minute warm-up and cool-down periods, stretching exercises, and gradual increases in exercise intensity help prevent musculoskeletal and cardiovascular complications.

Physical activity can be incorporated into any person's daily routine. For example, the clinician can advise a patient to take the stairs instead of the elevator, to walk or bike instead of driving, to do housework or yard work, to get off the bus one or two stops earlier and walk the rest of the way, to park at the far end of the parking lot, or to walk during the lunch hour. The basic message should be the more the better and anything is better than nothing.

To be more effective in counseling about exercise, clinicians can also incorporate motivational interviewing techniques, adopt a whole practice approach (eg, use practice nurses to assist), and establish linkages with community agencies. Clinicians can incorporate the “5 As” approach:

1. Ask (identify those who can benefit).
2. Assess (current activity level).

3. Advise (individualize plan).
4. Assist (provide a written exercise prescription and support material).
5. Arrange (appropriate referral and follow-up).

Such interventions have a moderate effect on self-reported physical activity and cardiorespiratory fitness, even if they do not always help patients achieve a predetermined level of physical activity. In their counseling, clinicians should advise patients about both the benefits and risks of exercise, prescribe an exercise program appropriate for each patient, and provide advice to help prevent injuries or cardiovascular complications.

Behavioral change interventions have been proven effective in increasing physical activity in sedentary older women, although evidence is lacking to support the use of pedometers to increase physical activity in this population. Although primary care providers regularly ask patients about physical activity and advise them with verbal counseling, few providers provide written prescriptions or perform fitness assessments. Tailored interventions may potentially help increase physical activity in individuals. Exercise counseling with a prescription, eg, for walking at either a hard intensity or a moderate intensity-high frequency, can produce significant long-term improvements in cardiorespiratory fitness. To be effective, exercise prescriptions must include recommendations on type, frequency, intensity, time, and progression of exercise and must follow disease-specific guidelines. In addition, published research suggests that getting patients to change physical activity levels requires motivational strategies beyond simple exercise instruction including patient education about goal-setting, self-monitoring, and problem-solving. For example, helping patients identify emotionally rewarding and physically appropriate activities, meet contingencies, and find social support will increase rates of exercise continuation.

Some physical activity is always preferable to a sedentary lifestyle. For home-bound elderly who have limited mobility and strength, such physical activity could focus on “functional fitness,” such as mobility, transfers, and performing activities of daily living. Exercise-based rehabilitation can protect against falls and fall-related injuries and improve functional performance.

PREVENTION OF OVERWEIGHT & OBESITY

Obesity is now a true epidemic and public health crisis that both clinicians and patients must face. Normal body weight is defined as a body mass index (BMI), calculated as the weight in kilograms divided by the height in meters squared, of < 25 kg/m²; overweight is defined as a BMI = 25.0–29.9 kg/m², and obesity as a BMI > 30 kg/m². Over the last several years, the prevalence of obesity in the US population has increased dramatically. Among US adults, rates of obesity have risen from 15.9% in 1995 to 27.2% in 2009. There is significant variation in rates of obesity by race. Between 2006 and 2008, blacks (35.7%) had 51% greater prevalence of obesity and Hispanics (28.7%) had 21% greater prevalence when compared with non-Hispanic whites (23.7%). This trend has been linked both to declines in physical activity and to increased caloric intake in diets rich in fats and carbohydrates.

Adequate levels of physical activity appear to be important for the prevention of weight gain and the development of obesity. Despite this, only 49% of Americans are physically active at a moderate level and 20% at a more vigorous level. In addition, only 3% of Americans meet four of the five recommendations for the intake of grains, fruits, vegetables, dairy products, and meat of the Food Guide Pyramid. Only one of four Americans eats the recommended five or more fruits and vegetables per day.

Risk assessment of the overweight and obese patient begins with determination of BMI, waist circumference for those with a BMI of 35 or less, presence of comorbid conditions, and a fasting blood glucose and lipid panel. Obesity is clearly associated with type 2 diabetes mellitus, hypertension, hyperlipidemia, cancer, osteoarthritis, cardiovascular disease, obstructive sleep apnea, and asthma. One of the most important sequelae of the rapid surge in prevalence of obesity has been a dramatic increase in the prevalence of diabetes. Diabetes mellitus affects approximately 8% of the US population, and in 2010, 27% of US residents aged 65 years and older were diabetic. In addition, almost one-quarter of the US population currently has the metabolic syndrome, putting them at high risk for the development of CHD. Metabolic syndrome is defined as the presence of any three of the following: waist measurement of 40 inches or more for men and 35 inches or more for women, triglyceride levels of 150 mg/dL or above, HDL cholesterol level < 40 mg/dL for men and < 50 mg/dL for women, blood pressure of 130/85 mm Hg or above, fasting blood glucose levels of 100 mg/dL or above.

The relationship between overweight and obesity and diabetes, hypertension, and coronary artery disease is thought to be due to insulin resistance and compensatory hyperinsulinemia. Persons with a BMI ≥ 40 have death rates from cancers that are 52% higher for men and 62% higher for women than the rates in men and women of normal weight. Significant trends of increasing risk of death with higher BMIs are observed for cancers of the stomach and prostate in men and for cancers of the breast, uterus, cervix, and ovary in women, and for cancers of the esophagus, colon and rectum, liver, gallbladder, pancreas, and kidney, non-Hodgkin lymphoma, and multiple myeloma in both men and women.

In the Framingham Heart Study, overweight and obesity were associated with large decreases in life expectancy. For example, 40-year-old female nonsmokers lost 3.3 years and 40-year-old male nonsmokers lost 3.1 years of life expectancy because of overweight, and 7.1 years and 5.8 years of life expectancy, respectively, because of obesity. Obese female smokers lost 7.2 years and obese male smokers lost 6.7 years of life expectancy compared with normal-weight smokers, and 13.3 years and 13.7 years, respectively, compared with normal-weight nonsmokers. Clinicians must work to identify and provide the best prevention and treatment strategies for patients who are overweight and obese. Patients with abdominal obesity (high waist to hip size ratio) are at particularly increased risk. Control of visceral obesity in addition to other cardiovascular risk factors (hypertension, insulin resistance, and dyslipidemia) is essential to reducing cardiovascular risk.

Prevention of overweight and obesity involves both increasing physical activity and dietary modification to reduce caloric intake. Clinicians can help guide patients to develop personalized eating plans to reduce energy intake, particularly by recognizing the contributions of fat, concentrated carbohydrates, and large portion sizes (see Chapter 29). Patients typically underestimate caloric content, especially when consuming food away from home. Providing patients with caloric and nutritional information may help address the current obesity epidemic. To prevent the long-term chronic disease sequelae of overweight or obesity, clinicians must work with patients to modify other risk factors, eg, by smoking cessation (see above) and strict blood pressure and glycemic control (see Chapters 11 and 27).

Lifestyle modification, including diet, physical activity, and behavior therapy has been shown to induce clinically significant weight loss. Other treatment options for obesity include pharmacotherapy and surgery. In overweight and obese persons, at least 60 minutes of moderate-high intensity physical activity may be necessary to maximize weight loss and prevent significant weight regain. Counseling interventions or pharmacotherapy can produce modest (3–5 kg) sustained weight loss over 6–12 months. Counseling appears to be most effective when intensive and combined with behavioral therapy. Pharmacotherapy appears safe in the short term; long-term safety is still not established. Lorcaserin, a selective 5-hydroxytryptamine (5-HT) (2C) agonist, has been shown to reduce body weight through a reduction of energy intake without influencing energy expenditure; however, it is not yet approved by the US Food and Drug Administration (FDA).

In dietary therapy, a 2008 study comparing various diets revealed that Mediterranean (moderate fat, restricted calorie) and low-carbohydrate (non-restricted calorie) diets are effective alternatives to low-fat diets. In a randomized trial comparing low carbohydrate and low fat diets combined with behavioral treatment, there was no difference in weight loss at 2 years (7%). Commercial weight loss programs are effective in promoting weight loss and weight loss management. A randomized controlled trial of over 400 overweight or obese women demonstrated the effectiveness of a free

prepared meal and incentivized structured weight loss program compared with usual care.

Weight loss strategies using dietary, physical activity, or behavioral interventions can produce significant improvements in weight among persons with prediabetes and a significant decrease in diabetes incidence. Lifestyle interventions including diet combined with physical activity are effective in achieving weight loss and reducing cardiometabolic risk factors among patients with severe obesity.

Bariatric surgical procedures, eg, vertical banded gastroplasty and Roux-en-Y gastric bypass, are reserved for patients with morbid obesity whose BMI exceeds 40, or for less severely obese patients (with BMIs between 35 and 40) with high-risk comorbid conditions such as life-threatening cardiopulmonary problems (eg, severe sleep apnea, Pickwickian syndrome, and obesity-related cardiomyopathy) or severe diabetes mellitus. In selected patients, surgery can produce substantial weight loss (10 to 159 kg) over 1 to 5 years, with rare but sometimes severe complications. Nutritional deficiencies are one complication of bariatric surgical procedures and close monitoring of a patient's metabolic and nutritional status is essential.

Clinicians seem to share a general perception that almost no one succeeds in long-term maintenance of weight loss. However, research demonstrates that approximately 20% of overweight individuals are successful at long-term weight loss (defined as losing $\geq 10\%$ of initial body weight and maintaining the loss for ≥ 1 year). National Weight Control Registry members who lost an average of 33 kg and maintained the loss for more than 5 years have provided useful information about how to maintain weight loss. Members report engaging in high levels of physical activity (approximately 60 min/d), eating a low-calorie, low-fat diet, eating breakfast regularly, self-monitoring weight, and maintaining a consistent eating pattern from weekdays to weekends. The development and implementation of innovative public health strategies is essential in the fight against obesity.

CANCER PREVENTION

► Primary Prevention

Cancer mortality rates continue to decrease in the United States; part of this decrease results from reductions in tobacco use, since cigarette smoking is the most important preventable cause of cancer. Primary prevention of skin cancer consists of restricting exposure to ultraviolet light

by wearing appropriate clothing and use of sunscreens. In the past 2 decades, there has been a threefold increase in the incidence of squamous cell carcinoma and a fourfold increase in melanoma in the United States. Persons who engage in regular physical exercise and avoid obesity have lower rates of breast and colon cancer. Prevention of occupationally induced cancers involves minimizing exposure to carcinogenic substances such as asbestos, ionizing radiation, and benzene compounds. Chemoprevention has been widely studied for primary cancer prevention (see above Chemoprevention section and Chapter 39). Use of tamoxifen, raloxifene, and aromatase inhibitors for breast cancer prevention is discussed in Chapters 17 and 39. Hepatitis B vaccination can prevent hepatocellular carcinoma (HCC), and screening and vaccination programs may be cost-effective and useful in preventing HCC in high-risk groups such as Asians and Pacific Islanders. The use of HPV vaccine to prevent cervical cancer is discussed above in the Prevention of Infectious Disease section.

► Screening & Early Detection

Screening prevents death from cancers of the breast, colon, and cervix. Current cancer screening recommendations from the USPSTF are shown in Table 1–6.

Table 1–6. Cancer screening recommendations for average-risk adults: US Preventive Services Task Force (USPSTF).¹

Test	USPSTF Recommendations
Breast self-examination	Recommends against teaching breast self-examination (D).
Clinical breast examination	Insufficient evidence to recommend for or against.
Mammography	Recommends biennial screening mammography for women aged 50 to 74 years (B). Decision to start biennial screening before the age of 50 should be an individual one and take patient context into account, including the patient's values regarding specific benefits and harms (C).
Papanicolaou test	Strongly recommends screening for cervical cancer in sexually active women who have a cervix (A). Recommends against routinely screening women older than age 65 if they have had adequate recent screening with normal Pap tests and are not otherwise at high risk for cervical cancer (D).
Colorectal cancer (CRC) screening	Recommends CRC screening using fecal occult blood testing, ² sigmoidoscopy, or colonoscopy, in adults, beginning at age 50 years and continuing until age 75 years (A). Recommends against routine screening in adults age 76–85 years (C). Recommends against screening in adults older than age 85 years (D).
Prostate cancer screening	Insufficient evidence to recommend for or against. Recommends against screening in men >75 years.

¹United States Preventive Services Task Force recommendations available at <http://www.ahrq.gov/clinic/pocketgd1011/gcp10s2.htm>.

²Home test with three samples.

Recommendation A: The USPSTF strongly recommends that clinicians routinely provide the service to eligible patients. (The USPSTF found good evidence that the service improves important health outcomes and concludes that benefits substantially outweigh harms.)

Recommendation B: The USPSTF recommends that clinicians routinely provide the service to eligible patients. (The USPSTF found at least fair evidence that the service improves important health outcomes and concludes that benefits substantially outweigh harms.)

Recommendation C: The USPSTF recommends against routinely providing the service. There may be considerations that support providing the service in an individual patient. There is at least moderate certainty that the net benefit is small.

Recommendation D: The USPSTF recommends against routinely providing the service to asymptomatic patients. (The USPSTF found at least fair evidence that the service is ineffective or that harms outweigh benefits.)

Evidence suggests that the benefit of screening mammography on breast cancer mortality may not outweigh the risks associated with screening. A 2011 Cochrane review estimated that screening with mammography led to a reduction in breast cancer mortality of 15% but resulted in 30% overdiagnosis and overtreatment. Currently, the appropriate form and frequency of screening for breast cancer remains controversial and screening guidelines vary. In 2009, the USPSTF updated its recommendation statement on breast cancer screening in the general population. A change, which generated discussion from many groups, was the recommendation against routine screening mammography in women aged 40–49 years. Clinicians should discuss the risks and benefits with each patient and consider individual patient preferences when deciding when to begin screening.

Digital mammography is more sensitive in women with dense breasts and younger women; however, studies exploring outcomes are lacking. The use of MRI is not currently recommended for general screening, although the American Cancer Society does recommend screening MRI for women at high risk (≥ 20 –25%), including those with a strong family history of breast or ovarian cancer. A 2008 systematic review reported that screening with both MRI and mammography might be superior to mammography alone in ruling out cancerous lesions in women with an inherited predisposition to breast cancer.

All current recommendations call for cervical and colorectal cancer screening. Screening for testicular cancers among asymptomatic adolescent or adult males is not recommended by the USPSTF. Prostate cancer screening, however, is controversial, as no completed studies have answered the question whether early detection and treatment after screen detection produce sufficient benefits to outweigh harms of treatment. A 2009 published study of 76,000 US men comparing annual screening (prostate-specific antigen [PSA] and digital rectal examination) to usual care did not reveal a difference in mortality. A 2011 Cochrane systematic review revealed that prostate cancer screening with PSA testing did not significantly decrease either all cause or prostate cancer–specific mortality in men aged 50–74 years. Furthermore, it appeared that any benefits from screening would take more than 10 years to accrue, and screening men with less than 10–15 years life expectancy was not advised.

Annual or biennial fecal occult blood testing reduces mortality from colorectal cancer by 16–33%. Immunochemical fecal occult blood tests (FIT) are superior to guaiac-based fecal occult blood tests (FOBT) in detecting advanced adenomatous polyps and colorectal cancer, and patients are more likely to favor FIT over FOBTs. The risk of death from colon cancer among patients undergoing at least one sigmoidoscopic examination is reduced by 60–80% compared with that among those not having sigmoidoscopy. Colonoscopy has also been advocated as a screening examination. It is more accurate than flexible sigmoidoscopy for detecting cancer and polyps, but its value in reducing colon cancer mortality has not been studied directly. CT colonography (virtual colonoscopy) is a noninvasive option in screening for colorectal cancer. It has

been shown to have a high safety profile and performance similar to colonoscopy.

Screening for cervical cancer with a Papanicolaou smear is indicated in sexually active adolescents and in adult women every 1–3 years. Screening for vaginal cancer with a Papanicolaou smear is not indicated in women who have undergone hysterectomies for benign disease with removal of the cervix—except in diethylstilbestrol (DES)-exposed women (see Chapter 18). Women over age 70 who have had normal results on three or more previous Papanicolaou smears may elect to stop screening.

In a randomized, controlled trial, transvaginal ultrasound combined with serum cancer antigen 125 (CA-125) as screening tools to detect ovarian cancer did not reduce mortality. Furthermore, complications were associated with diagnostic evaluations to follow up false-positive screening test results. Thus, screening for ovarian cancer with transvaginal ultrasound and CA-125 is not recommended.

Evidence suggests that chest CT is significantly more sensitive than chest radiography in identifying small asymptomatic lung cancers. The National Lung Screening Trial (NLST), a randomized clinical trial of over 53,000 individuals at high risk for lung cancer, revealed a 20% relative reduction and 6.7% absolute reduction in lung cancer mortality in those who were screened with annual low-dose CTs for 3 years compared with those who had chest radiographs. There were a greater number of false-positive results in the low-dose CT group compared with those in the radiography group (23.3% vs 6.5%).

PREVENTION OF INJURIES & VIOLENCE

Injuries remain the most important cause of loss of potential years of life before age 65. Homicide and motor vehicle accidents are a major cause of injury-related deaths among young adults, and accidental falls are the most common cause of injury-related death in the elderly. Other causes of injury-related deaths include suicide and accidental exposure to smoke, fire, and flames.

Motor vehicle accident deaths per miles driven continue to decline in the United States, and the rate of seatbelt use has increased from 69% in 1998 to 88% in 2009. Each year in the United States, more than 500,000 people are nonfatally injured while riding bicycles. The rate of helmet use by bicyclists and motorcyclists is significantly increased in states with helmet laws. Young men appear most likely to resist wearing helmets. Clinicians should try to educate their patients about seat belts, safety helmets, the risks of using cellular telephones while driving, drinking and driving—or using other intoxicants or long-acting benzodiazepines and then driving—and the risks of having guns in the home.

Long-term alcohol abuse adversely affects outcome from trauma and increases the risk of readmission for new trauma. Alcohol and illicit drug use are associated with an increased risk of violent death.

Males aged 16–35 are at especially high risk for serious injury and death from accidents and violence, with blacks and Latinos at greatest risk. For 16- and 17-year-old drivers, the risk of fatal crashes increases with the number of passengers. Deaths from firearms have reached epidemic levels in the United States and will soon surpass the number of deaths from motor vehicle accidents. Having a gun in the home increases the likelihood of homicide nearly threefold and of suicide fivefold. In 2007, an estimated 34,500 suicides occurred in the United States. Educating clinicians to recognize and treat depression as well as restricting access to lethal methods have been found to reduce suicide rates.

Finally, clinicians have a critical role in detection, prevention, and management of intimate partner violence. Inclusion of a single question in the medical history—“At any time, has a partner ever hit you, kicked you, or otherwise

physically hurt you?”—can increase identification of this common problem. Another screen consists of three questions: (1) “Have you ever been hit, kicked, punched, or otherwise hurt by someone within the past year? If so, by whom?” (2) “Do you feel safe in your current relationship?” (3) “Is there a partner from a previous relationship who is making you feel unsafe now?” Assessment for abuse and offering of referrals to community resources creates potential to interrupt and prevent recurrence of domestic violence and associated trauma. Screening patients in emergency departments for intimate partner violence appears to have no adverse effects related to screening and may lead to increased patient contact with community resources. Clinicians should take an active role in following up with patients whenever possible, since intimate partner violence screening with passive referrals to services may not be adequate. A randomized control trial to assess the impact of intimate partner violence screening on violence reduction and health outcomes in women revealed no difference in violence occurrence between screened and nonscreened women. Evaluation of services for patients *after* identification of intimate partner violence should be a priority.

Physical and psychological abuse, exploitation, and neglect of older adults are serious underrecognized problems. Clues to elder mistreatment include the patient’s appearance, recurrent urgent-care visits, missed appointments, suspicious physical findings, and implausible explanations for injuries.

Injuries at home are common, and the majority of injuries to children less than 5 years of age and adults aged 75 and older occur at home. The impact of physical adaptations to the home environment has not been shown to reduce injuries at home. Larger randomized controlled trials to measure injury outcomes are needed to assess more adequately the impact modifications to the home environment.

PREVENTION OF SUBSTANCE ABUSE: ALCOHOL & ILLICIT DRUGS

Substance abuse is a major public health problem in the United States. In the United States, approximately 52% of adults 18 years and older are current regular drinkers (at least 12 drinks in the past year). Alcohol dependence often coexists with other substance disorders as well as with mood, anxiety, and personality disorders. Underdiagnosis and treatment of alcohol abuse is substantial, both because of patient denial and lack of detection of clinical clues. Treatment rates for alcohol dependence have slightly declined over the last several years. Only a quarter of alcohol-dependent patients have ever been treated.

As with cigarette use, clinician identification and counseling about alcoholism may improve the chances of recovery. About 10% of all adults seen in medical practices are problem drinkers. An estimated 15–30% of hospitalized patients have problems with alcohol abuse or dependence, but the connection between patients' presenting complaints and their alcohol abuse is often missed. The CAGE test (Table 1–7) is both sensitive and specific for chronic alcoholism. However, it is less sensitive in detecting heavy or binge drinking in elderly patients and has been criticized for being less applicable to minority groups or to women.

The Alcohol Use Disorder Identification Test (AUDIT) consists of questions on the quantity and frequency of alcohol consumption, on alcohol dependence symptoms, and on alcohol-related problems (Table 1–7). The AUDIT questionnaire is a cost-effective and efficient diagnostic tool for routine screening of alcohol use disorders in primary care settings. Choice of therapy remains controversial. However, use of screening procedures and brief intervention methods (Table 1–8; see Chapter 25) can produce a 10–30% reduction in long-term alcohol use and alcohol-related problems. Brief advice and counseling without regular follow-up and reinforcement cannot sustain significant long-term reductions in unhealthy drinking behaviors.

Time restraints may prevent clinicians from screening patients and single-question screening tests for unhealthy alcohol use may help increase the frequency of screening in primary care settings. The National Institute on Alcohol Abuse and Alcoholism recommends the following single-question screening test: "How many times in the past year have you had X or more drinks in a day?" (X is 5 for men and 4 for women, and a response of >1 is considered positive.) The single-item screening test has been validated in primary care settings.

Several pharmacologic agents are effective in reducing alcohol consumption. In acute alcohol detoxification, standard treatment regimens use long-acting benzodiazepines, the preferred medications for alcohol detoxification, because they can be given on a fixed schedule or through "front-loading" or "symptom-triggered" regimens. Adjuvant sympatholytic medications can be used to treat hyperadrenergic symptoms that persist despite adequate sedation. Three drugs are FDA approved for treatment of alcohol dependence—disulfiram, naltrexone, and acamprosate. Disulfiram, an aversive agent, has significant adverse effects and consequently, compliance difficulties have resulted in no clear evidence that it increases abstinence rates, decreases relapse rates, or reduces cravings. Persons who receive short-term treatment with naltrexone have a lower chance of alcoholism relapse. Compared with placebo, naltrexone can lower the risk of treatment withdrawal in alcohol-dependent patients, and long-acting intramuscular formulation of naltrexone has been found to be well-tolerated and to reduce drinking significantly among treatment-seeking alcoholics over a 6-month period. In a randomized, controlled trial, patients receiving medical management with naltrexone, a combined behavioral intervention, or both, fared better on drinking outcomes, whereas acamprosate showed no evidence of efficacy with or without combined behavioral intervention. A depot formulation of naltrexone is available with good evidence for clinical efficacy. Topiramate is a promising treatment for alcohol dependence. A 6-month randomized trial of topiramate versus naltrexone revealed a greater reduction of alcohol intake and cravings in participants receiving topiramate. Topiramate's side effect profile is favorable, and the benefits appear to increase over time. Clinicians should be aware that although topiramate appears to be an effective treatment for alcohol dependence, the manufacturer has not pursued FDA approval for this indication.

Use of illegal drugs—including cocaine, methamphetamine, and so-called "designer drugs"—either sporadically or episodically remains an important problem. Lifetime prevalence of drug abuse is approximately 8% and is generally greater among men, young and unmarried individuals, Native Americans, and those of lower socioeconomic status. As with alcohol, drug abuse disorders often coexist with personality, anxiety, and other substance abuse disorders. Abuse of anabolic-androgenic steroids has been associated with use of other illicit drugs, alcohol, and cigarettes and with violence and criminal behavior.

As with alcohol abuse, the lifetime treatment rate for drug abuse is low (8%). The recognition of drug abuse presents special problems and requires that the clinician actively consider the diagnosis. Clinical aspects of substance abuse are discussed in Chapter 25.

Currently, evidence does not support the use of carbamazepine, disulfiram, mazindol, phenytoin, nimodipine, lithium, antidepressants, or dopamine agonists in the treatment of cocaine dependence.

Buprenorphine has potential as a medication to ameliorate the symptoms and signs of withdrawal from opioids and has been shown to be effective in reducing concomitant

Table 1-7. Screening for alcohol abuse.

A. CAGE screening test¹				
Have you ever felt the need to	Cut down on drinking?			
Have you ever felt	Annoyed by criticism of your drinking?			
Have you ever felt	Guilty about your drinking?			
Have you ever taken a morning	Eye opener?			
INTERPRETATION: Two "yes" answers are considered a positive screen. One "yes" answer should arouse a suspicion of alcohol abuse.				
B. The Alcohol Use Disorder Identification Test (AUDIT).² (Scores for response categories are given in parentheses. Scores range from 0 to 40, with a cutoff score of ≥ 5 indicating hazardous drinking, harmful drinking, or alcohol dependence.)				
1. How often do you have a drink containing alcohol?				
(0) Never	(1) Monthly or less	(2) Two to four times a month	(3) Two or three times a week	(4) Four or more times a week
2. How many drinks containing alcohol do you have on a typical day when you are drinking?				
(0) 1 or 2	(1) 3 or 4	(2) 5 or 6	(3) 7 to 9	(4) 10 or more
3. How often do you have six or more drinks on one occasion?				
(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
4. How often during the past year have you found that you were not able to stop drinking once you had started?				
(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
5. How often during the past year have you failed to do what was normally expected of you because of drinking?				
(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
6. How often during the past year have you needed a first drink in the morning to get yourself going after a heavy drinking session?				
(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
7. How often during the past year have you had a feeling of guilt or remorse after drinking?				
(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
8. How often during the past year have you been unable to remember what happened the night before because you had been drinking?				
(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
9. Have you or has someone else been injured as a result of your drinking?				
(0) No	(2) Yes, but not in the past year		(4) Yes, during the past year	
10. Has a relative or friend or a doctor or other health worker been concerned about your drinking or suggested you cut down?				
(0) No	(2) Yes, but not in the past year		(4) Yes, during the past year

cocaine and opiate abuse. The risk of overdose is lower with buprenorphine than methadone and is preferred for patients at high risk for methadone toxicity. Evidence does not support the use of naltrexone in maintenance treatment of opioid addiction. Rapid opioid detoxification with opioid antagonist induction using general anesthesia has emerged as an approach to treat opioid dependence. However, a randomized comparison of buprenorphine-assisted rapid opioid detoxification with naltrexone induction and clonidine-assisted opioid

detoxification with delayed naltrexone induction found no significant differences in rates of completion of inpatient detoxification, treatment retention, or proportions of opioid-positive urine specimens, and the anesthesia procedure was associated with more potentially life-threatening adverse events. Finally, cognitive behavior therapy, contingency management, couples and family therapy, and other types of behavioral treatment have been shown to be effective interventions for drug addiction.

COUGH

ESSENTIAL INQUIRIES

- ▶ Age.
- ▶ Duration of cough.
- ▶ Dyspnea (at rest or with exertion).
- ▶ Tobacco use history.
- ▶ Vital signs (heart rate, respiratory rate, body temperature).
- ▶ Chest examination.
- ▶ Chest radiography when unexplained cough lasts more than 3–6 weeks.

▶ General Considerations

Cough adversely affects personal and work-related interactions, disrupts sleep, and often causes discomfort of the throat and chest wall. Most people seeking medical attention for acute cough desire symptom relief; few are worried about serious illness. Cough results from stimulation of mechanical or chemical afferent nerve receptors in the bronchial tree. Effective cough depends on an intact afferent–efferent reflex arc, adequate expiratory and chest wall muscle strength, and normal mucociliary production and clearance.

▶ Clinical Findings

A. Symptoms

Distinguishing **acute** (< 3 weeks), **persistent** (3–8 weeks), and **chronic** (> 8 weeks) cough illness syndromes is a useful first step in evaluation. Postinfectious cough lasting 3–8 weeks has also been referred to as **subacute** cough to distinguish this common, distinct clinical entity from acute and chronic cough.

1. Acute cough—In healthy adults, most acute cough syndromes are due to viral respiratory tract infections. Additional features of infection such as fever, nasal

congestion, and sore throat help confirm the diagnosis. Dyspnea (at rest or with exertion) may reflect a more serious condition, and further evaluation should include assessment of oxygenation (pulse oximetry or arterial blood gas measurement), airflow (peak flow or spirometry), and pulmonary parenchymal disease (chest radiography). The timing and character of the cough have not been found to be very useful in establishing the cause of acute cough syndromes, although cough-variant asthma should be considered in adults with prominent nocturnal cough, and persistent cough with phlegm increases the patient's likelihood of chronic obstructive pulmonary disease (COPD). The presence of post-tussive emesis or inspiratory whoop modestly increases the likelihood of pertussis, and the absence of paroxysmal cough decreases the likelihood of pertussis in adolescents and adults with cough lasting more than 1 week. Uncommon causes of acute cough should be suspected in those with heart disease (congestive heart failure [CHF]) or hay fever (allergic rhinitis) and those with environmental risk factors (such as farm workers).

2. Persistent and chronic cough—Cough due to acute respiratory tract infection resolves within 3 weeks in the vast majority of patients (over 90%). Pertussis infection should be considered in adolescents and adults who present with persistent or severe cough lasting more than 3 weeks. In selected geographic areas, the prevalence of pertussis approaches 20% when cough has persisted beyond 3 weeks, although the exact prevalence of pertussis is difficult to ascertain due to the limited sensitivity of diagnostic tests.

When angiotensin-converting enzyme (ACE) inhibitor therapy, acute respiratory tract infection, and chest radiograph abnormalities are absent, the majority of cases of persistent and chronic cough are due to or exacerbated by postnasal drip, asthma, or gastroesophageal reflux disease (GERD). A history of nasal or sinus congestion, wheezing, or heartburn should direct subsequent evaluation and treatment, though these conditions frequently cause persistent cough in the absence of typical symptoms. Dyspnea at rest or with exertion is not commonly reported among patients with persistent cough. The report of dyspnea requires assessment for other evidence of chronic lung disease, CHF, or anemia.

Bronchogenic carcinoma is suspected when cough is accompanied by unexplained weight loss and fevers with

night sweats, particularly in persons with significant tobacco or occupational exposures. Persistent and chronic cough accompanied by excessive mucus secretions increases the likelihood of COPD, particularly among smokers, or bronchiectasis in a patient with a history of recurrent or complicated pneumonia; chest radiographs are helpful in diagnosis.

B. Physical Examination

Examination can direct subsequent diagnostic testing for acute and persistent cough. Pneumonia is suspected when acute cough is accompanied by vital sign abnormalities (tachycardia, tachypnea, fever). Findings suggestive of airspace consolidation (rales, decreased breath sounds, fremitus, egophony) are significant predictors of community-acquired pneumonia but are present in the minority of cases. Purulent sputum is associated with bacterial infections in patients with structural lung disease (eg, COPD, cystic fibrosis), but it is a poor predictor of pneumonia in the otherwise healthy adult. Wheezing and rhonchi are frequent findings in adults with acute bronchitis and do not represent adult-onset asthma in most cases.

Physical examination of patients with persistent cough should look for evidence of chronic sinusitis, contributing to postnasal drip syndrome or asthma. Chest and cardiac signs may help distinguish COPD from CHF. In patients with cough and dyspnea, a normal match test (ability to blow out a match from 25 cm away) and maximum laryngeal height > 4 cm (measured from the sternal notch to the cricoid cartilage at end expiration) substantially decrease the likelihood of COPD. Similarly, normal jugular venous pressure and no hepatojugular reflux decrease the likelihood of biventricular CHF.

C. Diagnostic Studies

1. Acute cough—Chest radiography should be considered for any adult with acute cough who shows abnormal vital signs or in whom the chest examination is suggestive of pneumonia. The relationship between specific clinical findings and the probability of pneumonia is shown in Figure 2–1. In patients with dyspnea, pulse oximetry and peak flow help exclude hypoxemia or obstructive airway disease.

▲ **Figure 2-1.** Revised pneumonia probabilities based on history and physical examination findings. (Reproduced, with permission, from Metlay JP et al. Testing strategies in the initial management of patients with community-acquired pneumonia. *Ann Intern Med.* 2003 Jan 21;138:109-118.)

However, a normal pulse oximetry value (eg, > 93%) does not rule out a significant alveolar–arterial (A–a) gradient when patients have effective respiratory compensation. During documented influenza outbreaks, the positive predictive value of the clinical diagnosis of influenza approaches 70% and usually obviates the usefulness of rapid diagnostic tests.

2. Persistent and chronic cough—Chest radiography is indicated when ACE inhibitor therapy–related and postinfectious cough are excluded by history or further diagnostic testing. If pertussis infection is suspected, testing should be performed using polymerase chain reaction on a nasopharyngeal swab or nasal wash specimen—keeping in mind that the ability to detect pertussis decreases as the duration of cough increases. When the chest film is normal, postnasal drip, asthma, and GERD are the most likely causes. The presence of typical symptoms of these conditions directs further evaluation or empiric therapy, though typical symptoms are often absent. Definitive procedures for determining the presence of each are available (Table 2–1). However, empiric treatment with a maximum-strength regimen for postnasal drip, asthma, or GERD for 2–4 weeks is one recommended approach since documenting the presence of postnasal drip, asthma, and GERD does not mean they are the cause of the cough illness. Alternative approaches to identifying patients who have corticosteroid-responsive cough include examining induced sputum for increased eosinophil counts (> 3%); measuring increased exhaled nitric oxide levels; or providing an empiric trial of prednisone, 30 mg daily for 2 weeks. Spirometry may help identify large airway obstruction in patients who have persistent cough and wheezing and who are not responding to asthma treatment. When empiric treatment trials are not helpful, additional evaluation with pH manometry, endoscopy, barium swallow, sinus CT or high-resolution chest CT may identify the cause.

► Differential Diagnosis

A. Acute Cough

Acute cough may be a symptom of acute respiratory tract infection, asthma, allergic rhinitis, and CHF, as well as a myriad of other less common causes.

Table 2-1. Empiric treatments or tests for persistent cough.

Suspected Condition	Step 1 (Empiric Therapy)	Step 2 (Diagnostic Testing)
Postnasal drip	Therapy for allergy or chronic sinusitis	ENT referral; sinus CT scan
Asthma	β_2 -Agonist	Spirometry; consider methacholine challenge if normal
GERD	Proton pump inhibitors	Esophageal pH monitoring

ENT, ear, nose, and throat; GERD, gastroesophageal reflux disease.

B. Persistent and Chronic Cough

Causes of persistent cough include environmental exposures (cigarette smoke, air pollution), pertussis infection, postnasal drip syndrome (or upper airway cough syndrome), asthma (including cough-variant asthma), GERD, COPD, bronchiectasis, eosinophilic bronchitis, tuberculosis or other chronic infection, interstitial lung disease, and bronchogenic carcinoma. COPD is a common cause of persistent cough among patients > 50 years of age. Persistent cough may also be psychogenic.

▶ Treatment

A. Acute Cough

Treatment of acute cough should target the underlying etiology of the illness, the cough reflex itself, and any additional factors that exacerbate the cough. When influenza is diagnosed, treatment with amantadine, rimantadine, oseltamivir, or zanamivir is equally effective (1 less day of illness) when initiated within 30–48 hours of illness onset, although treatment is recommended regardless of illness duration when patients present with severe illness requiring hospitalization. Furthermore, in the setting of H1N1 influenza, neuraminidase inhibitors are the preferred treatment due to resistance to amantadine/rimantidine. In the setting of *Chlamydia* or *Mycoplasma*-documented infection or outbreaks, first-line antibiotics include erythromycin, 250 mg orally four times daily for 7 days, or doxycycline, 100 mg orally twice daily for 7 days. In patients diagnosed with acute bronchitis, inhaled β_2 -agonist therapy reduces severity and duration of cough in some patients. Evidence supports a modest benefit of dextromethorphan, but not codeine, on cough severity in adults with cough due to acute respiratory tract infections. Treatment of postnasal drip (with antihistamines, decongestants, or nasal corticosteroids) or GERD (with H_2 -blockers or proton-pump inhibitors), when accompanying acute cough illness, can also be helpful. There is good evidence that vitamin C and echinacea are not effective in reducing the severity of acute cough after it develops; however, evidence does support vitamin C (at least 1 g daily) for prevention of colds among persons with major physical stressors (eg, post-marathon) or malnutrition. Treatment with zinc lozenges, when initiated within 24 hours of symptom onset, reduces the duration and severity of cold symptoms.

B. Persistent and Chronic Cough

Evaluation and management of persistent cough often requires multiple visits and therapeutic trials, which frequently lead to frustration, anger, and anxiety. When pertussis infection is suspected, treatment with a macrolide antibiotic (azithromycin 500 mg on day 1, then 250 mg once daily for days 2–5; clarithromycin 500 mg twice daily for 7 days; erythromycin 250 mg four times daily for 14 days) is appropriate to reduce shedding and transmission of the organism. When pertussis infection has lasted

more than 7–10 days, antibiotic treatment does not affect the duration of cough, which can last up to 6 months. Early identification and treatment of patients who work or live with persons at high-risk for complications from pertussis is encouraged (pregnant women, infants [particularly younger than 1 year], and immunosuppressed individuals). There is no evidence to guide how long treatment for persistent cough due to postnasal drip, asthma, or GERD should be continued.

▶ When to Refer

- Failure to control persistent or chronic cough following empiric treatment trials. The small percentage of patients with idiopathic persistent cough should be managed in consultation with an otolaryngologist or a pulmonologist; treatment options include nebulized lidocaine therapy and morphine sulfate, 5–10 mg orally twice daily.
- Patients with recurrent symptoms should be referred to an otolaryngologist or a pulmonologist.

▶ When to Admit

- Patient at high risk for tuberculosis for whom compliance with respiratory precautions is uncertain.
- Need for urgent bronchoscopy, such as suspected foreign body.
- Smoke or toxic fume inhalational injury.
- Intractable cough despite treatment, when cough impairs gas exchange or in patients at high risk for barotraumas (eg, recent pneumothorax).

DYSPNEA

ESSENTIAL INQUIRIES

- ▶ Fever.
- ▶ Cough.
- ▶ Chest pain.
- ▶ Vital sign measurements; pulse oximetry.
- ▶ Cardiac and chest examination.
- ▶ Chest radiography.
- ▶ Arterial blood gas measurement.

▶ General Considerations

Dyspnea is a subjective experience or perception of uncomfortable breathing. However, the relationship between level of dyspnea and the severity of underlying disease varies widely across individuals. Dyspnea can result from conditions that increase the mechanical effort of breathing (eg, COPD, restrictive lung disease, respiratory muscle weakness), from conditions that produce compensatory tachypnea (eg, hypoxemia or acidosis), or from psychogenic origins. The following factors play a role in how and when dyspnea presents in patients: rate of onset, previous dyspnea, medications, comorbidities, psychological profile, and the severity of underlying disorder. In patients with established COPD, the patient-reported severity of dyspnea is superior to forced expiratory volume in 1 second (FEV_1) in predicting quality of life and 5-year mortality.

▶ Clinical Findings

A. Symptoms

The duration, severity, and periodicity of dyspnea influence the tempo of the clinical evaluation. Rapid onset, severe dyspnea in the absence of other clinical features should raise concern for pneumothorax, pulmonary embolism, or increased left ventricular end-diastolic pressure (LVEDP). Spontaneous pneumothorax is usually accompanied by chest pain and occurs most often in thin, young males, or in those with underlying lung disease. Pulmonary embolism should always be suspected when a patient with new dyspnea reports a recent history (previous 4 weeks) of prolonged immobilization, estrogen therapy, or other risk factors for deep venous thrombosis (DVT) (eg, previous history of thromboembolism, cancer, obesity, lower extremity trauma) and when the cause of dyspnea is not apparent. Silent myocardial infarction, which occurs more frequently in diabetic persons and women, can result in acute heart failure and dyspnea.

Accompanying symptoms provide important clues to various etiologies of dyspnea. When cough and fever are present, pulmonary disease (particularly infections) is the primary concern, although myocarditis, pericarditis, and septic emboli can also present in this manner. Chest pain

should be further characterized as acute or chronic, pleuritic or exertional. Although acute pleuritic chest pain is the rule in acute pericarditis and pneumothorax, most patients with pleuritic chest pain in the outpatient clinic have pleurisy due to acute viral respiratory tract infection. Periodic chest pain that precedes the onset of dyspnea is suspicious for myocardial ischemia as well as pulmonary embolism. When associated with wheezing, most cases of dyspnea are due to acute bronchitis; however, when acute bronchitis seems unlikely, the clinician should also consider new-onset asthma, foreign body, and vocal cord dysfunction.

When a patient reports prominent dyspnea with mild or no accompanying features, consider noncardiopulmonary causes of impaired oxygen delivery (anemia, methemoglobinemia, cyanide ingestion, carbon monoxide), metabolic acidosis due to a variety of conditions, panic disorder, and chronic pulmonary embolism.

B. Physical Examination

A focused physical examination should include evaluation of the head and neck, chest, heart, and lower extremities. Visual inspection of the patient's respiratory pattern can suggest obstructive airway disease (pursed-lip breathing, use of extra respiratory muscles, barrel-shaped chest), pneumothorax (asymmetric excursion), or metabolic acidosis (Kussmaul respirations). Patients with impending upper airway obstruction (eg, epiglottitis, foreign body), or severe asthma exacerbation, sometimes assume a tripod position. Focal wheezing raises the suspicion for a foreign body or other bronchial obstruction. Maximum laryngeal height (the distance between the top of the thyroid cartilage and the suprasternal notch at end expiration) is a measure of hyperinflation. Obstructive airway disease is virtually nonexistent when a nonsmoking patient younger than 45 years has a maximum laryngeal height ≤ 4 cm (Table 2–2). Absent breath sounds suggests a pneumothorax. An accentuated pulmonic component of the second heart sound (loud P2) is a sign of pulmonary hypertension and pulmonary embolism.

Table 2–2. Clinical findings suggesting obstructive airway disease.

	Adjusted Likelihood Ratios	
	Factor Present	Factor Absent
> 40 pack-years smoking	11.6	0.9
Age ≥ 45 years	1.4	0.5
Maximum laryngeal height ≤ 4 cm	3.6	0.7
All three factors	58.5	0.3

Reproduced, with permission, from Straus SE et al. The accuracy of patient history, wheezing, and laryngeal measurements in diagnosing obstructive airway disease. CARE-COAD1 Group. Clinical Assessment of the Reliability of the Examination—Chronic Obstructive Airways Disease. JAMA. 2000 Apr 12;283(14):1853–7.

Table 2-3. Clinical findings suggesting increased left ventricular end-diastolic pressure.

Tachycardia
Systolic hypotension
Jugular venous distention (> 5–7 cm H ₂ O) ¹
Hepatojugular reflux (> 1 cm) ²
Crackles, especially bibasilar
Third heart sound ³
Lower extremity edema
Radiographic pulmonary vascular redistribution or cardiomegaly ¹

¹These findings are particularly helpful.

²Proper abdominal compression for evaluating hepatojugular reflux requires > 30 seconds of sustained right upper quadrant abdominal compression.

³Cardiac auscultation of the patient at 45-degree angle in left lateral decubitus position doubles the detection rate of third heart sounds.

Source: Badgett RG et al. Can the clinical examination diagnose left-sided heart failure in adults? *JAMA*. 1997 Jun 4;277(21):1712–9.

A systematic review has identified several clinical predictors of increased LVEDP useful in the evaluation of dyspneic patients with no prior history of CHF (Table 2–3). When none is present, there is a very low probability (< 10%) of increased LVEDP, and when two or more are present, there is a very high probability (> 90%) of increased LVEDP.

C. Diagnostic Studies

Causes of dyspnea that can be managed without chest radiography are few: ingestions causing lactic acidosis, methemoglobinemia, and carbon monoxide poisoning. The diagnosis of pneumonia should be confirmed by chest radiography in most patients. When COPD exacerbation is severe enough to require hospitalization, results of chest radiography can influence management decisions in up to 20% of patients. Chest radiography is fairly sensitive and specific for new-onset CHF (represented by redistribution of pulmonary venous circulation) and can help guide treatment decisions in patients with dyspnea secondary to cardiac disease. End-expiratory chest radiography enhances detection of a small pneumothorax.

A normal chest radiograph has substantial diagnostic value. When there is no physical examination evidence of COPD or CHF and the chest radiograph is normal, the major remaining causes of dyspnea include pulmonary embolism, *Pneumocystis jiroveci* infection (initial radiograph may be normal in up to 25%), upper airway obstruction, foreign body, anemia, and metabolic acidosis. If a patient has tachycardia and hypoxemia but a normal chest radiograph and electrocardiogram (ECG), then further tests to exclude pulmonary emboli are warranted (see Chapter 9), provided blood tests exclude significant anemia or metabolic acidosis. High-resolution chest CT is particularly useful in the evaluation of pulmonary embolism and has the added benefit of providing information about interstitial and alveolar lung disease.

Serum or whole blood brain natriuretic peptide (BNP or NT-proBNP) testing can be useful in distinguishing

cardiac from noncardiac causes of dyspnea in the emergency department, since elevated BNP levels are both sensitive and specific for increased LVEDP in symptomatic persons. Cut points for ruling out acute heart failure increase with age, with one study recommending < 300 g/L to rule out heart failure, and three cut points for ruling-in heart failure (> 450 ng/L for age < 50 years; > 900 ng/L for age 50–75 years; and > 1800 ng/L for age > 75 years).

Persistent uncertainty following clinical examination and routine diagnostic testing warrants arterial blood gas measurement. With two notable exceptions (carbon monoxide poisoning and cyanide toxicity), arterial blood gas measurement distinguishes increased mechanical effort causes of dyspnea (respiratory acidosis with or without hypoxemia) from compensatory tachypnea (respiratory alkalosis with or without hypoxemia or metabolic acidosis) from psychogenic dyspnea (respiratory alkalosis). Carbon monoxide and cyanide impair oxygen delivery with minimal alterations in PO₂; percent carboxyhemoglobin identifies carbon monoxide toxicity. Cyanide poisoning should be considered in a patient with profound lactic acidosis following exposure to burning vinyl (such as a theater fire or industrial accident). Suspected carbon monoxide poisoning or methemoglobinemia can also be confirmed with venous carboxyhemoglobin or methemoglobin levels.

Because arterial blood gas testing is impractical in most outpatient settings, **pulse oximetry** has assumed a central role in the office evaluation of dyspnea. Oxygen saturation values above 96% almost always correspond with a PO₂ > 70 mm Hg, and values < 94% almost always represent clinically significant hypoxemia. Important exceptions to this rule include carbon monoxide toxicity, which leads to a normal oxygen saturation (due to the similar wavelengths of oxyhemoglobin and carboxyhemoglobin), and methemoglobinemia, which results in an oxygen saturation of about 85% that fails to increase with supplemental oxygen. A delirious or obtunded patient with obstructive lung disease warrants immediate measurement of arterial blood gases to exclude hypercapnia and the need for intubation, regardless of the oxygen saturation. When pulse oximetry yields equivocal results, assessment of desaturation with ambulation (eg, a brisk walk around the clinic) can be a useful finding (eg, when *Pneumocystis jiroveci* pneumonia is suspected) for confirming impaired gas exchange.

Episodic dyspnea can be challenging if an evaluation cannot be performed during symptoms. Life-threatening causes include recurrent pulmonary embolism, myocardial ischemia, and reactive airway disease. When associated with audible wheezing, vocal cord dysfunction should be considered, particularly in a young woman who does not respond to asthma therapy. Spirometry is very helpful in further classifying patients with obstructive airway disease but is rarely needed in the initial or emergent evaluation of patients with acute dyspnea.

► Differential Diagnosis

Acute dyspnea, particularly as the chief complaint, demands urgent evaluation. Urgent and emergent conditions causing acute dyspnea include pneumonia, COPD, asthma, pneumothorax, pulmonary embolism, cardiac disease (eg, CHF,

acute myocardial infarction, valvular dysfunction, arrhythmia, cardiac shunt), metabolic acidosis, cyanide toxicity, methemoglobinemia, and carbon monoxide poisoning.

► Treatment

The treatment of urgent or emergent causes of dyspnea should aim to relieve the underlying cause. Pending diagnosis, patients with hypoxemia should be immediately provided supplemental oxygen unless significant hypercapnia is present or strongly suspected pending arterial blood gas measurement. Dyspnea frequently occurs in patients nearing the end of life; whereas opioid therapy can provide substantial relief independent of the severity of hypoxemia, oxygen therapy appears to be most beneficial to patients with significant hypoxemia (see Chapter 5). There appears to be limited benefit of supplemental oxygen when patients with life-limiting illness have $\text{PaO}_2 > 55$ mm Hg. In patients with severe COPD and hypoxemia, oxygen therapy improves mortality and exercise performance. Current clinical trials are attempting to determine benefits of supplemental oxygen in patients with COPD and moderate hypoxemia at rest or desaturation with exercise. Pulmonary rehabilitation programs are another therapeutic option for patients with moderate to severe COPD or interstitial pulmonary fibrosis.

► When to Refer

- Patients with advanced COPD should be referred to a pulmonologist, and patients with CHF or valvular heart disease should be referred to a cardiologist following acute stabilization.
- Cyanide toxicity should be managed in conjunction with a toxicologist.

► When to Admit

- Impaired gas exchange from any cause or high risk of pulmonary embolism pending definitive diagnosis.
- Suspected cyanide poisoning.

HEMOPTYSIS

ESSENTIAL INQUIRIES

- Smoking history.
- Fever, cough, and other symptoms of lower respiratory tract infection.
- Nasopharyngeal or gastrointestinal bleeding.
- Chest radiography and complete blood count.

► General Considerations

Hemoptysis is the expectoration of blood that originates below the vocal cords. It is commonly classified as trivial, mild, or massive—the latter defined as more than 200–600 mL (about 1–2 cups) in 24 hours. The dividing lines are arbitrary, since the amount of blood is rarely quantified with precision. Massive hemoptysis can be usefully defined as any amount that is hemodynamically significant or threatens ventilation, in which case the initial management goal is not diagnostic but therapeutic.

The lungs are supplied with a dual circulation. The pulmonary arteries arise from the right ventricle to supply the pulmonary parenchyma in a low-pressure circuit. The bronchial arteries arise from the aorta or intercostal arteries and carry blood under systemic pressure to the airways, blood vessels, hila, and visceral pleura. Although the bronchial circulation represents only 1–2% of total pulmonary blood flow, it can increase dramatically under conditions of chronic inflammation—eg, chronic bronchiectasis—and is frequently the source of hemoptysis.

The causes of hemoptysis can be classified anatomically. Blood may arise from the airways in COPD, bronchiectasis, and bronchogenic carcinoma; from the pulmonary vasculature in left ventricular failure, mitral stenosis, pulmonary embolism, idiopathic pulmonary arterial hypertension, and arteriovenous malformations; or from the pulmonary parenchyma in pneumonia, inhalation of crack cocaine, or granulomatosis with polyangiitis (formerly Wegener granulomatosis). Diffuse alveolar hemorrhage is due to small vessel bleeding usually caused by autoimmune or hematologic disorders and results in alveolar infiltrates on chest radiography. Most cases of hemoptysis presenting in the outpatient setting are due to infection (eg, acute or chronic bronchitis, pneumonia, tuberculosis). Hemoptysis due to lung cancer increases with age, accounting for up to 20% of cases among the elderly. Less commonly (< 10% of cases), pulmonary venous hypertension (eg, mitral stenosis, pulmonary embolism) causes hemoptysis. Most cases of

hemoptysis that have no visible cause on CT scan or bronchoscopy will resolve within 6 months without treatment, with the notable exception of patients at high risk for lung cancer (smokers older than 40 years). Iatrogenic hemorrhage may follow transbronchial lung biopsies, anticoagulation, or pulmonary artery rupture due to distal placement of a balloon-tipped catheter. No cause is identified in up to 15–30% of cases.

▶ Clinical Findings

A. Symptoms

Blood-tinged sputum in the setting of an upper respiratory tract infection in an otherwise healthy, young (age < 40 years) nonsmoker does not warrant an extensive diagnostic evaluation if the hemoptysis subsides with resolution of the infection. However, hemoptysis is frequently a sign of serious disease, especially in patients with a high prior probability of underlying pulmonary pathology. One should not distinguish between blood-streaked sputum and cough productive of blood alone with regard to the evaluation plan. The goal of the history is to identify patients at risk for one of the disorders listed above. Pertinent features include past or current tobacco use, duration of symptoms, and the presence of respiratory infection. Nonpulmonary sources of hemorrhage—from the nose or the gastrointestinal tract—should also be excluded.

B. Physical Examination

Elevated pulse, hypotension, and decreased oxygen saturation suggest large volume hemorrhage that warrants emergent evaluation and stabilization. The nares and oropharynx should be carefully inspected to identify a potential upper airway source of bleeding. Chest and cardiac examination may reveal evidence of CHF or mitral stenosis.

C. Diagnostic Studies

Diagnostic evaluation should include a chest radiograph and complete blood count. Kidney function tests, urinalysis, and coagulation studies are appropriate in specific circumstances. Hematuria that accompanies hemoptysis may be a clue to Goodpasture syndrome or vasculitis. Flexible bronchoscopy reveals endobronchial cancer in 3–6% of patients with hemoptysis who have a normal (non-lateralizing) chest radiograph. Nearly all of these patients are smokers over the age of 40, and most will have had symptoms for more than 1 week. Bronchoscopy is indicated in such patients. High-resolution chest CT scan complements bronchoscopy and should be strongly considered in patients with normal chest radiograph and low risk for malignancy. It can visualize unsuspected bronchiectasis and arteriovenous malformations and will show central endobronchial lesions in many cases. High-resolution chest CT scanning is the test of choice for suspected small peripheral malignancies. Helical CT pulmonary angiography has become the initial test of choice for evaluating patients with suspected pulmonary embolism, although caution should be taken to avoid large contrast loads in patients with even mild chronic kidney disease (serum

creatinine > 2.0 g/dL or rapidly rising creatinine in normal range). Helical CT scanning can be avoided in patients who are at “unlikely” risk for pulmonary embolism using the Wells clinical decision rule and who have a normal sensitive D-dimer test.

▶ Treatment

The management of mild hemoptysis consists of identifying and treating the specific cause. Massive hemoptysis is life-threatening. The airway should be protected with endotracheal intubation, ventilation ensured, and effective circulation maintained. If the location of the bleeding site is known, the patient should be placed in the decubitus position with the involved lung dependent. Uncontrollable hemorrhage warrants rigid bronchoscopy and surgical consultation. In stable patients, flexible bronchoscopy may localize the site of bleeding, and angiography can embolize the involved bronchial arteries. Embolization is effective initially in 85% of cases, although rebleeding may occur in up to 20% of patients over the following year. The anterior spinal artery arises from the bronchial artery in up to 5% of people, and paraplegia may result if it is inadvertently cannulated.

▶ When to Refer

- When bronchoscopic evaluation of lower respiratory tract is required, refer patients to a pulmonologist.
- Patients should be referred to an otolaryngologist for evaluation of upper respiratory tract bleeding source.
- Patients with severe coagulopathy complicating management should be referred to a hematologist.

▶ When to Admit

- To stabilize bleeding process in patients at risk for or experiencing massive hemoptysis.
- To correct disordered coagulation (clotting factors or platelets, or both).
- To stabilize gas exchange.

CHEST PAIN

ESSENTIAL INQUIRIES

- ▶ Chest pain onset, character, location/size, duration, periodicity, and exacerbators.
- ▶ Shortness of breath.
- ▶ Vital signs.
- ▶ Chest and cardiac examination.
- ▶ Electrocardiography.
- ▶ Biomarkers of myocardial necrosis.

▶ General Considerations

Chest pain (or chest discomfort) is a common symptom that can occur as a result of cardiovascular, pulmonary, pleural, or musculoskeletal disease, esophageal or other gastrointestinal disorders, or anxiety states. The frequency and distribution of life-threatening causes of chest pain, such as acute coronary syndrome (ACS), pericarditis, aortic dissection, pulmonary embolism, pneumonia, and esophageal perforation, vary substantially between clinical settings. Systemic lupus erythematosus, rheumatoid arthritis, and HIV are conditions that confer a strong risk for coronary artery disease. Because pulmonary embolism can present with a wide variety of symptoms, consideration of the diagnosis and rigorous risk factor assessment for venous thromboembolism (VTE) is critical. Classic VTE risk factors include cancer, trauma, recent surgery, prolonged immobilization, pregnancy, oral contraceptives, and family history and prior history of VTE. Other conditions associated with increased risk of pulmonary embolism include CHF and COPD. Sickle cell anemia can cause acute chest syndrome. Patients with this syndrome often have chest pain, fever, and cough.

Although uncommon in the office setting, delays in diagnosing life-threatening causes of chest pain can result in serious morbidity and mortality.

▶ Clinical Findings

A. Symptoms

Myocardial ischemia is usually described as dull, aching sensation of “pressure,” “tightness,” “squeezing,” or “gas,” rather than as sharp or spasmodic. Ischemic symptoms usually subside within 5–20 minutes but may last longer. Progressive symptoms or symptoms at rest may represent unstable angina. Prolonged chest pain episodes might represent myocardial infarction, although up to one-third of patients with acute myocardial infarction do not report chest pain. When present, pain due to myocardial ischemia is commonly accompanied by a sense of anxiety or uneasiness. The location is usually retrosternal or left precordial. Because the heart lacks somatic innervation, precise localization of pain due to cardiac ischemia is difficult; the pain is commonly referred to the throat, lower jaw, shoulders, inner arms,

upper abdomen, or back. Ischemic pain may be precipitated or exacerbated by exertion, cold temperature, meals, stress, or combinations of these factors and is usually relieved by rest. However, many episodes do not conform to these patterns; and atypical presentations of ACS are more common in the elderly, women, and persons with diabetes. Other symptoms that are associated with ACS include shortness of breath; dizziness; a feeling of impending doom; and vagal symptoms, such as nausea and diaphoresis. In the elderly, fatigue is a common presenting complaint of ACS. Likelihood ratios for cardinal symptoms considered in the evaluation of acute myocardial infarction are summarized in Table 2–4.

Hypertrophy of either ventricle or aortic stenosis may also give rise to chest pain with less typical features. Pericarditis may produce pain that is greater when supine than upright and may increase with respiration, coughing, or swallowing. Pleuritic chest pain is usually not ischemic,

Table 2–4. Likelihood ratios (LRs) for clinical features associated with acute myocardial infarction.

Clinical Feature	LR+ (95% CI)
History	
Chest pain that radiates to the left arm	2.3 (1.7–3.1)
Chest pain that radiates to the right shoulder	2.9 (1.4–3.0)
Chest pain that radiates to both arms	7.1 (3.6–14.2)
Pleuritic chest pain	0.2 (0.2–0.3)
Sharp or stabbing chest pain	0.3 (0.2–0.5)
Positional chest pain	0.3 (0.2–0.4)
Chest pain reproduced by palpation	0.2–0.4 ¹
Nausea or vomiting	1.9 (1.7–2.3)
Diaphoresis	2.0 (1.9–2.2)
Physical examination	
Systolic blood pressure ≤ 80 mm Hg	3.1 (1.8–5.2)
Pulmonary crackles	2.1 (1.4–3.1)
Third heart sound	3.2 (1.6–6.5)
Electrocardiogram	
Any ST segment elevation (≥ 1 mm)	11.2 (7.1–17.8)
Any ST segment depression	3.2 (2.5–4.1)
Any Q wave	3.9 (2.7–7.7)
Any conduction defect	2.7 (1.4–5.4)
New ST segment elevation (≥ 1 mm)	5.7–53.9 ¹
New ST segment depression	3.0–5.2 ¹
New Q wave	5.3–24.8 ¹
New conduction defect	6.3 (2.5–15.7)

¹Heterogenous studies do not allow for calculation of a point estimate.

and pain on palpation may indicate a musculoskeletal cause. Aortic dissection classically produces an abrupt onset of tearing pain of great intensity that often radiates to the back; however, this classic presentation occurs in a small proportion of cases. Anterior aortic dissection can also lead to myocardial or cerebrovascular ischemia.

Pulmonary embolism has a wide range of clinical presentations, with chest pain present in only 75% of cases. The chief objective in evaluating patients with suspected pulmonary embolism is to assess the patient's clinical risk for VTE based on medical history and associated signs and symptoms (see above and Chapter 9). Esophageal perforation of the thoracic region is another cause of chest pain, with most cases resulting from medical procedures of the esophagus.

B. Physical Examination

Findings on physical examination can occasionally yield important clues to the underlying cause of chest pain; however, a normal physical examination should never be used as the sole basis for ruling-out most diagnoses, particularly ACS and aortic dissection. Vital sign measurement, including pulse oximetry, is always the first step for assessing the urgency and tempo of the subsequent examination and diagnostic work-up.

Findings that increase the likelihood of ACS include diaphoresis, hypotension, S3 or S4 gallop, pulmonary crackles, or elevated jugular venous pressure (see Table 2–4). Although chest pain that is reproducible or worsened with palpation strongly suggests a musculoskeletal cause, up to 15% of patients with ACS will have reproducible chest wall tenderness. Pointing to the location of the pain with one finger has been shown to be highly correlated with nonischemic chest pain. Aortic dissection can result in differential blood pressures (> 20 mm Hg), pulse amplitude deficits, and new diastolic murmurs. Although hypertension is considered the rule in patients with aortic dissection, systolic blood pressure < 100 mm Hg is present in up to 25% of patients.

A cardiac friction rub represents pericarditis until proven otherwise. It can best be heard with the patient sitting forward at end-expiration. Tamponade should be excluded in all patients with a clinical diagnosis of pericarditis by assessing pulsus paradoxus (a decrease in systolic blood pressure during inspiration > 10 mm Hg) and inspection of jugular venous pulsations. Subcutaneous emphysema is common following cervical esophageal perforation but present in only about one-third of thoracic perforations (ie, those most commonly presenting with chest pain).

The absence of physical examination findings in patients with suspected pulmonary embolism usually serves to *increase* the likelihood of pulmonary embolism, although a normal physical examination is also compatible with the much more common conditions of panic/anxiety disorder and musculoskeletal disease.

C. Diagnostic Studies

Unless a competing diagnosis can be confirmed, an ECG is warranted in the initial evaluation of most patients with acute chest pain to help exclude ACS. ST segment elevation is the ECG finding that is the strongest predictor of acute

myocardial infarction (see Table 2–4); however, up to 20% of patients with ACS can have a normal ECG. A 2007 study concluded that patients with suspected ACS can be safely removed from cardiac monitoring in the emergency department if they are pain-free at initial physician assessment and have a normal or nonspecific ECG. This decision rule had 100% sensitivity for serious arrhythmia (95% confidence interval, 80–100%), but deserves further validation. Clinically stable patients with cardiovascular disease risk factors, normal ECG, normal cardiac biomarkers, and no alternative diagnoses (such as typical GERD or costochondritis) should be followed-up with a timely exercise stress test that includes perfusion imaging. The ECG can also provide evidence for alternative diagnoses, such as pericarditis and pulmonary embolism. Chest radiography is often useful in the evaluation of chest pain, and is always indicated when cough or shortness of breath accompanies chest pain. Findings of pneumomediastinum or new pleural effusion are consistent with esophageal perforation. Sixty-four-slice CT coronary angiography has been studied for diagnosing acute coronary syndromes and predicting outcomes in the emergency department. One study of 58 patients found a high positive predictive value for diagnosing acute coronary syndromes, and a negative predictive value of 97%. Another study found that it compared favorably with stress nuclear imaging in the detection and exclusion of ACS in low-risk chest pain patients. CT is the study of choice at most centers for the diagnosis of esophageal perforation as well as for aortic dissection (helical CT). Current generation highly-sensitive assays for cardiac troponin I have been studied in an effort to more rapidly prognosticate outcomes in patients presenting with suspected ACS. Patients presenting to the emergency department with chest pain of intermediate or high probability for ACS without electrocardiographic or biomarker evidence of a myocardial infarction can be safely discharged from an observation unit after stress cardiac magnetic imaging.

The role of CT coronary calcium assessment in the evaluation of chest pain in the emergency department is still being defined. A study suggests that the coronary artery calcium score appears to be an effective initial tool for risk stratification of low- to intermediate-risk patients with possible acute coronary syndromes, on the basis of its high negative predictive value and additive diagnostic value.

In the evaluation of pulmonary embolism, diagnostic test decisions and results must be interpreted in the context of the clinical likelihood of VTE. A negative D-dimer test is helpful for excluding pulmonary embolism in patients with low clinical probability of VTE (3 month incidence = 0.5%); however, the 3-month risk of VTE among patients with intermediate and high risk of VTE is sufficiently high in the setting of a negative D-dimer test (3.5% and 21.4%, respectively) to warrant further imaging given the life-threatening nature of this condition if left untreated. CT angiography (with helical or multidetector CT imaging) has replaced ventilation-perfusion scanning as the preferred diagnostic test for pulmonary embolism, having approximately 90–95% sensitivity and 95% specificity for detecting pulmonary embolism (compared with pulmonary angiography). However, according to guidelines

published by the American Academy of Family Physicians and the American College of Physicians (AAFP/ACP), the sensitivity of helical CT is probably not sufficiently high to exclude pulmonary embolism among patients with high clinical probability of VTE, in whom lower extremity ultrasound or pulmonary angiogram may be appropriate. When ventilation-perfusion scanning is performed, only results that are normal or high probability are useful for improving one's clinical assessment of pulmonary embolism.

Panic disorder is a common cause of chest pain, accounting for up to 25% of cases that present to emergency departments and a higher proportion of cases presenting in primary care office practices. Features that correlate with an increased likelihood of panic disorder include absence of coronary artery disease, atypical quality of chest pain, female sex, younger age, and a high level of self-reported anxiety.

► Treatment

Treatment of chest pain should be guided by the underlying etiology. The term “noncardiac chest pain” is used to describe patients who evade diagnosis after receiving extensive work-up. Although under-studied, one small trial of patients with noncardiac chest pain found that about half fulfilled criteria for anxiety or depression and almost half reported symptom improvement with high-dose proton-pump inhibitor therapy.

► When to Refer

- Refer patients with poorly controlled, noncardiac chest pain to a pain specialist.
- Refer patients with sickle cell anemia to a hematologist.

► When to Admit

- Failure to adequately exclude (to a sufficient degree) life-threatening causes of chest pain, particularly myocardial infarction, dissecting aortic aneurysm, pulmonary embolism, and esophageal rupture.
- Pain control for rib fracture that impairs gas exchange.

PALPITATIONS

ESSENTIAL INQUIRIES

- Forceful, rapid, or irregular beating of the heart.
- Rate, duration, and degree of regularity of heart beat.
- Age at first episode.
- Factors that precipitate or terminate episodes.
- Light-headedness or syncope.
- Neck pounding.
- Chest pain.

► General Considerations

Palpitations are defined as an unpleasant awareness of the forceful, rapid, or irregular beating of the heart. They are a common presenting complaint and are usually benign; however, they are occasionally the symptom of a life-threatening arrhythmia. To avoid missing a dangerous cause of the patient's symptom, clinicians sometimes pursue expensive

and invasive testing when a conservative diagnostic evaluation is sufficient. The converse is also true; in one study, 54% of patients with supraventricular tachycardia were initially wrongly diagnosed with panic, stress, or anxiety disorder. A disproportionate number of these misdiagnosed patients are women.

► Clinical Findings

A. Symptoms

Although described by patients in a myriad of ways, guiding the patient through a careful description of their palpitations may indicate a mechanism and narrow the differential diagnosis. Pertinent questions include the age at first episode; precipitants; and the rate, duration, and degree of regularity of the heart beat during the subjective palpitations. The examiner can ask the patient to “tap out” the rhythm with their fingers. The circumstances associated with onset and termination can also be helpful in determining the cause. Palpitations that start and stop abruptly suggest supraventricular or ventricular tachycardias. Patient-terminated palpitations using vagal maneuvers (such as the Valsalva maneuver) suggests supraventricular tachycardia.

Three common descriptions of palpitations are (1) “flip-flopping” (or “stop and start”), often caused by premature contraction of the atrium or ventricle, with the perceived “stop” from the pause following the contraction, and the “start” from the subsequent forceful contraction; (2) rapid “fluttering in the chest,” with regular “fluttering” suggesting supraventricular or ventricular arrhythmias (including sinus tachycardia) and irregular “fluttering” suggesting atrial fibrillation, atrial flutter, or tachycardia with variable block; and (3) “pounding in the neck” or neck pulsations, often due to “cannon” A waves in the jugular venous pulsations that occur when the right atrium contracts against a closed tricuspid valve.

Palpitations associated with chest pain suggests ischemic heart disease, or if the chest pain is relieved by leaning forward, pericardial disease is suspected. Palpitations associated with light-headedness, presyncope, or syncope suggests hypotension and may signify a life-threatening cardiac arrhythmia. Palpitations that occur regularly with exertion suggests a rate-dependent bypass tract or hypertrophic cardiomyopathy. If a benign etiology for these concerning symptoms cannot be ascertained at the index visit, then ambulatory monitoring or prolonged cardiac monitoring in the hospital might be warranted.

Noncardiac symptoms should also be elicited since the palpitations may be caused by a normal heart responding to a metabolic or inflammatory condition. Weight loss may suggest hyperthyroidism. Palpitations can be precipitated by vomiting or diarrhea that leads to electrolyte disorders and hypovolemia. Palpitations associated with hyperventilation, hand tingling, and nervousness are common when anxiety or panic disorder is the root cause.

B. Physical Examination

It is uncommon for the clinician to have the opportunity to examine a patient during an episode of palpitations.

However, careful cardiovascular examination can find abnormalities that can increase the likelihood of specific cardiac arrhythmias. The midsystolic click of mitral valve prolapse can suggest the diagnosis of a supraventricular arrhythmia as the cause for the palpitations. The harsh holosystolic murmur of hypertrophic cardiomyopathy, which occurs along the left sternal border and increases with the Valsalva maneuver, suggests atrial fibrillation or ventricular tachycardia. The presence of dilated cardiomyopathy, suggested on examination by a displaced and enlarged cardiac point-of-maximal impulse, increases the likelihood of ventricular tachycardia and atrial fibrillation. In patients with chronic atrial fibrillation, in-office exercise (eg, a brisk walk in the hallway) may reveal an intermittent accelerated ventricular response as the cause of the palpitations. The clinician should also look for signs of hyperthyroidism, such as tremulousness, brisk deep tendon reflexes, fine hand tremor, or signs of stimulant drug use (such as dilated pupils or skin or nasal septal lesions). The presence of visible neck pulsations (LR, 2.68; 95% CI, 1.25–5.78) in association with palpitations increases the likelihood of atrioventricular nodal reentry tachycardia.

C. Diagnostic Studies

The two cardiac studies that are commonly used in the initial evaluation of a patient with palpitations are the 12-lead ECG and ambulatory monitoring devices, such as the Holter monitor or the event recorder.

A 12-lead ECG should be performed on all patients reporting palpitations because it can provide evidence for a wide variety of causes. Although in most instances a specific arrhythmia will not be detected on the tracing, a careful evaluation of the ECG can help the clinician deduce a likely etiology in certain circumstances.

For instance, bradyarrhythmias and heart block can be associated with ventricular ectopy or escape beats that may be experienced as palpitations by the patient. Evidence of prior myocardial infarction by history or on ECG (eg, Q waves) increases the patient’s risk for nonsustained or sustained ventricular tachycardia. Ventricular preexcitation (Wolff-Parkinson-White syndrome) is suggested by a short PR interval (< 0.20 ms) and delta waves (upsloping PR segments). Left ventricular hypertrophy with deep septal Q waves in I, AVL, and V4 through V6 is seen in patients with hypertrophic obstructive cardiomyopathy. The presence of left atrial enlargement as suggested by a terminal P-wave force in V1 more negative than 0.04 msec and notched in lead II reflects a patient at increased risk for atrial fibrillation. A prolonged QT interval and abnormal T-wave morphology suggests the long-QT syndrome, which puts patients at increased risk for ventricular tachycardia.

For high-risk patients (Table 2–5), further diagnostic studies are warranted. A step-wise approach has been suggested—starting with ambulatory monitoring devices (Holter monitoring if the palpitations are expected to occur within the subsequent 72-hour period, event monitoring if less frequent), followed by invasive electrophysiologic testing if the ambulatory monitor records a worrisome arrhythmia or if serious arrhythmias are strongly suspected

Table 2–5. Palpitations: Patients at high risk for a cardiovascular cause.

Historical risk factors
Family history of significant arrhythmias
Personal or family history of syncope or resuscitated sudden death
History of myocardial infarction (and likely scarred myocardium)
Physical examination findings
Structural heart disease such as dilated or hypertrophic cardiomyopathies
Valvular disease (stenotic or regurgitant)
ECG findings
Long QT syndrome
Bradycardia
Second- or third-degree heart block
Sustained ventricular arrhythmias

despite normal findings on an appropriate ambulatory monitor.

In patients with a prior myocardial infarction, ambulatory cardiac monitoring or signal-averaged-ECG are appropriate next steps to assess ventricular tachycardia. ECG exercise testing is appropriate in patients who have palpitations with physical exertion and patients with suspected coronary artery disease. Echocardiography is useful when physical examination or ECG suggests structural abnormalities or decreased ventricular function.

► Differential Diagnosis

When assessing a patient with palpitations in an urgent care setting, the clinician must ascertain whether the symptoms represent (1) an arrhythmia that is minor and transient, (2) significant cardiovascular disease, (3) a cardiac manifestation of a systemic disease such as thyrotoxicosis, or (4) a benign somatic symptom that is amplified by underlying psychosocial characteristics of the patient.

Palpitations in patients with a known history of cardiac disease or palpitations that occur during sleep increase the likelihood of a cardiac arrhythmia. A history of panic disorder or palpitations that last < 5 minutes make a cardiac arrhythmia slightly less likely. Patients who seek medical attention in the emergency department instead of a medical clinic are more likely to have a cardiac etiology (47% versus 21%), while psychiatric causes are more common among patients with palpitations who seek medical attention in office practices (45% versus 27%). In a study of patients who went to a university medical clinic with the chief complaint of palpitations, etiologies were cardiac in 43%, psychiatric in 31%, and miscellaneous in 10% (including illicit drugs, medications, anemia, thyrotoxicosis, and mastocytosis).

Cardiac arrhythmias that can result in symptoms of palpitations include sinus bradycardia; sinus, supraventricular, and ventricular tachycardia; premature ventricular and atrial contractions; sick sinus syndrome; and advanced atrioventricular block.

Nonarrhythmic cardiac causes of palpitations include valvular heart diseases, such as aortic insufficiency or stenosis, atrial or ventricular septal defect, cardiomyopathy, congenital heart disease, and pericarditis.

Noncardiac causes of palpitations include fever, dehydration, hypoglycemia, anemia, thyrotoxicosis, and pheochromocytoma. Drugs such as cocaine, alcohol, caffeine, and pseudoephedrine can precipitate palpitations, as can prescription medications, including digoxin, phenothiazines, theophylline, and β -agonists as well as ephedra-containing herbal remedies or supplements, which are banned by the US Food and Drug Administration.

The most common psychiatric causes of palpitations are anxiety and panic disorder. The release of catecholamines during a panic attack or significant stress can trigger an arrhythmia. Asking a single question, “Have you experienced brief periods, for seconds or minutes, of an overwhelming panic or terror that was accompanied by racing heartbeats, shortness of breath, or dizziness?” can help identify patients with panic disorder.

► Treatment

After ambulatory monitoring, most patients with palpitations are found to have benign atrial or ventricular ectopy and nonsustained ventricular tachycardia. In patients with structurally normal hearts, these arrhythmias are not associated with adverse outcomes. Abstention from caffeine and tobacco may help. Often, reassurance suffices. If not, or in very symptomatic patients, a trial of a β -blocker may be prescribed. For treatment of specific atrial or ventricular arrhythmias, see Chapter 10.

► When to Refer

- For electrophysiologic studies.
- For advice regarding treatment of atrial or ventricular arrhythmias.

► When to Admit

- Palpitations associated with syncope or near-syncope, particularly when the patient is aged 75 years or older and has an abnormal ECG, hematocrit < 30%, shortness of breath, respiratory rate > 24/min, or a history of CHF.
- Patients with risk factors for a serious arrhythmia.

LOWER EXTREMITY EDEMA

ESSENTIAL INQUIRIES

- ▶ History of venous thromboembolism.
- ▶ Symmetry.
- ▶ Pain.
- ▶ Dependence.
- ▶ Skin findings.

▶ General Considerations

Acute and chronic lower extremity edema present important diagnostic and treatment challenges. Lower extremities can swell in response to increased venous or lymphatic pressures, decreased intravascular oncotic pressure, increased capillary leak, and local injury or infection. **Chronic venous insufficiency** is by far the most common cause, affecting up to 2% of the population, and the incidence of venous insufficiency has not changed during the past 25 years. Venous insufficiency is a common complication of DVT; however, only a small number of patients with chronic venous insufficiency report a history of this disorder. Venous ulcer formation commonly affects patients with chronic venous insufficiency, and management of venous ulceration is labor-intensive and expensive. Other causes of lower extremity edema include cellulitis, musculoskeletal disorders (Baker cyst rupture, gastrocnemius tear or rupture), lymphedema, CHF, cirrhosis, and nephrotic syndrome as well as side effects from calcium channel blockers, minoxidil, or thiazolidines.

▶ Clinical Findings

A. Symptoms and Signs

Normal lower extremity venous pressure (in the erect position: 80 mm Hg in deep veins, 20–30 mm Hg in superficial veins) and cephalad venous blood flow require competent bicuspid venous valves, effective muscle contractions, and normal respirations. When one or more of these components fail, venous hypertension may result. Chronic exposure to elevated venous pressure by the postcapillary venules in the legs leads to leakage of fibrinogen and growth factors into the interstitial space, leukocyte aggregation and activation, and obliteration of the cutaneous lymphatic network. These changes account for the brawny, fibrotic skin changes observed in patients with chronic venous insufficiency, and the predisposition toward skin ulceration, particularly in the medial malleolar area.

Among common causes of lower extremity swelling, DVT is the most life-threatening. Clues suggesting DVT include a history of cancer, recent limb immobilization, or confinement to bed for at least 3 days following major surgery within the past month (Table 2–6). A search for alternative explanations is equally important in excluding DVT. Bilateral involvement and significant improvement

Table 2–6. Risk stratification of adults referred for ultrasound to rule out DVT.

Step 1: Calculate risk factor score		
Score 1 point for each		
	Untreated malignancy	
	Paralysis, paresis, or recent plaster immobilization	
	Recently bedridden for > 3 days due to major surgery within 4 weeks	
	Localized tenderness along distribution of deep venous system	
	Entire leg swelling	
	Swelling of one calf > 3 cm more than the other (measured 10 cm below tibial tuberosity)	
	Ipsilateral pitting edema	
	Collateral superficial (nonvaricose) veins	
	Previously documented DVT	
Alternative diagnosis as likely as or more likely than DVT: subtract 2 points		
Step 2: Obtain ultrasound		
Score	Ultrasound Positive	Ultrasound Negative
≤ 0	Confirm with venogram	DVT ruled out
1–2	Treat for DVT	Repeat ultrasound in 3–7 days
≥ 3	Treat for DVT	Confirm with venogram

DVT, deep venous thrombosis.

upon awakening favor systemic causes (eg, venous insufficiency, CHF, and cirrhosis). “Heavy legs” are the most frequent symptom among patients with chronic venous insufficiency, followed by itching. Pain, particularly if severe, is uncommon in uncomplicated venous insufficiency. Lower extremity swelling and inflammation in a limb recently affected by DVT could represent anticoagulation failure and thrombus recurrence but more often are caused by **postphlebotic syndrome** with valvular incompetence. Other causes of a painful, swollen calf include ruptured popliteal cyst, calf strain or trauma, and cellulitis.

Lower extremity swelling is a familiar complication of therapy with calcium channel blockers (particularly felodipine and amlodipine), thiazolidines, and minoxidil. Bilateral lower extremity edema can be a presenting symptom of nephrotic syndrome or volume overload caused by renal failure. Prolonged airline flights (>10 hours) are associated with increased risk of edema. In those with low to medium risk of thromboembolism (eg, women taking oral contraceptives), long flights are associated with a 2% incidence of asymptomatic popliteal DVT.

B. Physical Examination

Physical examination should include assessment of the heart, lungs, and abdomen for evidence of pulmonary hypertension (primary, or secondary to chronic lung disease), CHF, or cirrhosis. Some patients with cirrhosis have

pulmonary hypertension without lung disease. There is a spectrum of skin findings related to chronic venous insufficiency that depends on the severity and chronicity of the disease, ranging from hyperpigmentation and stasis dermatitis to abnormalities highly specific for chronic venous insufficiency: lipodermatosclerosis (thick brawny skin; in advanced cases, the lower leg resembles an inverted champagne bottle) and atrophie blanche (small depigmented macules within areas of heavy pigmentation). The size of both calves should be measured 10 cm below the tibial tuberosity and elicitation of pitting and tenderness performed. Swelling of the entire leg or swelling of one leg 3 cm more than the other suggests deep venous obstruction. In normal persons, the left calf is slightly larger than the right as a result of the left common iliac vein coursing under the aorta.

An ulcer located over the medial malleolus is a hallmark of chronic venous insufficiency but can be due to other causes. Shallow, large, modestly painful ulcers are characteristic of venous insufficiency, whereas small, deep, and more painful ulcers are more apt to be due to arterial insufficiency, vasculitis, or infection (including cutaneous diphtheria). Diabetic vascular ulcers, however, may be painless. When an ulcer is on the foot or above the mid calf, causes other than venous insufficiency should be considered.

C. Diagnostic Studies

Most causes of lower extremity swelling can be demonstrated with color duplex ultrasonography. Patients without an obvious cause of acute lower extremity swelling (eg, calf strain) should have an ultrasound performed, since DVT is difficult to exclude on clinical grounds. A predictive rule allows a clinician to exclude a lower extremity DVT in patients without an ultrasound if the patient has low pretest probability for DVT and has a negative sensitive D-dimer test (the “Wells rule”). Assessment of the ankle-brachial pressure index (ABPI) is important in the management of chronic venous insufficiency, since peripheral arterial disease may be exacerbated by compression therapy. This can be performed at the same time as ultrasound. Caution is required in interpreting the results of ABPI in older patients and diabetics due to decreased compressibility of their arteries. A dipstick urine test that is strongly positive for protein can suggest nephrotic syndrome, and a serum creatinine can help estimate kidney function.

► Treatment

Treatment of lower extremity edema should be guided by the underlying etiology. See relevant chapters for treatment of edema in patients with CHF (Chapter 10), nephrosis (Chapter 22), cirrhosis (Chapter 16), and lymphedema (Chapter 12). Edema resulting from calcium channel blocker therapy responds to concomitant therapy with ACE inhibitors or angiotensin receptor blockers.

In patients with chronic venous insufficiency without a comorbid volume overload state (eg, CHF), it is best to avoid diuretic therapy. These patients have relatively decreased

intravascular volume, and administration of diuretics may result in acute renal insufficiency and oliguria. The most effective treatment involves (1) leg elevation, above the level of the heart, for 30 minutes three to four times daily, and during sleep; (2) compression therapy; and (3) ambulatory exercise to increase venous return through calf muscle contractions. A wide variety of stockings and devices are effective in decreasing swelling and preventing ulcer formation. They should be put on with awakening, before hydrostatic forces result in edema. To control simple edema, 20–30 mm Hg is usually sufficient; whereas, > 30–40 mm Hg is usually required to control moderate to severe edema associated with ulcer formation. Escin, 50 mg orally twice daily (or as horse chestnut seed extract, 300 mg orally twice daily) has been shown in several randomized trials to be equivalent to compression stockings and can be quite useful in nonambulatory patients; however, this medication is not approved by the US Food and Drug Administration. Patients with decreased ABPI should be managed in concert with a vascular surgeon. Compression stockings (12–18 mm Hg at the ankle) are effective in preventing edema and asymptomatic thrombosis associated with long airline flights in low- to medium-risk persons. See Chapter 12 for treatment of venous stasis ulcers.

► When to Refer

- Chronic lower extremity ulcerations requiring specialist wound care.
- Nephrotic syndrome should be managed with nephrology consultation.
- When there is coexisting severe arterial insufficiency (claudication) complicating treatment with compression stockings.

► When to Admit

- Pending definitive diagnosis in patients at high risk for DVT with normal lower extremity ultrasound.
- Concern for impending compartment syndrome.
- Severe edema that impairs ability to ambulate or perform activities of daily living.

FEVER & HYPERTHERMIA

ESSENTIAL INQUIRIES

- ▶ Age.
- ▶ Localizing symptoms.
- ▶ Weight loss.
- ▶ Joint pain.
- ▶ Injection substance use.
- ▶ Immunosuppression or neutropenia.
- ▶ History of cancer.
- ▶ Medications.
- ▶ Travel.

▶ General Considerations

The average normal oral body temperature taken in mid-morning is 36.7°C (range 36–37.4°C). This spectrum includes a mean and 2 standard deviations, thus encompassing 95% of a normal population, measured in mid-morning (normal diurnal temperature variation is 0.5–1°C). The normal rectal or vaginal temperature is 0.5°C higher than the oral temperature, and the axillary temperature is correspondingly lower. Rectal temperature is more reliable than oral temperature, particularly in patients who breathe through their mouth or in tachypneic states.

Fever is a regulated rise to a new “set point” of body temperature. When stimuli act on monocyte-macrophages, these cells elaborate pyrogenic cytokines, causing elevation of the set point through effects in the hypothalamus. These cytokines include interleukin-1 (IL-1), tumor necrosis factor (TNF), interferon-gamma, and interleukin-6 (IL-6). The elevation in temperature results from either increased heat production (eg, shivering) or decreased loss (eg, peripheral vasoconstriction). Body temperature in cytokine-induced fever seldom exceeds 41.1°C unless there is structural damage to hypothalamic regulatory centers.

1. Fever

Fever as a symptom provides important information about the presence of illness—particularly infections—and about changes in the clinical status of the patient. The fever pattern, however, is of marginal value for most specific diagnoses except for the relapsing fever of malaria, borreliosis, and occasional cases of lymphoma, especially Hodgkin disease. Furthermore, the degree of temperature elevation does not necessarily correspond to the severity of the illness. In general, the febrile response tends to be greater in children than in adults. In older persons, neonates, and in persons receiving certain medications (eg, NSAIDs or corticosteroids), a normal temperature or even hypothermia may be observed. Markedly elevated body temperature may result in profound metabolic disturbances. High temperature during the first trimester of pregnancy may cause

birth defects, such as anencephaly. Fever increases insulin requirements and alters the metabolism and disposition of drugs used for the treatment of the diverse diseases associated with fever.

2. Hyperthermia

Hyperthermia—not mediated by cytokines—occurs when body metabolic heat production or environmental heat load exceeds normal heat loss capacity or when there is impaired heat loss; heat stroke is an example. Body temperature may rise to levels (> 41.1°C) capable of producing irreversible protein denaturation and resultant brain damage; no diurnal variation is observed.

Neuroleptic malignant syndrome is a rare and potentially lethal idiosyncratic reaction to major tranquilizers, particularly haloperidol and fluphenazine; however, it has also been reported with the atypical neuroleptics (such as olanzapine or risperidone). **Serotonin syndrome** resembles neuroleptic malignant syndrome but occurs within hours of ingestion of agents that increase levels of serotonin in the central nervous system, including serotonin reuptake inhibitors, monoamine oxidase inhibitors, tricyclic antidepressants, meperidine, dextromethorphan, bromocriptine, tramadol, lithium, and psychostimulants (such as cocaine, methamphetamine, and MDMA). Clonus and hyperreflexia are more common in serotonin syndrome whereas “lead pipe” rigidity is more common in neuroleptic malignant syndrome. Neuroleptic malignant and serotonin syndromes share common clinical and pathophysiologic features to **malignant hyperthermia** of anesthesia (see Chapters 25 and 38).

3. Fever of Undetermined Origin

(See Fever of Unknown Origin, Chapter 30)

Most febrile illnesses are due to common infections, are short-lived, and are relatively easy to diagnose. In certain instances, however, the origin of the fever may remain obscure (“fever of undetermined origin,” FOU) even after protracted diagnostic examination. In upper respiratory tract infections, fever typically lasts no more than 3–5 days, beyond which additional evaluation should be considered. The term “FUO” has traditionally been reserved for unexplained cases of fever exceeding 38.3°C on several occasions for at least 3 weeks in patients without neutropenia or immunosuppression (see Chapter 30). Some authors have advocated for changing the definition of FOU in frail elderly nursing home patients to a persistent oral or tympanic membrane temperature of 37.2°C (99°F) or greater, or persistent rectal temperature of 37.5°C (99.5°F) or greater.

▶ Differential Diagnosis

See Table 2–7. The causes of FOU among elderly patients differ from those in younger patients, and a definitive diagnosis can be achieved in a larger proportion of elderly patients (up to 70%). Although the general diagnostic approach and distribution of infectious and noninfectious causes are roughly similar between age groups, tuberculosis

Table 2-7. Differential diagnosis of fever and hyperthermia.

Fever—common causes

Infections: bacterial, viral, rickettsial, fungal, parasitic
 Autoimmune diseases
 Central nervous system disease, including head trauma and mass lesions
 Malignant disease, especially renal cell carcinoma, primary or metastatic liver cancer, leukemia, and lymphoma

Fever—less common causes

Cardiovascular diseases, including myocardial infarction, thrombophlebitis, and pulmonary embolism
 Gastrointestinal diseases, including inflammatory bowel disease, alcoholic hepatitis, and granulomatous hepatitis
 Miscellaneous diseases, including drug fever, sarcoidosis, familial Mediterranean fever, tissue injury, hematoma, and factitious fever

Hyperthermia

Peripheral thermoregulatory disorders, including heat stroke, malignant hyperthermia of anesthesia, and malignant neuroleptic syndrome

and temporal arteritis are particularly more common causes of FUO in the elderly.

► Treatment

Most fever is well tolerated. When the temperature is > 40°C, symptomatic treatment may be required. A temperature > 41°C is likely to be hyperthermia and thus not cytokine mediated, and *emergent management is indicated*. (See Heat Stroke, Chapter 37.)

A. General Measures for Removal of Heat

Regardless of the cause of the fever, alcohol sponges, cold sponges, ice bags, ice-water enemas, and ice baths will lower body temperature. They are more useful in hyperthermia, since patients with cytokine-related fever will attempt to override these therapies.

B. Pharmacologic Treatment of Fever

1. Antipyretic drugs—Antipyretic therapy is not needed except for patients with marginal hemodynamic status. Aspirin or acetaminophen, 325–650 mg every 4 hours, is effective in reducing fever. These drugs are best administered continuously rather than as needed, since “prn” dosing results in periodic chills and sweats due to fluctuations in temperature caused by varying levels of drug.

2. Antimicrobial therapy—In most febrile patients, empiric antibiotic therapy should be deferred pending further evaluation. However, empiric antibiotic therapy is sometimes warranted. Prompt broad-spectrum antimicrobials are indicated for febrile patients who are clinically unstable, even before infection can be documented. These include patients with hemodynamic instability, those with neutropenia (neutrophils < 500/mcL), others who are asplenic (surgically or secondary

to sickle cell disease) or immunosuppressed (including individuals taking systemic corticosteroids, azathioprine, cyclosporine, or other immunosuppressive medications) (Tables 30–4 and 30–5), and those who are HIV infected (see Chapter 31). For treatment of fever during neutropenia following chemotherapy, outpatient parenteral antimicrobial therapy with an agent such as ceftriaxone can be provided effectively and safely. If a fungal infection is suspected in patients with prolonged fever and neutropenia, fluconazole is an equally effective but less toxic alternative to amphotericin B.

C. Treatment of Hyperthermia

Discontinuation of the offending agent is mandatory. Treatment of neuroleptic malignant syndrome includes dantrolene in combination with bromocriptine or levodopa (see Chapter 25). Treatment of serotonin syndrome includes administration of a central serotonin receptor antagonist—cyproheptadine or chlorpromazine—alone or in combination with a benzodiazepine (see Chapter 25). In patients for whom it is difficult to distinguish which syndrome is present, treatment with a benzodiazepine may be the safest therapeutic option.

► When to Refer

Once the diagnosis of FUO is made, referral to infectious disease specialist or rheumatologist may be appropriate to guide specific additional tests.

► When to Admit

- Malignant hyperthermia.
- Heat stroke.
- For measures to control temperature when it is > 41°C or when associated with seizure or other mental status changes.

INVOLUNTARY WEIGHT LOSS

ESSENTIAL INQUIRIES

- ▶ Age.
- ▶ Caloric intake.
- ▶ Fever.
- ▶ Change in bowel habits.
- ▶ Secondary confirmation (eg, changes in clothing size).
- ▶ Substance use.
- ▶ Age-appropriate cancer screening history.

▶ General Considerations

Body weight is determined by a person's caloric intake, absorptive capacity, metabolic rate, and energy losses. The metabolic rate can be affected by a multitude of medical conditions through the release of various cytokines such as cachectin and interleukins. Body weight normally peaks by the fifth or sixth decade and then gradually declines at a rate of 1–2 kg per decade. In NHANES II, a national survey of community-dwelling elders (age 50–80 years), recent involuntary weight loss (> 5% usual body weight) was reported by 7% of respondents, and this was associated with a 24% higher mortality.

▶ Etiology

Involuntary weight loss is regarded as clinically significant when it exceeds 5% or more of usual body weight over a 6- to 12-month period and often indicates serious physical or psychological illness. Physical causes are usually evident during the initial evaluation. Cancer (about 30%), gastrointestinal disorders (about 15%), and dementia or depression (about 15%) are the most common causes. When an adequately nourished-appearing patient complains of weight loss, inquiry should be made about exact weight changes (with approximate dates) and about changes in clothing size. Family members can provide confirmation of weight loss, as can old documents such as driver's licenses. A mild, gradual weight loss occurs in some older individuals. It is due to changes in body composition, including loss of height and lean body mass and lower basal metabolic rate, leading to decreased energy requirements. However, rapid involuntary weight loss is predictive of morbidity and mortality in any population. In addition to various disease states, causes in older individuals include loss of teeth and consequent difficulty with chewing, alcoholism, and social isolation.

▶ Clinical Findings

Once the weight loss is established, the history, medication profile, physical examination, and conventional laboratory

and radiologic investigations (such as complete blood count, serologic tests including HIV, thyroid-stimulating hormone [TSH] level, urinalysis, fecal occult blood test, chest radiography, and upper gastrointestinal series) usually reveal the cause. When these tests are normal, the second phase of evaluation should focus on more definitive gastrointestinal investigation (eg, tests for malabsorption; endoscopy) and cancer screening (eg, Papanicolaou smear, mammography, prostate specific antigen [PSA]).

If the initial evaluation is unrevealing, follow-up is preferable to further diagnostic testing. Death at 2-year follow-up was not nearly as high in patients with unexplained involuntary weight loss (8%) as in those with weight loss due to malignant (79%) and established nonmalignant diseases (19%). Psychiatric consultation should be considered when there is evidence of depression, dementia, anorexia nervosa, or other emotional problems. Ultimately, in approximately 15–25% of cases, no cause for the weight loss can be found.

▶ Differential Diagnosis

Malignancy, gastrointestinal disorders (eg, malabsorption, pancreatic insufficiency), dementia, depression, anorexia nervosa, hyperthyroidism, alcoholism, and social isolation are all established causes. "Meals on Wheels" is a useful mnemonic for remembering the common treatable causes of involuntary weight loss in the elderly (see box below).

MEALS ON WHEELS: A Mnemonic for Common Treatable Causes of Unintentional Weight Loss in the Elderly.

- Medication effects
- Emotional problems, especially depression
- Anorexia tardive (nervosa), alcoholism
- Late-life paranoia
- Swallowing disorders
- Oral factors (eg, poorly fitting dentures, cavities)
- No money
- Wandering and other dementia-related behaviors
- Hyperthyroidism, hypothyroidism, hyperparathyroidism, hypoadrenalism
- Enteric problems (eg, malabsorption)
- Eating problems (eg, inability to feed self)
- Low-salt, low-cholesterol diets
- Social problems (eg, isolation, inability to obtain preferred foods), gallstones

Adapted, with permission, from Morley JE et al. Nutritional issues in nursing home care. *Ann Intern Med.* 1995 Dec 1; 123(11):850–9.

▶ Treatment

Weight stabilization occurs in most surviving patients with both established and unknown causes of weight loss through treatment of the underlying disorder and caloric supplementation. Nutrient intake goals are established in relation to the severity of weight loss, in general ranging from 30 to 40 kcal/kg/d. In order of preference, route of administration options include oral, temporary nasogastric tube, or percutaneous gastric or jejunal tube. Parenteral nutrition is reserved for patients with serious associated problems. A variety of pharmacologic agents have been proposed for the treatment of weight loss. These can be categorized into appetite stimulants (corticosteroids, progestational agents, dronabinol, and serotonin antagonists); anabolic agents (growth hormone and testosterone derivatives); and anticatabolic agents (omega-3 fatty acids, pentoxifylline, hydrazine sulfate, and thalidomide).

▶ When to Refer

- Weight loss caused by malabsorption.
- Persistent nutritional deficiencies despite adequate supplementation.
- Weight loss as a result of anorexia or bulimia.

▶ When to Admit

- Severe protein-energy malnutrition, including the syndromes of kwashiorkor and marasmus.
- Vitamin deficiency syndromes.
- Cachexia with anticipated progressive weight loss secondary to unmanageable psychiatric disease.
- To carefully manage electrolyte and fluid replacement in protein-energy malnutrition and avoid “re-feeding syndrome.”

FATIGUE & CHRONIC FATIGUE SYNDROME

ESSENTIAL INQUIRIES

- ▶ Weight loss.
- ▶ Fever.
- ▶ Sleep-disordered breathing.
- ▶ Medications.
- ▶ Substance use.

▶ General Considerations

Fatigue, as an isolated symptom, accounts for 1–3% of visits to generalists. The symptom of fatigue is often poorly described and less well defined by patients than symptoms associated with specific dysfunction of organ systems. Fatigue or lassitude and the closely related complaints of weakness, tiredness, and lethargy are often attributed to overexertion, poor physical conditioning, sleep disturbance, obesity, undernutrition, and emotional problems. A history of the patient’s daily living and working habits may obviate the need for extensive and unproductive diagnostic studies.

Chronic fatigue syndrome may be due to retrovirus infection or an immune dysregulation mechanism, or both. Recent studies, however, have failed to show any differences in levels of xenotropic murine leukemia-virus-related virus in US patients with and without chronic fatigue syndrome. The diagnosis of chronic fatigue syndrome remains hotly debated because of the lack of a gold standard. Persons with chronic fatigue syndrome meeting specific criteria (such as those from the CDC) report a greater frequency of childhood trauma and psychopathology and demonstrate higher levels of emotional instability and self-reported stress than persons who do not have chronic fatigue. Neuropsychological, neuroendocrine, and brain imaging studies reveal neurobiologic abnormalities in most patients, but none with a consistent pattern. Sleep disorders have been reported in 40–80% of patients with chronic fatigue syndrome, but their treatment has provided only modest benefit, suggesting that it is an effect rather than a cause of the fatigue. Veterans of the Gulf War show a tenfold greater incidence of chronic fatigue syndrome compared with nondeployed military personnel.

▶ Clinical Findings

A. Fatigue

Clinically relevant fatigue is composed of three major components: generalized weakness (difficulty in initiating activities); easy fatigability (difficulty in completing activities); and mental fatigue (difficulty with concentration and memory). Important diseases that can cause fatigue include hyperthyroidism and hypothyroidism, CHF, infections (endocarditis, hepatitis), COPD, sleep apnea, anemia, autoimmune disorders, irritable bowel syndrome, and cancer. Alcoholism, side effects from such drugs as sedatives, and β -blockers may be the cause. Psychological conditions, such as insomnia, depression, anxiety, panic attacks, dysthymia,

and somatization disorder, may cause fatigue. Common outpatient infectious causes include mononucleosis and sinusitis. These conditions are usually associated with other characteristic signs, but patients may emphasize fatigue and not reveal their other symptoms unless directly asked. The lifetime prevalence of significant fatigue (present for at least 2 weeks) is about 25%. Fatigue of unknown cause or related to psychiatric illness exceeds that due to physical illness, injury, medications, drugs, or alcohol.

B. Chronic Fatigue Syndrome

A working case definition of chronic fatigue syndrome indicates that it is not a homogeneous abnormality, and there is no single pathogenic mechanism (Figure 2-2). No physical finding or laboratory test can be used to confirm the diagnosis of this disorder.

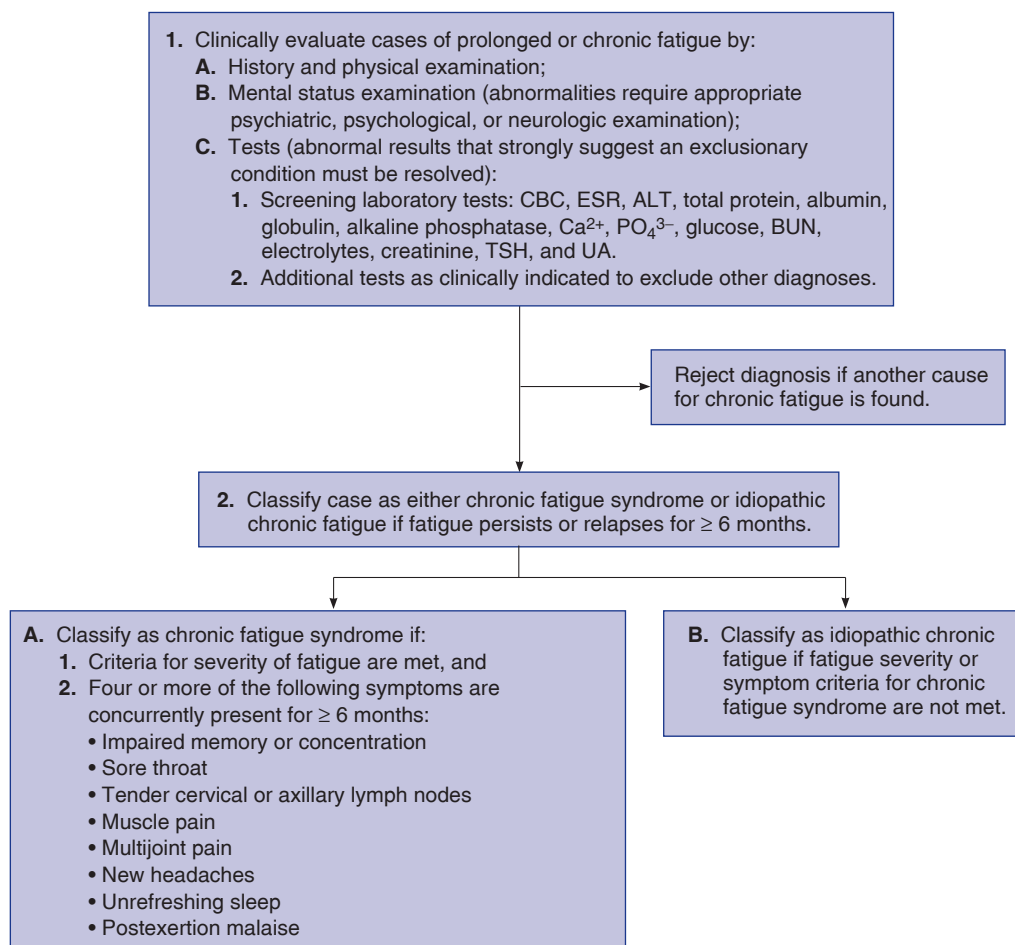

The evaluation of chronic fatigue syndrome includes a history and physical examination as well as complete blood count, erythrocyte sedimentation rate, serum chemistries—

blood urea nitrogen (BUN), electrolytes, glucose, creatinine, and calcium; liver and thyroid function tests—antinuclear antibody, urinalysis, and tuberculin skin test; and screening questionnaires for psychiatric disorders. Other tests to be performed as clinically indicated are serum cortisol, rheumatoid factor, immunoglobulin levels, Lyme serology in endemic areas, and tests for HIV antibody. More extensive testing is usually unhelpful, including antibody to Epstein-Barr virus. There may be an abnormally high rate of postural hypotension. MRI scans may show brain abnormalities on T₂-weighted images—chiefly small, punctate, subcortical white matter hyperintensities, predominantly in the frontal lobes; however, brain MRI is not recommended in the routine evaluation of chronic fatigue syndrome.

► Treatment

A. Fatigue

Management of fatigue involves identification and treatment of conditions that contribute to fatigue, such as cancer,

▲ **Figure 2-2.** Evaluation and classification of unexplained chronic fatigue. (CBC, complete blood count; ESR, erythrocyte sedimentation rate; ALT, alanine aminotransferase; Ca²⁺, calcium; PO₄³⁻, phosphate; BUN, blood urea nitrogen; TSH, thyroid-stimulating hormone; UA, urinalysis.) (Modified and reproduced, with permission, from Fukuda K et al. The chronic fatigue syndrome: a comprehensive approach to its definition and study. *Ann Intern Med.* 1994 Dec 15; 121(12):953-9.)

pain, depression, disordered sleep, weight loss, and anemia. Resistance training and aerobic exercise lessens fatigue and improves performance for a number of chronic conditions associated with a high prevalence of fatigue, including CHF, COPD, arthritis, and cancer. Continuous positive airway pressure is an effective treatment for obstructive sleep apnea. Psychostimulants such as methylphenidate have shown inconsistent results in randomized trials of treatment of cancer-related fatigue.

B. Chronic Fatigue Syndrome

A variety of agents and modalities have been tried for the treatment of chronic fatigue syndrome. Acyclovir, intravenous immunoglobulin, nystatin, and low-dose hydrocortisone/fludrocortisone do not improve symptoms except in patients with postural hypotension, some of whom report response to increases in dietary sodium as well as fludrocortisone, 0.1 mg orally daily. There is a greater prevalence of past and current psychiatric diagnoses in patients with this syndrome. Affective disorders are especially common. Patients with chronic fatigue syndrome have benefited from a comprehensive multidisciplinary intervention, including optimal medical management, treating any ongoing affective or anxiety disorder pharmacologically, and implementing a comprehensive cognitive-behavioral treatment program. **Cognitive-behavioral therapy**, a form of non-pharmacologic treatment emphasizing self-help and aiming to change perceptions and behaviors that may perpetuate symptoms and disability, is helpful. Although few patients are cured, the treatment effect is substantial. Response to cognitive-behavioral therapy is not predictable on the basis of severity or duration of chronic fatigue syndrome, although patients with low interest in psychotherapy rarely benefit. Graded exercise has also been shown to improve functional work capacity and physical function. At present, cognitive-behavioral therapy and graded exercise are the treatments of choice for patients with chronic fatigue syndrome. A 2011 randomized trial (PACE trial) has confirmed the independent benefits of cognitive behavioral therapy and graded exercise, and found no benefit of adaptive pacing therapy.

In addition, the clinician's sympathetic listening and explanatory responses can help overcome the patient's frustrations and debilitation by this still mysterious illness. All patients should be encouraged to engage in normal activities to the extent possible and should be reassured that full recovery is eventually possible in most cases.

► When to Refer

- Infections not responsive to standard treatment.
- Difficult to control hyperthyroidism or hypothyroidism.
- Severe psychological disease.
- Malignancy.

► When to Admit

- Failure to thrive.
- Fatigue severe enough to impair activities of daily living.

ACUTE HEADACHE

ESSENTIAL INQUIRIES

- Age > 50 years.
- Rapid onset and severe intensity (ie, “thunderclap” headache).
- Fever.
- Trauma.
- Vision changes.
- HIV infection.
- Current or past history of hypertension.
- Neurologic findings (mental status changes, motor or sensory deficits).

► General Considerations

Headache is a common reason that adults seek medical care, accounting for approximately 13 million visits each year in the United States to physicians' offices, urgent care clinics, and emergency departments. A broad range of disorders can cause headache. This chapter will deal only with the approach to the acute nontraumatic headache in adolescents and adults. The challenge in the initial evaluation of

acute headache is to identify which patients are presenting with an uncommon but life-threatening condition. In the emergency department setting, approximately 1% of patients seeking medical attention for acute headache will have a life-threatening condition, whereas the prevalence of life-threatening conditions in the office practice setting is considerably lower.

Regardless of the underlying cause, headache is currently believed to occur as a result of the release of neuropeptides from trigeminal nerve endings that encapsulate the blood vessels of the pia mater and dura mater, resulting in neurogenic inflammation. Because this represents a final common pathway for many etiologies, diminution of headache in response to typical migraine therapies (such as serotonin receptor antagonists or ketorolac) does not rule out critical conditions such as subarachnoid hemorrhage or meningitis as the underlying cause.

► Clinical Findings

A. Symptoms

A careful history and physical examination should aim to identify causes of acute headache that require immediate treatment. These causes can be broadly classified as imminent or completed **vascular events** (intracranial hemorrhage, thrombosis, vasculitis, malignant hypertension, arterial dissection, or aneurysm), **infections** (abscess, encephalitis, meningitis), **intracranial masses** causing intracranial hypertension, **preeclampsia**, and **carbon monoxide poisoning**. Having the patient carefully describe the onset of headache can be helpful in diagnosing a serious cause. Report of a sudden-onset headache that reaches maximal and severe intensity within seconds or a few minutes is the classic description of a “thunderclap headache” and should precipitate workup for subarachnoid hemorrhage, since the estimated prevalence of subarachnoid hemorrhage in the setting of a thunderclap headache is 43%.

The general medical history can also guide the need for additional work-up. A new headache in a patient over the age of 50 or with a history of HIV disease under most circumstances (including a normal neurologic examination) warrants neuroimaging immediately (Table 2–8). When the patient has a medical history of hypertension—particularly uncontrolled hypertension—a complete search for criteria satisfying a diagnosis of “malignant hypertension” is appropriate to determine the correct urgency level of hypertension management (see Chapter 11). Headache and hypertension associated with pregnancy may be due to preeclampsia. Episodic headache associated with the triad of hypertension, heart palpitations, and sweats is suggestive of pheochromocytoma. In the absence of thunderclap headache, advanced age, and HIV disease, a careful physical examination and detailed neurologic examination will usually determine acuity of the work-up and need for further diagnostic testing.

Patient symptoms can also be useful for diagnosing migraine headache in the absence of the “classic” migraine pattern involving scintillating scotoma followed by unilateral headache, photophobia, and nausea and vomiting (Table 2–9). The presence of three or more of these features

Table 2–8. Clinical features associated with acute headache that warrant urgent or emergent neuroimaging.

Prior to lumbar puncture
Abnormal neurologic examination
Abnormal mental status
Abnormal funduscopic examination (papilledema; loss of venous pulsations)
Meningeal signs
Emergent (conduct prior to leaving office or emergency department)
Abnormal neurologic examination
Abnormal mental status
Thunderclap headache
Urgent (scheduled prior to leaving office or emergency department)
HIV-positive patient ¹
Age > 50 years (normal neurologic examination)

¹Use CT with or without contrast or MRI if HIV positive.

Source: American College of Emergency Physicians. Clinical Policy: critical issues in the evaluation and management of patients presenting to the emergency department with acute headache. *Ann Emerg Med.* 2002 Jan;39(1):108–22.

can establish the diagnosis of migraine (in the absence of other clinical features that warrant neuroimaging studies), and the presence of none or one of these features (provided it is not nausea) can help to rule out migraine.

B. Physical Examination

Critical components of the physical examination of the patient with acute headache include vital sign measurements, neurologic examination, and vision testing with funduscopic examination. The finding of fever with acute headache warrants additional maneuvers to elicit evidence of meningeal inflammation, such as Kernig and Brudzinski signs. Besides malignant hypertension, significant hypertension can also be a sign of intracranial hemorrhage, preeclampsia, and pheochromocytoma. Patients over 60 years of age should be examined for scalp or temporal artery tenderness.

Careful assessment of visual acuity, ocular gaze, visual fields, pupillary defects, the optic disk, and retinal vein pulsations is crucial. Diminished visual acuity is suggestive of glaucoma, temporal arteritis, or optic neuritis. Ophthalmoplegia or visual field defects may be signs of venous sinus thrombosis, tumor, or aneurysm. Afferent

Table 2–9. Summary likelihood ratios (LRs) for individual clinical features associated with migraine diagnosis.

Clinical Feature	LR+ (95% CI)	LR- (95% CI)
Nausea	19 (15–25)	0.19 (0.18–0.20)
Photophobia	5.8 (5.1–6.6)	0.24 (0.23–0.26)
Phonophobia	5.2 (4.5–5.9)	0.38 (0.36–0.40)
Exacerbation by physical activity	3.7 (3.4–4.0)	0.24 (0.23–0.26)

pupillary defects can be due to intracranial masses or optic neuritis. Ipsilateral ptosis and miosis suggest Horner syndrome and in conjunction with acute headache may signify carotid artery dissection. Finally, papilledema or absent retinal venous pulsations are signs of elevated intracranial pressure—findings that should be followed by neuroimaging prior to performing lumbar puncture (Table 2–8).

Mental status and complete neurologic evaluations are also critical and should include assessment of motor and sensory systems, reflexes, gait, cerebellar function, and pronator drift. Any abnormality on mental status or neurologic evaluation warrants emergent neuroimaging (Table 2–8).

C. Diagnostic Studies

Guidance on when to perform neuroimaging is summarized in Table 2–8. Under most circumstances, a noncontrast head CT is sufficient to exclude intracranial hypertension with impending herniation, intracranial hemorrhage, and many types of intracranial masses (notable exceptions include lymphoma and toxoplasmosis in HIV-positive patients, herpes simplex encephalitis, and brain abscess). When appropriate, a contrast study can often be ordered to follow a normal noncontrast study. A normal neuroimaging study does not sufficiently exclude subarachnoid hemorrhage and should be followed by lumbar puncture. In patients for whom there is a high level of suspicion for subarachnoid hemorrhage or aneurysm, a normal CT and lumbar puncture should be followed by angiography within the next few days (provided the patient is medically stable). Lumbar puncture is also indicated to exclude infectious causes of acute headache, particularly in patients with fever or meningeal signs. Cerebrospinal fluid tests should routinely include Gram stain, white blood cell count with differential, red blood cell count, glucose, total protein, and bacterial culture. In appropriate patients, also consider testing cerebrospinal fluid for VDRL (syphilis), cryptococcal antigen (HIV-positive patients), acid-fast bacillus stain and culture, and complement fixation and culture for coccidioidomycosis. Storage of an extra tube with 5 mL of cerebrospinal fluid is also prudent for conducting unanticipated tests in the immediate future. Consultation with infectious disease experts regarding local availability of polymerase chain reaction tests for specific infectious pathogens (eg, herpes simplex 2) should also be considered in patients with evidence of central nervous system infection but no identifiable pathogen.

In addition to neuroimaging and lumbar puncture, additional diagnostic tests for exclusion of life-threatening causes of acute headache include erythrocyte sedimentation rate (temporal arteritis; endocarditis), urinalysis (malignant hypertension; preeclampsia), and sinus CT or radiograph (bacterial sinusitis, independently or as a cause of venous sinus thrombosis).

► Treatment

Treatment should be directed at the cause of acute headache. In patients in whom migraine or migraine-like headache has been diagnosed, early treatment with NSAIDs or triptans can often abort or provide significant

relief of symptoms. The effectiveness of NSAIDs and triptans appears to be equivalent, although combination sumatriptan-naproxen appears to provide a greater sustained response (2–24 hours) compared with monotherapy with either agent alone. Nonoral medication administration is often necessary for patients with significant nausea and vomiting, in which case nasal and subcutaneous triptans and intramuscular ketorolac are therapeutic options. Other causes of acute headache, such as subarachnoid hemorrhage, intracranial mass, or meningitis, usually require emergent treatment in the hospital.

► When to Refer

- Frequent migraines not responsive to standard therapy.
- Migraines with atypical features.
- Chronic daily headaches due to medication overuse.

► When to Admit

- Need for repeated doses of parenteral pain medication.
- To facilitate an expedited work-up requiring a sequence of procedures and neuroimaging.
- Monitoring for progression of symptoms and neurologic consultation when the initial emergency department work-up is inconclusive.
- Pain severe enough to impair activities of daily living or limit participation in follow-up appointments or consultation.

DYSURIA

ESSENTIAL INQUIRIES

- ▶ Fever.
- ▶ Nausea or vomiting.
- ▶ New back or flank pain.
- ▶ Vaginal discharge.
- ▶ Pregnancy risk.
- ▶ Structural abnormalities.
- ▶ Instrumentation of urethra or bladder.

▶ General Considerations

Dysuria (painful urination) is a common reason for adolescents and adults to seek urgent medical attention. An inflammatory process (eg, infection; autoimmune disorder) underlies most causes of dysuria. In women, cystitis will be diagnosed in up to 50–60% of cases and has an incidence of 0.5–0.7% per year in sexually active young women. The key objective in evaluating women with dysuria is to exclude serious upper urinary tract disease, such as acute pyelonephritis, and sexually transmitted diseases. In elderly men, dysuria may be a symptom of prostatitis. In contrast, in younger men, urethritis accounts for the vast majority of cases of dysuria.

▶ Clinical Findings

A. Symptoms

Well-designed cohort studies have shown that some women can be reliably diagnosed with uncomplicated cystitis without a physical examination or urinalysis, and randomized controlled trials show that telephone management of uncomplicated cystitis is safe and effective. An increased likelihood of cystitis is present when women report multiple irritative voiding symptoms (dysuria, urgency, frequency), fever, or back pain (likelihood ratios = 1.6–2.0). Inquiring about symptoms of vulvovaginitis is imperative. When women report dysuria and urinary frequency, and deny vaginal discharge and irritation, the likelihood ratio for culture-confirmed cystitis is 24.5. In contrast, when vaginal discharge or irritation is present, as well as dysuria or urinary frequency, the likelihood ratio is 0.7. Gross hematuria in women with voiding symptoms usually represents hemorrhagic cystitis but can also be a sign of bladder cancer (particularly in older patients) or upper tract disease. Failure of hematuria to resolve with antibiotic treatment should prompt further evaluation of the bladder and kidneys. Chlamydial infection should be strongly considered among women age 25 years or younger who are sexually active and seeking medical attention for a suspected urinary tract infection for the first time or have a new partner.

Because fever and back pain, as well as nausea and vomiting, are considered harbingers of (or clinical criteria for) acute pyelonephritis, women with these symptoms should

usually be examined by a clinician prior to treatment in order to exclude coexistent urosepsis, hydronephrosis, or nephrolithiasis. Other major risk factors for acute pyelonephritis (among women 18–49 years of age) relate to sexual behaviors (frequency of sexual intercourse three or more times per week, new sexual partner in previous year, recent spermicide use), as well as diabetes mellitus and recent urinary tract infection or incontinence. Finally, pregnancy, underlying structural factors (polycystic kidney disease, nephrolithiasis, neurogenic bladder), immunosuppression, diabetes, and a history of recent bladder or urethral instrumentation usually alter the treatment regimen (antibiotic choice or duration of treatment, or both) of uncomplicated cystitis. In men, lower urinary tract symptoms and depressive symptoms are strongly associated and reciprocally related. Erectile dysfunction increases the odds of both disorders.

B. Physical Examination

The presence of fever, tachycardia, or hypotension should alert the clinician to the possibility of urosepsis and the potential need for hospitalization. A focused examination in women, in uncomplicated circumstances, could be limited to ascertainment of costovertebral angle tenderness and to a lower abdominal and pelvic examination, if the history suggests vulvovaginitis or cervicitis.

C. Diagnostic Studies

1. Urinalysis—Urinalysis is probably overutilized in the evaluation of dysuria. The probability of culture-confirmed urinary tract infection among women with a history and physical examination compatible with uncomplicated cystitis is about 70–90%. Urinalysis is most helpful when the woman with dysuria does not have other typical features of cystitis. Dipstick detection (> trace) of leukocytes, nitrites, or blood supports a diagnosis of cystitis. When both leukocyte and nitrite tests are positive, the likelihood ratio is 4.2, and when both are negative, the likelihood ratio is 0.3. The negative predictive value of urinalysis is not sufficient to exclude culture-confirmed urinary tract infection in women with multiple and typical symptoms; and randomized trial evidence shows that antibiotic treatment is beneficial to women with typical symptoms and negative urinalysis dipstick tests.

2. Urine culture—Urine culture should be considered for all women with upper tract symptoms (prior to initiating antibiotic therapy), as well as those with dysuria and a negative urine dipstick test. In symptomatic women, a clean-catch urine culture is considered positive when 10^2 – 10^3 colony-forming units/mL of a uropathogenic organism is detected.

3. Renal imaging—When severe flank or back pain is present, the possibility of complicated kidney infection (perinephric abscess, nephrolithiasis) or of hydronephrosis should be considered. Depending on local availability, acceptable imaging options to assess for hydronephrosis include abdominal radiographs, renal ultrasound, or CT scanning. To exclude nephrolithiasis, noncontrast helical CT scanning is more accurate than intravenous urography and is rapidly becoming the diagnostic test of choice for

this purpose. In a meta-analysis, the positive and negative likelihood ratios of helical CT scanning for diagnosis of nephrolithiasis were 23.2 and 0.05, respectively.

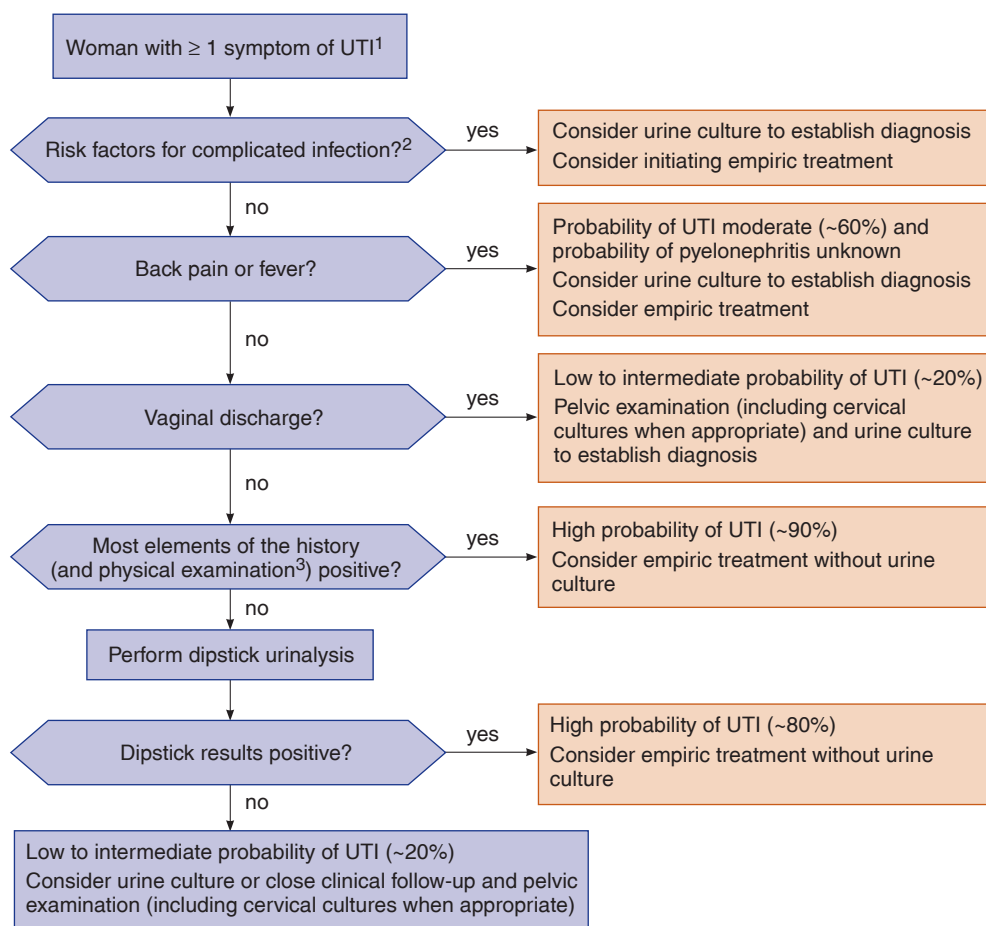

► Differential Diagnosis

The differential diagnosis of dysuria in women includes acute cystitis, acute pyelonephritis, vaginitis (*Candida*, bacterial vaginosis, *Trichomonas*, herpes simplex), urethritis/cervicitis (*Chlamydia*, gonorrhea), and interstitial cystitis/painful bladder syndrome. Nucleic acid amplification tests from first-void urine or vaginal swab specimens are highly

sensitive for detecting chlamydial infection. Other infectious pathogens associated with dysuria and urethritis in men include *Mycoplasma genitalium* and Enterobacteriaceae.

► Treatment

Definitive treatment is directed to the underlying cause of the dysuria. An evidence-informed algorithm for managing suspected urinary tract infection in women is shown in Figure 2–3. This algorithm supports antibiotic treatment of most women with multiple and typical symptoms of urinary tract infection without performing urinalysis or urine culture.

¹In women who have risk factors for sexually transmitted diseases, consider testing for *Chlamydia*. The US Preventive Services Task Force recommends screening for *Chlamydia* for all women 25 years or younger and women of any age with more than one sexual partner, a history of sexually transmitted disease, or inconsistent use of condoms.

²A complicated UTI is one in an individual with a functional or anatomic abnormality of the urinary tract, including a history of polycystic renal disease, nephrolithiasis, neurogenic bladder, diabetes mellitus, immunosuppression, pregnancy, indwelling urinary catheter, or recent urinary tract instrumentation.

³The only physical examination finding that increases the likelihood of UTI is costovertebral angle tenderness, and clinicians may consider not performing this test in patients with typical symptoms of acute uncomplicated UTI (as in telephone management).

▲ **Figure 2-3.** Proposed algorithm for evaluating women with symptoms of acute urinary tract infection (UTI). (Modified and reproduced, with permission, from Bent S et al. Does this woman have an acute uncomplicated urinary tract infection? JAMA. 2002 May 22-29;287(20):2701-10.)

Symptomatic relief can be provided with phenazopyridine, a urinary analgesic that is available over-the-counter; it is used in combination with antibiotic therapy (when a urinary tract infection has been confirmed) but for no more than 2 days. Patients should be informed that phenazopyridine will cause orange/red discoloration of their urine and other bodily fluids (eg, some contact lens wearers have reported discoloration of their lenses). Rare cases of methemoglobinemia and hemolytic anemia have been reported, usually with overdoses or underlying renal dysfunction.

In cases of interstitial cystitis/painful bladder syndrome (see Chapter 23), patients will often respond to a multimodal approach that may include urethral/vesicular dilation, bio-feedback, cognitive behavioral therapy, antidepressants, dietary changes, vaginal emollients, and other supportive measures.

► When to Refer

- Anatomic abnormalities leading to repeated urinary infections.
- Infections associated with nephrolithiasis.
- Persistent interstitial cystitis/painful bladder syndrome.

► When to Admit

- Severe pain requiring parenteral medication or impairing ambulation or urination (such as severe primary herpes simplex genitalis).
- Dysuria associated with urinary retention or obstruction.

Preoperative Evaluation & Perioperative Management

Hugo Q. Cheng, MD

EVALUATION OF THE ASYMPTOMATIC PATIENT

Patients without significant medical problems—especially those under age 50—are at very low risk for perioperative complications. Their preoperative evaluation should include a history and physical examination. Special emphasis is placed on the assessment of functional status, exercise tolerance, and cardiopulmonary symptoms and signs in an effort to reveal previously unrecognized disease (especially cardiopulmonary disorders) that may require further evaluation prior to surgery. In addition, a directed bleeding history (Table 3–1) should be taken to uncover coagulopathy that could contribute to excessive surgical blood loss. Routine preoperative testing of asymptomatic healthy patients under age 50 has not been found to help predict or prevent complications.

Patients who are older than 50 years and those with risk factors for coronary artery disease should have a 12-lead ECG because evidence of clinically silent coronary artery disease should prompt further cardiac evaluation before surgery. Minor ECG abnormalities such as bundle branch block, T wave changes, and premature ventricular contractions do not predict adverse postoperative outcomes. Of note, patients undergoing minor or minimally invasive procedures (such as cataract surgery) may not require any routine preoperative tests.

CARDIAC RISK ASSESSMENT & REDUCTION

Cardiac complications of noncardiac surgery are a major cause of perioperative morbidity and mortality. The most important perioperative cardiac complications are myocardial infarction (MI) and cardiac death. Other complications include congestive heart failure (CHF), arrhythmias,

and unstable angina. The principal patient-specific risk factor is the presence of end-organ cardiovascular disease. This includes not only coronary artery disease and CHF, but also cerebrovascular disease and chronic kidney disease if due to atherosclerosis. Diabetes mellitus, especially if treated with insulin, is considered a cardiovascular disease equivalent and has also been shown to increase the risk of cardiac complications. Major abdominal, thoracic, and vascular surgical procedures (especially abdominal aortic aneurysm repair) carry a higher risk of postoperative cardiac complications, likely due to their associated major fluid shifts, hemorrhage, and hypoxemia. These risk factors were identified in a validated multifactorial risk prediction tool: the Revised Cardiac Risk Index (Table 3–2). The Revised Cardiac Risk Index has become a widely used tool for assessing and communicating cardiac risk and has been incorporated into perioperative management guidelines. Limited exercise capacity (eg, the inability to walk for two blocks at a normal pace or climb a flight of stairs without resting) and greater severity of cardiac symptoms also predict higher cardiac risk. Emergency operations are also associated with greater cardiac risk. However, emergency operations should not be delayed by extensive cardiac evaluation. Instead, patients facing emergency surgery should be medically optimized for surgery as quickly as possible and closely monitored for cardiac complications during the perioperative period.

▶ Role of Preoperative Noninvasive Ischemia Testing

Most patients can be accurately risk-stratified by history, physical examination, and electrocardiogram (ECG). Patients without clinical predictors for cardiac complications (Table 3–2), who are undergoing minor operations, or who have at least fair functional capacity are at low risk for cardiac complications. Noninvasive testing in these patients generally does not improve risk stratification or management. Patients with poor functional capacity, or a high Revised Cardiac Risk Index score are much more likely to suffer cardiac complications. Stress testing prior to vascular surgery in these patients can stratify them into low-risk and high-risk subgroups. The absence of ischemia

Table 3-1. Findings suggestive of a bleeding disorder.

Unprovoked bruising on the trunk of > 5 cm in diameter
Frequent unprovoked epistaxis or gingival bleeding
Menorrhagia with iron deficiency
Hemarthrosis with mild trauma
Prior excessive surgical blood loss or reoperation for bleeding
Family history of abnormal bleeding
Presence of severe kidney or liver disease

on dipyridamole scintigraphy or dobutamine stress echocardiography is reassuring. Similarly, the presence of only mild, limited ischemia in vascular surgery patients with multiple Revised Cardiac Risk Index predictors, but who are optimally managed with perioperative β -blockers, predicts a generally acceptable risk of perioperative cardiac death or MI. In contrast, extensive inducible ischemia in this population predicts a very high risk of cardiac complications, which may not be modifiable by either medical management or coronary revascularization. The predictive value of an abnormal stress test result for nonvascular surgery patients is less well established. An approach to perioperative cardiac risk assessment and management in patients with known or suspected stable coronary artery disease is shown in Figure 3-1.

► Perioperative Management of Patients with Coronary Artery Disease

Patients with acute coronary syndromes require immediate management of their cardiac disease prior to any preoperative

Table 3-2. Revised cardiac risk index.

Independent Predictors of Postoperative Cardiac Complications	
1. Intrathoracic, intraperitoneal, or infrainguinal vascular surgery	
2. History of ischemic heart disease	
3. History of congestive heart failure	
4. Insulin treatment for diabetes mellitus	
5. Serum creatinine level > 2 mg/dL [> 176.8 $\mu\text{mol/L}$]	
6. History of cerebrovascular disease	
Scoring (Number of Predictors Present)	Risk of Major Cardiac Complications ¹
None	0.4%
One	0.9%
Two	7.0%
More than two	11%

¹Myocardial infarction, pulmonary edema, ventricular fibrillation, cardiac arrest, and complete heart block.

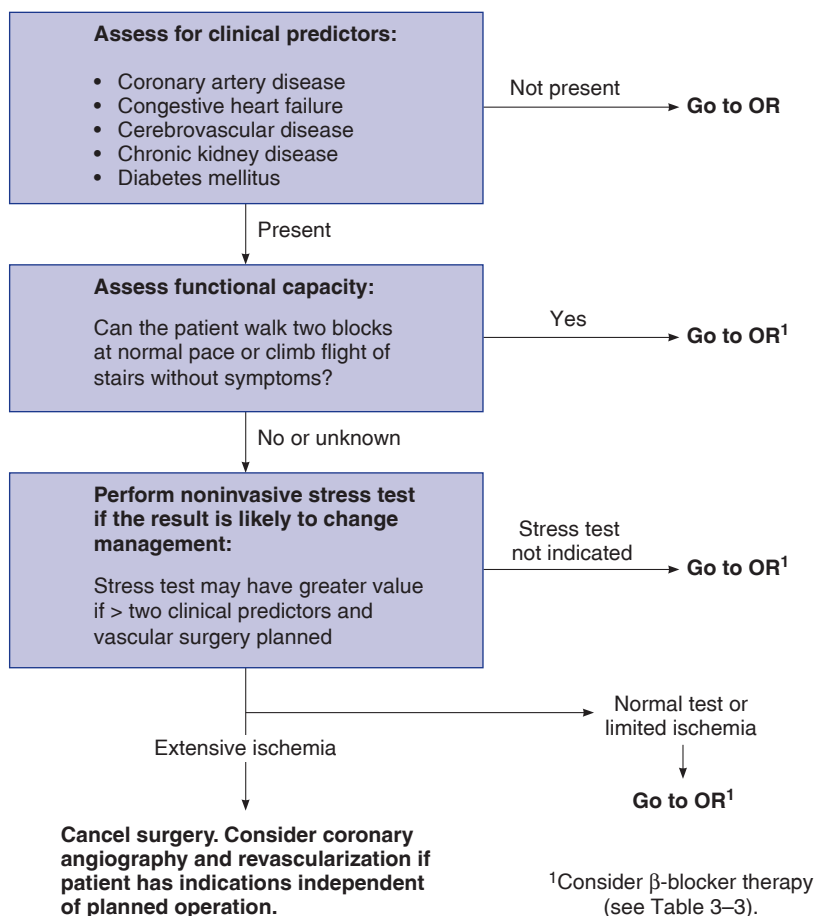

Data from Lee TH et al. Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation*. 1999 Sept 7; 100(10):1043-9.

evaluation (see Chapter 10). Patients with stable coronary artery disease undergoing major surgery have a 1–5% risk of MI and about a 1% mortality rate. In a large cohort study, postoperative MI as evidenced by ECG changes and an elevated biomarker level typically occurred within 3 days of surgery, and was associated with a 30-day mortality rate of 11.6%. Postoperative MI is usually silent or may present atypically. Symptoms and signs that should prompt consideration of postoperative MI include unexplained hypotension, hypoxemia, or delirium. However, current evidence is insufficient to formulate specific recommendations for screening asymptomatic patients for perioperative ischemia through the use of ECG or cardiac enzyme monitoring.

A. Medications

Preoperative antianginal medications, including β -blockers, calcium channel blockers, and nitrates, should be continued preoperatively and during the postoperative period. Evidence for a cardioprotective effect of perioperative β -adrenergic blockade has been mixed. A randomized trial in vascular surgery patients with ischemia on dobutamine stress echocardiography found that bisoprolol reduced the 30-day risk of cardiac mortality or nonfatal MI from 34% to 3% in these high-risk patients. In contrast, subsequent trials found less benefit and potential harm in lower risk patients. In the largest of these studies, a high, fixed dose of β -blocker (metoprolol succinate 100 mg given by mouth a few hours before and after surgery) reduced the absolute risk of cardiac complications by only 1.1% in patients with at least one Revised Cardiac Risk Index predictor who underwent major surgery. This was offset, however, by a 0.8% absolute increase in total mortality. Hypotension and bradycardia were more common when patients received β -blockers; in addition, the risks of stroke and death from sepsis were higher in these patients. In contrast, a subsequent study demonstrated a 6% absolute risk reduction in cardiac mortality and nonfatal MI in patients who received a more conservative, titrated dose of β -blocker (bisoprolol 2.5 mg, started a median of 1 month prior to surgery, and increased by 1.25–2.5 mg daily after surgery to a maximum dose of 10 mg daily). Because of the uncertain benefit-to-risk ratio of perioperative β -blockade, it should be reserved for patients with a relatively high risk of cardiac complications. Suggested indications for prophylactic β -blockade are presented in Table 3-3. Comparative trials between different cardioselective β -blockers are lacking. Reasonable starting oral doses for normotensive patients are atenolol 25 mg daily, metoprolol 25 mg twice daily, or bisoprolol 2.5 mg daily. Ideally, β -blockers should be started well in advance of surgery, to allow time to gradually titrate up the dose without causing excessive bradycardia or hypotension. The dose should be adjusted to maintain a heart rate between 50 and 70 beats per minute while keeping systolic blood pressure above 100 mm Hg. β -Blockers should be continued for at least 3–7 days after surgery.

Observational studies show an association between the use of HMG-CoA reductase inhibitors (statins) during the perioperative period and lower rates of mortality and postoperative MI. A randomized trial in statin-naïve patients

▲ **Figure 3-1.** Assessment and management of patients with known or suspected stable coronary artery disease (CAD) undergoing elective major noncardiac surgery. (OR, operating room.)

undergoing vascular surgery found that extended-release fluvastatin 80 mg orally daily reduced the 30-day risk of cardiac death or nonfatal MI from 10.1% to 4.8%. Statins should be considered in all patients undergoing vascular surgery and other patients deemed to be at high risk for

cardiac complications, regardless of lipid levels. Patients already taking statins should continue these agents during the perioperative period.

B. Coronary Revascularization

Retrospective studies suggest that patients who had previously undergone coronary artery bypass grafting (CABG) surgery or percutaneous coronary interventions (PCI) have a relatively low risk of cardiac complications when undergoing subsequent noncardiac surgery. However, one trial randomized over 500 patients with angiographically proven coronary artery disease to either coronary revascularization (with either CABG or PCI) or medical management alone before vascular surgery. Postoperative nonfatal MI, 30-day mortality, and long-term mortality did not differ, suggesting that prophylactic revascularization before noncardiac surgery does not prevent cardiac complications. Thus, current data argue that preoperative CABG or PCI should only be performed on patients who have indications for the procedure independent of the planned noncardiac operation. In patients who have undergone recent intracoronary stenting, observational studies suggest that perioperative cardiac

Table 3-3. Indications for prophylactic perioperative β -blockade.

Strong indications	Patient already taking β -blocker to treat ischemia, arrhythmia, or hypertension
Possible indications	Patients with coronary artery disease undergoing vascular or other major surgery Patient with multiple clinical predictors (heart failure, chronic kidney disease, diabetes mellitus, or cerebrovascular disease) undergoing vascular or other major surgery

The dose of β -blocker should be carefully titrated to keep heart rate < 70 bpm and systolic blood pressure > 100 mm Hg.

mortality rate may be very high if antiplatelet therapy is stopped prematurely due to concern for surgical site bleeding. The presumed mechanism of this increased mortality is acute stent thrombosis that results from premature discontinuation of antiplatelet therapy. Therefore, elective surgery should be deferred for at least 4–6 weeks after placement of a bare-metal stent and for a full year after placement of a drug-eluting stent if antiplatelet therapy must be stopped preoperatively.

► CHF & Left Ventricular Dysfunction

Decompensated CHF, manifested by an elevated jugular venous pressure, an audible third heart sound, or evidence of pulmonary edema on physical examination or chest radiography, significantly increases the risk of perioperative pulmonary edema (roughly 15%) and cardiac death (2–10%). Elective surgery should be postponed in patients with decompensated CHF until it can be evaluated and brought under control.

Patients with compensated left ventricular dysfunction are at increased risk for cardiac complications. In a cohort of over 1000 vascular surgery patients who had preoperative echocardiography, asymptomatic left ventricular dysfunction (either systolic or diastolic) was associated with a twofold increase in cardiac complications. A history of symptomatic CHF was much more predictive, being associated with a sevenfold increase in risk. Current guidelines recommend preoperative echocardiography in patients without known CHF with unexplained dyspnea and in patients with known CHF with clinical deterioration.

Patients should continue taking all medications for chronic heart failure up to the day of surgery. Patients receiving digoxin and diuretics should have serum electrolyte and digoxin levels measured prior to surgery because abnormalities in these levels may increase the risk of perioperative arrhythmias. Clinicians must be cautious not to give too much diuretic, since the volume-depleted patient will be much more susceptible to intraoperative hypotension. The surgeon and anesthesiologist should be made aware of the presence and severity of left ventricular dysfunction so that appropriate decisions can be made regarding perioperative fluid management and intraoperative monitoring.

► Valvular Heart Disease

Candidates for valve replacement surgery or valvuloplasty independent of the planned noncardiac surgery should have the valve correction procedure performed first. The severity of valvular lesions should be evaluated by echocardiography or cardiac catheterization before noncardiac surgery to allow for appropriate fluid management and consideration of invasive intraoperative monitoring. Patients with severe symptomatic aortic stenosis are at markedly increased risk for cardiac complications and should not undergo elective surgery. In a series of patients with aortic stenosis who underwent noncardiac surgery, death or nonfatal MI occurred in 31% in patients with severe aortic stenosis (aortic valve area $< 0.7 \text{ cm}^2$), in 11%

in those with moderate aortic stenosis (aortic valve area $0.7\text{--}1.0 \text{ cm}^2$), and in 2% in those without aortic stenosis. Other studies have found that patients with asymptomatic aortic stenosis appeared to be at lower risk than patients with symptomatic aortic stenosis. Patients with atrial fibrillation due to mitral stenosis require heart rate control to maintain diastolic filling time. Patients with aortic or mitral regurgitation likely benefit from afterload reduction and careful attention to volume status.

► Arrhythmias

The finding of a rhythm disturbance on preoperative evaluation should prompt consideration of further cardiac evaluation, particularly when the finding of structural heart disease would alter perioperative management. Patients with a rhythm disturbance without evidence of underlying heart disease are at low risk for perioperative cardiac complications. Patients with symptomatic arrhythmias should not undergo elective surgery until their cardiac condition has been addressed.

Management of patients with arrhythmias in the preoperative period should be guided by factors independent of the planned surgery. In patients with atrial fibrillation or other supraventricular arrhythmias, adequate rate control should be established prior to surgery. Symptomatic ventricular tachycardia must be controlled prior to surgery. There is no evidence that the use of antiarrhythmic medications to suppress an asymptomatic arrhythmia alters perioperative risk.

Patients who have indications for a permanent pacemaker should have it placed prior to noncardiac surgery. When surgery is urgent, these patients may be managed perioperatively with temporary transvenous pacing. Patients with bundle branch block who do not meet recognized criteria for a permanent pacemaker do not require pacing during surgery. The anesthesiologist must be notified that a patient has an implanted pacemaker or defibrillator so that steps may be taken to prevent device malfunction caused by electromagnetic interference from the intraoperative use of electrocautery.

► Hypertension

Mild to moderate hypertension (systolic blood pressure below 180 mm Hg and diastolic blood pressure below 110 mm Hg) is associated with intraoperative blood pressure lability and asymptomatic myocardial ischemia but does not appear to be an independent risk factor for more serious cardiac complications. No evidence supports delaying surgery in order to better control mild to moderate hypertension. Most medications for chronic hypertension should generally be continued up to and including the day of surgery. Consideration should be given to holding angiotensin-converting enzyme inhibitors and angiotensin receptor blockers on the day of surgery, as these agents may increase the risk of intraoperative hypotension. Diuretic agents, if not needed to control heart failure, are also frequently held on the day of surgery to prevent hypovolemia and electrolyte disorders.

Severe hypertension, defined as a systolic pressure > 180 mm Hg or diastolic pressure > 110 mm Hg, appears to be an independent predictor of perioperative cardiac complications, including MI and CHF. It seems wise to delay surgery in patients with severe hypertension until blood pressure can be controlled, although it is not known whether the risk of cardiac complications is reduced with this approach.

PULMONARY EVALUATION IN NON-LUNG RESECTION SURGERY

Pneumonia and respiratory failure requiring prolonged mechanical ventilation are the most important postoperative pulmonary complications and occur in 2–19% of surgical procedures. The occurrence of a postoperative pulmonary complication has been associated with a significant increase in hospital length of stay.

► Risk Factors for the Development of Postoperative Pulmonary Complications

The risk of developing a pulmonary complication is highest in patients undergoing cardiac, thoracic, and upper abdominal surgery, with reported complication rates ranging from 9% to 19%. The risk in patients undergoing lower abdominal or pelvic procedures ranges from 2% to 5%, and for extremity procedures the range is < 1–3%. The pulmonary complication rate for laparoscopic procedures appears to be much lower than that for open procedures. In one series of over 1500 patients who underwent laparoscopic cholecystectomy, the pulmonary complication rate was < 1%. Other procedure-related risk factors include prolonged anesthesia time, need for general anesthesia, and emergency operations.

Among the many patient-specific risk factors for postoperative pulmonary complications, the strongest predictor appears to be advanced age. Surgical patients in their seventh decade had a fourfold higher risk of pulmonary complications compared with patients under age 50. Patients with chronic obstructive pulmonary disease (COPD) or

Table 3–4. Clinical risk factors for postoperative pulmonary complications.

Upper abdominal or cardiothoracic surgery
Prolonged anesthesia time (> 4 hours)
Age > 60 years
Chronic obstructive pulmonary disease
Congestive heart failure
Tobacco use (> 20 pack-years)
Impaired cognition or sensorium
Functional dependency or prior stroke
Morbid obesity
Low serum albumin level
Obstructive sleep apnea

CHF have at least twice the risk compared with patients without these conditions. In a large prospective cohort of US military veterans, additional clinical risk factors for the development of postoperative pneumonia included dependent functional status, impaired sensorium, prior stroke, long-term corticosteroid use, heavy alcohol consumption, and current cigarette smoking.

Patients with asthma are at slightly increased risk for bronchospasm during tracheal intubation and extubation and during the postoperative period. However, if patients are at their optimal pulmonary function (as determined by symptoms, physical examination, or peak flow rate) at the time of surgery, they are not at increased risk for other pulmonary complications. Obesity causes restrictive pulmonary physiology, which may increase pulmonary risk in surgical patients. However, it is unclear if obesity is an independent risk predictor. Obstructive sleep apnea has been associated with a variety of postoperative complications, particularly in patients undergoing bariatric surgery. The STOP screening questionnaire asks whether a patient has snoring, tiredness during the day, observed apnea, and high blood pressure. The presence of two or more of these findings had a 78% positive predictive value for obstructive sleep apnea and was associated with a doubled risk for postoperative pulmonary complications. A summary of risk factors for pulmonary complications is presented in Table 3–4.

► Pulmonary Function Testing & Laboratory Studies

Few data support the use of preoperative testing to assess pulmonary risk. Pulmonary function testing (PFT) in unselected patients is not helpful in predicting postoperative pulmonary complications. The main role for preoperative PFT is to help identify and characterize pulmonary disease in patients with unexplained symptoms prior to major abdominal or cardiothoracic surgery. In patients with diagnosed lung disease, PFT often adds little information above clinical assessment. Furthermore, there is no clear degree of PFT abnormality that can be used as an absolute contraindication to non-lung resection surgery. Chest radiographs in unselected patients also rarely add

clinically useful information. In one study, only 0.1% of routine preoperative chest radiographs changed clinical management. They may be more useful in patients who are undergoing abdominal or thoracic surgery who are over age 50 or have known cardiopulmonary disease. Some experts have also advocated polysomnography to diagnose obstructive sleep apnea prior to bariatric surgery, but the benefits of this approach are unproven. Abnormally low or high blood urea nitrogen levels (indicating malnutrition and renal insufficiency, respectively) and hypoalbuminemia predict postoperative pulmonary complications and mortality, although the role of laboratory testing is uncertain. Arterial blood gas measurement is not routinely recommended except in patients with known lung disease and suspected hypoxemia or hypercapnia.

► Perioperative Management

The preoperative period may be an optimal time to initiate smoking cessation efforts. A systematic review found that smoking cessation programs started in a preoperative evaluation clinic increased the odds of abstinence at 3–6 months by nearly 60%. Retrospective studies have shown that smoking cessation reduced the incidence of pulmonary complications, but only if it was initiated at least 1–2 months before surgery. In several randomized trials, preoperative smoking cessation programs reduced surgical wound complications, but these studies did not have adequate statistical power to detect an impact on respiratory complications.

The incidence of postoperative pulmonary complications in patients with COPD or asthma may be reduced by preoperative optimization of pulmonary function. Patients who are wheezing should receive preoperative therapy with bronchodilators and, in certain cases, corticosteroids. Antibiotics may be beneficial for patients with COPD who cough with purulent sputum. Patients receiving oral theophylline should continue taking the drug perioperatively. A serum theophylline level should be measured to rule out toxicity. Most patients with COPD can be treated with cardioselective β -blockers if indicated to prevent perioperative cardiac complications without suffering respiratory compromise.

Postoperative risk reduction strategies have centered on promoting lung expansion through the use of incentive spirometry, continuous positive airway pressure (CPAP), intermittent positive-pressure breathing (IPPB), and deep breathing exercises. Although trial results have been mixed, all these techniques have been shown to reduce the incidence of postoperative atelectasis and, in a few studies, to reduce the incidence of postoperative pulmonary complications. In most comparative trials, these methods were equally effective. Given the higher cost of CPAP and IPPB, incentive spirometry and deep breathing exercises are the preferred methods for most patients. Incentive spirometry must be performed for 15 minutes every 2 hours. Deep breathing exercises must be performed hourly and consist of 3-second breath-holding, pursed lip breathing, and coughing. These measures should be started preoperatively and be continued for 1–2 days postoperatively.

EVALUATION OF THE PATIENT WITH LIVER DISEASE

Patients with serious liver disease are at increased risk for perioperative morbidity and demise. Appropriate preoperative evaluation requires consideration of the effects of anesthesia and surgery on postoperative liver function and of the complications associated with anesthesia and surgery in patients with preexisting liver disease.

► The Effects of Anesthesia & Surgery on Liver Function

Postoperative elevation of serum aminotransferase levels is a relatively common finding after major surgery. Most of these elevations are transient and not associated with hepatic dysfunction. General anesthetic agents may cause deterioration of hepatic function either via intraoperative reduction in hepatic blood flow leading to ischemic injury or, in the case of inhalational agents, direct hepatotoxicity. The latter effect, however, is rare with modern anesthetic agents such as desflurane and sevoflurane. Medications used for regional anesthesia produce similar reductions in hepatic blood flow and thus may be equally likely to lead to ischemic liver injury. Intraoperative hypotension, hemorrhage, and hypoxemia may also contribute to liver injury.

► Risk Factors for Surgical Complications

Observational studies have found that surgery in patients with serious liver disease is associated with a variety of complications, including hemorrhage, infection, renal failure, and encephalopathy, and with a substantial mortality rate. A key limitation in interpreting these data is our inability to determine the contribution of the liver disease to the observed complications independent of the surgical procedure.

Acute hepatitis appears to increase surgical risk. In three small series of patients with acute viral hepatitis who underwent abdominal surgery, the mortality rate was roughly 10%. Similarly, patients with undiagnosed alcoholic hepatitis had high mortality rates when undergoing abdominal surgery. Thus, elective surgery in patients with acute viral or alcoholic hepatitis should be delayed until the acute episode has resolved. There are few data regarding the risks of surgery in patients with chronic hepatitis. In the absence of cirrhosis or synthetic dysfunction, chronic viral

hepatitis is unlikely to increase risk significantly. A large cohort study of hepatitis C seropositive patients who underwent surgery found a mortality rate of less than 1%. Similarly, nonalcoholic fatty liver disease by itself probably does not pose a serious risk in surgical patients.

In patients with cirrhosis, postoperative complication rates correlate with the severity of liver dysfunction. Traditionally, severity of dysfunction has been assessed with the Child-Turcotte-Pugh score (see Chapter 16). Patients with Child-Turcotte-Pugh class C cirrhosis who underwent portosystemic shunt surgery, biliary surgery, or trauma surgery during the 1970s and 1980s had a 50–85% mortality rate. Patients with Child-Turcotte-Pugh class A or B cirrhosis who underwent abdominal surgery during the 1990s, however, had relatively low mortality rates (hepatectomy 0–8%, open cholecystectomy 0–1%, laparoscopic cholecystectomy 0–1%). A conservative approach would be to avoid elective surgery in patients with Child-Turcotte-Pugh class C cirrhosis and pursue it with great caution in class B patients. The Model for End-stage Liver Disease (MELD) score, based on bilirubin and creatinine levels, and the prothrombin time expressed as the International Normalized Ratio, also predicted surgical mortality and outperformed the Child-Turcotte-Pugh classification in some studies. A web-based risk assessment calculator incorporating age and MELD score can predict both perioperative and long-term mortality (mayoclinic.org/meld/mayomodel9.html).

In addition, when surgery is elective, it is prudent to attempt to reduce the severity of ascites, encephalopathy, and coagulopathy preoperatively. Ascites is a particular problem in abdominal operations, where it can lead to wound dehiscence or hernias. Great care should be taken when using analgesics and sedatives, as this can worsen hepatic encephalopathy. In general, short-acting agents and lower doses should be used. Patients with coagulopathy should receive vitamin K and may need plasma transfusion at the time of surgery.

O'Leary JG et al. Surgery in the patient with liver disease. *Clin Liver Dis.* 2009 May;13(2):211–31. [PMID: 19442915]

PREOPERATIVE HEMATOLOGIC EVALUATION

Three of the more common clinical situations faced by the medical consultant are the patient with preexisting anemia, the assessment of bleeding risk, and the perioperative management of oral anticoagulation.

The key issue in the anemic patient is to determine the need for preoperative diagnostic evaluation and the need for transfusion. When feasible, the diagnostic evaluation of the patient with previously unrecognized anemia should be done prior to surgery because certain types of anemia (particularly sickle cell disease and immune hemolytic anemia) may have implications for perioperative management. Preoperative anemia is common, with a prevalence of 43% in a large cohort of elderly veterans undergoing surgery. In this cohort, morbidity and mortality increased as the preoperative hemoglobin level decreased, even after adjusting for comorbidities. No data exist to identify a specific preoperative hemoglobin level that should prompt

transfusion prior to surgery. It is also not known whether such transfusions will improve postoperative outcomes. Determination of the need for preoperative transfusion in an individual patient must consider factors other than the absolute hemoglobin level, including the presence of cardiopulmonary disease, the type of surgery, and the likely severity of surgical blood loss. The few studies that have compared different postoperative transfusion thresholds failed to demonstrate improved outcomes with a more aggressive transfusion strategy. One trial randomized patients undergoing hip fracture repair to either transfusion to maintain a hemoglobin level > 10 g/dL or transfusion for symptomatic anemia. Patients receiving symptom-triggered transfusion received far fewer units of packed red blood cells without increased mortality or complication rates.

The most important component of the bleeding risk assessment is a directed bleeding history (see Table 3–1). Patients who are reliable historians and who reveal no suggestion of abnormal bleeding on directed bleeding history and physical examination are at very low risk for having an occult bleeding disorder. Laboratory tests of hemostatic parameters in these patients are generally not needed. When the directed bleeding history is unreliable or incomplete or when abnormal bleeding is suggested, a formal evaluation of hemostasis should be done prior to surgery and should include measurement of the prothrombin time, activated partial thromboplastin time, and platelet count (see Chapter 13).

Patients receiving long-term oral anticoagulation are at risk for thromboembolic complications when an operation requires interruption of this therapy. In a cohort study of 1293 interruptions of warfarin therapy for invasive procedures, the 30-day thromboembolic risk was 0.7%. There are insufficient data to determine the excess risk incurred by holding warfarin therapy or whether this risk may be mitigated through the practice of “bridging” anticoagulation, where unfractionated or low-molecular-weight heparin is administered parenterally while oral anticoagulants are held until just prior to surgery. The bleeding risk associated with bridging anticoagulation can be substantial. Patients in this cohort who received bridging anticoagulation had a 13% incidence of clinically significant bleeding, compared with 0.8% for patients who did not receive bridging anticoagulation. Although firm evidence-based guidelines for perioperative bridging are lacking, most experts recommend bridging therapy only in patients at high risk for thromboembolism. An approach to perioperative anticoagulation management is shown in Table 3–5, but the recommendations must be considered in the context of patient preference and hemorrhagic risk.

Table 3-5. Recommendations for perioperative anticoagulation management.

Thromboembolic Risk without Anticoagulation	Recommendation
Low (< 8% annual risk: eg, atrial fibrillation with no more than two other stroke risk factors, ¹ mechanical bileaflet aortic valve prosthesis with no more than one other stroke risk factors, or single venous thromboembolism > 3 months ago without hypercoagulable condition ²)	<ol style="list-style-type: none"> 1. Stop oral anticoagulation 4-5 days before surgery 2. Measure INR the day before surgery to confirm that it is < 1.6 3. Resume oral anticoagulation the night of surgery, if possible 4. No bridging with parenteral anticoagulants before or after surgery
High (> 8% annual risk: eg, atrial fibrillation or mechanical heart valve with prior stroke, mechanical mitral valve prosthesis, caged-ball or tilting disk valve prosthesis, or venous thrombosis < 3 months ago or associated with hypercoagulable condition ²)	<ol style="list-style-type: none"> 1. Stop oral anticoagulation 4-5 days before surgery 2. Begin therapeutic dose UFH or LMWH 2 days after stopping oral anticoagulation, and discontinue it 12-24 hours before surgery 3. Measure INR the day before surgery to confirm that it is < 1.6 4. Resume oral anticoagulation the night of surgery, if possible 5. If procedure has a low risk of bleeding, consider therapeutic dose UFH or LMWH beginning 24-48 hours after surgery and continuing until the INR is therapeutic

¹Congestive heart failure, hypertension, diabetes mellitus, age > 75 years.

²Patients should receive venous thromboembolism prophylaxis after surgery (see Chapter 14).

INR, international normalized ratio; LMWH, low-molecular-weight heparin; UFH, unfractionated heparin.

NEUROLOGIC EVALUATION

Delirium occurs after major surgery in 5–50% of patients over the age of 50 years and is particularly common after hip fracture repair and aortic surgery, occurring in 30–60% of such patients. Postoperative delirium has been associated with higher rates of major postoperative cardiac and pulmonary complications, poor functional recovery, an increased length of hospital stay, an increased risk of subsequent dementia and functional decline, and increased mortality. Several preoperative and postoperative factors have been associated with the development of postoperative delirium, most notably age, preoperative functional or cognitive impairment, preoperative psychotropic drug use, and derangements of serum chemistry. Patients with multiple risk factors are at especially high risk. Delirium occurred in half of the patients with at least three of the risk factors listed in Table 3-6.

Two types of delirium reducing interventions have been evaluated: focused geriatric care and psychotropic medications. In a randomized, controlled trial of hip fracture surgery patients, those who received daily visits and targeted

recommendations from a geriatrician had a lower risk of postoperative delirium (32%) than the control patients (50%). The most frequent interventions to prevent delirium were maintenance of the hematocrit > 30%; minimizing the use of benzodiazepines and anticholinergic medications; maintenance of regular bowel function; and early discontinuation of urinary catheters. Other studies comparing postoperative care in specialized geriatrics units with standard wards have shown similar reductions in the incidence of delirium. Although the use of neuroleptics to prevent postoperative delirium is uncommon, limited data support their effectiveness. A randomized trial in cardiac surgery patients demonstrated that risperidone (1 mg sublingual after regaining consciousness) reduced the incidence of postoperative delirium compared with placebo (11.1% vs. 31.7%). Another trial found that prophylactic oral haloperidol in orthopedic surgery patients failed to prevent delirium but did reduce its severity and duration.

Postoperative cognitive dysfunction is defined as a reduction in memory, language comprehension, visuospatial comprehension, attention, or concentration. Postoperative cognitive dysfunction may occur in up to 25% patients after cardiopulmonary bypass and in 15% of patients after major noncardiac surgery. The symptoms are generally transient, lasting < 3 months. It is more common in older patients and occurs with equal frequency after general or regional anesthesia.

Stroke complicates < 1% of all surgical procedures but may occur in 1–6% of patients undergoing cardiac or carotid artery surgery. Most of the strokes in cardiac surgery patients are embolic in origin, and about half occur within the first postoperative day. Stroke after cardiac surgery is associated with significantly increased mortality, up to 22% in some studies. A prediction model for stroke after coronary artery bypass surgery includes the following risk factors: age > 60 years, female sex, urgent or emergency surgery, diabetes mellitus, chronic kidney disease, peripheral vascular disease, and systolic dysfunction.

Table 3-6. Risk factors for the development of postoperative delirium.

Preoperative factors
Age > 70 years
Alcohol abuse
Cognitive impairment
Poor physical function status
Markedly abnormal serum sodium, potassium, or glucose level
Aortic, thoracic, hip fracture surgery, or emergency surgery
Postoperative factors
Use of meperidine or benzodiazepines, anticholinergics, antihistamines
Postoperative hematocrit < 30%
Use of urinary catheters

Symptomatic carotid artery stenosis is associated with a high risk for stroke in patients undergoing cardiac surgery. In general, symptomatic carotid lesions should be treated prior to elective cardiac surgery. In contrast, most studies suggest that asymptomatic carotid bruits and asymptomatic carotid stenosis are associated with little or no increased risk of stroke in surgical patients. Prophylactic carotid endarterectomy in patients with asymptomatic carotid artery disease is unlikely to be beneficial in most patients, as the stroke risk of the carotid procedure likely outweighs any risk reduction it provides in a subsequent operation. On the other hand, patients with carotid disease with independent indications for carotid endarterectomy (see Chapter 12) should probably have the carotid surgery prior to the elective surgery.

MANAGEMENT OF ENDOCRINE DISEASES

▶ Diabetes Mellitus

Patients with diabetes mellitus are at increased risk for postoperative infections, particularly those involving the surgical site. Patients with a preoperative hemoglobin $A_{1c} < 7\%$ have roughly half the risk for developing a postoperative infection compared with those with a hemoglobin $A_{1c} > 7\%$. Furthermore, diabetic patients are at increased risk for postoperative cardiac complications. The most challenging issue in diabetic patients, however, is the maintenance of glucose control during the perioperative period. The increased secretion of cortisol, epinephrine, glucagon, and growth hormone during surgery is associated with insulin resistance and hyperglycemia in diabetic patients. The goal of management is the prevention of severe hyperglycemia or hypoglycemia in the perioperative period.

The ideal postoperative blood glucose level is not known. Tighter perioperative glycemic control leads to better clinical outcomes in cardiac surgery patients. In a study of 1200 patients in a critical care unit, most of whom had undergone cardiac surgery, those randomized to strict normalization of serum glucose (80–110 mg/dL) had significantly less morbidity and a shorter length of stay in the critical care unit than patients who were treated only for serum glucose > 215 mg/dL. These results do not apply to other surgical patients, however, as a subsequent trial demonstrated increased mortality with tight control in critically ill surgical patients. The specific pharmacologic management of diabetes during the perioperative period depends on the type of diabetes (insulin-dependent or not), the level of glycemic control, and the type and length of surgery. In general, all patients with type 1 diabetes and some with type 2 diabetes will need an intravenous insulin infusion perioperatively. In a randomized trial, basal-bolus

Table 3–7. Perioperative management of diabetic patients who do not need insulin.

Patient	Recommended Management
Diabetes well controlled on diet alone	Measure glucose every 4 hours while fasting or NPO and give subcutaneous regular insulin as needed to maintain blood glucose < 130 mg/dL [> 7.08 mmol/L] Avoid glucose-containing solutions during surgery
Diabetes well controlled on an oral sulfonylurea, metformin, or a thiazolidinedione	The last dose of medication should be taken on the evening before surgery Measure glucose every 4 hours while fasting or NPO and give subcutaneous regular insulin as needed to maintain blood glucose < 130 mg/dL [> 7.08 mmol/L] Measure blood glucose level every 4 hours (or more frequently as indicated) during surgery Resume oral hypoglycemic therapy when the patient returns to baseline diet

NPO, nothing by mouth.

insulin dosing improved glycemic control and reduced postoperative complications in patients with type 2 diabetes mellitus, when compared with sliding scale insulin. Mild hyperglycemia was more common with basal-bolus dosing. Perioperative management of all diabetic patients requires frequent blood glucose monitoring to prevent hypoglycemia and to ensure prompt treatment of hyperglycemia. Recommendations for glycemic control in patients who generally do not need intraoperative insulin are shown in Table 3–7. Perioperative use of corticosteroids, common in neurosurgical and organ transplant procedures, increases glucose intolerance. Patients receiving corticosteroids often require additional regular insulin with meals, while their fasting glucose levels may remain relatively unchanged.

▶ Corticosteroid Replacement

Perioperative complications (predominantly hypotension) resulting from primary or secondary adrenocortical insufficiency are rare. The common practice of administering high-dose corticosteroids during the perioperative period in patients at risk for adrenocortical insufficiency has not been rigorously studied. While definitive recommendations regarding perioperative corticosteroid therapy cannot be made, a conservative approach would be to consider any patient to be at risk for having adrenocortical insufficiency who has received either the equivalent of 20 mg of prednisone daily for 3 weeks or the equivalent of 7.5 mg of prednisone daily for 1 month within the past year. A commonly used regimen is 50–100 mg of hydrocortisone given intravenously every 8 hours beginning before induction of anesthesia and continuing for 24–48 hours. Tapering the dose is not necessary. Patients being maintained on long-term corticosteroids should also continue their usual dose throughout the perioperative period.

► Thyroid Disease

Severe symptomatic hypothyroidism has been associated with several perioperative complications, including intraoperative hypotension, CHF, cardiac arrest, and death. Elective surgery should be delayed in patients with severe hypothyroidism until adequate thyroid hormone replacement can be achieved. Similarly, patients with symptomatic hyperthyroidism are at risk for perioperative thyroid storm and should not undergo elective surgery until their thyrotoxicosis is controlled. An endocrinologist should be consulted if emergency surgery is needed in such patients. Conversely, patients with asymptomatic or mild hypothyroidism generally tolerate surgery well, with only a slight increase in the incidence of intraoperative hypotension; surgery need not be delayed for the month or more required to ensure adequate thyroid hormone replacement.

KIDNEY DISEASE

Approximately 1% of patients suffer a significant reduction in kidney function after major surgery. The risk is much higher, however, in patients undergoing cardiac operations, where 10–30% of patients develop acute kidney injury. The development of acute kidney injury is an independent predictor of mortality, even if renal dysfunction resolves. The mortality associated with the development of perioperative acute kidney injury that requires dialysis exceeds 50%. Risk factors associated with postoperative deterioration in kidney function are shown in Table 3–8. Several

medications, including “renal dose” dopamine, mannitol, *N*-acetylcysteine, and furosemide, have been evaluated in an attempt to preserve kidney function during the perioperative period. None of these have proved effective in clinical trials and generally should not be used for this indication. Maintenance of adequate intravascular volume is likely to be the most effective method to reduce the risk of perioperative deterioration in kidney function. Exposure to renal toxic agents such as nonsteroidal anti-inflammatory drugs and intravenous contrast should be minimized or avoided. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers reduce renal perfusion and may increase the risk of perioperative acute kidney injury. Although firm evidence is lacking, it may be useful to temporarily discontinue these medications in patients at risk for perioperative acute kidney injury.

Although the mortality rate for elective major surgery is low (1–4%) in patients with dialysis-dependent chronic kidney disease, the risk for perioperative complications, including postoperative hyperkalemia, pneumonia, fluid overload, and bleeding, is substantially increased. Postoperative hyperkalemia requiring emergent hemodialysis has been reported to occur in 20–30% of patients. Patients should undergo dialysis preoperatively within 24 hours before surgery, and their serum electrolyte levels should be measured just prior to surgery and monitored closely during the postoperative period.

ANTIBIOTIC PROPHYLAXIS OF SURGICAL SITE INFECTIONS

There are an estimated 0.5–1 million surgical site infections annually in the United States. Surgical site infection is estimated to occur in roughly 4% of general or vascular operations. For most major procedures, the use of prophylactic antibiotics has been demonstrated to reduce the incidence of surgical site infections significantly. For example, antibiotic prophylaxis in colorectal surgery reduces the incidence of surgical site infection from 25–50% to below 20%. In addition, in a case-control study of Medicare beneficiaries, the use of preoperative antibiotics within 2 hours of surgery was associated with a twofold reduction in 60-day mortality.

Other strategies to prevent surgical site infections have proven to be controversial. Evidence suggests that nasal carriage with *Staphylococcus aureus* is associated with a twofold to ninefold increased risk of surgical site and catheter-related infections in surgical patients. Treatment of nasal carriers of *S aureus* with 2% mupirocin ointment (twice daily intranasally for 3 days) prior to cardiac surgery

decreases the risk of surgical site infections. However, in a 2008 cohort study, universal screening for methicillin-resistant *S aureus* in surgical patients failed to reduce infection rates from this pathogen. An early finding that high concentration oxygen delivered in the immediate postoperative period reduced surgical site infections was not verified in subsequent trials. Thus, high-flow supplemental oxygen specifically to prevent these infections is not recommended. Preoperative bathing with antiseptic agents and preoperative hair removal are common practices but have not demonstrated a reduction in surgical site infections in randomized trials. The use of razors for hair removal actually seems to increase the risk of surgical site infections and is therefore specifically not recommended. If preoperative hair removal is indicated, the use of clippers is preferred.

Guidelines for antibiotic prophylaxis against infective endocarditis in patients undergoing invasive procedures are presented in Chapter 33. The American Association of Orthopaedic Surgeons recommends consideration of prophylactic antibiotics in patients with prosthetic joints on a case-by-case basis. More definitive or evidence-based guidelines for antibiotic prophylaxis against prosthetic joint infection are lacking.

Geriatric Disorders

C. Bree Johnston, MD, MPH,
G. Michael Harper, MD,
& C. Seth Landefeld, MD

4

GENERAL PRINCIPLES OF GERIATRIC CARE

The following principles help in caring for older adults:

1. Many disorders are multifactorial in origin and are best managed by multifactorial interventions.
2. Diseases often present atypically.
3. Not all abnormalities require evaluation and treatment.
4. Complex medication regimens, adherence problems, and polypharmacy are common challenges.

ASSESSMENT OF THE OLDER ADULT

Comprehensive assessment addresses three topics in addition to conventional assessment of symptoms and diseases: prognosis, values and preferences, and ability to function independently. Each topic merits at least brief consideration in each clinical decision. Comprehensive assessment is warranted before major clinical decisions (eg, whether major surgery should be performed, or whether a patient should be admitted to the hospital).

► Assessment of Prognosis

When an older person's life expectancy is > 10 years (ie, 50% of similar persons live longer than 10 years), it is reasonable to consider effective tests and treatments much as they are considered in younger persons. When life expectancy is < 10 years (and especially when it is much less), choices of tests and treatments should be made on the basis of their ability to improve that particular patient's prognosis and quality of life in the shorter term of that patient's life expectancy. The relative benefits and harms of tests and treatments often change as prognosis worsens.

When an older patient's clinical situation is dominated by a single disease process (eg, lung cancer metastatic to brain), prognosis can be estimated well with a disease-specific instrument. Even in this situation, however, prognosis generally worsens with age (especially age > 90 years) and with the presence of serious age-related conditions, such as dementia, malnutrition, or impaired ability to walk.

When an older patient's clinical situation is not dominated by a single disease process, prognosis can be estimated

initially by considering the patient's age, sex, and general health (Figure 4-1). For example, $< 25\%$ of men age 95 years will live 5 years, whereas nearly 75% of women age 70 years will live 10 years.

The prognosis of older persons living at home can be estimated by considering age, sex, comorbid conditions, and function (Table 4-1). The prognosis of older persons discharged from the hospital is worse than that of those living at home and can be estimated by considering gender, comorbid conditions, and function at discharge (Table 4-2).

► Assessment of Values & Preferences

Although patients vary in their values and preferences, most frail older patients prioritize maintaining their independence over prolonging survival or relieving pain or other symptoms. Values and preferences are determined by speaking directly with a patient or, when the patient cannot express preferences reliably, with the patient's surrogate. Values and preferences can be assessed most readily in the context of a specific medical decision. For example, the clinician might ask a patient considering a hip replacement, "How would you like your hip pain and function to be different? Tell me about the risk and discomfort you are willing to go through to achieve that improvement."

In assessing values and preferences, it is important to keep in mind the following:

1. Patients are experts about their preferences for outcomes and experiences; however, they often do not have adequate information to express informed preferences for specific tests or treatments.
2. Patients' preferences often change over time. For example, some patients find living with a disability more acceptable than they thought before experiencing it.

► Assessment of Function

People often lose function in multiple domains as they age, with the results that they may not be able to do some activities as quickly or capably and may need assistance with other activities. Assessment of function improves prognostic estimates (see above). Assessment of function is essential to

▲ **Figure 4-1.** Median life expectancy of older women and men. (Adapted, with permission, from Walter LC et al. Screening for colorectal, breast, and cervical cancer in the elderly: a review of the evidence. *Am J Med.* 2005 Oct; 118(10):1078-86.) Copyright © Elsevier.

determining an individual's needs in the context of their values and preferences, and the possible effects of prescribed treatment.

About one-fourth of patients over 65 have impairments in their IADLs (instrumental activities of daily living: transportation, shopping, cooking, using the telephone, managing money, taking medications, housecleaning, laundry) or ADLs (basic activities of daily living: bathing, dressing, eating, transferring from bed to chair, continence, toileting). Half of those persons older than 85 years have these latter impairments.

In general, persons who need help only with IADLs can usually live independently with minimal supports, such as financial services (eg, a representative payee) or a chore worker. If institutional care is needed, residential care, board-and-care, or assisted living is usually sufficient. While many persons who need help with ADLs may require a nursing home level of care, most live at home with caregivers and other community services (eg, day care).

► Caregiver Issues

Most elders with functional impairment live in the community with the help of an "informal" caregiver, most commonly a spouse or daughter. The health and well-being of the patient and caregiver are closely linked. High levels of functional dependency place an enormous burden on a caregiver, and may result in caregiver "burnout," depression, morbidity, and even increased mortality.

An older patient's need for nursing home placement is predicted better by the caregiver's ability and stress than the severity of the patient's illness. Therefore, part of caring for a frail elder involves paying attention to the well-being of the caregiver. The older patient who is also a caregiver is at risk for depression and should be screened for it. For the

stressed caregiver, a social worker may help identify programs such as caregiver support groups, respite programs, adult day care, or hired home health aides.

▶ Functional Screening Instrument

Functional screening should include assessment of ADL and IADL and questions to detect weight loss, falls, incontinence, depressed mood, self neglect, fear for personal safety, and common serious impairments (eg, hearing, vision, cognition, and mobility). Standard functional screening measures may not be useful in capturing subtle impairments in highly functional independent elders. One technique for these patients is to identify and regularly ask about a target activity, such as bowling or gardening. If the patient begins to have trouble with or discontinues such an “advanced activity of daily living,” it may indicate early impairment, such as dementia, incontinence, or worsening hearing loss, which additional gentle questioning or assessment may uncover.

Busy providers may find it more manageable to perform the elements of functional geriatric assessment over three or four visits or to train office personnel to perform some elements of the assessment.

MANAGEMENT OF COMMON GERIATRIC PROBLEMS

1. Dementia

ESSENTIALS OF DIAGNOSIS

- ▶ Progressive decline of intellectual function.
- ▶ Loss of short-term memory and at least one other cognitive deficit.
- ▶ Deficit severe enough to cause impairment of function.
- ▶ Not delirious.

▶ General Considerations

Dementia is an acquired persistent and progressive impairment in intellectual function, with compromise of memory and at least one other cognitive domain, most commonly aphasia (typically, word finding difficulty), apraxia (inability to perform motor tasks, such as cutting a loaf of bread, despite intact motor function), agnosia (inability to recognize objects), and impaired executive function (poor abstraction, mental flexibility, planning, and judgment). The diagnosis of dementia requires a significant decline in function that is severe enough to interfere with work or social life.

Dementia has a prevalence that doubles every 5 years in the older population, reaching 30–50% at age 85. Women suffer disproportionately, both as patients and as caregivers. Alzheimer disease accounts for roughly two-thirds of dementia cases in the United States, with vascular dementia (either alone or combined with Alzheimer disease) and dementia with Lewy bodies accounting for much of the rest. Some of the risk factors for Alzheimer disease are older age, family history, lower education level, and female sex. Education, cognitive “exercises,” and social support may be protective. Risk factors for vascular dementia are those for stroke, ie, older age, hypertension, cigarette use, atrial fibrillation, diabetes mellitus, and hyperlipidemia.

Depression and delirium are also common in elders, may coexist with dementia, and may also present with

cognitive impairment. Depression is a common concomitant of early dementia. A patient with depression and cognitive impairment whose intellectual function improves with treatment of the mood disorder has an almost fivefold greater risk of suffering irreversible dementia later in life. Delirium, characterized by acute confusion, occurs much more commonly in patients with underlying dementia.

► Clinical Findings

A. Screening

1. Cognitive impairment—Although there is no consensus at present on whether older patients should be screened for dementia, the benefits of early detection include identification of potentially reversible causes, planning for the future (including discussing values and completing advance care directives), and providing support and counseling for the caregiver.

The combination of a clock drawing task with a three-item word recall (also known as the “mini-cog”) is a simple screening test that is fairly quick to administer. While different methods for administering and scoring the clock draw test have been described, the authors of this chapter favor the approach of pre-drawing a four inch circle on a sheet of paper and instructing the patient to “draw a clock” with the time set at 10 minutes after 11. Scores are classified as normal, almost normal, or abnormal. When a patient is able to draw a clock normally and can remember all 3 objects, dementia is unlikely. When a patient fails this simple screen, further cognitive evaluation with a standardized instrument is warranted. The Montreal Cognitive Assessment (MoCA ©) is a 30-point test that takes about 10 minutes to administer and examines several areas of cognitive function. A score below 26 is considered abnormal. Free downloadable versions in multiple languages are available at <http://www.mocatest.org>.

2. Decision-making capacity—Cognitively impaired elders commonly face serious medical decisions, and the clinicians involved in their care must ascertain whether the capacity exists to make the choice. While no single test of capacity exists, the following five elements should be considered in a thorough assessment: (1) ability to express a choice; (2) understanding relevant information about the risks and benefits of planned therapy and the alternatives, in the context of one’s values, including no treatment; (3) comprehension of the problem and its consequences; (4) ability to reason; and (5) consistency. A patient’s choice should follow from an understanding of the consequences.

Sensitivity must be used in applying these five components to people of various cultural backgrounds. Decision-making capacity varies over time: A delirious patient may regain his capacity after an infection is treated, and so reassessments are often appropriate. Furthermore, the capacity to make a decision is a function of the decision in question. A woman with mild dementia may lack the capacity to consent to coronary artery bypass grafting yet retain the capacity to designate a surrogate decision maker.

B. Symptoms and Signs

The clinician can gather important information about the type of dementia that may be present by asking about: (1) the rate of progression of the deficits as well as their nature (including any personality or behavioral change); (2) the presence of other neurologic symptoms, particularly motor problems; (3) risk factors for HIV; (4) family history of dementia; and (5) medications, with particular attention to recent changes.

Work-up is directed at identifying any potentially reversible causes of dementia. However, such cases are indeed rare. For a detailed description of the symptoms and signs of different forms of dementia, see Chapter 24.

C. Physical Examination

The neurologic examination emphasizes assessment of mental status but should also include evaluation for sensory deficits, possible previous strokes, parkinsonism, or peripheral neuropathy. The remainder of the physical examination should focus on identifying comorbid conditions that may aggravate the individual’s disability. For a detailed description of the neuropsychological assessment, see Chapter 24.

D. Laboratory Findings

Laboratory studies should include a complete blood count, electrolytes, calcium, creatinine, glucose, thyroid-stimulating hormone (TSH), and vitamin B₁₂ levels. While hypothyroidism or vitamin B₁₂ deficiency may contribute to the cognitive impairment, treating these conditions typically does not completely reverse the dementia. HIV testing, RPR (rapid plasma reagin) test, heavy metal screen, and liver biochemical tests may be informative in selected patients but should not be considered part of routine testing. For a detailed description of laboratory findings, see Chapter 24.

E. Imaging

Most patients should receive neuroimaging as part of the diagnostic work-up to rule out subdural hematoma, tumor, previous stroke, and hydrocephalus (usually normal pressure). Those who are younger and those who have focal neurologic symptoms or signs, seizures, gait abnormalities, and an acute or subacute onset are most likely to yield positive findings and most likely to benefit from MRI scanning. In older patients with a more classic picture of Alzheimer disease in whom neuroimaging is desired, a non-contrast CT scan is sufficient. For a detailed description of imaging, see Chapter 24.

► Differential Diagnosis

Older individuals experience occasional difficulty retrieving items from memory (usually manifested as word-finding complaints) and experience a slowing in their rate of information processing. **Mild cognitive impairment** is an increasingly recognized condition in which a patient complains of memory problems, demonstrates mild deficits

(most commonly in short-term memory) on formal testing, but does not meet criteria for dementia. Dementia will develop in more than half of people with mild cognitive impairment within 5 years. Acetylcholinesterase inhibitors have not consistently demonstrated a delay in the progression of mild cognitive impairment to Alzheimer disease. An elderly patient with intact cognition but with severe impairments in vision or hearing commonly becomes confused in an unfamiliar medical setting and consequently may be falsely labeled as demented. Cognitive testing is best performed after optimal correction of the sensory deficits.

Delirium can be distinguished from dementia by its acute onset, fluctuating course, and deficits in attention rather than memory. Because delirium and dementia often coexist, it may not be possible to determine how much impairment is attributable to each condition until the patient is fully recovered and back in their usual setting. Many medications have been associated with delirium and other types of cognitive impairment in older patients. Anticholinergic agents, hypnotics, neuroleptics, opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), antihistamines (including H₁ and H₂-antagonists), and corticosteroids are just some of the medications that have been associated with cognitive impairment in elders.

► Treatment

Patients and families should be made aware of the Alzheimer's Association (<http://www.alz.org>) as well as the wealth of helpful community and online resources and publications available. Caregiver support, education, and counseling can prevent or delay nursing home placement. Education should include the manifestations and natural history of dementia as well as the availability of local support services such as respite care. Even under the best of circumstances, caregiver stress can be substantial. Collaborative care models and disease management programs appear to improve the quality of care for patients with dementia.

A. Cognitive Impairment

Because demented patients have greatly diminished cognitive reserve, they are at high risk for experiencing acute cognitive or functional decline in the setting of new medical illness. Consequently, fragile cognitive status may be best maintained by ensuring that comorbid diseases such as congestive heart failure and infections are detected and treated.

1. Acetylcholinesterase inhibitors—Many experts recommend considering a trial of acetylcholinesterase inhibitors (eg, donepezil, galantamine, rivastigmine) in most patients with mild to moderate Alzheimer disease. These medications produce a modest improvement in cognitive function that is not likely to be detected in routine clinical encounters. Acetylcholinesterase inhibitors may also have similarly modest cognitive benefits in patients with vascular dementia or dementia with Lewy bodies. However, acetylcholinesterase inhibitors have not convincingly been shown to delay institutionalization or functional decline.

Starting doses, respectively, of donepezil, galantamine, and rivastigmine, are 5 mg orally once daily (maximum 10 mg once daily), 4 mg orally twice daily (maximum 12 mg twice daily), and 1.5 mg orally twice daily (maximum 6 mg twice daily). The doses are increased gradually as tolerated. The most bothersome side effects include diarrhea, nausea, anorexia, weight loss, and syncope. In those patients who have had no apparent benefit, experience side effects, or for whom the financial outlay is a burden, the drug should be discontinued.

2. Memantine—In clinical trials, patients with more advanced disease have been shown to have statistical benefit from the use of memantine, an *N*-methyl-D-aspartate (NMDA) antagonist, with or without concomitant use of an acetylcholinesterase inhibitor. Long-term and meaningful functional outcomes have yet to be demonstrated.

B. Behavioral Problems

1. Nonpharmacologic approaches—Behavioral problems in demented patients are often best managed with a nonpharmacologic approach. Initially, it should be established that the problem is not unrecognized delirium, pain, urinary obstruction, or fecal impaction. It also helps to inquire whether the caregiver or institutional staff can tolerate the behavior, as it is often easier to find ways to accommodate to the behavior than to modify it. If not, the caregiver should keep a brief log in which the behavior is described along with antecedent events and consequences. Recurring precipitants of the behavior are often found to be present or it may be that the behavior is rewarded—for example, by increased attention. Caregivers are taught to use simple language when communicating with the patient, to break down activities into simple component tasks, and to use a “distract, not confront” approach when the patient seems disturbed by a troublesome issue. Additional steps to address behavioral problems include providing structure and routine, discontinuing all medications except those considered absolutely necessary, and correcting, if possible, sensory deficits.

2. Pharmacologic approaches—There is no clear consensus about pharmacologic approaches to treatment of behavioral problems in patients who have not benefited from nonpharmacologic therapies. The target symptoms—depression, anxiety, psychosis, mood lability, or pain—may suggest which class of medications might be most helpful in a given patient. Patients with depressive symptoms may show improvement with antidepressant therapy. Patients with dementia with Lewy bodies have shown clinically significant improvement in behavioral symptoms when treated with rivastigmine (3–6 mg orally twice daily).

For those with Alzheimer disease and agitation, no agents have demonstrated consistent efficacy. Despite the lack of strong evidence, antipsychotic medications have remained a mainstay for the treatment of behavioral disturbances, largely because of the lack of alternatives. The newer atypical antipsychotic agents (risperidone, olanzapine, quetiapine, aripiprazole, clozapine, ziprasidone) are reported to be better tolerated than older agents but should be avoided in patients with vascular risk factors due to an increased risk

of stroke; they can cause weight gain and are also associated with hyperglycemia in diabetic patients and are considerably more expensive. Both typical and atypical antipsychotics in several short-term trials and one long-term trial have been demonstrated to increase mortality compared with placebo when used to treat elderly demented patients with behavioral disturbances. When the choice is made to use these agents, patients and caregivers should be carefully warned of the risks. Starting and target dosages should be much lower than those used in schizophrenia (eg, haloperidol, 0.5–2 mg orally; risperidone, 0.25–2 mg orally). Federal regulations require that if antipsychotic agents are used in treatment of a nursing home patient, drug reduction efforts must be made at least every 6 months.

C. Driving

A common yet vexing problem that providers are regularly asked to assess is whether a patient with dementia is able to continue driving. The consequences of a decision to either stop or continue driving can be far-reaching for both the patient and the general public and therefore every case requires careful consideration. Although drivers with dementia are at an increased risk for motor vehicle accidents, many patients continue to drive safely well beyond the time of diagnosis, making the timing of when to recommend that a patient stop driving particularly challenging.

There is no clear-cut evidence to suggest a single best approach to determining an individual patient's risk, and there is no accepted "gold standard" test. The result is that clinicians must consider several factors upon which to base their judgment. For example, determining the severity of dementia can be useful. Patients with very mild or mild dementia according to the Clinical Dementia Rating Scale were able to pass formal road tests at rates of 88% and 69%, respectively. Experts agree that patients with moderately severe or more advanced dementia should be counseled to stop driving. Although not well studied, clinicians should also consider the effects of comorbid conditions and medications and the role each may play in contributing to the risk of driving by a patient with dementia. Assessment of the ability to carry out IADLs may also add to the determination of risk. Caregivers of patients with at least a 30% decline in their IADL score were more likely to rate them as unable to drive safely than other, less impaired patients. Finally, in some cases of mild dementia, referral may be needed to a driver rehabilitation specialist for evaluation. Although not standardized, this evaluation often consists of both off- and on-road testing. The cost for this assessment can be substantial, and it is typically not covered by health insurance. Experts recommend such an evaluation for patients with mild dementia, for those with dementia for whom new impairment in driving skills is observed, and for those with significant deficits in cognitive domains such as attention, executive function, and visuospatial skills. At present, there is no convincing evidence to support the use of interventions to improve driving skills and driver safety.

Clinicians must also be aware of the reporting requirements in their individual jurisdictions. Some states have

mandatory reporting laws for clinicians, but in other states, the decision to report an unsafe driver with dementia is voluntary. When a clinician has made the decision to report an unsafe driver to the Department of Motor Vehicles, he or she must consider the impact as a potential breach in confidentiality and must weigh and address, in advance when possible, the consequences from the loss of driving independence.

D. Advance Financial Planning

Difficulty in managing financial affairs often develops early in the course of dementia. The patient's caregiver may seek advice from the patient's primary care clinician. Although expertise is not expected, clinicians should have some proficiency to address financial concerns. Just as clinicians counsel patients and families about advance care planning, the same should be done to educate about the need for advance financial planning and to recommend that patients complete a durable power of attorney for finance matters (DPOAF) when the capacity to do so still exists. In most states the DPOAF can be executed with or without the aid of an attorney. Other options to assist in managing and monitoring finances include online banking, automatic bill payments, direct deposits and joint bank accounts. A potential risk of the joint account is that the joint account holder has no obligation to act in the best interest of the patient.

No gold standard test is available to identify when a patient with dementia no longer has financial capacity. However, the clinician should be on the lookout for signs that a patient is either at risk for or actually experiencing financial incapacity. Because financial impairment can occur when dementia is mild, making that diagnosis should alone be enough to warrant further investigation. Questioning patients and caregivers about late, missed or repeated bill payments, unusual or uncharacteristic purchases or gifts, overdrawn bank accounts and reports of missing funds can provide evidence of suspected financial impairment. Patients with dementia are also at increased risk for becoming victims of financial abuse and some answers to these same questions might also be signs of potential financial abuse. When financial abuse is suspected, clinicians should be aware of the reporting requirements in their local jurisdictions.

► Prognosis

Life expectancy after a diagnosis of Alzheimer disease is typically 3–15 years; it may be shorter than previously reported. Other neurodegenerative dementias, such as dementia with Lewy bodies, show more rapid decline. Hospice is often appropriate for patients with end-stage dementia.

► When to Refer

Referral for neuropsychological testing may be helpful in the following circumstances: to distinguish dementia from depression, to diagnose dementia in persons of very poor education or very high premorbid intellect, and to aid diagnosis when impairment is mild.

- Carr DB et al. The older adult driver with cognitive impairment: "It's a very frustrating life". *JAMA*. 2010 April 28;303(16):1632–41. [PMID: 20424254]

2. Depression

ESSENTIALS OF DIAGNOSIS

- ▶ Depressed elders may not admit to depressed mood.
- ▶ Depression screening in elders should include a question about anhedonia.

▶ General Considerations

Depressive symptoms—often related to loss, disease, and life changes—may be present in more than 25% of elders; however, the prevalence of major depression is similar in younger and older populations. Depression is particularly common in hospitalized and institutionalized elders. Older single men have the highest suicide rate of any demographic group. Geriatric patients with depression are more likely to have somatic complaints, less likely to report depressed mood, and more likely to experience delusions than younger patients. In addition, depression may be an early symptom of a neurodegenerative condition such as dementia. Depressed patients who have other comorbidities, such as congestive heart failure or diabetes, have worse outcomes than their non-depressed counterparts.

▶ Clinical Findings

A simple two-question screen—which consists of asking “During the past 2 weeks, have you felt down, depressed, or hopeless?” and “During the past 2 weeks, have you felt little interest or pleasure in doing things?”—is highly sensitive for detecting major depression in persons over age 65. Positive responses can be followed up with more comprehensive, structured interviews, such as the Geriatric Depression Scale (<http://www.stanford.edu/~yesavage/GDS.html>) or the PHQ-9 (<http://www.depression-primarycare.org>).

Elderly patients with depressive symptoms should be questioned about medication use, since many drugs

(eg, benzodiazepines, corticosteroids) may contribute to the clinical picture. Similarly, several medical problems can cause fatigue, lethargy, or hypoactive delirium, all of which may be mistaken for depression. Particularly when delirium is the differential diagnosis, laboratory testing should include a complete blood count; liver, thyroid, and kidney function tests; serum calcium; urinalysis; and electrocardiogram.

▶ Treatment

Choice of antidepressant agent in elders is usually based on side effect profile and cost. Citalopram and sertraline are often used as first-line agents because of their low side-effect profiles. In general, fluoxetine is avoided because of its long duration of action and tricyclic antidepressants are avoided because of their high anticholinergic side effects. Mirtazapine is often used for patients with weight loss, anorexia, or insomnia. Venlafaxine can be useful in patients who also have neuropathic pain. Regardless of the drug chosen, many experts recommend starting elders at a relatively low dose, titrating to full dose slowly, and continuing for a longer trial (at least 9 weeks) before trying a different medication. Problem-solving therapy and cognitive behavioral therapy can be effective alone or in combination with medication therapy. Depressed elders may do better with a collaborative care model that includes socialization and other support elements than with usual care, and such models may also improve comorbid conditions. Recurrence of major depression is common in elders; any elder with a history of depression should be closely monitored for recurrence and considered for longer-term maintenance medication therapy.

▶ When to Refer

Referral should be considered for patients who have not responded to an initial antidepressant drug trial and for patients with symptoms of mania, suicidality, or psychosis.

▶ When to Admit

Patients who are suicidal, homicidal, psychotic, or a danger to self or others should be considered for acute psychiatric hospitalization.

3. Delirium

ESSENTIALS OF DIAGNOSIS

- ▶ Rapid onset and fluctuating course.
- ▶ Primary deficit in attention rather than memory.
- ▶ May be hypoactive or hyperactive.
- ▶ Dementia frequently coexists.

▶ General Considerations

Delirium is an acute, fluctuating disturbance of consciousness, associated with a change in cognition or the development of perceptual disturbances (see also Chapter 25). It is the pathophysiologic consequence of an underlying general medical condition such as infection, coronary ischemia, hypoxemia, or metabolic derangement. Delirium persists in up to 25% of patients and is associated with worse clinical outcomes (higher in-hospital and postdischarge mortality, longer lengths of stay, greater probability of placement in a nursing facility).

Although the acutely agitated elderly patient often comes to mind when considering delirium, many episodes are more subtle. Such quiet, or hypoactive, delirium may only be suspected if one notices new cognitive slowing or inattention.

Cognitive impairment is an important risk factor for delirium. Approximately 25% of delirious patients are demented, and 40% of demented hospitalized patients are delirious. Other risk factors are male sex, severe illness, hip fracture, fever or hypothermia, hypotension, malnutrition, polypharmacy and use of psychoactive medications, sensory impairment, use of restraints, use of intravenous lines or urinary catheters, metabolic disorders, depression, and alcoholism.

▶ Clinical Findings

A number of bedside instruments for the assessment of delirium are available. The confusion assessment method (CAM), which requires (1) acute onset and fluctuating course and (2) inattention and *either* (3) disorganized thinking *or* (4) altered level of consciousness, is easy to administer and performs well.

A key component of a delirium work-up is review of medications because a large number of drugs, the addition of a new drug, or the discontinuation of a medication known to cause withdrawal symptoms are all associated with the development of delirium. Medications that are particularly likely to increase the risk of delirium include opioids, benzodiazepines, dihydropyridines, and antihistamines.

Laboratory evaluation of most patients should include a complete blood count, electrolytes, blood urea nitrogen (BUN) and serum creatinine, glucose, calcium, albumin, liver function studies, urinalysis, and electrocardiography.

In selected cases, serum magnesium, serum drug levels, arterial blood gas measurements, blood cultures, chest radiography, urinary toxin screen, head CT scan, and lumbar puncture may be helpful.

▶ Prevention

Prevention is the best approach in the management of delirium. Measures include improving cognition (frequent reorientation, activities, socialization with family and friends, when possible), sleep (massage, noise reduction, minimizing interruptions at night), mobility, vision (visual aids and adaptive equipment), hearing (portable amplifiers, cerumen disimpaction), and hydration status (volume repletion). No medications have been consistently shown to prevent delirium or reduce its duration or severity.

▶ Treatment

Management of established episodes of delirium is largely supportive and includes reassurance and reorientation, treatment of underlying causes, eliminating unnecessary medications, and avoidance of indwelling catheters and restraints. Antipsychotic agents (such as haloperidol, 0.5–1 mg, or quetiapine, 25 mg, at bedtime or twice daily) are considered the medication of choice when drug treatment of delirium is necessary. Other medications (eg, trazodone, acetylcholinesterase inhibitors, and mood stabilizers) have also been used, but evidence in support of these approaches is weak. In ventilated patients in the intensive care unit setting, dexmedetomidine or propofol (or both) may also be useful alternatives or adjuncts to antipsychotic therapy in patients with delirium.

Most episodes of delirium clear in a matter of days after correction of the precipitant, but some patients suffer episodes of longer duration, and a few never return to their former baseline level of functioning. These individuals merit closer follow-up for the development of dementia if not already diagnosed.

▶ When to Refer

If an initial evaluation does not reveal the cause of delirium or if entities other than delirium are in the differential diagnosis, referral to a neuropsychologist, neurologist, or geropsychiatrist should be considered.

▶ When to Admit

Patients with delirium of unknown cause should be admitted for an expedited work-up if consistent with the patient's goals of care.

Wong CL et al. Does this patient have delirium? Value of bedside instruments. *JAMA*. 2010 Aug 18;304 (7):779–86. [PMID: 20716741]

4. Immobility

Although common in older people, reduced mobility is never normal and is often treatable if its causes are identified. Bed rest is an important cause of hospital-induced functional decline. Among hospitalized medical patients over 70, about 10% experience a decline in function, much of which results from preventable reductions in mobility.

The hazards of bed rest in older adults are multiple, serious, quick to develop, and slow to reverse. Deconditioning of the cardiovascular system occurs within days and involves fluid shifts, decreased cardiac output, decreased peak oxygen uptake, and increased resting heart rate. More striking changes occur in skeletal muscle, with loss of contractile velocity and strength. Pressure sores, deep venous thrombosis, and pulmonary embolism are additional serious risks. Within days after being confined to bed, the risk of postural hypotension, falls, and skin breakdown rises rapidly in the older patient. Moreover, recovery from these changes usually takes weeks to months.

► Prevention & Treatment

When immobilization cannot be avoided, several measures can be used to minimize its consequences. Skin, particularly areas over pressure points, should be inspected at least daily. If the patient is unable to shift position, staff should do so every 2 hours. To minimize cardiovascular deconditioning, patients should be positioned as close to the upright position as possible, several times daily. To reduce the risks of contracture and weakness, range of motion and strengthening exercises should be started immediately and continued as long as the patient is in bed. Whenever possible, patients should assist with their own positioning, transferring, and self-care. As long as the patient remains immobilized, antithrombotic measures should be used if that is consistent with the patient's goals of care.

Avoiding restraints and discontinuing invasive devices (intravenous lines, urinary catheters) may increase an elderly patient's prospects for early mobility. Graduated ambulation should begin as soon as it is feasible. Advice from a physical therapist is often helpful both before and after discharge. Prior to discharge, physical therapists can recommend appropriate exercises and assistive devices; after discharge, they can recommend safety modifications and maintenance exercises.

Covinsky KE et al. Hospitalization-associated disability: "She was probably able to ambulate, but I'm not sure". *JAMA*. 2011 Oct 26;306(16):1782-93. [PMID: 22028354]

5. Falls & Gait Disorders

About one-third of people over age 65 fall each year, and the frequency of falls increases markedly with advancing age. About 10% of falls result in serious injuries such as fractures, soft tissue injuries, and traumatic brain injuries. Complications from falls are the leading cause of death from injury in persons over age 65. Hip fractures are common precursors to functional impairment, nursing home

placement, and death. Furthermore, fear of falling may lead some elders to restrict their activities.

Every older person should be asked about falls; many will not volunteer such information. Assessment of patients who fall should include postural blood pressure and pulse, thorough cardiac examination, evaluations of strength, range of motion, cognition, and proprioception, and examination of feet and footwear. A thorough gait assessment should be performed in all older people. Gait and balance can be readily assessed by the "Up and Go Test," in which the patient is asked to stand up from a sitting position without use of hands, walk 10 feet, turn around, walk back, and sit down. Patients who take < 10 seconds are usually normal, patients who take longer than 30 seconds tend to need assistance with many mobility tasks, and those in between tend to vary widely with respect to gait, balance, and function. The ability to recognize common patterns of gait disorders is an extremely useful clinical skill to develop. Examples of gait abnormalities and their causes are listed in Table 4-3.

► Causes of Falls

Balance and ambulation require a complex interplay of cognitive, neuromuscular, and cardiovascular function. With age, balance mechanisms can become compromised and postural sway increases. These changes predispose the older person to a fall when challenged by an additional insult to any of these systems.

A fall may be the clinical manifestation of an occult problem, such as pneumonia or myocardial infarction, but much more commonly falls are due to the interaction between an impaired patient and an environmental risk factor. Falls in older people are rarely due to a single cause, and effective intervention entails a comprehensive assessment of the patient's intrinsic deficits (usually diseases and medications), the activity engaged in at the time of the fall, and environmental obstacles.

Intrinsic deficits are those that impair sensory input, judgment, blood pressure regulation, reaction time, and balance and gait. Dizziness may be closely related to the deficits associated with falls and gait abnormalities. While it may be impossible to isolate a sole "cause" or a "cure" for falls, gait abnormalities, or dizziness, it is often possible to identify and ameliorate some of the underlying contributory conditions and improve the patient's overall function.

As for most geriatric conditions, medication use is one of the most common, significant, and reversible causes of falling. A meta-analysis found that sedative/hypnotics, antidepressants, and benzodiazepines were the classes of drugs most likely to be associated with falling. The use of multiple medications simultaneously has also been associated with an increased fall risk. Other often overlooked but treatable contributors include postural hypotension (including postprandial, which peaks 30-60 minutes after a meal), insomnia, use of multifocal lenses, and urinary urgency.

Since most falls occur in or around the home, a visit by a visiting nurse, physical therapist, or health care provider reaps substantial benefits in identifying environmental obstacles and is generally reimbursed by third-party payers, including Medicare.

Table 4-3. Evaluation of gait abnormalities.

Gait Abnormality	Possible Cause
Inability to stand without use of hands	Deconditioning Myopathy (hyperthyroidism, alcohol, statin-induced) Hip or knee pain
Unsteadiness upon standing	Orthostatic hypotension Balance problem (peripheral neuropathy, vision problem, vestibular, other central nervous system causes) Generalized weakness
Stagger with eyes closed	Often indicates that vision is compensating for another deficit
Short steps	Weakness Parkinson disease or related condition
Asymmetry	Cerebrovascular accident Focal pain or arthritis
Wide-based gait	Fear, balance problems
Flexed knees	Contractures, quadriceps weakness
Slow gait	Fear of falling, weakness, deconditioning, peripheral vascular disease, chronic obstructive pulmonary disease, congestive heart failure, angina pectoris

► Complications of Falls

The most common fractures resulting from falls are of the wrist, hip, and vertebrae. There is a high mortality rate (approximately 20% in 1 year) in elderly women with hip fractures, particularly if they were debilitated prior to the time of the fracture.

Fear of falling again is a common, serious, but treatable factor in the elderly person's loss of confidence and independence. Referral to a physical therapist for gait training with special devices is often all that is required.

Chronic subdural hematoma is an easily overlooked complication of falls that must be considered in any elderly patient presenting with new neurologic symptoms or signs. Headache or known history of trauma may both be absent.

Patients who are unable to get up from a fall are at risk for dehydration, electrolyte imbalance, pressure sores, rhabdomyolysis, and hypothermia.

► Prevention & Management

The risk of falling and consequent injury, disability, and potential institutionalization can be reduced by modifying those factors outlined in Table 4-4. Emphasis is placed on treating all contributory medical conditions (eg, cataracts), minimizing environmental hazards, and eliminating medications where the harms may outweigh the benefits—particularly those that induce orthostasis and parkinsonism (eg, α -blockers, nitrates, antipsychotics). Also important are strength, balance, and gait training as well as screening and treatment for osteoporosis, if present. Falls and fractures may be prevented by prescribing vitamin D at a dose of 800 international units daily or higher.

Assistive devices, such as canes and walkers, are useful for many older adults but are often used incorrectly. Canes should be used on the “good” side. The height of walkers and canes should generally be about the level of the wrist. Physical therapists are invaluable in assessing the need for

an assistive device, selecting the best device, and training a patient in its correct use.

Early surgery for patients with cataracts may reduce falls, but eyeglasses, particularly bifocal or graduated lenses, may actually increase the risk of falls, particularly in the early weeks of use. Patients should be counseled about the need to take extra care when new eyeglasses are being used (eg, to look down to use the lens above the bifocal when going up or down stairs).

Patients with repeated falls are often reassured by the availability of phones at floor level, a portable phone, or a lightweight radio call system. Their therapy should also include training in techniques for arising after a fall. The clinical utility of anatomically designed external hip protectors in reducing fractures is currently uncertain.

► When to Refer

Patients with a recent history of falls should be referred for physical therapy, eye examination, and home safety evaluation.

► When to Admit

If the patient has new falls that are unexplained, particularly in combination with a change in the physical examination, hospitalization should be considered.

Table 4-4. Fall risk factors and targeted interventions and best evidence for fall prevention.

Risk Factor	Targeted Intervention
Postural hypotension (> 20 mm Hg drop in systolic blood pressure, or systolic blood pressure < 90 mm Hg)	Behavioral recommendations, such as hand clenching, elevation of head of bed; discontinuation or substitution of high-risk medications
Use of benzodiazepine or sedative-hypnotic agent	Education about sleep hygiene; discontinuation or substitution of medications
Use of multiple prescription medications	Review of medications
Environmental hazards	Appropriate changes; installation of safety equipment (eg, grab bars)
Gait impairment	Gait training, assistive devices, balance or strengthening exercises
Impairment in transfer or balance	Balance exercises, training in transfers, environmental alterations (eg, grab bars)
Impairment in leg or arm muscle strength or limb range of motion	Exercise with resistance bands or putty, with graduated increases in resistance
Best Evidence for Fall Prevention ¹	Number of Trials and Risk Ratios
Exercise or physical therapy	16 randomized controlled trials Risk ratio for falls 0.87 (confidence interval 0.81-0.94)
Vitamin D supplementation	9 randomized controlled trials Risk ratio for falls 0.83 (confidence interval 0.77-0.89)
Multifactorial Intervention	19 randomized controlled trials Risk ratio for falls 0.94 (confidence interval 0.87-1.02)

¹Adapted, with permission, from Michael YL et al. Primary care-relevant interventions to prevent falling in older adults: a systematic evidence review for the U.S. Preventive Services Task Force. *Ann Intern Med.* 2010 Dec 21;153(12):815-25. [PMID: 21173416]

6. Urinary Incontinence

ESSENTIALS OF DIAGNOSIS

- ▶ Involuntary loss of urine.
- ▶ *Stress* incontinence: leakage of urine upon coughing, sneezing, or standing.
- ▶ *Urge* incontinence: urgency and inability to delay urination.
- ▶ *Overflow* incontinence: may have variable presentation.

▶ General Considerations

Incontinence in older adults is common, and interventions can improve most patients. Many patients fail to tell their providers about it. A simple question about involuntary leakage of urine is a reasonable screen: “Do you have a problem with urine leaks or accidents?”

▶ Classification

Because continence requires adequate mobility, mentation, motivation, and manual dexterity, problems outside the bladder often result in incontinence. In general, the authors of this chapter find it useful to differentiate between “transient” or “potentially reversible” causes of incontinence and more “established” causes.

A. Transient Causes

Use of the mnemonic “DIAPPERS” may be helpful in remembering the categories of transient incontinence.

1. Delirium—A clouded sensorium impedes recognition of both the need to void and the location of the nearest toilet. Delirium is the most common cause of incontinence in hospitalized patients; once it clears, incontinence usually resolves.

2. Infection—Symptomatic urinary tract infection commonly causes or contributes to urgency and incontinence. Asymptomatic bacteriuria does not.

3. Atrophic urethritis or vaginitis—Atrophic urethritis can usually be diagnosed presumptively by the presence of vaginal mucosal telangiectasia, petechiae, erosions, erythema, or friability. Urethral inflammation, if symptomatic, may contribute to incontinence in some women. Some experts suggest a trial of topical estrogen in these cases.

4. Pharmaceuticals—Drugs are one of the most common causes of transient incontinence. Typical offending agents include potent diuretics, anticholinergics, psychotropics, opioid analgesics, α -blockers (in women), α -agonists (in men), and calcium channel blockers.

5. Psychological factors—Severe depression with psychomotor retardation may impede the ability or motivation to reach a toilet.

6. Excess urinary output—Excess urinary output may overwhelm the ability of an older person to reach a toilet in time. In addition to diuretics, common causes include excess

fluid intake; metabolic abnormalities (eg, hyperglycemia, hypercalcemia, diabetes insipidus); and disorders associated with peripheral edema, with its associated heavy nocturia when previously dependent legs assume a horizontal position in bed.

7. Restricted mobility—(See Immobility section, above.) If mobility cannot be improved, access to a urinal or commode (eg, at the bedside) may improve continence.

8. Stool impaction—This is a common cause of urinary incontinence in hospitalized or immobile patients. Although the mechanism is still unknown, a clinical clue to its presence is the onset of both urinary and fecal incontinence. Disimpaction usually restores urinary continence.

B. Established Causes

Causes of established incontinence should be addressed after the transient causes have been uncovered and managed appropriately. Risk factors for incontinence include older age, female sex, increased body mass index, and limited physical activity.

1. Detrusor overactivity (urge incontinence)—Detrusor overactivity refers to uninhibited bladder contractions that cause leakage. It is the most common cause of established geriatric incontinence, accounting for two-thirds of cases, and is usually idiopathic. Women will complain of urinary leakage after the onset of an intense urge to urinate that cannot be forestalled. In men, the symptoms are similar, but detrusor overactivity commonly coexists with urethral obstruction from benign prostatic hyperplasia. Because detrusor overactivity also may be due to bladder stones or tumor, the abrupt onset of otherwise unexplained urge incontinence—especially if accompanied by perineal or suprapubic discomfort or sterile hematuria—should be investigated by cystoscopy and cytologic examination of a urine specimen.

2. Urethral incompetence (stress incontinence)—Urethral incompetence is the second most common cause of established urinary incontinence in older women. Stress incontinence is most commonly seen in men after radical prostatectomy. Stress incontinence is characterized by instantaneous leakage of urine in response to a stress maneuver. It commonly coexists with detrusor overactivity. Typically, urinary loss occurs with laughing, coughing, or lifting heavy objects. Leakage is worse or occurs only during the day, unless another abnormality (eg, detrusor overactivity) is also present. To test for stress incontinence, have the patient relax her perineum and cough vigorously (a single cough) while standing with a full bladder. Instantaneous leakage indicates stress incontinence if urinary retention has been excluded by postvoiding residual determination using ultrasound. A delay of several seconds or persistent leakage suggests that the problem is instead caused by an uninhibited bladder contraction induced by coughing.

3. Urethral obstruction—Urethral obstruction (due to prostatic enlargement, urethral stricture, bladder neck contracture, or prostatic cancer) is a common cause of established incontinence in older men but is rare in older women.

It can present as dribbling incontinence after voiding, urge incontinence due to detrusor overactivity (which coexists in two-thirds of cases), or overflow incontinence due to urinary retention. Renal ultrasound is required to exclude hydronephrosis in men whose postvoiding residual urine exceeds 150 mL.

4. Detrusor underactivity (overflow incontinence)—Detrusor underactivity is the least common cause of incontinence. It may be idiopathic or due to sacral lower motor nerve dysfunction. When it causes incontinence, detrusor underactivity is associated with urinary frequency, nocturia, and frequent leakage of small amounts. The elevated postvoiding residual urine (generally over 450 mL) distinguishes it from detrusor overactivity and stress incontinence, but only urodynamic testing differentiates it from urethral obstruction in men. Such testing usually is not required in women, in whom obstruction is rarely present.

► Treatment

A. Transient Causes

Each identified transient cause should be treated regardless of whether an established cause coexists. For patients with urinary retention induced by an anticholinergic agent, discontinuation of the drug should first be considered. If this is not feasible, substituting a less anticholinergic agent may be useful.

B. Established Causes

1. Detrusor overactivity—The cornerstone of treatment is bladder training. Patients start by voiding on a schedule based on the shortest interval recorded on a bladder record. They then gradually lengthen the interval between voids by 30 minutes each week using relaxation techniques to postpone the urge to void. Lifestyle modifications, including weight loss and caffeine reduction, may also improve incontinence symptoms. For cognitively impaired patients and nursing home residents who are unable to manage on their own, timed and prompted voiding initiated by caregivers is effective.

Pelvic floor muscle (“Kegel”) exercises, with or without biofeedback, can reduce the frequency of incontinence episodes when performed correctly and sustained. If behavioral approaches prove insufficient, drug therapy with antimuscarinic agents may provide additional benefit. The two oral drugs for which there is the most experience are tolterodine and oxybutynin. Available regimens of these drugs follow: short-acting tolterodine, 1–2 mg twice a day; long-acting tolterodine, 2–4 mg daily; short-acting oxybutynin, 2.5–5 mg twice or three times a day; long-acting oxybutynin, 5–15 mg daily; and oxybutynin transdermal patch, 3.9 mg per day applied twice weekly. All of these agents can produce delirium, dry mouth, or urinary retention; long-acting preparations may be better tolerated. Agents such as fesoterodine (4–8 mg orally once daily), trospium chloride (20 mg orally once or twice daily), darifenacin (7.5–15 mg orally daily), and solifenacin (5–10 mg orally daily)

appear to have similar efficacy and have not been clearly demonstrated to be better tolerated than the older agents in long-acting form.

The combination of behavioral therapy and antimuscarinics appears to be more effective than either alone although one study in a group of younger women showed that adding behavioral therapy to individually titrated doses of extended-release oxybutynin was no better than drug treatment alone.

In men with both benign prostatic hyperplasia and detrusor overactivity and who have postvoid residual volumes of 150 mL or less, an antimuscarinic agent added to an α -blocker may provide additional relief of lower urinary tract symptoms.

2. Urethral incompetence (stress incontinence)—

Lifestyle modifications, including limiting caffeine intake and timed voiding, may be helpful for some women, particularly women with mixed stress/urge incontinence. Pelvic floor muscle exercises are effective for women with mild to moderate stress incontinence; the exercises can be combined, if necessary, with biofeedback, electrical stimulation, or vaginal cones. Instruct the patient to pull in the pelvic floor muscles and hold for 6–10 seconds and to perform three sets of 8–12 contractions daily. Benefits may not be seen for 6 weeks. Pessaries or vaginal cones may be helpful in some women but should be prescribed by providers who are experienced with using these modalities.

Although a last resort, surgery is the most effective treatment for stress incontinence, resulting in a cure rate as high as 96% even in older women. Drug therapy is limited. Clinical trials have shown that duloxetine, a serotonin and norepinephrine reuptake inhibitor, reduces stress incontinence episodes in women but efficacy in older women remains unknown. It is approved for use for this indication in some countries but not the United States. Side effects, including nausea, are common.

3. Urethral obstruction—Surgical decompression is the most effective treatment for obstruction, especially in the setting of urinary retention due to benign prostatic hyperplasia. A variety of less invasive techniques make decompression feasible even for frail men. For the nonoperative candidate with urinary retention, intermittent or indwelling catheterization is used. For a man with prostatic obstruction who does not require or desire immediate surgery, treatment with α -blocking agents (eg, terazosin, 1–10 mg daily; prazosin, 1–5 mg orally twice daily; tamsulosin, 0.4–0.8 mg daily) can improve symptoms and delay obstruction. Finasteride, 5 mg daily, can provide additional benefit to an α -blocking agent in men with an enlarged prostate.

4. Detrusor underactivity—For the patient with a poorly contractile bladder, augmented voiding techniques (eg, double voiding, suprapubic pressure) often prove effective. If further emptying is needed, intermittent or indwelling catheterization is the only option. Antibiotics should be used only for symptomatic upper urinary tract infection or as prophylaxis against recurrent symptomatic infections in a patient using intermittent catheterization; they should not be used as prophylaxis with an indwelling catheter.

► When to Refer

- Men with urinary obstruction who do not respond to medical therapy should be referred to a urologist.
- Women who do not respond to medical and behavioral therapy should be referred to a urogynecologist or urologist.

Goode PS et al. Incontinence in older women. *JAMA*. 2010 Jun 2;303(21):2172–81. [PMID: 20516418]

7. Undernutrition & Frailty

► General Considerations

Undernutrition affects substantial numbers of elderly. The degree of unintended weight loss that deserves evaluation is not agreed upon, although a reasonable threshold is loss of 5% of body weight in 1 month or 10% of body weight in 6 months.

“Frailty” is a term that may be clinically useful for describing a subgroup of patients—almost always elders—who have delicate health, are not robust, and have decreased functional reserve. Although clinicians generally agree on most of the clinical characteristics that define the frailty syndrome, there is not yet a consensus definition of frailty. Frailty may be accompanied by physiologic changes in inflammatory and neuroendocrine systems. The label of “failure to thrive” is typically applied when some triggering event—loss of social support, a bout of depression or pneumonia, the addition of a new medication—pulls a struggling elderly person below the threshold of successful independent living.

► Clinical Findings

Useful laboratory and radiologic studies for the patient with weight loss include complete blood count, serum chemistries (including glucose, TSH, creatinine, calcium), urinalysis, and chest radiograph. These studies are intended to uncover an occult metabolic or neoplastic cause but are not exhaustive. Exploring the patient’s social situation, cognition, mood, and dental health are at least as important as looking for a purely medical cause of weight loss.

There is not yet a standard assessment tool for frailty. However, the most widely recognized definition of frailty requires that the patient exhibit at least three of the five following clinical criteria: (1) slow gait speed; (2) low hand grip strength; (3) exhaustion; (4) weight loss; and (5) low energy expenditure. Few physicians screen for the syndrome, since an evidence-based treatment for frailty does not yet exist. Patients who meet criteria for the frailty syndrome are at increased risk for poor clinical outcomes.

► Treatment

Oral nutritional supplements of 200–1000 kcal/d can increase weight and improve outcomes in malnourished hospitalized elders. Megestrol acetate as an appetite stimulant has not been shown to increase body mass or lengthen life in the elderly population. For those who have lost the ability to feed themselves, assiduous hand feeding may allow maintenance of weight. Although artificial nutrition and hydration (“tube feeding”) may seem a more convenient alternative, it deprives the patient of the taste and texture of food as well as the social milieu typically associated with mealtime; before this option is chosen, the patient or his or her surrogate should be offered the opportunity to review the benefits and burdens of the treatment in light of overall goals of care. If the patient makes repeated attempts to pull out the tube during a trial of artificial nutrition, the treatment burden becomes substantial, and the utility of tube feeding should be reconsidered. Although commonly used, there is no evidence that tube feeding prolongs life in patients with end-stage dementia.

The ideal strategies for preventing the frailty syndrome are unknown. At present, treatment is largely supportive, multifactorial, and individualized based on patient goals, life expectancy, and comorbidities. Sometimes, transitioning a patient to a palliative approach or a hospice program is the most appropriate clinical intervention when efforts to prevent functional decline fail.

8. Pressure Ulcers

ESSENTIALS OF DIAGNOSIS

- Examine at-risk patients on admission to hospital and daily thereafter.
- Pressure ulcers should be described by one of six stages:
 - Blanchable hyperemia (stage I).
 - Extension through epidermis (stage II).
 - Full thickness skin loss (stage III).
 - Full thickness wounds with extension into muscle, bone, or supporting structures (stage IV).
 - If eschar or slough overlies the wound, the wound is unstageable.
 - Suspected deep tissue injury is an area of discolored or blistered skin.

► General Considerations

The majority of pressure ulcers develop during a hospital stay for an acute illness. Incident rates range from 3% to 30% and vary according to patient characteristics. The primary risk factor for pressure ulcers is immobility. Other contributing risk factors include reduced sensory perception, moisture (urinary and fecal incontinence), poor nutritional status, and friction and shear forces.

In 2007, the National Pressure Ulcer Advisory Panel added two stages to the original four pressure ulcer stages: suspected deep tissue injury and unstageable. Ulcers in which the base is covered by slough (yellow, tan, gray, green or brown) and/or eschar (tan, brown or black) are considered unstageable. Suspected deep tissue injury is an area of purple or maroon discolored intact skin or blood-filled blister. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer or cooler compared with adjacent tissue.

A number of risk assessment instruments including the Braden Scale and the Norton score can be used to assess the risk of developing pressure ulcers; both have reasonable performance characteristics. These instruments can be used to identify the highest risk patients who might benefit most from scarce resources such as mattresses that reduce or relieve pressure.

As of October 2008, Medicare will no longer reimburse for hospital-acquired pressure ulcers. Pressure ulcers present on admission will qualify for a higher reimbursement. The medical record must contain documentation of pressure ulcers present on admission, and coders are required to use physician documentation as the basis for coding and reporting; therefore, physicians should include a full skin assessment on every admission history and physical.

► Prevention

Using specialized support surfaces (including mattresses, beds, and cushions), patient repositioning, optimizing nutritional status, and moisturizing sacral skin are strategies that have been shown to reduce pressure ulcers. For moderate- to high-risk patients, mattresses or overlays that reduce tissue pressure below a standard mattress appear to be superior to standard mattresses. The literature comparing specific products is sparse and inconclusive.

► Evaluation

Evaluation of pressure ulcers should include patient’s risk factors and goals of care, wound stage, size, depth, presence or absence of exudate, type of exudate present, appearance of the wound bed, and whether there appears to be surrounding infection, sinus tracking, or cellulitis. In poorly healing or atypical pressure ulcers, biopsy should be performed to rule out malignancy or other less common lesions such as pyoderma gangrenosum.

► Treatment

Treatment is aimed toward removing necrotic debris and maintaining a moist wound bed that will promote healing and formation of granulation tissue. The type of dressing that is recommended depends on the location and depth of

Table 4-5. Treatment of pressure ulcers.

Ulcer Type	Dressing Type and Considerations
Stage I and suspected deep tissue injury	Polyurethane film Hydrocolloid wafer Semipermeable foam dressing
Stage II	Hydrocolloid wafers Semipermeable foam dressing Polyurethane film
Stage III/IV	For highly exudative wounds , use highly absorptive dressing or packing, such as calcium alginate Wounds with necrotic debris must be debrided Debridement can be autolytic, mechanical (wet to moist), or surgical Shallow, clean wounds can be dressed with hydrocolloid wafers, semipermeable foam, or polyurethane film Deep wounds can be packed with gauze; if the wound is deep and highly exudative, an absorptive packing should be used
Heel ulcer	Do not remove eschar on heel ulcers because it can help promote healing (eschar in other locations should be debrided)
Unstageable	Debride before deciding on further therapy

the wound, whether necrotic tissue or dead space is present, and the amount of exudate (Table 4-5). Pressure-reducing devices (eg, air-fluid beds and low air loss beds) are associated with improved healing rates. Although poor nutritional status is a risk factor for the development of pressure ulcers, the results of trials of nutritional supplementation in the treatment of pressure ulcers have been disappointing.

Providers can become easily overwhelmed by the array of products available for treatment of established pressure ulcers. Most institutions should designate a wound care expert or wound care team to select a streamlined wound care product line that has simple guidelines. In a patient with end-stage disease who is receiving palliative care, appropriate treatment might be directed toward comfort (including minimizing dressing changes and odors) rather than efforts directed at healing.

► Complications

Pressure ulcers are associated with increased mortality rates, although a causal link has not been proven. Complications include pain, cellulitis, osteomyelitis, systemic sepsis, and prolongation of lengths of stay in the inpatient or nursing home setting.

► When to Refer

Ulcers that are large or nonhealing should be referred to a plastic or general surgeon or dermatologist for biopsy, debridement, and possible skin grafting.

► When to Admit

Patients with pressure ulcers should be admitted if the primary residence is unable to provide adequate wound care or pressure reduction, if the wound is infected, or for complex or surgical wound care.

9. Pharmacotherapy & Polypharmacy

There are several reasons for the greater incidence of iatrogenic drug reactions in the elderly population, the most important of which is the high number of medications that elders take. Drug metabolism is often impaired in this group due to a decrease in glomerular filtration rate as well as reduced hepatic clearance. The latter is due to decreased activity of microsomal enzymes and reduced hepatic perfusion with aging. The volume of distribution of drugs is also affected. Since older adults have a decrease in total body water and a relative increase in body fat, water-soluble drugs become more concentrated and fat-soluble drugs have longer half-lives. Older individuals often have varying responses to a given serum drug level. Thus, they are more sensitive to some drugs (eg, opioids) and less sensitive to others (eg, β -blocking agents). Most emergency hospitalizations for recognized adverse drug events among older persons result from a only a few medications used alone or in combination; examples include warfarin, antiplatelet agents, insulins, oral hypoglycemic agents, and to a lesser extent, opioid analgesics and digoxin.

► Precautions in Administering Drugs

Nonpharmacologic interventions can often be a first-line alternative to drugs (eg, diet for mild hypertension or type 2 diabetes mellitus). Therapy is begun with less than the usual adult dosage and the dosage increased slowly, consistent with its pharmacokinetics in older patients. However, age-related changes in drug distribution and clearance are variable among individuals, and some require full doses. After determining acceptable measures of success and toxicity, the dose is increased until one or the other is reached.

Despite the importance of beginning new drugs in a slow, measured fashion, all too often an inadequate trial is attempted (in terms of duration or dose) before discontinuation. Antidepressants, in particular, are frequently stopped before therapeutic dosages are reached.

A number of simple interventions can help improve adherence to the prescribed medical regimen. When possible, the provider should keep the dosing schedule simple,

the number of pills low, the medication changes as infrequent as possible, and encourage the patient to use a single pharmacy. Pillboxes or “medi-sets” help some patients with adherence.

Having the patient or caregiver bring in all medications at each visit can help the provider perform medication reconciliation and reinforce reasons for drug use, dosage, frequency of administration, and possible adverse effects. Medication reconciliation is particularly important if the patient sees multiple providers.

Although serum drug levels may be useful for monitoring certain drugs with narrow therapeutic windows (eg, digoxin), toxicity can still occur even with “normal” therapeutic levels of many drugs. The risk of toxicity goes up with the number of medications prescribed. Certain combinations of medications (eg, warfarin and many types of antibiotics, digoxin and clarithromycin, angiotensin-converting enzyme inhibitors and NSAIDs) are particularly likely to cause drug-drug interactions, and should be watched carefully.

Trials of individual drug discontinuation should be considered (including sedative-hypnotics, antipsychotic medications, digoxin, proton pump inhibitors, NSAIDs) when the original indication is unclear, the goals of care have changed, or the patient might be experiencing side effects.

► When to Refer

Patients with poor or uncertain adherence may benefit from referral to a pharmacist or a home health nurse.

10. Vision Impairment

Although visual loss is not severe in many elders, visual impairment is an independent risk factor for falls; it also has a significant impact on quality of life. The prevalence of serious and correctable visual disorders in elders is sufficient to warrant a complete eye examination by an ophthalmologist or optometrist annually or biannually for most elders. Many patients with visual loss benefit from a referral to a low vision program, and primary care providers should not assume that an ophthalmologist or optometrist will automatically make this referral.

Rosenberg EA et al. The visually impaired patient. *Am Fam Physician.* 2008 May 15;77(10):1431–6. [PMID: 18533377]

11. Hearing Impairment

Over one-third of persons over age 65 and half of those over age 85 have some hearing loss. This deficit is correlated with

social isolation and depression. A reasonable screen is to ask patients if they have hearing impairment. Those who answer “yes” should be referred for audiometry. Those who answer “no” may still have hearing impairment and can be screened by a handheld audioscope or the whispered voice test. The whispered voice test is administered by standing 2 feet behind the subject, whispering three random numbers, and simultaneously rubbing the external auditory canal of the non-tested ear to mask the sound. If the patient is unable to identify all three numbers, the test should be repeated with different numbers, and if still abnormal, a referral should be made to audiometry. To determine the degree to which hearing impairment interferes with functioning, the provider may ask if the patient becomes frustrated when conversing with family members, is embarrassed when meeting new people, has difficulty watching TV, or has problems understanding conversations. Caregivers or family members often have important information on the impact of hearing loss on the patient’s social interactions.

Hearing amplification can improve hearing-related quality of life in patients with hearing loss. However, compliance with hearing amplification can be a challenge because of the stigma associated with hearing aid use as well as the cost of such devices, which are not paid for under most Medicare plans. Special telephones, amplifiers for the television, and many other devices are available to aid the person with hearing loss. Portable amplifiers are pager-sized units with earphones attached; they can be purchased inexpensively at many electronics stores and can be useful in health care settings for improving communication with hearing impaired patients. In general, facing the patient and speaking slowly in a low tone is a more effective communication strategy than yelling for patients with age-related hearing loss.

12. Elder Mistreatment & Self Neglect

Elder mistreatment is defined as “actions that cause harm or create a serious risk of harm to an older adult by a caregiver or other person who stands in a trust relationship to the older adult, or failure by a caregiver to satisfy the elder’s basic needs or to protect the elder from harm.” Self neglect is the most common form of elder mistreatment and occurs among all demographic strata of the aging population. According to the best available estimates, the prevalence of potential neglect and psychological and financial abuse, are each about 5%, with other forms of abuse being less common.

Clues to the possibility of elder abuse include behavioral changes in the presence of the caregiver, delays between occurrence of injuries and sought treatment, inconsistencies between an observed injury and associated explanation, lack of appropriate clothing or hygiene, and not filling prescriptions. Many elders with cognitive impairment become targets of financial abuse. Both elder

Table 4-6. Phrases and actions that may be helpful in situations of suspected abuse or neglect.

Questions for the Elder

1. Has anyone hurt you?
2. Are you afraid of anybody?
3. Is anyone taking or using your money without your permission?

Questions for the Caregiver

1. Are your dad's needs more than you can handle?
2. Are you worried that you might hit your dad?
3. Have you hit your dad?

If abuse is suspected

Tell the patient that you are concerned, want to help, and will call Adult Protective Services to see if there is anything that they can do to help

Document any injuries

Document the patient's words

Document whether or not the patient has decision making capacity using a tool such as Aid to Capacity Evaluation

abuse and self neglect are associated with an increased risk of mortality.

It is helpful to observe and talk with every older person alone for at least part of a visit in order to ask questions directly about possible abuse and neglect (Table 4-6). When self neglect is suspected, it is critical to establish whether a patient has decision making capacity in order to determine what course of action needs to be taken. A patient who has full decision making capacity should be provided with help and support but can choose to live in conditions of self neglect, providing that the public is not endangered by the actions of the person. In contrast, a patient who lacks decision making capacity who lives in conditions of self neglect will require more aggressive

intervention, which may include guardianship, in-home help, or placement in a supervised setting. Mental state scores, such as the MOCA or the Mini-Mental State Exam (MMSE), may provide some insight into the patient's cognitive status but are not designed to assess decision making capacity. A standardized tool, such as the "Aid to Capacity Evaluation," is easy to administer, has good performance characteristics for determining decision making capacity, and is available free online at www.jointcentreforbioethics.ca/tools/ace_download.shtml.

► When to Refer

The laws in most states require health care providers to report suspected abuse or neglect to Adult Protective Services; agencies are available in all 50 states to assist in cases of suspected elder abuse. The Web site for the National Center for Elder Abuse is <http://www.ncea.aoa.gov>. When it is unclear whether a patient has decision making capacity after an initial assessment, or whether an untreated mental health disorder is contributing to the problem, a referral to a mental health professional is appropriate.

► When to Admit

Hospital admission is appropriate when a patient is unsafe in the community and an alternate plan cannot be put into place in a timely manner.

Palliative Care & Pain Management

Michael W. Rabow, MD
Steven Z. Pantilat, MD

DEFINITION & SCOPE OF PALLIATIVE CARE

The focus of palliative care is to improve symptoms and quality of life at any stage of illness, utilizing the expertise of an interdisciplinary team. At the end of life, palliative care often becomes the only focus of care, but palliative care alongside cure-focused treatment is beneficial throughout the course of serious chronic and terminal illnesses, regardless of prognosis, whether the goal is to cure disease or manage chronic illness.

The World Health Organization defines palliative care as “an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual.” Palliative care commonly involves management of pain and other symptoms, including dyspnea, nausea and vomiting, constipation, and agitation; emotional distress, such as depression, anxiety, and interpersonal strain; and existential distress, such as spiritual crisis. While palliative care has been recognized formally as a medical subspecialty by the American Board of Medical Specialties and palliative care experts are increasingly available in hospital and outpatient settings, all clinicians should possess the basic skills to be able to manage pain; treat dyspnea; identify possible depression; communicate about important issues, such as prognosis and patient preferences for care; and help address spiritual distress. In 2011, the Joint Commission began offering advanced certification in palliative care to hospitals providing high quality palliative services.

Symptoms that cause significant suffering are a medical emergency that should be managed aggressively with frequent elicitation, continuous reassessment, and individualized treatment. While patients at the end of life may experience a host of distressing symptoms, pain, dyspnea, and delirium are among the most feared and burdensome. The palliation of these common symptoms is described later in this chapter. The principles of palliative care dictate that properly informed patients or their surrogates may decide to pursue aggressive symptom relief at the end of life even if, as a known but unintended consequence,

the treatments preclude further unwanted curative interventions or even hasten death. There is a growing awareness and data from a randomized trial that scrupulous symptom control for patients with end-stage illness may even prolong life.

Bakitas M et al. Effects of a palliative care intervention on clinical outcomes in patients with advanced cancer: the Project ENABLE II randomized controlled trial. *JAMA*. 2009 Aug 19;302(7):741–9. [PMID: 19690306]

PAIN MANAGEMENT

PRINCIPLES OF PAIN MANAGEMENT

The experience of pain includes the patient’s emotional reaction to it and is influenced by many factors, including the patient’s prior experiences with pain, meaning given to the pain, emotional stresses, and family and cultural influences. Pain is a subjective phenomenon, and clinicians cannot reliably detect its existence or quantify its severity without asking the patient directly. A useful means of assessing pain and evaluating the effectiveness of analgesia is to ask the patient to rate the degree of pain along a numeric or visual pain scale (Table 5–1).

General guidelines for management of pain are recommended for the treatment of all patients with pain (Table 5–2). Clinicians should ask about the nature, severity, timing, location, quality, and aggravating and relieving factors of the pain. Distinguishing between neuropathic and nociceptive (somatic or visceral) pain is essential to proper tailoring of pain treatments. The goal of pain management is properly decided by the patient. Some patients may wish to be completely free of pain even at the cost of significant sedation, while others will wish to control pain to a level that still allows maximal functioning.

Table 5-1. Pain assessment scales.

A. Numeric Rating Scale					
B. Numeric Rating Scale Translated into Word and Behavior Scales					
Pain intensity	Word scale	Nonverbal behaviors			
0	No pain	Relaxed, calm expression			
1-2	Least pain	Stressed, tense expression			
3-4	Mild pain	Guarded movement, grimacing			
5-6	Moderate pain	Moaning, restless			
7-8	Severe pain	Crying out			
9-10	Excruciating pain	Increased intensity of above			
C. Wong Baker FACES Pain Rating Scale ¹					
0 No hurt	1 Hurts Little Bit	2 Hurts Little More	3 Hurts Even More	4 Hurts Whole Lot	5 Hurts Worst

¹Especially useful for patients who cannot read English and for pediatric patients.

Reprinted, with permission, from Hockenberry M, Wilson D, Winkelstein ML. *Wong's Essentials of Pediatric Nursing*, ed. 8. Copyright © 2009, Mosby, St. Louis.

Chronic severe pain should be treated continuously. For ongoing pain, a long-acting analgesic can be given around the clock with a short-acting medication as needed for “breakthrough” pain. Whenever possible, the oral route of administration is preferred because it is easier to administer at home, is not painful, and imposes no risk from needle

exposure. Near the end of life, rectal, transdermal, subcutaneous, and intravenous administration are also frequently used; intrathecal administration is used when necessary (albeit rarely). Patient-controlled analgesia (PCA) of intravenous medications can achieve better analgesia faster with less medication use and its principles have been adapted for use with oral administration.

The underlying cause of pain should be diagnosed and treated, balancing the burden of diagnostic tests with the patient’s suffering. For example, radiation therapy for painful bone metastases or mechanical stents for obstructing lesions, may obviate the need for ongoing treatment with analgesics and their side effects. Regardless of decisions about seeking and treating the underlying cause of pain, every patient should be offered prompt relief.

Table 5-2. Recommended clinical approach to pain management.

Ask about pain regularly. Assess pain systematically (quality, description, location, intensity or severity, aggravating and ameliorating factors, cognitive responses). Ask about goals for pain control, management preferences.

Believe the patient and family in their reports of pain and what relieves it.

Choose pain control options appropriate for the patient, family, and setting. Consider drug type, dosage, route, contraindications, side effects. Consider nonpharmacologic adjunctive measures.

Deliver interventions in a timely, logical, coordinated manner.

Empower patients and their families. Enable patients to control their course to the greatest extent possible.

Follow up to reassess persistence of pain, changes in pain pattern, development of new pain.

Data from Jacox AK et al. *Management of Cancer Pain: Quick Reference Guide No. 9*. AHCPR Publication No. 94-0593. Rockville, MD: Agency for Health Care Policy and Research, Public Health Service, U.S. Department of Health and Human Services. March 1994.

PAIN AT THE END OF LIFE

▶ Definition & Prevalence

Pain is a common problem for patients at the end of life. Up to 75% of patients dying of cancer or other diseases experience pain, and up to 50% of severely ill hospitalized patients spent half of their time during the last 3 days of life in moderate to severe pain. Pain is what many people say they fear most about dying and is routinely undertreated. Joint Commission reviews of healthcare organizations now include pain management standards.

► Barriers to Good Care

Deficiencies in pain management at the end of life have been documented in many settings. Some clinicians refer pain management to others when they believe that a patient's pain is not due to the disease for which they are treating the patient. Even oncologists often misperceive the origin of their patients' pain and inappropriately ignore complaints of pain.

Many clinicians have limited training and clinical experience with pain management and thus are understandably reluctant to attempt to manage severe pain. Lack of knowledge about the proper selection and dosing of analgesic medications carries with it attendant and typically exaggerated fears about the side effects of pain medications, including the possibility of respiratory depression from opioids. Most clinicians, however, can develop good pain management skills, and nearly all pain, even at the end of life, can be managed without hastening death through respiratory depression. In rare instances, palliative sedation may be necessary to control intractable suffering as an intervention of last resort.

A misunderstanding of the physiologic effects of opioids can lead to unfounded concerns on the part of clinicians, patients, or family members that patients will become addicted to opioids. While physiologic **tolerance** (requiring increasing dosage to achieve the same analgesic effect) and **dependence** (requiring continued dosing to prevent symptoms of medication withdrawal) are expected with regular opioid use, the use of opioids at the end of life for relief of pain and dyspnea is not generally associated with a risk of psychological **addiction** (misuse of a substance for purposes other than one for which it was prescribed and despite negative consequences in health, employment, or legal and social spheres). The risk for problematic use of pain medications is higher, however, in patients with a history of addiction. Yet even patients with such a history need pain relief, albeit with closer monitoring. Some patients who demonstrate behaviors associated with addiction (demand for specific medications and doses, anger and irritability, poor cooperation or disturbed interpersonal reactions) may have **pseudo-addiction**, defined as exhibiting behaviors associated with addiction but only because their pain is inadequately treated. Once pain is relieved, these behaviors cease. In all cases, clinicians must be prepared to use appropriate doses of opioids in order to relieve distressing symptoms for patients at the end of life.

Some clinicians fear legal repercussions from prescribing the high doses of opioids sometimes necessary to control pain at the end of life. Some states have special training, licensing and documentation requirements for opioid prescribing. However, governmental and professional medical groups, regulators, and the US Supreme Court have made it clear that appropriate treatment of pain is the right of the patient and a fundamental responsibility of the clinician. In fact, clinicians have been successfully sued for undertreatment of pain. Although clinicians may feel trapped between consequences of over- or under-prescribing opioids, there remains a wide range

of practice in which clinicians can appropriately treat pain. Referral to pain or palliative care experts is appropriate whenever pain cannot be controlled expeditiously by the primary clinician.

PHARMACOLOGIC PAIN MANAGEMENT STRATEGIES

In general, pain can be well controlled with analgesic medications—both opioid and nonopioid—at any stage of illness. Evidence-based summaries and guidelines are available from the Agency for Healthcare Research and Quality (<http://www.ncbi.nlm.nih.gov/books/bv.fcgi?rid=hstat1.chapter.86205>) and other organizations (http://www.nccn.org/professionals/physician_gls/PDF/pain.pdf). For mild to moderate pain, acetaminophen, aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs) may be sufficient. For moderate to severe pain, these agents combined with opioids may be helpful.

► Acetaminophen & NSAIDs

Appropriate doses of acetaminophen may be just as effective an analgesic and antipyretic as NSAIDs but without the risk of gastrointestinal bleeding or ulceration. Acetaminophen can be given at a dosage of 500–1000 mg orally every 6 hours, although it can be taken every 4 hours as long as the risk of hepatotoxicity is kept in mind. Hepatotoxicity is of particular concern because of how commonly acetaminophen is also an ingredient in various over-the-counter medications. Total acetaminophen doses should not exceed 3–4 g/d long-term or 2 g/d for older patients and for those with liver disease.

Aspirin (325–650 mg orally every 4 hours) is an effective analgesic, antipyretic, and anti-inflammatory medication. Gastrointestinal irritation and bleeding are side effects that are lessened with enteric-coated formulations of aspirin and concomitant use of proton-pump inhibitor medication. Bleeding, allergy, and an association with Reye syndrome in children and teenagers further limit its use.

Commonly used NSAIDs and their dosages are listed in Table 5–3. Like aspirin, the NSAIDs are antipyretic, analgesic, and anti-inflammatory. NSAIDs increase the risk of gastrointestinal bleeding by 1.5 times normal. The risks of bleeding and nephrotoxicity from NSAIDs are both increased in elders. Gastrointestinal bleeding and ulceration may be prevented with the concurrent use of proton pump inhibitors (eg, omeprazole, 20–40 mg orally daily) or with the class of NSAIDs that inhibit only cyclooxygenase (COX)-2. Celecoxib (100 mg/d to 200 mg orally twice daily) is the only COX-2 inhibitor available and should be used with caution in patients with cardiac disease. The NSAIDs, including COX-2 inhibitors, can lead to fluid retention and exacerbations of congestive heart failure and should be used with caution in patients with that condition. Topical formulations of NSAIDs (such as diclofenac 1.3% patch or 1% gel), placed over the painful body part, result in lower systemic levels of the medication and may be associated with fewer side effects than oral administration.

Table 5-3. Acetaminophen, COX-2 inhibitors, and useful nonsteroidal anti-inflammatory drugs.

Drug	Usual Dose for Adults ≥ 50 kg	Usual Dose for Adults < 50 kg ¹	Cost per Unit	Cost for 30 Days ²	Comments ³
Acetaminophen ⁴ (Tylenol, Datril, etc)	650 mg every 4 hours or 975 mg every 6 hours	10-15 mg/kg every 4 hours (oral); 15-20 mg/kg every 4 hours (rectal)	\$0.02/325 mg (oral) OTC; \$0.71/650 mg (rectal) OTC	\$7.20 (oral); \$127.80 (rectal)	Not an NSAID because it lacks peripheral anti-inflammatory effects. Equivalent to aspirin as analgesic and antipyretic agent. Limit dose to 3-4 g/d and to 2 g/d in older patients and those with liver disease. Be mindful of multiple sources of acetaminophen as in combination analgesics, cold remedies and sleep aids.
Aspirin ⁵	650 mg every 4 hours or 975 mg every 6 hours	10-15 mg/kg every 4 hours (oral); 15-20 mg/kg every 4 hours (rectal)	\$0.02/325 mg OTC; \$1.51/600 mg (rectal) OTC	\$7.20 (oral); \$271.80 (rectal)	Available also in enteric-coated form that is more slowly absorbed but better tolerated.
Celecoxib ⁴ (Celebrex)	200 mg once daily (osteoarthritis); 100-200 mg twice daily (RA)	100 mg once or twice daily	\$3.21/100 mg; \$5.26/200 mg	\$157.80 OA; \$315.60 RA	Cyclooxygenase-2 inhibitor. No antiplatelet effects. Lower doses for elderly who weigh < 50 kg. Lower incidence of endoscopic gastrointestinal ulceration. Not known if true lower incidence of gastrointestinal bleeding. Possible link to cardiovascular toxicity. Celecoxib is contraindicated in sulfonamide allergy.
Choline magnesium salicylate ⁶ (Trilasate, others)	1000-1500 mg three times daily	25 mg/kg three times daily	\$0.46/500 mg	\$124.20	Salicylates cause less gastrointestinal distress and kidney impairment than NSAIDs but are probably less effective in pain management than NSAIDs.
Diclofenac (Voltaren, Cataflam, others)	50-75 mg orally two or three times daily; 1% gel 2-4 g four times daily; 1.3% patch two times daily		\$1.56/50 mg; \$1.77/75 mg	\$140.40; \$159.30	May impose higher risk of hepatotoxicity. Enteric-coated product; slow onset. Topical formulations may result in fewer side effects than oral formulations.
Diclofenac sustained release (Voltaren-XR, others)	100-200 mg once daily		\$2.81/100 mg	\$168.60	
Diflunisal ⁷ (Dolobid, others)	500 mg every 12 hours		\$1.55/500 mg	\$93.00	Fluorinated acetylsalicylic acid derivative.
Etodolac (Lodine, others)	200-400 mg every 6-8 hours		\$1.47/400 mg	\$176.40	
Fenoprofen calcium (Nalfon, others)	300-600 mg every 6 hours		\$1.78/600 mg	\$213.60	Perhaps more side effects than others, including tubulointerstitial nephritis.
Flurbiprofen (Ansaid)	50-100 mg three or four times daily		\$0.79/50 mg; \$1.19/100 mg	\$94.80; \$142.80	Adverse gastrointestinal effects may be more common among elderly.
Ibuprofen (Motrin, Advil, Rufen, others)	400-800 mg every 6 hours	10 mg/kg every 6-8 hours	\$0.28/600 mg Rx; \$0.05/200 mg OTC	\$33.60; \$9.00	Relatively well tolerated and inexpensive.
Indomethacin (Indocin, Indometh, others)	25-50 mg two to four times daily		\$0.38/25 mg; \$0.64/50 mg	\$45.60; \$76.80	Higher incidence of dose-related toxic effects, especially gastrointestinal and bone marrow effects.
Ketoprofen (Orudis, Oruvail, others)	25-75 mg every 6-8 hours (max 300 mg/d)		\$0.96/50 mg Rx; \$1.07/75 mg Rx; \$0.09/12.5 mg OTC	\$172.80; \$128.40; \$16.20	Lower doses for elderly.

(continued)

Table 5-3. Acetaminophen, COX-2 inhibitors, and useful nonsteroidal anti-inflammatory drugs. (continued)

Drug	Usual Dose for Adults ≥ 50 kg	Usual Dose for Adults < 50 kg ¹	Cost per Unit	Cost for 30 Days ²	Comments ³
Ketorolac tromethamine (Toradol)	10 mg every 4–6 hours to a maximum of 40 mg/d orally		\$0.93/10 mg	Not recommended	Short-term use (< 5 days) only; otherwise, increased risk of gastrointestinal side effects.
Ketorolac tromethamine ⁸ (Toradol)	60 mg IM or 30 mg IV initially, then 30 mg every 6 hours IM or IV		\$1.50/30 mg	Not recommended	Intramuscular or intravenous NSAID as alternative to opioid. Lower doses for elderly. Short-term use (< 5 days) only.
Magnesium salicylate (various)	467–934 mg every 6 hours		\$0.23/467 mg OTC	\$9.60	
Meclofenamate sodium ⁹ (Meclomen)	50–100 mg every 6 hours		\$4.35/100 mg	\$522.00	Diarrhea more common.
Mefenamic acid (Ponstel)	250 mg every 6 hours		\$17.41/250 mg	\$2089.20	
Nabumetone (Relafen)	500–1000 mg once daily (max dose 2000 mg/d)		\$1.38/500 mg; \$1.63/750 mg	\$97.80	May be less ulcerogenic than ibuprofen, but overall side effects may not be less.
Naproxen (Naprosyn, Anaprox, Aleve [OTC], others)	250–500 mg every 6–8 hours	5 mg/kg every 8 hours	\$1.29/500 mg Rx; \$0.08/220 mg OTC	\$154.80; \$7.20 OTC	Generally well tolerated. Lower doses for elderly.
Oxaprozin (Daypro, others)	600–1200 mg once daily		\$1.50/600 mg	\$90.00	Similar to ibuprofen. May cause rash, pruritus, photosensitivity.
Piroxicam (Feldene, others)	20 mg daily		\$2.64/20 mg	\$79.20	Not recommended in the elderly due to high adverse drug reaction rate. Single daily dose convenient. Long half-life. May cause higher rate of gastrointestinal bleeding and dermatologic side effects.
Sodium salicylate	325–650 mg every 3–4 hours		\$0.08/650 mg OTC	\$19.20	
Sulindac (Clinoril, others)	150–200 mg twice daily		\$0.98/150 mg; \$1.21/200 mg	\$58.80; \$72.60	May cause higher rate of gastrointestinal bleeding. May have less nephrotoxic potential.
Tolmetin (Tolectin)	200–600 mg four times daily		\$0.75/200 mg; \$3.22/600 mg	\$90.00; \$386.40	Perhaps more side effects than others, including anaphylactic reactions.

¹Acetaminophen and NSAID dosages for adults weighing < 50 kg should be adjusted for weight.

²Average wholesale price (AWP) for AB-rated generic when available) for quantity listed. Source: *Red Book Online*, 2012, Thomson Reuters (Healthcare) Inc. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.

³The adverse effects of headache, tinnitus, dizziness, confusion, rashes, anorexia, nausea, vomiting, gastrointestinal bleeding, diarrhea, nephrotoxicity, visual disturbances, etc, can occur with any of these drugs. Tolerance and efficacy are subject to great individual variations among patients. Note: All NSAIDs can increase serum lithium levels.

⁴Acetaminophen and celecoxib lack antiplatelet effects.

⁵May inhibit platelet aggregation for 1 week or more and may cause bleeding.

⁶May have minimal antiplatelet activity.

⁷Administration with antacids may decrease absorption.

⁸Has the same gastrointestinal toxicities as oral NSAIDs.

⁹Coombs-positive autoimmune hemolytic anemia has been associated with prolonged use.

COX-2, cyclooxygenase-2; OA, osteoarthritis; RA, rheumatoid arthritis; OTC, over-the-counter; Rx, prescription;

Data from Jacox AK et al. *Management of Cancer Pain: Quick Reference Guide for Clinicians No. 9*. AHCPR Publication No. 94-0593. Rockville, MD: Agency for Health Care Policy and Research, Public Health Service, U.S. Department of Health and Human Services. March 1994.

► Opioid Medications

For many patients, opioids are the mainstay of pain management. Opioids are appropriate for severe pain due to any cause, including neuropathic pain. Opioid medications are listed in Table 5–4. Full opioid agonists such as morphine, hydromorphone, oxycodone, methadone, fentanyl, hydrocodone, and codeine are used most commonly. Hydrocodone and codeine are typically combined with acetaminophen or an NSAID, although the US Food and Drug Administration will be restricting the amounts of acetaminophen in these combinations due to the risk for toxicity. **Short-acting formulations** of oral morphine sulfate (starting dosage 4–8 mg orally every 3–4 hours), hydro-morphine (1–2 mg orally every 3–4 hours), or oxycodone (5 mg orally every 3–4 hours) are useful for acute pain not controlled with other analgesics. These same oral medications, or oral transmucosal fentanyl (200 mcg orally dissolved in mouth) or buccal fentanyl (100 mcg dissolved in the mouth), can be used for “rescue” treatment for patients experiencing pain that breaks through long-acting medications. For chronic stable pain, **long-acting medications** are preferred, such as oral sustained-release morphine (one to three times a day), oxycodone (two or three times a day), or methadone (three or four times a day). Methadone is inexpensive, available in a liquid formulation, and may have added efficacy for neuropathic pain. However, equianalgesic dosing is complex because it varies with the patient’s opioid dose and caution must be used at higher methadone doses (generally > 100–150 mg/d) because of the risk of QT prolongation. Consultation with a palliative medicine or pain specialist may be appropriate.

Transdermal fentanyl is appropriate for patients already tolerant to other opioids at a dose equivalent to at least 60 mg/d of oral morphine (equivalent to transdermal fentanyl 25 mcg/h every 72 hours) and therefore should not be used in the postoperative setting or be the first opioid used. Medications that inhibit cytochrome P450 3A4, such as ritonavir, ketoconazole, itraconazole, troleandomycin, clarithromycin, nelfinavir, nefazodone, amiodarone, amprenavir, aprepitant, diltiazem, erythromycin, fluconazole, fosamprenavir, and verapamil, and grapefruit juice can cause increased levels and duration of transdermal fentanyl. Since the fentanyl patch can require 24–48 hours to achieve pharmacologic “steady state,” patients should be given short-acting opioids while awaiting the full analgesic effect of transdermal fentanyl, and changes in dose of the fentanyl patch should be made no more frequently than every 6 days. For complete information about prescribing guidelines for the fentanyl patch see <http://www.duragesic.com/prescribing-information.html>.

A useful technique for opioid management of chronic pain is equianalgesic dosing (Table 5–4). The dosages of any full opioid agonists used to control pain can be converted into an equivalent dose of any other opioid. In this way, 24-hour opioid requirements and dosing regimens established using shorter-acting opioid medications can be converted into equivalent dosages of long-acting medications or formulations. Cross-tolerance is often incomplete, however, so less than the full calculated equianalgesic dosage is generally administered initially when switching between

opioid formulations. Equianalgesic dosing for methadone is more complex and varies by dose and duration of use.

While some clinicians and patients inexperienced with the management of severe chronic pain may feel more comfortable with combined nonopioid-opioid agents, full agonist opioids are typically a better choice in patients with severe pain because the dose of opioid is not limited by the toxicities of the acetaminophen, aspirin, or NSAID component of combination preparations. There is no maximal allowable or effective dose for full opioid agonists. The dose should be increased to whatever is necessary to relieve pain, remembering that certain types of pain, such as neuropathic pain, may respond better to agents other than opioids, or to combinations of opioids with co-analgesics (see below).

While physiologic tolerance is possible with opioids, failure of a previously effective opioid dose to adequately relieve pain is usually due to worsening of the underlying condition causing pain, such as growth of a tumor or a new metastasis in a patient with cancer. In this case, for moderate unrelieved pain, the dose of opioid can be increased by 25–50%. For severe unrelieved pain, a dose increase of 50–100% may be appropriate. The frequency of dosing should be adjusted so that pain control is continuous. Long-term dosing may then be adjusted by adding the average daily amount of short-acting opioid necessary for breakthrough pain over the preceding 72–96 hours to the long-acting medication dose. In establishing or reestablishing adequate dosing, frequent reassessment of the patient’s pain and medication side effects is necessary.

As opioids are titrated upwards, increasing difficulty with the side effects can be expected. Constipation is common at any dose of opioid, and tolerance to this side effect does not develop over time. Opioid-induced constipation should be anticipated and prevented in all patients (see below).

Sedation can be expected with opioids, although tolerance to this effect typically develops within 24–72 hours at a stable dose. Sedation typically appears well before significant respiratory depression. If treatment for sedation is desired, dextroamphetamine (2.5–7.5 mg orally at 8 AM and noon) or methylphenidate (2.5–10 mg orally at 8 AM and noon) may be helpful. Caffeinated beverages can also ameliorate minor opioid sedation.

Although sedation is more common, patients may experience euphoria when first taking opioids or when the dose is increased. However, tolerance to sedation or euphoria typically develops after a few days at a stable dose. Opioid-induced neurotoxicity—characterized by myoclonus, followed by hyperalgesia, delirium with hallucinosis, and seizures—may develop in patients who take high doses of opioids for a prolonged period. These symptoms may resolve after lowering the dose or switching opioids, especially to ones like fentanyl or methadone that do not have active metabolites. While waiting for the level of the offending opioid to fall, low doses of lorazepam, baclofen, or gabapentin may be helpful for treating myoclonus; haloperidol may be useful for treating delirium. Avoiding or correcting dehydration may be helpful for prevention and treatment of opioid-induced neurotoxicity.

Table 5-4. Useful opioid agonist analgesics.

Drug	Approximate Equianalgesic Dose (compared to morphine 30 mg orally or 10 mg IV/SC) ¹		Usual Starting Dose				Potential Advantages	Potential Disadvantages
			Adults ≥ 50 kg Body Weight		Adults < 50 kg Body Weight			
	Oral	Parenteral	Oral	Parenteral	Oral	Parenteral		
Opioid agonists²								
Buprenorphine transdermal	Not available	Not available	Not available orally. Transdermal doses available: 5, 10, and 20 mcg/h Initiate 5 mcg/h patch for opioid-naïve patients (may currently be using non-opioid analgesics) \$60.00/10 mcg/h	Not available	Not available	Not available	7-day analgesia, may be initiated in opioid-naïve patients. Can titrate up dose after 72 hours.	QT prolongation
Fentanyl	Not available	100 mcg every hour	Not available	50–100 mcg IV/IM every hour or 0.5–1.5 mcg/kg/h IV infusion \$0.41/100 mcg	Not available	0.5–1 mcg/kg IV every 1–4 hours or 1–2 mcg/kg IV × 1, then 0.5–1 mcg/kg/h infusion	Possibly less neuroexcitatory effects, including in kidney failure.	
Fentanyl oral transmucosal (Actiq); buccal (Fentora)	Not available	Not available	200 mcg transmucosal; 100 mcg buccal; \$18.80/200 mcg transmucosal; \$36.13/200 mcg buccal	Not available	Not available	Not available	For pain breaking through long-acting opioid medication.	Transmucosal and buccal formulations are not bioequivalent; there is higher bioavailability of buccal formulation.

Fentanyl transdermal	Conversion to fentanyl patch is based on total daily dose of oral morphine ² : morphine 60–134 mg/d orally = fentanyl 25 mcg/h patch; morphine 135–224 mg/d orally = fentanyl 50 mcg/h patch; morphine 225–314 mg/day orally = fentanyl 75 mcg/h patch; and morphine 315–404 mg/d orally = fentanyl 100 mcg/h patch	Not available	Not available orally 12.5–25 mcg/h patch every 72 hours; \$14.42/25 mcg/h	Not available	12.5–25 mcg/h patch every 72 hours	Not available	Stable medication blood levels.	Not for use in opioid-naïve patients.
Hydromorphone ³ (Dilaudid)	7.5 mg every 3–4 hours	1.5 mg every 3–4 hours	1–2 mg every 3–4 hours; \$0.48/2 mg	1.5 mg every 3–4 hours; \$1.14/2 mg	0.06 mg/every 3–4 hours	0.015 mg/kg every 3–4 hours	Similar to morphine. Available in injectable high-potency preparation, rectal suppository.	Short duration.
Levorphanol (Levo-Dromoran)	4 mg every 6–8 hours	2 mg every 6–8 hours	4 mg every 6–8 hours; \$1.07/2 mg	Not available	0.04 mg/kg every 6–8 hours	Not available	Longer-acting than morphine sulfate.	
Meperidine ⁴ (Demerol)	300 mg every 2–3 hours; normal dose 50–150 mg every 3–4 hours	100 mg every 3 hours	Not recommended	100 mg every 3 hours; \$1.32/100 mg	Not recommended	0.75 mg/kg every 2–3 hours	Use only when single dose, short duration analgesia is needed as for outpatient procedures like colonoscopy. Not recommended for chronic pain or for repeated dosing.	Short duration. Normeperidine metabolite accumulates in kidney failure and other situations, and in high concentrations may cause irritability and seizures.
Methadone (Dolophine, others)	10–20 mg every 6–8 hours (when converting from < 100 mg long-term daily oral morphine ²)	5–10 mg every 6–8 hours	5–20 mg every 6–8 hours; \$0.15/10 mg	2.5–10 mg every 6–8 hours; \$8.60/10 mg	0.2 mg/kg every 6–8 hours	0.1 mg/kg every 6–8 hours	Somewhat longer-acting than morphine. Useful in cases of intolerance to morphine. May be particularly useful for neuropathic pain. Available in liquid formulation.	Analgesic duration shorter than plasma duration. May accumulate, requiring close monitoring during first weeks of treatment. Equianalgesic ratios vary with opioid dose.

(continued)

Table 5-4. Useful opioid agonist analgesics. (continued)

Drug	Approximate Equianalgesic Dose (compared to morphine 30 mg orally or 10 mg IV/SC) ¹		Usual Starting Dose				Potential Advantages	Potential Disadvantages
			Adults ≥ 50 kg Body Weight		Adults < 50 kg Body Weight			
	Oral	Parenteral	Oral	Parenteral	Oral	Parenteral		
Morphine ³ immediate release (Morphine sulfate tablets, Roxanol liquid)	30 mg every 3-4 hours (repeat around-the-clock dosing); 60 mg every 3-4 hours (single or intermittent dosing)	10 mg every 3-4 hours	4-8 mg every 3-4 hours; Used for breakthrough pain in patients already taking controlled-release preparations \$0.18/15 mg tab; 0.69/20 mg liquid	10 mg every 3-4 hours; \$1.57/10 mg	0.3 mg/kg every 3-4 hours	0.1 mg/kg every 3-4 hours	Standard of comparison; multiple dosage forms available.	No unique problems when compared with other opioids.
Morphine controlled-release ³ (MS Contin, Oramorph)	90-120 mg every 12 hours	Not available	15-60 mg every 12 hours; \$1.69/30 mg	Not available	Not available	Not available		
Morphine extended release (Kadian, Avinza)	180-240 mg every 24 hours	Not available	20-30 mg every 24 hours; \$6.32/30 mg	Not available	Not available	Not available	Once-daily dosing possible.	
Oxycodone (Roxicodone, OxyIR)	20-30 mg every 3-4 hours	Not available	5-10 mg every 3-4 hours; \$0.48/5 mg	Not available	0.2 mg/kg every 3-4 hours	Not available	Similar to morphine.	
Oxycodone controlled release (Oxycontin)	40 mg every 12 hours	Not available	20-40 mg every 12 hours; \$4.42/20 mg					
Oxymorphone ⁶ oral, immediate release (Opana)	10 mg every 3-4 hours	Not available	5-10 mg every 3-4 hours; \$2.95/5 mg	Not available				New formulation with less known about equianalgesic dosing.
Oxymorphone ⁶ extended release (Opana ER)	30-40 mg every 12 hours	Not available	15-30 mg every 12 hours; \$4.35/10 mg	Not available				New formulation with less known about equianalgesic dosing.

Combination Opioid-NSAID Preparations								
Codeine ^{7,8} (with aspirin or acetaminophen) ⁹	180-200 mg every 3-4 hours; commonly available dose in combination with acetaminophen, 15-60 mg every 4-6 hours	130 mg every 3-4 hours	60 mg every 4-6 hours; \$0.64/60 mg	60 mg every 2 hours (IM/SC); \$3.05/60 mg	0.5-1 mg/kg every 3-4 hours	Not recommended	Similar to morphine.	Closely monitor for efficacy as patients vary in their ability to convert the prodrug codeine to morphine.
Hydrocodone ⁶ (in Lorcet, Lortab, Vicodin, others) ⁹	30 mg every 3-4 hours	Not available	10 mg every 3-4 hours; \$0.45/5 mg	Not available	0.2 mg/kg every 3-4 hours	Not available		Combination with acetaminophen limits dosage titration.
Oxycodone ⁷ (in Percocet, Percodan, Tylox, others) ⁹	30 mg every 3-4 hours	Not available	10 mg every 3-4 hours; \$0.52/5 mg	Not available	0.2 mg/kg every 3-4 hours	Not available	Similar to morphine.	Combination with acetaminophen and aspirin limits dosage titration.

¹Published tables vary in the suggested doses that are equianalgesic to morphine. Clinical response is the criterion that must be applied for each patient; titration to clinical efficacy is necessary. Because there is not complete cross-tolerance among these drugs, it is usually necessary to use a lower than equianalgesic dose initially when changing drugs and to retitrate to response.

²Conversion is conservative; therefore, do not use these equianalgesic doses for converting back from fentanyl patch to other opioids because they may lead to inadvertent overdose. Patients may require breakthrough doses of short-acting opioids during conversion to transdermal fentanyl.

³**Caution:** For morphine, hydromorphone, and oxymorphone, rectal administration is an alternative route for patients unable to take oral medications. Equianalgesic doses may differ from oral and parenteral doses. A short-acting opioid should normally be used for initial therapy.

⁴Not recommended for chronic pain. Doses listed are for brief therapy of acute pain only. Switch to another opioid for long-term therapy.

⁵Methadone conversion varies depending on the equivalent total daily dose of morphine. Consult with a pain management or palliative care expert for conversion.

⁶**Caution:** Recommended doses do not apply for adult patients with kidney or hepatic insufficiency or other conditions affecting drug metabolism.

⁷**Caution:** Doses of aspirin and acetaminophen in combination products must also be adjusted to the patient's body weight.

⁸**Caution:** Doses of codeine above 60 mg often are not appropriate because of diminishing incremental analgesia with increasing doses but continually increasing nausea, constipation, and other side effects.

⁹**Caution:** Monitor total acetaminophen dose carefully, including any OTC use. Total acetaminophen dose maximum 3-4 g/d. If liver impairment or heavy alcohol use, maximum is 2 g/d. Available dosing formulations of these combination medications are being adjusted to reflect increased caution about acetaminophen toxicity. Acetaminophen doses in a single combination tablet or capsule will be limited to no more than 325 mg.

Note: Average wholesale price (AWP, generic when available) for quantity listed. Source: *Red Book Online*, 2012, Thomson Reuters (Healthcare) Inc. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.

Data from Jacox AK et al. *Management of Cancer Pain: Quick Reference Guide for Clinicians No. 9*. AHCPR Publication No. 94-0593. Rockville, MD. Agency for Health Care Policy and Research, Public Health Service, U.S. Department of Health and Human Services. March 1994, and from Erstad BL. A rational approach to the management of acute pain states. *Hosp Formul* 1994;29 (8 Part 2):586.

Nausea due to opioids may occur with initiation of therapy and resolve after a few days. Severe or persistent nausea can be treated by switching opioids or by giving haloperidol, 0.5–4 mg orally, subcutaneously, or intravenously every 6 hours; prochlorperazine, 10 mg orally or intravenously or 25 mg rectally every 6 hours; or metoclopramide, 5–20 mg orally, subcutaneously, or intravenously before meals and bed; or ondansetron, 4–8 mg orally or intravenously every 6 hours. Notably, unrelieved constipation may be a more common cause of nausea in the setting of opioid use than opioid-induced nausea.

Although clinicians may worry about respiratory depression with opioids, this side effect is uncommon when a low dose is given initially and titrated upward slowly. Patients at particular risk for respiratory depression include those with chronic obstructive pulmonary disease, obstructive sleep apnea, and baseline CO₂ retention, those with liver or kidney or combined liver-kidney failure, and those with adrenal insufficiency or frank myxedema. Yet, even patients with severe pulmonary disease can tolerate low-dose opioids, but they should be monitored carefully. Clinicians should not allow concerns about respiratory depression to prevent them from treating pain adequately.

True allergy (with urticaria) to opioids is rare. More commonly, patients will describe intolerance due to side effects such as nausea, pruritus, or urinary retention in response to a particular opioid. If such symptoms develop, they can usually be relieved by lowering the dose or switching to another opioid.

► Medications for Neuropathic Pain

It is essential when taking a patient's history to listen for descriptions such as burning, shooting, pins and needles, or electricity, and for pain associated with numbness. Such a history suggests neuropathic pain, which is treated with some medications not typically used for other types of pain. While opioids are effective for neuropathic pain, a number of nonopioid medications have been found to be effective in randomized trials (Table 5–5). Successful management of neuropathic pain often requires the use of more than one effective medication.

The tricyclic antidepressants (TCAs) are good first-line therapy. Desipramine, 10–200 mg/d orally, and nortriptyline, 10–150 mg/d orally, are good first choices because they cause less orthostatic hypotension and have fewer anticholinergic effects than amitriptyline. Start with a low dosage (10–25 mg orally daily) and titrate upward every 4 or 5 days.

The calcium channel α 2- δ ligands gabapentin and pregabalin are also considered first-line therapy for neuropathic pain. Both medications can cause sedation, dizziness, ataxia, and gastrointestinal side effects but have no significant drug interactions. Both drugs require dose adjustments in patients with kidney dysfunction. Gabapentin should be started at low dosages of 100–300 mg orally three times a day and titrated upward by 300 mg/d every 4 or 5 days with a typical effective dose of 1800–3600 mg/d. Pregabalin should be started at 150 mg/d in two or three divided doses. If necessary, the dose of pregabalin can be titrated upward to 300–600 mg/d in two or three divided

Table 5–5. Pharmacologic management of neuropathic pain.

Drug ¹	Starting Dose	Typical Dose
Antidepressants²		
Nortriptyline	10 mg orally at bedtime	10–150 mg orally at bedtime
Desipramine	10 mg orally at bedtime	10–200 mg orally at bedtime
Calcium-channel α2-δ ligands		
Gabapentin ³	100–300 mg orally once to three times daily	300–1200 mg orally three times daily
Pregabalin ⁴	50 mg orally three times daily	100 mg orally three times daily
Selective serotonin norepinephrine reuptake inhibitors		
Duloxetine	60 mg orally daily or 20 mg orally twice daily in elders	60 mg orally daily
Venlafaxine ⁵	75 mg orally daily divided into two or three doses	150–225 mg orally daily divided into two or three doses
Opioids	(see Table 5-4)	(see Table 5-4)
Other medications		
Lidocaine transdermal	5% patch applied daily, for a maximum of 12 hours	1–3 patches applied daily for a maximum of 12 hours
Tramadol hydrochloride	50 mg orally four times daily	100 mg orally two to four times daily

¹Begin at the starting dose and titrate up every 4 or 5 days. Within each category, drugs listed in order of prescribing preference.

²Begin with a low dose. Pain relief may be achieved at doses below antidepressant doses, thereby minimizing adverse side effects.

³Common side effects include nausea, somnolence, and dizziness. Take medication on a full stomach. Do not combine with serotonin or norepinephrine uptake inhibitors, or with tricyclic antidepressants.

⁴Common side effects include dizziness, somnolence, peripheral edema, and weight gain. Must adjust dose for kidney impairment.

⁵Caution: Can cause hypertension and ECG changes. Obtain baseline ECG and monitor.

doses. Both drugs are relatively safe in accidental overdose and may be preferred over TCAs for a patient with a history of congestive heart failure or arrhythmia or if there is a risk of suicide. Prescribing gabapentin and morphine for neuropathic pain may provide better analgesia at lower doses than if each is used as a single agent.

The selective serotonin norepinephrine reuptake inhibitors (SSNRIs), duloxetine (60 mg/d or 20 mg twice daily in elders), and venlafaxine (150–225 mg/d) are also considered first-line treatments for neuropathic pain. Patients should be advised to take duloxetine on a full stomach because nausea is a common side effect. Duloxetine should not be combined with other serotonin or norepinephrine uptake inhibitors, but it can be combined with gabapentin or pregabalin. Because venlafaxine can cause hypertension and induce ECG changes, patients with cardiovascular risk factors should be carefully monitored when starting this drug.

Other medications effective for neuropathic pain include tramadol and the 5% lidocaine patch. Tramadol should be started at 50 mg orally daily and can be titrated up to 100 mg orally four times daily. The 5% lidocaine patch (1–4 patches at a time) is effective in postherpetic neuralgia and may be effective in other types of localized neuropathic pain. A new patch is applied to the painful region daily for up to 12 hours daily.

▶ Adjuvant Pain Medications & Treatments

If pain cannot be controlled without uncomfortable medication side effects, clinicians should consider using lower doses of multiple medications, as is done commonly for neuropathic pain, rather than larger doses of one or two medications. For metastatic bone pain, the anti-inflammatory effect of NSAIDs can be particularly helpful. Radiation therapy and bisphosphonates may also relieve bone pain. For some patients, a nerve block can provide substantial relief, such as a celiac plexus block for pain from pancreatic cancer. Intrathecal pumps may be useful for patients with severe pain responsive to opioids but who require such large doses that systemic side effects (eg, sedation and constipation) become limiting. There is some evidence for the use of cannabinoids as analgesics.

Corticosteroids such as dexamethasone or prednisone can be helpful for patients with headache due to increased intracranial pressure, pain from spinal cord compression, metastatic bone pain, and neuropathic pain due to invasion or infiltration of nerves by tumor. Because of the side effects of long-term corticosteroid administration, they are most appropriate in patients with end-stage disease. Low-dose intravenous or oral ketamine has been used successfully for neuropathic and other pain syndromes refractory to opioids. Haloperidol and benzodiazepines may be used prophylactically to minimize ketamine's psychotomimetic side effects.

NONPHARMACOLOGIC TREATMENTS

Nonpharmacologic therapies are valuable in treating pain. Hot or cold packs, massage, and physical therapy can be

helpful for musculoskeletal pain. Similarly, biofeedback, acupuncture, chiropractic, meditation, music therapy, cognitive behavioral therapy, guided imagery, cognitive distraction, and framing may be of help in treating pain. Because mood and psychological issues play an important role in the patient's perception of and response to pain, psychotherapy, support groups, prayer, and pastoral counseling can also help in the management of pain. Major depression, which may be instigated by chronic pain or may alter the response to pain, should be treated aggressively.

▶ When to Refer

- Pain not responding to opioids at typical doses.
- Neuropathic pain not responding to first-line treatments.
- Complex methadone management issues.
- Intolerable side effects from oral opioids.
- Severe pain from bone metastases.
- For a surgical or anesthesia-based procedure, intrathecal pump, or nerve block.

▶ When to Admit

- Patients should be hospitalized for severe exacerbation of pain that is not responsive to previous stable oral opioid around-the-clock plus breakthrough doses.
- Patients whose pain is so severe that they cannot be cared for at home should be hospitalized.
- Uncontrollable side effects from opioids, including nausea, vomiting, and altered mental status, should prompt hospitalization.

PALLIATION OF OTHER COMMON SYMPTOMS

DYSPNEA

Dyspnea is the subjective experience of difficulty breathing and may be characterized by patients as tightness in the chest, shortness of breath, or a feeling of suffocation. Up to 50% of terminally ill patients may experience severe dyspnea.

Treatment of dyspnea is usually first directed at the cause (see Chapter 9). At the end of life, dyspnea is often treated nonspecifically with opioids. **Immediate-release morphine** given orally (2–4 mg every 4 hours) or intravenously (1–2 mg every 4 hours) treats dyspnea effectively. Doses are typically lower than would be necessary for the relief of moderate pain. **Sustained-release morphine** given at 10 mg daily appears to be safe and effective for most patients with dyspnea. Supplemental oxygen may be useful for the dyspneic patient *who is hypoxic*. However, a nasal cannula and face mask are sometimes not well tolerated, and fresh air from a window or fan may provide relief. Judicious use of noninvasive ventilation as well as nonpharmacologic relaxation techniques such as meditation and guided imagery may be beneficial for some patients. Benzodiazepines may be useful adjuncts for treatment of dyspnea.

NAUSEA & VOMITING

Nausea and vomiting are common and distressing symptoms. As with pain, the management of nausea may be maximized by regular dosing. An understanding of the four major inputs to the vomiting center may help direct treatment (see Chapter 15).

Vomiting associated with a particular opioid may be relieved by dose reduction or substitution with an equianalgesic dose of another opioid or a sustained-release formulation. In addition to the other dopamine receptor antagonist antiemetics listed in Table 15–2 that block the trigger zone, haloperidol (0.5–4 mg orally every 4–6 hours) is commonly used empirically.

Vomiting may be due to stimulation of peripheral afferent nerves from the gut. Offering patients small amounts of food only when they are hungry may prevent nausea and vomiting. Nasogastric suction may provide rapid, short-term relief for vomiting associated with constipation, gastroparesis, or gastric outlet obstruction, with the addition of laxatives; prokinetic agents (only in the setting of partial not complete obstruction), such as metoclopramide (5–20 mg orally or intravenously four times a day); scopolamine (1.5-mg patch every 3 days); and high-dose corticosteroids as more definitive treatment. Nausea often requires treatment with more than one agent; when it is refractory to other treatments or due to increased intracranial pressure, it may respond to high-dose corticosteroids (eg, dexamethasone, 20 mg orally or intravenously daily in divided doses).

Vomiting due to disturbance of the vestibular apparatus may be treated with anticholinergic and antihistaminic agents (including diphenhydramine, 25 mg orally or intravenously every 8 hours, or scopolamine, 1.5-mg patch every 3 days).

Benzodiazepines can be effective in preventing the anticipatory nausea associated with chemotherapy but are otherwise not indicated for nausea and vomiting. Finally, many patients find medical marijuana or dronabinol (2.5–20 mg orally every 4–6 hours) helpful in the management of nausea and vomiting.

CONSTIPATION

Given the frequent use of opioids, poor dietary intake, and physical inactivity, constipation is a common problem in the dying. Clinicians must inquire about any difficulty with hard or infrequent stools. Constipation is an easily preventable and treatable cause of discomfort, distress, and nausea and vomiting (see Chapter 15).

Constipation may be prevented or relieved if patients can increase their activity and their intake of fluids. Simple considerations such as privacy, undisturbed toilet time, and a bedside commode rather than a bedpan may be important for some patients.

For patients taking opioids, anticipating and preventing constipation is important. A prophylactic bowel regimen with a stimulant laxative (bisacodyl or senna) should be started when opioid treatment is begun. Table 15–4 lists other agents (including polyethylene glycol) that can be added as needed. Docusate, a stool softener, adds little to senna in hospitalized patients, has a lingering bad taste that may suppress appetite, and thus is no longer recommended. Methylnaltrexone, a subcutaneous medication, is a peripherally acting mu-receptor antagonist and is available for severe, unrelieved, opioid-induced constipation.

FATIGUE

Fatigue is a distressing symptom and is the most common complaint among patients with cancer. Specific abnormalities that can contribute to fatigue, including anemia, hypothyroidism, hypogonadism, cognitive and functional impairment, and malnutrition, should be corrected. Pain, depression, and fatigue often coexist in patients with cancer; pain and depression should be managed adequately in the setting of patients with fatigue. Fatigue from medication adverse effects and polypharmacy is common and should be addressed. For nonspecific fatigue, exercise and physical rehabilitation may be most effective. Low-doses of psychostimulants, such as methylphenidate 5mg orally in the morning and afternoon or modafinil 200 mg orally in the morning, can be effective. Corticosteroids may have a short-term benefit and selective androgen receptor modulators are being investigated in the treatment of fatigue.

DELIRIUM & AGITATION

Many terminally ill patients die in a state of delirium—a disturbance of consciousness and a change in cognition that develops over a short time and is manifested by misinterpretations, illusions, hallucinations, disturbances in the sleep-wake cycle, psychomotor disturbances (eg, lethargy, restlessness), and mood disturbance (eg, fear, anxiety). Delirium may be hyperactive, hypoactive, or mixed. Agitated delirium at the end of life has been called **terminal restlessness**.

Careful attention to patient safety and nonpharmacologic strategies to help the patient remain oriented (clocks, calendars, a familiar environment, reassurance and redirection from caregivers) may be sufficient to prevent or manage

minor delirium. Some delirious patients may be “pleasantly confused,” and a decision by the patient’s family and the clinician not to treat delirium may be justified.

More commonly, however, delirium at the end of life is distressing to patients and family and requires treatment. Delirium may interfere with the family’s ability to feel comforting to the patient and may prevent a patient from being able to recognize and report important symptoms. While there are many reversible causes of delirium (see Chapter 25), identifying and correcting the underlying cause at the end of life is often complex because a patient may have many possible causes. When the cause of delirium cannot be identified, treated, or corrected rapidly enough, delirium may be treated symptomatically with neuroleptics, such as haloperidol (1–10 mg orally, subcutaneously, intramuscularly, or intravenously twice or three times a day) or risperidone (1–3 mg orally twice a day). The benefits of neuroleptics in the treatment of agitation must be weighed carefully against potential harms, based on evidence showing an association between antipsychotic medications and increased mortality for older adults with dementia. The role of hydration as a treatment of delirium at the end of life is unclear. When delirium is refractory to treatment and remains intolerable, sedation may be required to provide relief and may be achieved rapidly with midazolam (0.5–5 mg/h subcutaneously or intravenously) or barbiturates.

END-OF-LIFE CARE

In the United States, approximately 2.5 million people die each year. Caring for patients at the end of life is an important responsibility and a rewarding opportunity for clinicians. Clinicians focused on prolonging life must also recognize when life is ending in order to continue caring properly for their patients. From the medical perspective,

the end of life may be defined as that time when death—whether due to terminal illness or acute or chronic illness—is expected within weeks to months and can no longer be reasonably forestalled by medical intervention. End-of-life care refers to focusing care for those approaching death on the goals of relieving distressing symptoms and promoting quality of life rather than attempting to cure underlying disease. Unfortunately, most clinical practice guidelines devote scant attention to end-of-life care.

► Prognosis at the End of Life

Clinicians must help patients understand when they are approaching the end of life. This information influences patients’ treatment decisions and may change how they spend their remaining time but does not impact patient survival.

While certain diseases such as cancer are more amenable to prognostic estimates regarding the time course to death, the other common causes of mortality in the United States—including heart disease, stroke, chronic lung disease, and dementia—have more variable trajectories and difficult to predict prognoses. Even for patients with cancer, clinician estimates of prognosis are often inaccurate and generally overly optimistic. Nonetheless, clinical experience, epidemiologic data, guidelines from professional organizations (eg, the National Hospice and Palliative Care Organization), and computer modeling and prediction tools (eg, the Acute Physiology and Chronic Health Evaluation [APACHE] system, the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment [SUPPORT] model, or the Palliative Performance Scale) may be used to help patients identify the end period of their lives. Clinicians can also ask themselves “Would I be surprised if this patient died in the next year?” to determine whether a discussion of prognosis and focus on end-of-life care would be appropriate. If the answer is “no,” then the clinician should initiate a discussion. Recognizing that patients may have different levels of comfort with prognostic information, clinicians can introduce the topic by simply saying, “I have information about the likely time course of your illness. Would you like to talk about it?”

► Expectations About the End of Life

Patients’ experiences at the end of life are influenced by their expectations about how they will die and the meaning of death. Many people fear how they will die more than death itself. Patients report fears of dying in pain or of suffocation, of loss of control, indignity, isolation, and of being a burden to their families. All of these anxieties may be ameliorated with good supportive care provided by an attentive group of caretakers.

Death is often regarded by clinicians, patients, and families as a failure of medical science. This attitude can create or heighten a sense of guilt about the failure to prevent dying. Both the general public and clinicians often are complicit in denying death, treating dying persons merely as patients and death as an enemy to be battled furiously in

hospitals rather than as an inevitable outcome to be experienced as a part of life at home. As a result, approximately 75–80% of people in the United States die in hospitals or long-term care facilities.

Even when the clinician continues to pursue cure of potentially reversible disease, relieving suffering, providing support, and helping the patient prepare for death are foremost considerations. Patients at the end of life and their families identify a number of elements as important to quality end-of-life care: managing pain and other symptoms adequately, avoiding inappropriate prolongation of dying, preserving dignity, preparing for death, achieving a sense of control, relieving the burden on others, and strengthening relationships with loved ones.

► Communication & Care of the Patient

Caring for patients at the end of life requires the same skills clinicians use in other tasks of medical care: diagnosing treatable conditions, providing patient education, facilitating decision-making, and expressing understanding and caring. Communication skills are vitally important and can be improved through training. Higher-quality communication is associated with greater satisfaction and awareness of patient wishes. When needed, the use of a professional interpreter can facilitate clear communication and help broker cultural issues. In particular, clinicians must become proficient at delivering bad news and then dealing with its consequences (Table 5–6).

Three further obligations are central to the clinician's role at this time. First, he or she must work to identify, understand, and relieve suffering, which may include physical, psychological, social, or spiritual distress. Second, clinicians can serve as facilitators or catalysts for hope. While hope for a particular outcome may fade (such as cure of advanced cancer following exhaustive conventional and experimental treatments), it can be redefined by the patient's belief of what is *still* possible. Although expecting a "miraculous cure" may be simplistic and even harmful, hope for relief of pain, for reconciliation with loved ones, for discovery of meaning, and for spiritual transformation is realistic at the end of life. With such questions as "What is still possible now for you?" "When you look to the future, what do you hope for?" "What good might come of this?" clinicians can help patients uncover hope, explore meaningful and realistic goals, and develop strategies to realize them.

Table 5–6. Suggestions for the delivery of bad news.

- Prepare an appropriate place and time.
- Address basic information needs.
- Be direct; avoid jargon and euphemisms.
- Allow for silence and emotional ventilation.
- Assess and validate patient reactions.
- Respond to immediate discomforts and risks.
- Listen actively and express empathy.
- Achieve a common perception of the problem.
- Reassure about pain relief.
- Ensure basic follow-up and make specific plans for the future.

Finally, dying patients' feelings of isolation and fear demand that clinicians assert that they will care for the patient throughout the final stage of life. The promise of nonabandonment is perhaps the central principle of end-of-life care and is a clinician's pledge to an individual patient to serve as a caring partner, a resource for creative problem-solving and relief of suffering, a guide during uncertain times, and a witness to the patient's experiences—no matter what happens. Clinicians can say to a patient, "I will care for you whatever happens." Dying patients need their clinicians to offer their presence—not necessarily the ability to solve all problems but rather a commitment to recognize and receive the patients' difficulties and experiences with respect and empathy. At its best, the patient-clinician relationship can be a covenant of compassion and a recognition of common humanity.

► Caring for the Family

In caring for patients at the end of life, clinicians must appreciate the central role played by family, friends, and partners and often must deal with strong emotions of fear, anger, shame, sadness, and guilt experienced by those individuals. While significant others may support and comfort a patient at the end of life, the threatened loss of a loved one may also create or reveal dysfunctional or painful family dynamics. Furthermore, clinicians must be attuned to the potential impact of illness on the patient's family: substantial physical caregiving responsibilities and financial burdens as well as increased rates of anxiety, depression, chronic illness, and even mortality. Family caregivers, typically women, commonly provide the bulk of care for patients at the end of life, yet their work is often not acknowledged or compensated.

Clinicians can help families confront the imminent loss of a loved one (Table 5–7) and often must negotiate amid complex and changing family needs. Identifying a

Table 5–7. Clinician interventions helpful to families of dying patients.

- Excellent communication**, including clinician willingness to talk about death, timely and clear information, proactive guidance, listening, and empathic responses
- Advance care planning and clear decision-making**, including culturally sensitive communication, achieving consensus among family members and an understanding that surrogate decision-makers are trying to determine what the *patient* would have wanted, not what the surrogate would want
- Support for home care**, including orienting family members to the scope and details of family caregiving, providing clear direction about how to contact professional caregivers, and informing patients and families of the benefits of hospice care
- Empathy for family emotions and relationships**, including recognizing and validating common positive and negative feelings
- Attention to grief and bereavement**, including support for anticipatory grief and follow-up with the family after the patient's death

Data from Rabow MW et al. Supporting family caregivers at the end of life: "they don't know what they don't know." *JAMA*. 2004 Jan 28;291(4):483–91.

spokesperson for the family, conducting family meetings, allowing all to be heard, and providing time for consensus may help the clinician work effectively with the family.

► Clinician Self-Care

Many clinicians find caring for patients at the end of life to be one of the most rewarding aspects of practice. However, working with the dying requires tolerance of uncertainty, ambiguity, and existential challenges. Clinicians must recognize and respect their own limitations and attend to their own needs in order to avoid being overburdened, overly distressed, or emotionally depleted.

► Decision-Making, Advance Care Planning, & Advance Directives

Well-informed, competent adults have a right to refuse medical intervention even if this is likely to result in death. Many are willing to sacrifice some quantity of life to protect a certain quality of life. In order to promote patient autonomy, clinicians are obligated to inform patients about the risks, benefits, alternatives, and expected outcomes of end-of-life medical interventions such as cardiopulmonary resuscitation (CPR), mechanical ventilation, hospitalization and ICU care, and nutrition and hydration. Advance directives are oral or written statements made by patients when they are competent that are intended to guide care should they become incompetent. Advance directives allow patients to project their autonomy into the future and are an important part of advance care planning—a process whereby clinicians help

patients match treatments and care to their goals and values. Advance directives take effect when the patient can no longer communicate his or her preferences directly. While oral statements about these matters are ethically binding, they are not legally binding in all states. State-specific advance directive forms are available from a number of sources, including <http://www.caringinfo.org>.

Clinicians should educate all patients—ideally, well before the end of life—about the opportunity to formulate an advance directive. Most patients with serious illness have already thought about end-of-life issues, want to discuss them with their clinician, want the clinician to bring up the subject, and feel better for having had the discussion. Patients who have such discussions with their clinicians are perceived by their family as having a better quality of life at the end of life and their loved ones are less likely to suffer from depression during bereavement.

One type of advance directive is the Durable Power of Attorney for Health Care (DPOA-HC) that, in addition to documenting patient preferences for care, allows the patient to designate a surrogate decision-maker. The DPOA-HC is particularly useful because it is often difficult to anticipate what decisions will need to be made. The responsibility of the surrogate is to provide “substituted judgment”—to decide as the *patient* would, not as the *surrogate* wants, although about one-third of surrogates suffer negative emotional effects as a result of the burden of their responsibility. Clinicians should encourage patients to talk with their surrogates about their preferences generally and about scenarios that are likely to arise, such as the need for mechanical ventilation in a patient with end-stage emphysema. In the absence of a designated surrogate, clinicians usually turn to family members or next of kin. Despite regulations requiring health care institutions to inform patients of their rights to formulate an advance directive, only about 10% of people in the United States (including clinicians themselves) have completed them. POLST (Physician Orders for Life-Sustaining Treatment) forms are physician orders that accompany patients wherever they are cared for—home, hospital, or nursing home—and complement advance directives.

► Do Not Attempt Resuscitation Orders

As part of advance care planning, clinicians can elicit patient preferences about CPR. Most patients and many clinicians overestimate the chances of success of CPR. Only about 15% of all patients who undergo CPR in the hospital survive to hospital discharge. Moreover, among certain populations—especially those with multisystem organ failure, metastatic cancer, and sepsis—the likelihood of survival to hospital discharge following CPR is virtually nil. Clinicians must also inform patients about the sequelae of surviving CPR including fractured ribs, lacerated internal organs, neurologic disability, and the need for other aggressive interventions (such as ICU care). Patients may ask their clinician to write an order that CPR not be attempted on them. Although this order initially was referred to as a DNR (do not resuscitate) order, many clinicians prefer the term “DNAR” (do not attempt resuscitation) to emphasize the low likelihood of success.

For some patients at the end of life, decisions about CPR may not be about whether they will live but about how they will die. Clinicians should correct the misconception that withholding CPR in appropriate circumstances is tantamount to “not doing everything” or “just letting someone die.” While respecting the patient’s right ultimately to make the decision—and keeping in mind their own biases and prejudices—clinicians should offer explicit recommendations about DNAR orders and protect dying patients and their families from feelings of guilt and from the sorrow associated with vain hopes. Clinicians should discuss what interventions will be continued and started to promote quality of life rather than focusing only on what is not to be done. For patients with internal cardiac defibrillators, clinicians must also address issues of turning off these devices as death approaches to prevent them from discharging during the dying process.

► Hospice & Other Palliative Care Institutions

In the United States, hospice is a service focused on addressing the physical and emotional needs of the dying. In the United States, 41% of people who die use hospice. About 80% of patients receiving hospice care remain at home where they can be cared for by their family and visiting hospice staff, although hospice care can also be provided in hospitals and institutional residences. Hospice embodies the palliative care philosophy that emphasizes individualized attention, human contact, and an interdisciplinary team approach. Hospice care can include arranging for respite for family caregivers and providing legal, financial, and other services. Primary care clinicians are strongly encouraged to continue caring for their patients during the time they are receiving hospice care.

Hospice care is highly rated by families and has been shown to increase patient satisfaction, to reduce costs (depending on when patients are referred to hospice care), and to decrease family caregiver mortality. Despite evidence that suggests that hospice care does not increase mortality and may even extend life, hospice care tends to be used very near the end of life. The average length of stay in hospices in the United States is 67 days, with 31% of patients dying within 7 days of beginning hospice care.

Most hospice organizations require clinicians to estimate the patient’s probability of survival to be < 6 months, since this is a criterion for eligibility to receive Medicare or other insurance coverage. Regrettably, the hospice benefit can be difficult to provide to people who are homeless or isolated or who have terminal prognoses that are difficult to quantify.

► Cultural Issues

The individual patient’s experience of dying occurs in the context of a complex interaction of personal, philosophic, and cultural influences. Various religious, ethnic, gender, class, and cultural traditions help determine patients’ styles of communication, comfort in discussing particular topics, expectations about dying and medical interventions, and attitudes about the appropriate disposition of dead bodies.

While each patient is an individual, being sensitive to a person’s cultural beliefs and respecting ethnic traditions are important responsibilities of the clinician caring for a patient at the end of life, especially when the cultures of origin of the clinician and patient differ. A clinician may ask a patient, “What do I need to know about you and your beliefs that will help me take care of you?”

► Nutrition & Hydration

People approaching the end of life often lose their appetite and ultimately stop eating and drinking. The anorexia-cachexia syndrome frequently occurs in patients with advanced cancer, and cachexia is a common and poor prognostic sign in patients with heart failure. Ill people often have no hunger with total caloric deprivation, and the associated ketonemia produces a sense of well-being, analgesia, and mild euphoria. However, carbohydrate intake even in small amounts (such as that provided by 5% intravenous dextrose solution) blocks ketone production and may blunt the well-being effects of total caloric deprivation. Although it is unclear to what extent withholding hydration at the end of life creates an uncomfortable sensation of thirst, any such sensation is usually relieved by simply moistening the dry mouth. Ice chips, hard candy, swabs, popsicles, or minted mouthwash may be effective. Although this normal process of diminishing oral intake and accompanying weight loss is very common, it can be distressing to patients and families who may associate the offering of food with compassion and love and lack of eating with distressing images of starvation. In response, patients and families often ask about supplemental enteral or parenteral nutrition.

Unfortunately supplemental, artificial nutrition and hydration offers little benefit and rarely achieves patient and family goals. For example, although tube feedings are often considered in patients who aspirate, they do not prevent aspiration pneumonia and there is debate about whether artificial nutrition prolongs life in the terminally ill. Furthermore, force feeding may cause nausea and vomiting in ill patients, and eating can lead to diarrhea in the setting of malabsorption. Artificial nutrition and hydration may increase oral and airway secretions as well as increase the risk of choking, aspiration, and dyspnea; ascites, edema, and

effusions may be worsened. Nasogastric and gastrostomy tube feeding and parenteral nutrition impose risks of infection, epistaxis, pneumothorax, electrolyte imbalance, and aspiration—as well as the need to physically restrain the delirious patient to prevent dislodgment of catheters and tubes.

Individuals at the end of life have a right to refuse nutrition and hydration. Because they may have deep social and cultural significance for patients, families, and clinicians themselves, decisions about nutrition and hydration are not simply medical. Eliciting perceived goals of artificial nutrition and hydration and correcting misperceptions can help patients and families make clear decisions. Family and friends can be encouraged to express their love and caring in ways other than intrusive attempts at force feeding or hydration.

► Withdrawal of Curative Efforts

Requests from appropriately informed and competent patients or their surrogates for withdrawal of life-sustaining interventions must be respected. In addition, clinicians may determine unilaterally that particular interventions are medically inappropriate—eg, continuing kidney dialysis in a patient dying of multiorgan failure. In such cases, the clinician's intention to withdraw a specific intervention should be communicated to the patient and family. If differences of opinion persist about the appropriateness of what is being done, the assistance of an institutional ethics committee should be sought.

Limitation of life support prior to death is an increasingly common practice in intensive care units. The withdrawal of life-sustaining interventions such as mechanical ventilation must be approached carefully to avoid needless patient suffering and distress for those in attendance. Clinicians should educate the patient and family about the expected course of events and the difficulty of determining the precise timing of death after withdrawal of interventions. Sedative and analgesic agents should be administered to ensure patient comfort even at the risk of respiratory depression or hypotension. Scopolamine (10 mcg/h subcutaneously or intravenously, or a 1.5-mg patch every 3 days), glycopyrrolate (1 mg orally every 4 hours), or atropine (1% ophthalmic solution, 1 or 2 drops sublingually as often as every hour) can be used for controlling airway secretions and the resultant “death rattle.” A guideline for withdrawal of mechanical ventilation is provided in Table 5–8.

► Psychological, Social, & Spiritual Issues

Dying is not exclusively or even primarily a biomedical event. It is an intimate personal experience with profound psychological, interpersonal, and existential meanings. For many people at the end of life, the prospect of impending death stimulates a deep and urgent assessment of their identity, the quality of their relationships, and the meaning and purpose of their existence.

A. Psychological Challenges

In 1969, Elisabeth Kübler-Ross identified five psychological stages or patterns of emotions that patients at the end of

Table 5–8. Guidelines for withdrawal of mechanical ventilation.

1. Stop neuromuscular blocking agents.
2. Administer opioids or sedatives to eliminate distress. If not already sedated, begin with fentanyl 100 mcg (or morphine sulfate 10 mg) by intravenous bolus and infusion of fentanyl 100 mcg/h intravenously (or morphine sulfate 10 mg/h intravenously). Distress is indicated by RR > 24, nasal flaring, use of accessory muscles of respiration, HR increase > 20%, MAP increase > 20%, grimacing, clutching.
3. Discontinue vasoactive agents and other agents unrelated to patient comfort, such as antibiotics, intravenous fluids, and diagnostic procedures.
4. Decrease F_{iO_2} to room air and PEEP to 0 cm H_2O .
5. Observe patient for distress. If patient is distressed, increase opioids by repeating bolus dose and increasing hourly infusion rate by 50 mcg fentanyl (or 5 mg morphine sulfate),¹ then return to observation. If patient is not distressed, place on T piece and observe. If patient continues without distress, extubate patient and continue to observe for distress.

¹Ventilatory support may be increased until additional opioids have effect.

RR, respiratory rate; HR, heart rate; MAP, mean airway pressure; F_{iO_2} , fraction of inspired oxygen; PEEP, positive end-expiratory pressure. Adapted, with permission, from San Francisco General Hospital Guidelines for Withdrawal of Mechanical Ventilation/Life Support.

life may experience: denial and isolation, anger, bargaining, depression, and acceptance. Not every patient will experience all these emotions, and typically not in an orderly progression. In addition to these five stages are the perpetual challenges of anxiety and fear of the unknown. Simple information, listening, assurance, and support may help patients with these psychological challenges. In fact, patients and families rank emotional support as one of the most important aspects of good end-of-life care. Psychotherapy and group support may be beneficial as well.

Despite the significant emotional stress of facing death, clinical depression is not normal at the end of life and should be treated. Cognitive and affective signs of depression (such as hopelessness) may help distinguish depression from the low energy and other vegetative signs common with end-stage illness. Although traditional antidepressant treatments such as selective serotonin reuptake inhibitors are effective, more rapidly acting medications such as dextroamphetamine or methylphenidate (in doses used for sedation described earlier in this chapter) may be particularly useful when the end of life is near or while waiting for other antidepressant medication to take effect. Some research suggests a mortality benefit from treating depression in the setting of serious illness.

B. Social Challenges

At the end of life, patients should be encouraged to discharge personal, professional, and business obligations. This might include completing important work or personal projects, distributing possessions, writing a will, and making funeral and burial arrangements. The prospect of death often prompts patients to examine the quality of

Table 5-9. Five statements often necessary for the completion of important interpersonal relationships.

(1) "Forgive me."	(An expression of regret)
(2) "I forgive you."	(An expression of acceptance)
(3) "Thank you."	(An expression of gratitude)
(4) "I love you."	(An expression of affection)
(5) "Goodbye."	(Leave-taking)

Reprinted, with permission, from Byock I. *Dying Well: Peace and Possibilities at the End of Life*. New York: Riverhead Books, 1997.

their interpersonal relationships and to begin the process of saying goodbye (Table 5-9). Dying may intensify a patient's need to feel cared for by the clinician and the need for clinician empathy and compassion. Concern about estranged relationships or "unfinished business" with significant others and interest in reconciliation may become paramount at this time.

C. Spiritual Challenges

Spirituality is the attempt to understand or accept the underlying meaning of life, one's relationships to oneself and other people, one's place in the universe, and the possibility of a "higher power" in the universe. Spirituality is distinguished from particular religious practices or beliefs and is generally considered a universal human concern.

Perhaps because of an inappropriately exclusive attention to the biologic challenge of forestalling death or perhaps from feelings of discomfort or incompetence, clinicians frequently ignore their patients' spiritual concerns or reflexively refer these important issues to chaplains, psychiatrists or other caretakers (nurses, social workers, clergy). However, the existential challenges of dying are central to the well-being of people at the end of life and are the proper concern of clinicians. Clinicians can help dying patients by providing care to the whole person—by providing physical comfort and social support and by helping patients discover their own unique meaning in the world and an acceptance of death as a part of life. Dignity therapy has been shown to be effective in improving quality of life and spiritual well-being.

Unlike physical ailments such as infections and fractures, which usually require a clinician's intervention to be treated, the patient's spiritual concerns often require only a clinician's attention, listening, and witness. Clinicians might choose to inquire about the patient's spiritual concerns and ask whether the patient wishes to discuss them. For example, asking, "How are you within yourself?" communicates that the clinician is interested in the patient's whole experience and provides an opportunity for the patient to share perceptions about his or her inner life. Questions that might constitute an existential "review of systems" are presented in Table 5-10.

While dying may be a period of inevitable loss of physical functioning, the end of life also offers an opportunity for psychological, interpersonal, and spiritual development. Individuals may grow—even achieve a heightened sense of well-being or transcendence—in the process of dying. Through listening, support, and presence, clinicians may help foster

Table 5-10. An existential review of systems.

Intrapersonal

What does your illness/dying mean to you?
 What do you think caused your illness?
 How have you been healed in the past?
 What do you think is needed for you to be healed now?
 What is right with you now?
 What do you hope for?

Interpersonal

Who is important to you?
 To whom does your illness/dying matter?
 Do you have any unfinished business with significant others?

Transpersonal

What is your source of strength, help, or hope?
 Do you have spiritual concerns or a spiritual practice?
 If so, how does your spirituality relate to your illness/dying, and how can I help integrate your spirituality into your health care?
 What do you think happens after we die?
 What purpose might your illness/dying serve?
 What do you think is trying to happen here?

this learning and be a catalyst for this transformation. Rather than thinking of dying simply as the termination of life, clinicians and patients may be guided by a developmental model of dying that recognizes a series of lifelong developmental tasks and landmarks and allows for growth at the end of life.

TASKS AFTER DEATH

After the death of a patient, the clinician is called upon to perform a number of tasks, both required and recommended. The clinician must plainly and directly inform the family of the death, complete a death certificate, contact an organ procurement organization, and request an autopsy. Providing words of sympathy and reassurance, time for questions and initial grief, and a quiet private room for the family at this time is appropriate and much appreciated.

► The Pronouncement & Death Certificate

In the United States, state policies direct clinicians to confirm the death of a patient in a formal process called “pronouncement.” The clinician must verify the absence of spontaneous respirations and cardiac activity. A note describing these findings and the time of death is entered in the patient’s chart. In many states, when a patient whose death is expected dies outside of the hospital (at home or in prisons, for example) nurses may be authorized to report the death over the telephone to a physician who must then sign the death certificate within 24 hours. For traumatic deaths, some states allow emergency medical technicians to pronounce a patient dead at the scene based on clearly defined criteria and with physician telephonic or radio supervision.

While the pronouncement may often seem like an awkward and unnecessary formality, clinicians may use this time to reassure the patient’s loved ones at the bedside that the patient died peacefully and that all appropriate care had been given. Both clinicians and families may use the ritual of the pronouncement as an opportunity to begin to process emotionally the death of the patient.

Physicians are legally required to accurately report the underlying cause of death on the death certificate. This reporting is important both for patients’ families (for insurance purposes and the need for an accurate family medical history) and for the epidemiologic study of disease and public health. The physician should be specific about the major cause of death being the condition without which the patient would not have died (eg, “decompensated cirrhosis”) and its contributory cause (eg, “hepatitis B and hepatitis C infections and chronic alcoholic hepatitis”) as well as any associated conditions (eg, “acute kidney injury”)—and not simply put down “cardiac arrest” as the cause of death.

► Autopsy & Organ Donation

Discussing the options and obtaining consent for autopsy and organ donation with patients prior to death is usually the best practice. This approach advances the principle of patient autonomy and lessens the responsibilities of distressed family members during the period immediately following the death. However, after a patient dies, or in the case of brain death, designated organ transplant personnel are more successful than the treating clinicians at obtaining consent for organ donation from surviving family members. Federal regulations require that a designated representative of an organ procurement organization approach the family about organ donation if the organs are appropriate for transplantation. Most people in the United States support the donation of organs for transplants. Currently, however, organ transplantation is severely limited by the availability of donor organs. Many potential donors and the families of actual donors experience a sense of reward in contributing, even through death, to the lives of others.

Clinicians must be sensitive to ethnic and cultural differences in attitudes about autopsy and organ donation. Patients or their families should be reminded of their right to limit autopsy or organ donation in any way they choose,

although such restriction may limit the utility of autopsy. Pathologists can perform autopsies without interfering with funeral plans or the appearance of the deceased.

The results of an autopsy may help surviving family members and clinicians understand the exact cause of a patient’s death and foster a sense of closure. A clinician-family conference to review the results of the autopsy provides a good opportunity for clinicians to assess how well families are grieving and to answer questions. Despite the advantages of conducting postmortem examinations, autopsy rates are < 15%. Families report refusing autopsies out of fear of disfigurement of the body or delay of the funeral or say they were simply not asked. They allow autopsies in order to advance medical knowledge, to identify the exact cause of their loved one’s death, and to be reassured that appropriate care was given. Routinely addressing these issues when discussing autopsy may help increase the autopsy rate; the most important mistake is the failure to ask for permission to perform it.

► Follow-up & Grieving

Proper care of patients at the end of life includes following up with surviving family members after the patient has died, although clinicians often do not facilitate adequate bereavement services. Following up by telephone enables the clinician to assuage any guilt about decisions the family may have made, assess how families are grieving, reassure them about the nature of normal grieving, and identify complicated grief or depression. Clinicians can recommend support groups and counseling as needed. A card or telephone call from the clinician to the family days to weeks after the patient’s death (and perhaps on the anniversary of the death) allows the clinician to express concern for the family and the deceased.

After a patient dies, the clinician too may need to grieve. Although clinicians may be relatively unaffected by the deaths of some patients, other deaths may cause distressing feelings of sadness, loss, and guilt. These emotions should be recognized as the first step toward processing them or preventing them in the future. Each clinician may find personal or communal resources that help with the process of grieving. Shedding tears, the support of colleagues, time for reflection, and traditional or personal mourning rituals all may be effective. Attending the funeral of a patient who has died can be a satisfying personal experience that is almost universally appreciated by families and that may be the final element in caring well for people at the end of life.

Dermatologic Disorders

Timothy G. Berger, MD

Dermatologic diseases are diagnosed by the types of lesions they cause. To make a diagnosis: (1) identify the type of lesion(s) the patient exhibits by morphology establishing a differential diagnosis (Table 6–1); and (2) obtain the elements of the history, physical examination, and appropriate laboratory tests to confirm the diagnosis. Unique clinical situations, such as the ill ICU patient, lead to different diagnostic considerations.

PRINCIPLES OF DERMATOLOGIC THERAPY

► Frequently Used Treatment Measures

A. Bathing

Soap should be used only in the axillae and groin and on the feet by persons with dry or inflamed skin. Soaking in water for 10–15 minutes before applying topical corticosteroids enhances their efficacy (Soak and Smear). Bath oils can be used, but add little above the use of moisturizers, and may make the tub slippery, increasing the risk of falling.

B. Topical Therapy

Nondermatologists should become familiar with a representative agent in each category for each indication (eg, topical corticosteroid, topical retinoid, etc).

1. Corticosteroids—Topical corticosteroid creams, lotions, ointments, gels, foams, and sprays are presented in Table 6–2. Topical corticosteroids are divided into classes based on potency. There is little (except price) to recommend one agent over another within the same class. For a given agent, an ointment is more potent than a cream. The potency of a topical corticosteroid may be dramatically increased by applying an occlusive dressing over the corticosteroid. Optimally, at least 4 hours of occlusion should be prescribed to enhance penetration. Such dressings may include gloves, plastic wrap, or plastic occlusive suits for patients with generalized erythroderma or atopy. Caution should be used in applying topical corticosteroids to areas of thin skin (face, scrotum, vulva, skin folds). Topical corticosteroid use on the eyelids may result in glaucoma or

cataracts. One may estimate the amount of topical corticosteroid needed by using the “rule of nines” (as in burn evaluation; see Figure 37–2). In general, it takes an average of 20–30 g to cover the body surface of an adult once. Systemic absorption does occur, but adrenal suppression, diabetes mellitus, hypertension, osteoporosis, and other complications of systemic corticosteroids are very rare with topical corticosteroid therapy.

2. Emollients for dry skin (“moisturizers”)—Dry skin is not related to water intake but to abnormal function of the epidermis. Many types of emollients are available. Petrolatum, mineral oil, Aquaphor, Vanicream, and Eucerin cream are the heaviest and best. Emollients are most effective when applied to wet skin. If the skin is too greasy after application, pat dry with a damp towel. Vanicream is relatively allergen-free and can be used if allergic contact dermatitis to topical products is suspected.

The scaly appearance of dry skin may be improved by urea, lactic acid, or glycolic acid-containing products provided no inflammation (erythema or pruritus) is present.

3. Drying agents for weepy dermatoses—If the skin is weepy from infection or inflammation, drying agents may be beneficial. The best drying agent is water, applied as repeated compresses for 15–30 minutes, alone or with aluminum salts (Burow solution, Domeboro tablets) or colloidal oatmeal (Aveeno).

4. Topical antipruritics—Lotions that contain 0.5% each of camphor and menthol (Sarna) or pramoxine hydrochloride 1% (with or without 0.5% menthol, eg, Prax, PrameGel, Aveeno Anti-Itch lotion) are effective antipruritic agents. Hydrocortisone, 1% or 2.5%, may be incorporated for its anti-inflammatory effect (Pramosone cream, lotion, or ointment). Doxepin cream 5% may reduce pruritus but may cause drowsiness. Pramoxine and doxepin are most effective when applied with topical corticosteroids. Monoamine oxidase inhibitors should be discontinued at least 2 weeks before treatment with doxepin. Topical capsaicin can be effective in some forms of neuropathic itch. Ice in a plastic bag covered by a thin cloth applied to itchy spots can be effective.

Table 6-1. Morphologic categorization of skin lesions and diseases.

Pigmented	Freckle, lentigo, seborrheic keratosis, nevus, blue nevus, halo nevus, atypical nevus, melanoma
Scaly	Psoriasis, dermatitis (atopic, stasis, seborrheic, chronic allergic contact or irritant contact), xerosis (dry skin), lichen simplex chronicus, tinea, tinea versicolor, secondary syphilis, pityriasis rosea, discoid lupus erythematosus, exfoliative dermatitis, actinic keratoses, Bowen disease, Paget disease, intertrigo
Vesicular	Herpes simplex, varicella, herpes zoster, dyshidrosis (vesicular dermatitis of palms and soles), vesicular tinea, dermatophytid, dermatitis herpetiformis, miliaria crystallina, scabies, photosensitivity
Weepy or encrusted	Impetigo, acute contact allergic dermatitis, any vesicular dermatitis
Pustular	Acne vulgaris, acne rosacea, folliculitis, candidiasis, miliaria pustulosa, any vesicular dermatitis
Figurate ("shaped") erythema	Urticaria, erythema multiforme, erythema migrans, cellulitis, erysipelas, erysipeloid, arthropod bites
Bullous	Impetigo, blistering dactylitis, pemphigus, pemphigoid, porphyria cutanea tarda, drug eruptions, erythema multiforme, toxic epidermal necrolysis
Papular	Hyperkeratotic: warts, corns, seborrheic keratoses Purple-violet: lichen planus, drug eruptions, Kaposi sarcoma Flesh-colored, umbilicated: molluscum contagiosum Pearly: basal cell carcinoma, intradermal nevi Small, red, inflammatory: acne, miliaria rubra, candidiasis, scabies, folliculitis
Pruritus ¹	Xerosis, scabies, pediculosis, bites, systemic causes, anogenital pruritus
Nodular, cystic	Erythema nodosum, furuncle, cystic acne, follicular (epidermal) inclusion cyst
Photodermatitis (photodistributed rashes)	Drug, polymorphic light eruption, lupus erythematosus
Morbilliform	Drug, viral infection, secondary syphilis
Erosive	Any vesicular dermatitis, impetigo, aphthae, lichen planus, erythema multiforme
Ulcerated	Decubiti, herpes simplex, skin cancers, parasitic infections, syphilis (chancre), chancroid, vasculitis, stasis, arterial disease

¹Not a morphologic class but included because it is one of the most common dermatologic presentations.

Table 6-2. Useful topical dermatologic therapeutic agents.

Agent	Formulations, Strengths, and Prices ¹	Apply	Potency Class	Common Indications	Comments
Corticosteroids					
Hydrocortisone acetate	Cream 1%: \$3.00/30 g Ointment 1%: \$3.00/30 g Lotion 1%: \$7.20/120 mL	Twice daily	Low	Seborrheic dermatitis Pruritus ani Intertrigo	Not the same as hydrocortisone butyrate or valerate Not for poison oak OTC lotion (Aquihal HC) OTC solution (Scalpicin, T Scalp)
	Cream 2.5%: \$26.40/30 g	Twice daily	Low	As for 1% hydrocortisone	Perhaps better for pruritus ani Not clearly better than 1% More expensive Not OTC
Alclometasone dipropionate (Acloivate)	Cream 0.05%: \$20.25/15 g Ointment 0.05%: \$19.95/15 g	Twice daily	Low	As for hydrocortisone	More efficacious than hydrocortisone Perhaps causes less atrophy
Desonide	Cream 0.05%: \$15.45/15 g Ointment 0.05%: \$40.15/60 g Lotion 0.05%: \$99.60/60 mL	Twice daily	Low	As for hydrocortisone For lesions on face or body folds resistant to hydrocortisone	More efficacious than hydrocortisone Can cause rosacea or atrophy Not fluorinated

(continued)

Table 6-2. Useful topical dermatologic therapeutic agents. (continued)

Agent	Formulations, Strengths, and Prices ¹	Apply	Potency Class	Common Indications	Comments
Clocortolone (Cloderm)	Cream 0.1%: \$129.96/30 g	Three times daily	Medium	Contact dermatitis Atopic dermatitis	Does not cross-react with other corticosteroids chemically and can be used in patients allergic to other corticosteroids
Prednicarbate (Dermatop)	Emollient cream 0.1%: \$56.76/60 g Ointment 0.1%: \$30.00/15 g	Twice daily	Medium	As for triamcinolone	May cause less atrophy No generic formulations Preservative-free
Triamcinolone acetonide	Cream 0.1%: \$5.55/15 g Ointment 0.1%: \$5.55/15 g Lotion 0.1%: \$42.44/60 mL	Twice daily	Medium	Eczema on extensor areas Used for psoriasis with tar Seborrheic dermatitis and psoriasis on scalp	Caution in body folds, face Economical in 0.5-lb and 1-lb sizes for treatment of large body surfaces Economical as solution for scalp
	Cream 0.025%: \$4.45/15 g Ointment 0.025%: \$11.20/80 g	Twice daily	Medium	As for 0.1% strength	Possibly less efficacy and few advantages over 0.1% formulation
Fluocinolone acetonide	Cream 0.025%: \$33.75/15 g Ointment 0.025%: \$33.75/15 g	Twice daily	Medium	As for triamcinolone	
	Solution 0.01%: \$90.00/60 mL	Twice daily	Medium	As for triamcinolone solution	
Mometasone furoate (Elocon)	Cream 0.1%: \$26.90/15 g Ointment 0.1%: \$24.45/15 g Lotion 0.1%: \$57.00/60 mL	Once daily	Medium	As for triamcinolone	Often used inappropriately on the face or on children Not fluorinated
Diflorasone diacetate	Cream 0.05%: \$53.54/15 g Ointment 0.05%: \$51.86/30 g	Twice daily	High	Nummular dermatitis Allergic contact dermatitis Lichen simplex chronicus	
Amcinonide (Cyclocort)	Cream 0.1%: \$26.00/15 g Ointment 0.1%: \$194.40/60 g	Twice daily	High	As for betamethasone	
Fluocinonide (Lidex)	Cream 0.05%: \$19.95/15 g Gel 0.05%: \$24.60/15 g Ointment 0.05%: \$6.60/15 g Solution 0.05%: \$50.40/60 mL	Twice daily	High	As for betamethasone Gel useful for poison oak	Economical generics Lidex cream can cause stinging on eczema Lidex emollient cream preferred
Betamethasone dipropionate (Diprolene)	Cream 0.05%: \$35.70/15 g Ointment 0.05%: \$30.00/15 g Lotion 0.05%: \$112.80/60 mL	Twice daily	Ultra-high	For lesions resistant to high-potency corticosteroids Lichen planus Insect bites	Economical generics available
Clobetasol propionate (Temovate)	Cream 0.05%: \$24.75/15 g Ointment 0.05%: \$24.75/15 g Lotion 0.05%: \$294.00/60 mL	Twice daily	Ultra-high	As for betamethasone dipropionate	Somewhat more potent than diflorasone Limited to 2 continuous weeks of use Limited to 50 g or less per week Cream may cause stinging; use "emollient cream" formulation Generic available
Halobetasol propionate (Ultravate)	Cream 0.05%: \$31.50/15 g Ointment 0.05%: \$31.50/15 g	Twice daily	Ultra-high	As for clobetasol	Same restrictions as clobetasol Cream does not cause stinging Compatible with calcipotriene (Dovonex)
Flurandrenolide (Cordran)	Tape: \$88.10/80" × 3" roll Lotion 0.05%: \$358.80/60 mL	Every 12 hours	Ultra-high	Lichen simplex chronicus	Protects the skin and prevents scratching

Terbinafine (Lamisil)	Cream 1%: \$8.15/12 g OTC	Once daily	N/A	Dermatophytes	Fast clinical response OTC
Antipruritics					
Camphor/menthol (Sarna)	Lotion 0.5%/0.5%: \$7.80/222 mL	Two to three times daily	N/A	Mild eczema, xerosis, mild contact dermatitis	
Pramoxine hydrochloride (Prax)	Lotion 1%: \$19.07/120 mL OTC	Four times daily	N/A	Dry skin, varicella, mild eczema, pruritus ani	OTC formulations (Prax, Aveeno Anti-Itch Cream or Lotion; Itch-X Gel) By prescription mixed with 1% or 2% hydrocortisone
Doxepin (Zonalon)	Cream 5%: \$183.28/30 g	Four times daily	N/A	Topical antipruritic, best used in combination with appropriate topical corticosteroid to enhance efficacy	Can cause sedation
Emollients					
Aveeno	Cream, lotion, others	Once to three times daily	N/A	Xerosis, eczema	Choice is most often based on personal preference by patient
Aqua glycolic	Cream, lotion, shampoo, others	Once to three times daily	N/A	Xerosis, ichthyosis, keratosis pilaris Mild facial wrinkles Mild acne or seborrheic dermatitis	Contains 8% glycolic acid Available from other makers, eg, Alpha Hydrox, or generic 8% glycolic acid lotion May cause stinging on eczematous skin
Aquaphor	Ointment: \$5.91/100 g	Once to three times daily	N/A	Xerosis, eczema For protection of area in pruritus ani	Not as greasy as petrolatum
Carmol	Lotion 10%: \$18.89/180 mL Cream 20%: \$17.38/90 g	Twice daily	N/A	Xerosis	Contains urea as humectant Nongreasy hydrating agent (10%); debrides keratin (20%)
Complex 15	Lotion: \$6.48/240 mL Cream: \$4.82/75 g	Once to three times daily	N/A	Xerosis Lotion or cream recommended for split or dry nails	Active ingredient is a phospholipid
DML	Cream, lotion, facial moisturizer: \$5.95/240 mL	Once to three times daily	N/A	As for Complex 15	Face cream has sunscreen
Eucerin	Cream: \$7.37/240 g Lotion: \$5.10/240 mL	Once to three times daily	N/A	Xerosis, eczema	Many formulations made Eucerin Plus contains alpha-hydroxy acid and may cause stinging on eczematous skin Facial moisturizer has SPF 25 sunscreen

(continued)

Table 6-2. Useful topical dermatologic therapeutic agents. (continued)

Agent	Formulations, Strengths, and Prices ¹	Apply	Potency Class	Common Indications	Comments
Lac-Hydrin-Five	Lotion: \$11.37/226 g OTC	Twice daily	N/A	Xerosis, ichthyosis, keratosis pilaris	Prescription strength is 12%
Lubriderm	Lotion: \$7.33/473 mL	Once to three times daily	N/A	Xerosis, eczema	Unscented usually preferred
Neutrogena	Cream, lotion, facial moisturizer: \$7.39/240 mL	Once to three times daily	N/A	Xerosis, eczema	Face cream has titanium-based sunscreen
Ceratopic Cream	Cream: \$60.00/6 oz	Twice daily	N/A	Xerosis, eczema	Contains ceramide; anti-inflammatory and nongreasy moisturizer
U-Lactin	Lotion: \$14.16/240 mL OTC	Once daily	N/A	Hyperkeratotic heels	Moisturizes and removes keratin

²Topical tacrolimus and pimecrolimus should only be used when other topical treatments are ineffective. Treatment should be limited to an area and duration to be as brief as possible. Treatment with these agents should be avoided in persons with known immunosuppression, HIV infection, bone marrow and organ transplantation, lymphoma, at high risk for lymphoma, and those with a prior history of lymphoma. N/A, not applicable; OTC, over-the-counter.

C. Systemic antipruritic drugs

1. Antihistamines—H₁-blockers are the agents of choice for pruritus when due to histamine, such as in urticaria. Otherwise, they appear to relieve pruritus only by their sedating effects. Except in the case of urticaria, nonsedating antihistamines are of limited value in inflammatory skin diseases. Hydroxyzine, 25–50 mg nightly, can be an effective initial treatment. When inadequate, the combination of antihistamines of different classes may lead to better control of non-urticarial pruritus (for example, cetirizine or loratadine 10 mg orally twice daily plus fexofenadine 180 mg orally once or twice daily plus hydroxyzine 25–50 mg orally nightly). Some antidepressants, such as doxepin, mirtazapine, sertraline, and paroxetine can be effective antipruritics. Neurally active agents such as gabapentin, pregabalin, and duloxetine are especially useful in neuropathic pruritus, such as seen in diabetic neuropathy.

2. Systemic corticosteroids

(See Chapter 26.)

▶ Sunscreens

Protection from ultraviolet light should begin at birth and will reduce the incidence of actinic keratoses, melanoma, and some nonmelanoma skin cancers when initiated at

any age. The best protection is shade, but protective clothing, avoidance of direct sun exposure during the peak hours of the day, and daily use of chemical sunscreens are important.

Fair-complexioned persons should use a sunscreen with an SPF (sun protective factor) of at least 15 and preferably 30–40 every day. Sunscreens with high SPF values (> 30) usually afford some protection against UVA as well as UVB and are helpful in managing photosensitivity disorders. The actual SPF achieved is about one-quarter or less than that listed on the product, since patients apply only one-quarter as much sunscreen per unit area when compared with the amount used in tests to determine the SPF listed on the product. Aggressive sunscreen use should be accompanied by vitamin D supplementation in persons at risk for osteopenia (eg, organ transplant recipients).

▶ Complications of Topical Dermatologic Therapy

Complications of topical therapy can be largely avoided. They fall into several categories:

A. Allergy

Of the topical antibiotics, neomycin and bacitracin have the greatest potential for sensitization. Diphenhydramine, benzocaine, vitamin E, aromatic essential oils, and bee pollen are potential sensitizers in topical medications. Preservatives and even the topical corticosteroids themselves can cause allergic contact dermatitis.

B. Irritation

Preparations of tretinoin, benzoyl peroxide, and other acne medications should be applied sparingly to the skin.

C. Overuse

Topical corticosteroids may induce acne-like lesions on the face (steroid rosacea) and atrophic striae in body folds.

COMMON DERMATOSES

PIGMENTED LESIONS

MELANOCYTIC NEVI (Normal Moles)

In general, a **benign mole** is a small (< 6 mm) lesion with a well-defined border and a single shade of pigment from beige or pink to dark brown. The physical examination must take precedence over the history.

Moles have a normal natural history. In the patient's first decade of life, moles often appear as flat, small, brown lesions. They are called **junctional nevi** because the nevus cells are at the junction of the epidermis and dermis. Over the next 2 decades, these moles grow in size and often become raised, reflecting the appearance of a dermal component, giving rise to **compound nevi** (Figure 6-1). Moles may darken and grow during pregnancy. As white patients enter their seventh and eighth decades, most moles have lost their junctional component and dark pigmentation. At every stage of life, normal moles should be well-demarcated, symmetric, and uniform in contour and color.

Marsden JR et al; British Association of Dermatologists (BAD) Clinical Standards Unit. Revised UK guidelines for the management of cutaneous melanoma 2010. *J Plast Reconstr Aesthet Surg*. 2010 Sep;63(9):1401-19. [PMID: 20728418]
 U.S. Preventive Services Task Force. Screening for skin cancer: U.S. Preventive Services Task Force recommendation statement. *Ann Intern Med*. 2009 Feb 3;150(3):188-93. [PMID: 19189908]

ATYPICAL NEVI

The term "atypical nevus" or "atypical mole" has supplanted "dysplastic nevus." The diagnosis of atypical moles is made clinically and not histologically, and moles should be removed only if they are suspected to be melanomas. Clinically, these moles are large (≥ 6 mm in diameter), with an ill-defined, irregular border and irregularly distributed pigmentation (Figure 6-2). It is estimated that 5-10% of the white population in the United States has one or more

▲ **Figure 6-1.** Benign, flat and macular compound nevus on the arm. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

atypical nevi, and recreational sun exposure is a primary risk for the development of atypical nevi in nonfamilial settings. Studies have defined an increased risk of melanoma in the following populations: patients with 50 or more nevi with one or more atypical moles and one mole

▲ **Figure 6-2.** Atypical (dysplastic) nevus on the chest. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

at least 8 mm or larger, and patients with a few to many definitely atypical moles. These patients deserve education and regular (usually every 6–12 months) follow-up. Kindreds with familial melanoma (numerous atypical nevi and a strong family history) deserve even closer attention, as the risk of developing single or even multiple melanomas in these individuals approaches 50% by age 50.

Clark LE. Dysplastic nevi. *Clin Lab Med.* 2011 Jun;31(2):255–65. [PMID: 21549239]
 Lasithiotakis KG et al. Factors associated with the prevalence of atypical nevus in a Mediterranean pigmented skin lesion clinic. *Melanoma Res.* 2011 Oct;21(5):469–73. [PMID: 21760555]

BLUE NEVI

Blue nevi are small, slightly elevated, blue-black lesions (Figure 6–3) that favor the dorsal hands. They are common in persons of Asian descent, and an individual patient may have several of them. If present without change for many years, they may be considered benign, since malignant blue nevi are rare. However, blue-black papules and nodules that

▲ **Figure 6–3.** Blue nevus on the left cheek, with some resemblance to a melanoma. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine.* McGraw-Hill, 2009.)

are new or growing must be evaluated to rule out nodular melanoma.

Murali R et al. Blue nevi and related lesions: a review highlighting atypical and newly described variants, distinguishing features and diagnostic pitfalls. *Adv Anat Pathol.* 2009 Nov;16(6):365–82. [PMID: 19851128]

FRECKLES & LENTIGINES

Freckles (ephelides) and lentigines are flat brown spots. Freckles first appear in young children, darken with ultraviolet exposure, and fade with cessation of sun exposure. In adults lentigines gradually appear in sun-exposed areas, particularly the dorsa of the hands, upper back, and upper chest, starting in the fourth to fifth decade of life. They are macular, usually 3–5 mm in diameter. On the upper back, they may have a very irregular border (inkspot lentigines). They do not fade with cessation of sun exposure. They should be evaluated like all pigmented lesions: If the pigmentation is homogeneous and they are symmetric and flat, they are most likely benign. They can be treated with topical 0.1% tretinoin, 0.1% tazarotene, 2% 4-hydroxyanisole with 0.01% tretinoin (Solage), laser therapy, or cryotherapy.

Kim J et al. Quantitative comparison of MiTF, Melan-A, HMB-45 and Mel-5 in solar lentigines and melanoma in situ. *J Cutan Pathol.* 2011 Oct;38(10):775–9. [PMID: 21797920]

SEBORRHEIC KERATOSES

Seborrheic keratoses are benign plaques, beige to brown or even black, 3–20 mm in diameter, with a velvety or warty surface (Figure 6–4). They appear to be stuck or pasted onto the skin. They are extremely common—especially in

▲ **Figure 6–4.** Seborrheic keratosis with “stuck on appearance” but irregular borders and color variation suspicious for possible melanoma. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine.* McGraw-Hill, 2009.)

the elderly—and may be mistaken for melanomas or other types of cutaneous neoplasms. Although they may be frozen with liquid nitrogen or curetted if they itch or are inflamed, no treatment is needed.

Fink AM et al. Seborrheic keratoses in patients with internal malignancies: a case-control study with prospective accrual of patients. *J Eur Acad Dermatol Venereol*. 2009 Nov;23(11):1316–9. [PMID: 19309432]

MALIGNANT MELANOMA

ESSENTIALS OF DIAGNOSIS

- ▶ May be flat or raised.
- ▶ Should be suspected in any pigmented skin lesion with recent change in appearance.
- ▶ Examination with good light may show varying colors, including red, white, black, and bluish.
- ▶ Borders typically irregular.

▶ General Considerations

Malignant melanoma is the leading cause of death due to skin disease. In 2010, there were 68,130 cases of melanoma in the United States, with 38,870 cases in men (representing 5% of all cancers in men) and 29,260 cases in women (representing 4% of all cancers in women). There were 8461 deaths from melanoma in 2009; of those, 5506 were in men. One in four cases of melanoma occurs before the age of 40. Increased detection of early melanomas has led to increased survival, but melanoma fatalities continue to increase, especially in elderly men.

Tumor thickness is the single most important prognostic factor. Ten-year survival rates—related to thickness in millimeters—are as follows: < 1 mm, 95%; 1–2 mm, 80%; 2–4 mm, 55%; and > 4 mm, 30%. With lymph node involvement, the 5-year survival rate is 30%; with distant metastases, it is < 10%.

▶ Clinical Findings

Primary malignant melanomas may be classified into various clinicohistologic types, including lentigo maligna melanoma (arising on chronically sun-exposed skin of older individuals); superficial spreading malignant melanoma (two-thirds of all melanomas arising on intermittently sun-exposed skin); nodular malignant melanoma; acral-lentiginous melanomas (arising on palms, soles, and nail beds); ocular melanoma; and malignant melanomas on mucous membranes. These different clinical types of melanoma appear to have different oncogenic mutations, which may be important in the treatment of patients with advanced disease. Clinical features of pigmented lesions suspicious for melanoma are an irregular notched border where the pigment appears to be leaking into the normal surrounding skin; a topography that may be irregular, ie,

▲ **Figure 6-5.** Malignant melanoma, with multiple colors and classic “ABCDE” features. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

partly raised and partly flat (Figure 6–5). Color variegation is present, and colors such as pink, blue, gray, white, and black are indications for referral. A useful mnemonic is the ABCD rule: “ABCD = Asymmetry, Border irregularity, Color variegation, and Diameter > 6 mm.” “E” for Evolution can be added. The history of a changing mole (evolution) is the single most important historical reason for close evaluation and possible referral. Bleeding and ulceration are ominous signs. A mole that stands out from the patient’s other moles deserves special scrutiny—the “ugly duckling sign.” A patient with a large number of moles is statistically at increased risk for melanoma and deserves careful and periodic examination, particularly if the lesions are atypical. Referral of suspicious pigmented lesions is always appropriate.

While superficial spreading melanoma is largely a disease of whites, persons of other races are still at risk for this and other types of melanoma, particularly acral lentiginous melanoma. These occur as dark, sometimes irregularly shaped lesions on the palms and soles and as new, often broad and solitary, darkly pigmented longitudinal streaks in the nails. Acral lentiginous melanoma may be a difficult diagnosis because benign pigmented lesions of the hands, feet, and nails occur commonly in more darkly pigmented persons and clinicians may hesitate to biopsy the palms, soles, and nail beds. As a result, the diagnosis is often delayed until the tumor has become clinically obvious and histologically thick. Clinicians should give special attention to new or changing lesions in these areas.

▶ Treatment

Treatment of melanoma consists of excision. After histologic diagnosis, the area is usually reexcised with margins dictated by the thickness of the tumor. Thin low-risk and intermediate-risk tumors require only conservative margins of 1–3 cm. More specifically, surgical margins of 0.5–1 cm for melanoma in situ and 1 cm for lesions < 1 mm in thickness are recommended.

Sentinel lymph node biopsy (selective lymphadenectomy) using preoperative lymphoscintigraphy and intraoperative lymphatic mapping is effective for staging

melanoma patients with intermediate risk without clinical adenopathy and is recommended for all patients with lesions over 1 mm in thickness or with high-risk histologic features. Referral of intermediate-risk and high-risk patients to centers with expertise in melanoma is strongly recommended. Identifying the oncogenic mutations in patients with advanced melanoma may be important in their treatment. The long-term use of β -blockers may reduce the risk of progression of high-risk melanoma.

SCALING DISORDERS

ATOPIC DERMATITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Pruritic, exudative, or lichenified eruption on face, neck, upper trunk, wrists, and hands and in the antecubital and popliteal folds.
- ▶ Personal or family history of allergic manifestations (eg, asthma, allergic rhinitis, atopic dermatitis).
- ▶ Tendency to recur.
- ▶ Onset in childhood in most patients. Onset after age 30 is very uncommon.

▶ General Considerations

Atopic dermatitis looks different at different ages and in people of different races. Diagnostic criteria for atopic dermatitis must include pruritus, typical morphology and distribution (flexural lichenification, hand eczema, nipple eczema, and eyelid eczema in adults), onset in childhood, and chronicity. Also helpful are: (1) a personal or family history of atopic disease (asthma, allergic rhinitis, atopic dermatitis), (2) xerosis-ichthyosis, (3) facial pallor with infraorbital darkening, (4) elevated serum IgE, and (5) repeated skin infections.

▶ Clinical Findings

A. Symptoms and Signs

Itching may be severe and prolonged. Rough, red plaques usually without the thick scale and discrete demarcation of psoriasis affect the face, neck, and upper trunk. The flexural surfaces of elbows and knees are often involved. In chronic cases, the skin is dry, leathery, and lichenified. Pigmented persons may have poorly demarcated hypopigmented patches (pityriasis alba) on the cheeks and extremities. In black patients with severe disease, pigmentation may be lost in lichenified areas. During acute flares, widespread redness with weeping, either diffusely or in discrete plaques, is common.

B. Laboratory Findings

Food allergy is an uncommon cause of flares of atopic dermatitis in adults. Radioallergosorbent tests (RASTs) or skin tests may suggest dust mite allergy. Eosinophilia and increased serum IgE levels may be present.

▶ Differential Diagnosis

Atopic dermatitis must be distinguished from seborrheic dermatitis (less pruritic, frequent scalp and face involvement, greasy and scaly lesions, and quick response to therapy). Secondary staphylococcal infections may exacerbate atopic dermatitis, and should be considered during hyperacute, weepy flares of atopic dermatitis. Fissuring where the earlobe connects to the neck is a cardinal sign of secondary infection. Since virtually all patients with atopic dermatitis have skin disease before age 5, a new diagnosis of atopic dermatitis in an adult over age 30 should be made cautiously and only after consultation. Atopic-like dermatitis associated with marked elevation of IgE, recurrent staphylococcal abscesses, recurrent pneumonia with pneumatocele formation, and retained primary dentition may indicate hyper-IgE syndrome.

▶ Treatment

Patient education regarding gentle skin care and exactly how to use medications is critical in the successful management of atopic dermatitis.

A. General Measures

Atopic patients have hyperirritable skin. Anything that dries or irritates the skin will potentially trigger dermatitis. Atopic individuals are sensitive to low humidity and often get worse in the winter. Adults with atopic disorders should not bathe more than once daily. Soap should be confined to the armpits, groin, scalp and feet. Washcloths and brushes should not be used. After rinsing, the skin should be patted dry (not rubbed) and then immediately—within three minutes—covered with a thin film of an emollient such as Aquaphor, Eucerin, petrolatum, Vanicream, or a corticosteroid as needed. Vanicream can be used if contact dermatitis resulting from additives in medication is suspected. Atopic patients may be irritated by scratchy fabrics, including wools and acrylics. Cottons

are preferable, but synthetic blends also are tolerated. Other triggers of eczema in some patients include sweating, ointments, hot baths, and animal danders.

B. Local Treatment

Corticosteroids should be applied sparingly to the dermatitis once or twice daily and rubbed in well. Their potency should be appropriate to the severity of the dermatitis. In general, one should begin with triamcinolone 0.1% or a stronger corticosteroid then taper to hydrocortisone or another slightly stronger mild corticosteroid (alclometasone, desonide). It is vital that patients taper off corticosteroids and substitute emollients as the dermatitis clears to avoid the side effects of corticosteroids. Tapering is also important to avoid rebound flares of the dermatitis that may follow their abrupt cessation. Tacrolimus ointment (Protopic 0.03% or 0.1%) and pimecrolimus cream (Elidel 1%) can be effective in managing atopic dermatitis when applied twice daily. Burning on application occurs in about 50% of patients using Protopic and in 10–25% of Elidel users, but it may resolve with continued treatment. These medications do not cause skin atrophy or striae, and are safe for application on the face and even the eyelids.

The US Food and Drug Administration (FDA) has issued a black box warning for both topical tacrolimus and pimecrolimus due to concerns about the development of T-cell lymphoma. The agents should be used sparingly and only in locations where less expensive corticosteroids cannot be used. Tacrolimus and pimecrolimus should be avoided in patients at high risk for lymphoma (ie, those with HIV, iatrogenic immunosuppression, prior lymphoma).

The treatment of atopic dermatitis is dictated by the pattern and stage of the dermatitis—acute/weepy, subacute/scaly, or chronic/lichenified.

1. Acute weeping lesions—Use water or aluminum subacetate solution (Domeboro tablets, one in a pint of cool water) or colloidal oatmeal (Aveeno; dispense one box, and use as directed on box) as soothing or astringent soaks, baths, or wet dressings for 10–30 minutes two to four times daily. Lesions on extremities particularly may be bandaged for protection at night. Use high-potency corticosteroids after soaking but spare the face and body folds. Tacrolimus is usually not tolerated at this stage. Systemic corticosteroids may be required (see below).

2. Subacute or scaly lesions—At this stage, the lesions are dry but still red and pruritic. Mid- to high-potency corticosteroids in ointment form should be continued until scaling and elevated skin lesions are cleared and itching is decreased substantially. At that point, patients should begin a 2- to 4-week taper from twice-daily to daily to alternate-day dosing with topical corticosteroids to reliance on emollients, with occasional use of corticosteroids on specific itchy areas. Instead of tapering the frequency of usage of a more potent corticosteroid, it may be preferable to switch to a low-potency corticosteroid. Tacrolimus and pimecrolimus are more expensive alternatives and may be added if corticosteroids cannot be stopped. They avoid the complications of long-term topical corticosteroid use.

3. Chronic, dry, lichenified lesions—Thickened and usually well-demarcated, they are best treated with high-potency to ultra-high-potency corticosteroid ointments. Nightly occlusion for 2–6 weeks may enhance the initial response. Occasionally, adding tar preparations such as LCD (liquor carbonis detergens) 10% in Aquaphor or 2% crude coal tar may be beneficial.

4. Maintenance treatment—Once symptoms have improved, constant application of effective moisturizers is recommended to prevent flares. In patients with moderate disease, weekend only use of topical anti-inflammatories can prevent flares.

C. Systemic and Adjuvant Therapy

Systemic corticosteroids are indicated only for severe acute exacerbations. Oral prednisone dosages should be high enough to suppress the dermatitis quickly, usually starting with 40–60 mg daily for adults. The dosage is then tapered to nil over a period of 2–4 weeks. Owing to the chronic nature of atopic dermatitis and the side effects of chronic systemic corticosteroids, long-term use of these agents is not recommended for maintenance therapy. Classic antihistamines may relieve severe pruritus. Hydroxyzine, diphenhydramine, or doxepin may be useful—the dosage increased gradually to avoid drowsiness. Fissures, crusts, erosions, or pustules indicate staphylococcal infection clinically. Antistaphylococcal antibiotics given systemically—such as a first-generation cephalosporin or doxycycline if methicillin-resistant *Staphylococcus aureus* is suspected—may be helpful in management. Cultures to exclude methicillin-resistant *S aureus* are recommended. Phototherapy can be an important adjunct for severely affected patients, and the properly selected patient with recalcitrant disease may benefit greatly from therapy with UVB with or without coal tar or PUVA (psoralen plus ultraviolet A). Oral cyclosporine, mycophenolate mofetil, methotrexate, or azathioprine may be used for the most severe and recalcitrant cases.

► Complications of Treatment

The clinician should monitor for skin atrophy. **Eczema herpeticum**, a generalized herpes simplex infection manifested by monomorphic vesicles, crusts, or scalloped erosions superimposed on atopic dermatitis or other extensive eczematous processes, is treated successfully with oral acyclovir, 200 mg five times daily, or intravenous acyclovir in a dose of 10 mg/kg intravenously every 8 hours (500 mg/m² every 8 hours). Tacrolimus and pimecrolimus may increase the risk of eczema herpeticum. Smallpox vaccination is absolutely contraindicated in patients with atopic dermatitis or a history thereof because of the risk of eczema vaccinatum (widespread vaccinia infection, preferentially in areas of dermatitis).

► Prognosis

Atopic dermatitis runs a chronic or intermittent course. Affected adults may have only hand dermatitis. Poor

prognostic factors for persistence into adulthood in atopic dermatitis include onset early in childhood, early generalized disease, and asthma. Only 40–60% of these patients have lasting remissions.

LICHEN SIMPLEX CHRONICUS (Circumscribed Neurodermatitis)

ESSENTIALS OF DIAGNOSIS

- ▶ Chronic itching and scratching.
- ▶ Lichenified lesions with exaggerated skin lines overlying a thickened, well-circumscribed scaly plaque.
- ▶ Predisposition for nape of neck, wrists, external surfaces of forearms, lower legs, scrotum, and vulva.

▶ General Considerations

Lichen simplex chronicus represents a self-perpetuating scratch-itch cycle—a learned behavior that is hard to disrupt.

▶ Clinical Findings

Intermittent itching incites the patient to scratch the lesions. Itching may be so intense as to interfere with sleep. Dry, leathery, hypertrophic, lichenified plaques appear on the neck, ankles, or perineum (Figure 6–6). The patches are rectangular, thickened, and hyperpigmented. The skin lines are exaggerated.

▶ Differential Diagnosis

This disorder can be differentiated from plaque-like lesions such as psoriasis (redder lesions having whiter scales on the elbows, knees, and scalp and nail findings), lichen planus (violaceous, usually smaller polygonal papules), and nummular (coin-shaped) dermatitis. Lichen simplex chronicus may complicate chronic atopic dermatitis.

▶ Treatment

For lesions in extra-genital regions, superpotent topical corticosteroids are effective, with or without occlusion,

▲ **Figure 6-6.** Lichen simplex chronicus. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

when used twice daily for several weeks. In some patients, flurandrenolide (Cordran) tape may be effective, since it prevents scratching and rubbing of the lesion. The injection of triamcinolone acetonide suspension (5–10 mg/mL) into the lesions may occasionally be curative. Continuous occlusion with a flexible hydrocolloid dressing for 7 days at a time for 1–2 months may also be helpful. For genital lesions, see the section Pruritus Ani.

▶ Prognosis

The disease tends to remit during treatment but may recur or develop at another site.

Martin-Brufau R et al. Personality differences between patients with lichen simplex chronicus and normal population: a study of pruritus. *Eur J Dermatol.* 2010 May–Jun;20(3):359–63. [PMID: 20388609]

PSORIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Silvery scales on bright red, well-demarcated plaques, usually on the knees, elbows, and scalp.
- ▶ Nail findings including pitting and onycholysis (separation of the nail plate from the bed).
- ▶ Mild itching (usually).
- ▶ May be associated with psoriatic arthritis.
- ▶ Psoriasis patients are at increased risk for metabolic syndrome and lymphoma.
- ▶ Histopathology is not often useful and can be confusing.

▶ General Considerations

Psoriasis is a common benign, chronic inflammatory skin disease with both a genetic basis and known environmental triggers. Injury or irritation of normal skin tends to induce lesions of psoriasis at the site (Koebner phenomenon). Obesity worsens psoriasis, and significant weight loss in persons with high body mass index (BMI) may lead to substantial improvement of their psoriasis. Psoriasis has several variants—the most common is the plaque type. Eruptive (guttate) psoriasis consisting of myriad lesions 3–10 mm in diameter occurs occasionally after streptococcal pharyngitis. Rarely, grave, occasionally life-threatening forms (generalized pustular and erythrodermic psoriasis) may occur. Plaque type or extensive erythrodermic psoriasis with abrupt onset may accompany HIV infection.

▶ Clinical Findings

There are often no symptoms, but itching may occur and be severe. Favored sites include the scalp, elbows, knees, palms and soles, and nails (Figure 6–7). The lesions are red,

▲ **Figure 6–7.** Nail pitting due to psoriasis. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

▲ **Figure 6–8.** Plaque psoriasis in the sacral region and intergluteal fold. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

sharply defined plaques covered with silvery scales (Figure 6–8). The glans penis and vulva may be affected. Occasionally, only the flexures (axillae, inguinal areas) are involved. Fine stippling (“pitting”) in the nails is highly suggestive of psoriasis. Patients with psoriasis often have a pink or red intergluteal fold. Not all patients have findings in all locations, but the occurrence of a few may help make the diagnosis when other lesions are not typical. Some patients have mainly hand or foot dermatitis and only minimal findings elsewhere. There may be associated arthritis that is most commonly distal and oligoarticular, although the rheumatoid variety with a negative rheumatoid factor may occur. The psychosocial impact of psoriasis is a major factor in determining the treatment of the patient.

▶ Differential Diagnosis

The combination of red plaques with silvery scales on elbows and knees, with scaliness in the scalp or nail findings, is diagnostic (see Figure 6–7). Psoriasis lesions are well demarcated and affect extensor surfaces—in contrast to atopic dermatitis, with poorly demarcated plaques in flexural distribution. In body folds, scraping and culture for *Candida* and examination of scalp and nails will distinguish psoriasis from intertrigo and candidiasis. Dystrophic changes in nails may simulate onychomycosis, but again, the general examination combined with a potassium

hydroxide (KOH) preparation or fungal culture will be valuable in diagnosis. The cutaneous features of reactive arthritis (Reiter syndrome) mimic psoriasis.

► Treatment

There are many therapeutic options in psoriasis to be chosen according to the extent (body surface area [BSA] affected) and the presence of other findings (for example, arthritis). Certain drugs, such as β -blockers, antimalarials, statins, and lithium, may flare or worsen psoriasis. Even tiny doses of systemic corticosteroids given to patients with psoriasis may lead to severe rebound flares of their disease when they are tapered. Never use systemic corticosteroids to treat flares of psoriasis. In general, patients with moderate to severe psoriasis should be managed by or in conjunction with a dermatologist.

A. Limited Disease

For patients with numerous small plaques, phototherapy is the best therapy (see below). For patients with large plaques and < 10% of the BSA involved, the easiest regimen is to use a high-potency to ultra-high-potency topical corticosteroid cream or ointment. It is best to restrict the ultra-high-potency corticosteroids to 2–3 weeks of twice-daily use and then use them in a pulse fashion three or four times on weekends or switch to a midpotency corticosteroid. Topical corticosteroids rarely induce a lasting remission. They may cause psoriasis to become unstable. Additional measures are therefore commonly added to topical corticosteroid therapy. Calcipotriene ointment 0.005% or calcitriol ointment 0.003%, both vitamin D analogs, are used twice daily for plaque psoriasis. Initially, patients are treated with twice-daily corticosteroids plus a vitamin D analog twice daily. This rapidly clears the lesions. The vitamin D analog is then used alone once daily and with the corticosteroid once daily for several weeks. Eventually, the topical corticosteroids are stopped, and once- or twice-daily application of the vitamin D analog is continued long-term. Calcipotriene usually cannot be applied to the groin or on the face because of irritation. Treatment of extensive psoriasis with vitamin D analogs may result in hypercalcemia, so that the maximum dose for calcipotriene is 100 g/week and for calcitriol is 200 g/week. Calcipotriene is incompatible with many topical corticosteroids (but not halobetasol), so if used concurrently it must be applied at a different time. Tar preparations such as Fototar cream, LCD (liquor carbonis detergens) 10% in Nutraderm lotion, alone or mixed directly with triamcinolone 0.1%, are useful adjuncts when applied twice daily. Occlusion alone has been shown to clear isolated plaques in 30–40% of patients. Thin, occlusive hydrocolloid dressings are placed on the lesions and left undisturbed for as long as possible (a minimum of 5 days, up to 7 days) and then replaced. Responses may be seen within several weeks.

For the scalp, start with a tar shampoo, used daily if possible. For thick scales, use 6% salicylic acid gel (eg, Keralyt), P & S solution (phenol, mineral oil, and glycerin), or fluocinonide acetonide 0.01% in oil (Derma-Smoother/FS)

under a shower cap at night, and shampoo in the morning. In order of increasing potency, triamcinolone 0.1%, or fluocinonide, betamethasone dipropionate, fluocinonide or amcinonide, and clobetasol are available in solution form for use on the scalp twice daily. For psoriasis in the body folds, treatment is difficult, since potent corticosteroids cannot be used and other agents are poorly tolerated. Tacrolimus ointment 0.1% or 0.03% or pimecrolimus cream 1% may be effective in penile, groin, and facial psoriasis.

B. Moderate Disease

Psoriasis affecting 10–30% of the patient's BSA is frequently treated with UV phototherapy, either in a medical office or via a home light unit. Systemic agents listed below may also be used.

C. Generalized Disease

If psoriasis involves > 30% of the body surface, it is difficult to treat with topical agents. The treatment of choice is outpatient narrowband UVB (NB-UVB) three times weekly. Clearing occurs in an average of 7 weeks, but maintenance may be required. Severe psoriasis unresponsive to outpatient ultraviolet light may be treated in a psoriasis day care center with the Goeckerman regimen, which involves use of crude coal tar for many hours and exposure to UVB light. Such treatment may offer the best chance for prolonged remissions.

PUVA may be effective even in patients who have not responded to standard NB-UVB treatment. Long-term use of PUVA is associated with an increased risk of skin cancer (especially squamous cell carcinoma and perhaps melanoma), particularly in persons with fair complexions. Thus, periodic examination of the skin is imperative. Atypical lentigines are a common complication. There can be rapid aging of the skin in fair individuals. Cataracts have not been reported with proper use of protective glasses. PUVA may be used in combination with other therapy, such as acitretin or methotrexate.

Methotrexate is very effective for severe psoriasis in doses up to 25 mg once weekly. It should be used according to published protocols. Long-term methotrexate use may be associated with cirrhosis. After receiving a 1.5–2 g cumulative dose, the patient should be referred to a hepatologist for consideration of a liver biopsy. Administration of folic acid, 1–2 mg daily, can eliminate nausea caused by methotrexate without compromising efficacy.

Acitretin, a synthetic retinoid, is most effective for pustular psoriasis in dosages of 0.5–0.75 mg/kg/d. Liver enzymes and serum lipids must be checked periodically. Because acitretin is a teratogen and persists for long periods in fat, women of childbearing age must wait at least 3 years after completing acitretin treatment before considering pregnancy. When used as single agents, retinoids will flatten psoriatic plaques, but will rarely result in complete clearing. Retinoids find their greatest use when combined with phototherapy—either UVB or PUVA, with which they are synergistic.

Cyclosporine dramatically improves psoriasis and may be used to control severe cases. Rapid relapse (rebound) is the rule after cessation of therapy, so another agent must be

added if cyclosporine is stopped. The tumor necrosis factor (TNF) inhibitors etanercept (Enbrel), 50 mg twice weekly; infliximab (Remicade); and adalimumab (Humira) are effective in pustular and chronic plaque psoriasis and are also effective for the associated arthritis. Infliximab provides the most rapid response and can be used for severe pustular or erythrodermic flares. Etanercept is used more frequently for long-term treatment at a dose of 50 mg twice weekly for 3 months, then 50 mg once weekly. All three TNF inhibitors can also induce or worsen psoriasis. Alefacept (Amevive) generally has moderate efficacy, but in a small percentage of patients, it is dramatically effective. IL-12/23 monoclonal antibodies (ustekinumab [Stelara]) are also effective and may be considered instead of using a TNF inhibitor. Given the large number of immunosuppressive and biologic agents available, consultation with a dermatologist is recommended when considering institution of treatment with a systemic agent for moderate to severe psoriasis.

► Prognosis

The course tends to be chronic and unpredictable, and the disease may be refractory to treatment. Patients (especially those older than 40 years) should be monitored for metabolic syndrome, which correlates with the severity of their skin disease.

Langan SM et al. Prevalence of metabolic syndrome in patients with psoriasis: a population-based study in the United Kingdom. *J Invest Dermatol.* 2011 (2012 Mar;132(3Pt1):556–62. [PMID: 22113483]

PITYRIASIS ROSEA

ESSENTIALS OF DIAGNOSIS

- ▶ Oval, fawn-colored, scaly eruption following cleavage lines of trunk.
- ▶ Herald patch precedes eruption by 1–2 weeks.
- ▶ Occasional pruritus.

► General Considerations

This is a common mild, acute inflammatory disease that is 50% more common in females. Young adults are principally affected, mostly in the spring or fall. Concurrent household cases have been reported.

► Clinical Findings

Itching is common but is usually mild. The diagnosis is made by finding one or more classic lesions. The lesions consist of oval, fawn-colored plaques up to 2 cm in diameter. The centers of the lesions have a crinkled or “cigarette paper” appearance and a collarette scale, ie, a thin bit of scale that is bound at the periphery and free in the center. Only a few lesions in the eruption may have this characteristic appearance, however. Lesions follow cleavage lines on the trunk (so-called Christmas tree pattern, Figure 6–9), and the proximal portions of the extremities are often involved. A variant that affects the flexures (axillae and groin), so called inverse pityriasis rosea, and a papular variant, especially in black patients, also occur. An initial lesion (“herald patch”) that is often larger than the later lesions often precedes the general eruption by 1–2 weeks. The eruption usually lasts 6–8 weeks and heals without scarring.

► Differential Diagnosis

A serologic test for syphilis should be performed if at least a few perfectly typical lesions are not present and especially

▲ **Figure 6-9.** Pityriasis rosea with scaling lesions following skin lines and resembling a Christmas tree. (Courtesy of EJ Mayeaux, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine.* McGraw-Hill, 2009.)

if there are palmar and plantar or mucous membrane lesions or adenopathy, features that are suggestive of secondary syphilis. For the nonexpert, an RPR (rapid plasma reagin) test in all cases is not unreasonable. Tinea corporis may present with red, slightly scaly plaques, but rarely are there more than a few lesions of tinea corporis compared to the many lesions of pityriasis rosea. Seborrheic dermatitis on occasion presents on the body with poorly demarcated patches over the sternum, in the pubic area, and in the axillae. Tinea versicolor lacks the typical collarette rimmed lesions. Certain drugs (eg, angiotensin-converting enzyme [ACE] inhibitors and metronidazole) and influenza immunization may induce a skin eruption mimicking pityriasis rosea.

▶ Treatment

Pityriasis rosea often requires no treatment. In Asians, Hispanics, or blacks, in whom lesions may remain hyperpigmented for some time, more aggressive management may be indicated. Treatment is, otherwise, only indicated if the patient is symptomatic. No treatment has been demonstrated efficacious in pityriasis rosea in adequately controlled and reproduced trials. Most dermatologists recommend UVB treatments, or prednisone as used for contact dermatitis for severe or severely symptomatic cases. For mild to moderate cases, topical corticosteroids of medium strength (triamcinolone 0.1%) and oral antihistamines may also be used if pruritus is bothersome.

▶ Prognosis

Pityriasis rosea is usually an acute self-limiting illness that disappears in about 6 weeks.

Rebora AE et al. A novel influenza A (H1N1) virus as a possible cause of pityriasis rosea? A comment. *J Eur Acad Dermatol Venereol.* 2011 Aug;25(8):991–2. [PMID: 21585559]
 Wollenberg A et al. Skin diseases following a Christmas tree pattern. *Clin Dermatol.* 2011 Mar–Apr;29(2):189–94. [PMID: 21396559]

SEBORRHEIC DERMATITIS & DANDRUFF

ESSENTIALS OF DIAGNOSIS

- ▶ Dry scales and underlying erythema.
- ▶ Scalp, central face, presternal, interscapular areas, umbilicus, and body folds.

▶ General Considerations

Seborrheic dermatitis is an acute or chronic papulosquamous dermatitis that often coexists with psoriasis.

▶ Clinical Findings

Pruritus is an inconstant finding. The scalp, face, chest, back, umbilicus, eyelid margins, and body folds have dry scales or oily yellowish scurf (Figure 6–10). Patients with Parkinson

▲ **Figure 6–10.** Seborrheic dermatitis. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

disease, HIV infection, and patients who become acutely ill and are hospitalized often have seborrheic dermatitis.

▶ Differential Diagnosis

There is a spectrum from seborrheic dermatitis to scalp psoriasis. Extensive seborrheic dermatitis may simulate intertrigo in flexural areas, but scalp, face, and sternal involvement suggests seborrheic dermatitis.

▶ Treatment

A. Seborrhea of the Scalp

Shampoos that contain zinc pyrithione or selenium are used daily if possible. These may be alternated with ketoconazole shampoo (1% or 2%) used twice weekly. A combination of shampoos is used in refractory cases. Tar shampoos are also effective for milder cases and for scalp psoriasis. Topical corticosteroid solutions or lotions are then added if necessary and are used twice daily. (See treatment for scalp psoriasis, above.)

B. Facial Seborrheic Dermatitis

The mainstay of therapy is a mild corticosteroid (hydrocortisone 1%, alclometasone, desonide) used intermittently and not near the eyes. If the disorder cannot be controlled with intermittent use of a mild topical corticosteroid alone, ketoconazole (Nizoral) 2% cream is added twice daily. Topical tacrolimus (Protopic) and pimecrolimus (Elidel) are steroid-sparing alternatives.

C. Seborrheic Dermatitis of Nonhairy Areas

Low-potency corticosteroid creams—ie, 1% or 2.5% hydrocortisone, desonide, or alclometasone dipropionate—are highly effective.

D. Seborrhea of Intertriginous Areas

Apply low-potency corticosteroid lotions or creams twice daily for 5–7 days and then once or twice weekly for maintenance as necessary. Ketoconazole or clotrimazole cream may be a useful adjunct. Tacrolimus or pimecrolimus topically may avoid corticosteroid atrophy in chronic cases.

E. Involvement of Eyelid Margins

“Marginal blepharitis” usually responds to gentle cleaning of the lid margins nightly as needed, with undiluted Johnson and Johnson Baby Shampoo using a cotton swab.

► Prognosis

The tendency is for lifelong recurrences. Individual outbreaks may last weeks, months, or years.

FUNGAL INFECTIONS OF THE SKIN

Mycotic infections are traditionally divided into two principal groups—superficial and deep. In this chapter, we will discuss only the superficial infections: tinea corporis and tinea cruris; dermatophytosis of the feet and dermatophytid of the hands; tinea unguium (onychomycosis); and tinea versicolor. See Chapter 36 for discussion of deep mycoses.

The diagnosis of fungal infections of the skin is usually based on the location and characteristics of the lesions and on the following laboratory examinations: (1) Direct demonstration of fungi in 10% KOH of scrapings from suspected lesions. “If it’s scaly, scrape it” is a time-honored maxim (Figure 6–11). (2) Cultures of organisms from skin scrapings. (3) Histologic sections of biopsies stained with

periodic acid-Schiff (Hotchkiss-McManus) technique may be diagnostic if scrapings and cultures are negative.

► Principles of Treatment

A diagnosis should always be confirmed by KOH preparation, culture, or biopsy. Many other diseases cause scaling, and use of an antifungal agent without a firm diagnosis makes subsequent diagnosis more difficult. In general, fungal infections are treated topically except for those involving the nails, those that are very extensive, or those that involve the hair follicles.

Griseofulvin is safe and effective for treating dermatophyte infections of the skin (except for the scalp and nails). Itraconazole, an azole antifungal, and terbinafine, an allylamine oral antifungal, have excellent activity against dermatophytes and can be used in shorter courses than griseofulvin.

Fluconazole has excellent activity against yeasts and may be the treatment of choice for many forms of mucocutaneous candidiasis. Itraconazole, fluconazole, and terbinafine can all cause elevation of liver function tests and—though rarely in the dosing regimens used for the treatment of dermatophytosis—clinical hepatitis. Ketoconazole is no longer recommended for the treatment of dermatophytosis (except for tinea versicolor) because of the higher rate of hepatitis when it is used for more than a month.

► General Measures & Prevention

Since moist skin favors the growth of fungi, dry the skin carefully after bathing or after perspiring heavily. Talc or other drying powders may be useful. The use of topical corticosteroids for other diseases may be complicated by intercurrent tinea or candidal infection, and topical antifungals are often used in intertriginous areas with corticosteroids to prevent this.

1. Tinea Corporis or Tinea Circinata (Body Ringworm)

ESSENTIALS OF DIAGNOSIS

- Ring-shaped lesions with an advancing scaly border and central clearing or scaly patches with a distinct border.
- On exposed skin surfaces or the trunk.
- Microscopic examination of scrapings or culture confirms the diagnosis.

► General Considerations

The lesions are often on exposed areas of the body such as the face and arms. A history of exposure to an infected cat may occasionally be obtained, usually indicating *Microsporum* infection. *Trichophyton rubrum* is the most common pathogen, usually representing extension onto the trunk or extremities of tinea cruris, pedis, or manuum.

▲ **Figure 6–11.** KOH preparation of fungus demonstrating pseudohyphae and budding yeast forms. (Reproduced, with permission, from Nicoll D et al. *Pocket Guide to Diagnostic Tests*, 6th ed. McGraw-Hill, 2012.)

► Clinical Findings

A. Symptoms and Signs

Itching may be present. In classic lesions, rings of erythema have an advancing scaly border and central clearing (Figure 6–12).

B. Laboratory Findings

The diagnosis may be confirmed by KOH preparation or culture.

► Differential Diagnosis

Positive fungal studies distinguish tinea corporis from other skin lesions with annular configuration, such as the

annular lesions of psoriasis, lupus erythematosus, syphilis, granuloma annulare, and pityriasis rosea. Psoriasis has typical lesions on elbows, knees, scalp, and nails. Secondary syphilis is often manifested by characteristic palmar, plantar, and mucous membrane lesions. Tinea corporis rarely has the large number of symmetric lesions seen in pityriasis rosea. Granuloma annulare lacks scales.

► Complications

Complications include extension of the disease down the hair follicles (in which case it becomes much more difficult to cure) and pyoderma.

► Prevention

Treat infected household pets (*Microsporum* infections).

► Treatment

A. Local Measures

Tinea corporis responds to most topical antifungals, including miconazole, clotrimazole, butenafine, and terbinafine, which are available over the counter (see Table 6–2). Terbinafine and butenafine require shorter courses and lead to the most rapid response. Treatment should be continued for 1–2 weeks after clinical clearing. Betamethasone dipropionate with clotrimazole (Lotrisone) is not recommended. Long-term improper use may result in side effects from the high-potency corticosteroid component, especially in body folds. Cases of tinea that are clinically resistant to this combination but respond to topical antifungals without the topical corticosteroid can occur.

B. Systemic Measures

Griseofulvin (ultramicrosize), 250–500 mg twice daily, is used. Typically, only 4–6 weeks of therapy are required. Itraconazole as a single week-long pulse of 200 mg daily is also effective in tinea corporis. Terbinafine, 250 mg daily for 1 month, is an alternative.

► Prognosis

Body ringworm usually responds promptly to conservative topical therapy or to an oral agent within 4 weeks.

2. Tinea Cruris (Jock Itch)

▲ **Figure 6–12.** Tinea pedis and corporis. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

ESSENTIALS OF DIAGNOSIS

- ▶ Marked itching in intertriginous areas, usually sparing the scrotum.
- ▶ Peripherally spreading, sharply demarcated, centrally clearing erythematous lesions.
- ▶ May have associated tinea infection of feet or toenails.
- ▶ Laboratory examination with microscope or culture confirms diagnosis.

▶ General Considerations

Tinea cruris lesions are confined to the groin and gluteal cleft. Intractable pruritus ani may occasionally be caused by a tinea infection.

▶ Clinical Findings

A. Symptoms and Signs

Itching may be severe, or the rash may be asymptomatic. The lesions have sharp margins, cleared centers, and active, spreading scaly peripheries. Follicular pustules are sometimes encountered. The area may be hyperpigmented on resolution.

B. Laboratory Findings

Hyphae can be demonstrated microscopically in KOH preparations. The organism may be cultured.

▶ Differential Diagnosis

Tinea cruris must be distinguished from other lesions involving the intertriginous areas, such as candidiasis, seborrheic dermatitis, intertrigo, psoriasis of body folds (“inverse psoriasis”), and erythrasma. Candidiasis is generally bright red and marked by satellite papules and pustules outside of the main border of the lesion. *Candida* typically involves the scrotum. Seborrheic dermatitis also often involves the face, sternum, and axillae. Intertrigo tends to be more red, less scaly, and present in obese individuals in moist body folds with less extension onto the thigh. Inverse psoriasis is characterized by distinct plaques. Other areas of typical psoriatic involvement should be checked, and the KOH examination will be negative. Erythrasma is best diagnosed with Wood (ultraviolet) light—a brilliant coral-red fluorescence is seen.

▶ Treatment

A. General Measures

Drying powder (eg, miconazole nitrate [Zeamorb-AF]) can be dusted into the involved area in patients with excessive perspiration or occlusion of skin due to obesity.

B. Local Measures

Any of the topical antifungal preparations listed in Table 6–2 may be used. Terbinafine cream is curative in over 80% of cases after once-daily use for 7 days.

C. Systemic Measures

Griseofulvin ultramicrosize is reserved for severe cases. Give 250–500 mg orally twice daily for 1–2 weeks. One week of either itraconazole, 200 mg daily, or terbinafine, 250 mg daily, can be effective.

▶ Prognosis

Tinea cruris usually responds promptly to topical or systemic treatment but often recurs.

3. Tinea Manuum & Tinea Pedis (Dermatophytosis, Tinea of Palms & Soles, “Athlete’s Foot”)

ESSENTIALS OF DIAGNOSIS

- ▶ Most often presenting with asymptomatic scaling.
- ▶ May progress to fissuring or maceration in toe web spaces.
- ▶ Common cofactor in lower leg cellulitis.
- ▶ Itching, burning, and stinging of interdigital web; scaling palms, and soles; vesicles of soles in inflammatory cases.
- ▶ The fungus is shown in skin scrapings examined microscopically or by culture of scrapings.

▶ General Considerations

Tinea of the feet is an extremely common acute or chronic dermatosis. Most infections are caused by *Trichophyton* species.

▶ Clinical Findings

A. Symptoms and Signs

The presenting symptom may be itching, burning, or stinging. Pain may indicate secondary infection with complicating cellulitis. Interdigital tinea pedis is the most common predisposing cause of lower leg cellulitis in healthy individuals. Regular examination of the feet of diabetic patients for evidence of scaling and fissuring and treatment of any identified tinea pedis may prevent complications. Tinea pedis has several presentations that vary with the location. On the sole and heel, tinea may appear as chronic noninflammatory scaling, occasionally with thickening and fissuring. This may extend over the sides of the feet in a “moccasin” distribution. The KOH preparation is usually positive. Tinea pedis often appears as a scaling or fissuring of the toe webs, perhaps with sodden maceration (Figure 6–13). As the web spaces become more macerated, the KOH preparation and fungal culture are less often positive because bacterial species begin to dominate. Finally, there may also be grouped vesicles distributed anywhere on the soles, generalized exfoliation of the skin of the soles, or nail involvement in the form of discoloration and thickening and crumbling of the nail plate.

B. Laboratory Findings

KOH and culture does not always demonstrate pathogenic fungi from macerated areas.

▶ Differential Diagnosis

Differentiate from other skin conditions involving the same areas, such as interdigital erythrasma (use Wood light). Psoriasis may be a cause of chronic scaling on the palms or soles and may cause nail changes. Repeated fungal cultures should be negative, and the condition will not

▲ **Figure 6-13.** Tinea pedis in the interdigital space between fourth and fifth digits. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

respond to antifungal therapy. Contact dermatitis (from shoes) will often involve the dorsal surfaces and will respond to topical or systemic corticosteroids. Vesicular lesions should be differentiated from pompholyx (dyshidrosis) and scabies by proper scraping of the roofs of individual vesicles. Rarely, gram-negative organisms may cause toe web infections, manifested as an acute erosive flare of interdigital disease. This entity is treated with aluminum salts (see below) and imidazole antifungal agents or ciclopirox.

► Prevention

The essential factor in prevention is personal hygiene. Wear open-toed sandals if possible. Use of sandals in community showers and bathing places is often recommended, though the effectiveness of this practice has not been studied. Careful drying between the toes after showering is essential. A hair dryer used on low setting may be used. Socks should be changed frequently, and absorbent nonsynthetic socks are preferred. Apply dusting and drying powders as necessary. The use of powders containing antifungal agents (eg, Zeasorb-AF) or chronic use of antifungal creams may prevent recurrences of tinea pedis.

► Treatment

A. Local Measures

1. Macerated stage—Treat with aluminum subacetate solution soaks for 20 minutes twice daily. Broad-spectrum antifungal creams and solutions (containing imidazoles or ciclopirox instead of tolnaftate and haloprogin) will help combat diphtheroids and other gram-positive organisms present at this stage and alone may be adequate therapy. If topical imidazoles fail, 1 week of once-daily topical allylamine treatment (terbinafine or butenafine) will often result in clearing.

2. Dry and scaly stage—Use any of the antifungal agents listed in Table 6-2. The addition of urea 10–20% lotion or cream may increase the efficacy of topical treatments in thick (“moccasin”) tinea of the soles.

B. Systemic Measures

Griseofulvin may be used for severe cases or those recalcitrant to topical therapy. If the infection is cleared by systemic therapy, the patient should be encouraged to begin maintenance with topical therapy, since recurrence is common. Itraconazole, 200 mg daily for 2 weeks or 400 mg daily for 1 week, or terbinafine, 250 mg daily for 2–4 weeks, may be used in refractory cases.

► Prognosis

For many individuals, tinea pedis is a chronic affliction, temporarily cleared by therapy only to recur.

Matricciani L et al. Safety and efficacy of tinea pedis and onychomycosis treatment in people with diabetes: a systematic review. *J Foot Ankle Res*. 2011 Dec 4;4:26. [PMID: 22136082]
Parish LC et al. A randomized, double-blind, vehicle-controlled efficacy and safety study of naftifine 2% cream in the treatment of tinea pedis. *J Drugs Dermatol*. 2011 Nov 1;10(11):1282–8. [PMID: 22052309]

4. Tinea Versicolor (Pityriasis Versicolor)

ESSENTIALS OF DIAGNOSIS

- ▶ Velvety, tan, or pink macules or white macules that do not tan.
- ▶ Fine scales that are not visible but are seen by scraping the lesion.
- ▶ Central upper trunk the most frequent site.
- ▶ Yeast and short hyphae observed on microscopic examination of scales.

► General Considerations

Tinea versicolor is a mild, superficial *Malassezia* infection of the skin (usually of the upper trunk). This yeast is a colonizer of all humans, which accounts for the high recurrence rate after treatment. The eruption is often called to patients' attention by the fact that the involved areas will not tan, and the resulting hypopigmentation may be mistaken for vitiligo. A hyperpigmented form is not uncommon.

► Clinical Findings

A. Symptoms and Signs

Lesions are asymptomatic, but a few patients note itching. The lesions are velvety, tan, pink, or white macules that vary from 4–5 mm in diameter to large confluent areas. The lesions initially do not look scaly, but scales may be readily obtained by scraping the area. Lesions may appear on the trunk, upper arms, neck, and groin.

B. Laboratory Findings

Large, blunt hyphae and thick-walled budding spores (“spaghetti and meatballs”) are seen on KOH. Fungal culture is not useful.

▶ Differential Diagnosis

Vitiligo usually presents with larger periorificial lesions. Vitiligo (and not tinea versicolor) is characterized by total depigmentation, not just a lessening of pigmentation. Vitiligo does not scale. Pink and red-brown lesions on the chest are differentiated from seborrheic dermatitis of the same areas by the KOH preparation.

▶ Treatment & Prognosis

Topical treatments include selenium sulfide lotion, which may be applied from neck to waist daily and left on for 5–15 minutes for 7 days; this treatment is repeated weekly for a month and then monthly for maintenance. Ketoconazole shampoo, 1% or 2%, lathered on the chest and back and left on for 5 minutes may also be used weekly for treatment and to prevent recurrence. Clinicians must stress to the patient that the raised and scaly aspects of the rash are being treated; the alterations in pigmentation may take months to fade or fill in.

Ketoconazole, 200 mg daily orally for 1 week or 400 mg as a single oral dose, with exercise to the point of sweating after ingestion, results in short-term cure of 90% of cases. Patients should be instructed not to shower for 8–12 hours after taking ketoconazole, because it is delivered in sweat to the skin. The single dose may not work in more hot and humid areas, and more protracted therapy carries a small risk of drug-induced hepatitis. Two doses of oral fluconazole, 300 mg, 14 days apart has similar efficacy. Without maintenance therapy, recurrences will occur in over 80% of “cured” cases over the subsequent 2 years. Imidazole creams, solutions, and lotions are quite effective for localized areas but are too expensive for use over large areas such as the chest and back.

Bonifaz A et al. Tinea versicolor, tinea nigra, white piedra, and black piedra. *Clin Dermatol.* 2010 Mar 4;28(2):140–5. [PMID: 20347655]

DISCOID & SUBACUTE LUPUS ERYTHEMATOSUS (Chronic Cutaneous Lupus Erythematosus)

ESSENTIALS OF DIAGNOSIS

- ▶ Localized red plaques, usually on the face.
- ▶ Scaling, follicular plugging, atrophy, dyspigmentation, and telangiectasia of involved areas.
- ▶ Histology distinctive.
- ▶ Photosensitive.

▶ General Considerations

The two most common forms of chronic cutaneous lupus erythematosus (CCLE) are chronic scarring (discoid) lesions (DLE) and erythematous non-scarring red plaques (subacute cutaneous LE) (SCLE). Both occur most frequently in areas exposed to solar irradiation. Permanent hair loss and loss of pigmentation are common sequelae of discoid lesions. Systemic lupus erythematosus (SLE) is discussed in Chapter 20. Patients with SLE may have DLE or SCLE lesions.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms are usually mild. The lesions consist of dusky red, well-localized, single or multiple plaques, 5–20 mm in diameter, usually on the head in DLE and the trunk in SCLE. In DLE, the scalp, face, and external ears may be involved. In discoid lesions, there is atrophy, telangiectasia, depigmentation, and follicular plugging. On the scalp, significant permanent hair loss may occur in lesions of DLE. In SCLE, the lesions are erythematous annular or psoriasisiform plaques up to several centimeters in diameter and favor the upper chest and back.

B. Laboratory Findings

In patients with DLE, the diagnosis of SLE should be considered if the following findings are present: positive anti-nuclear antibody (ANA), other positive serologic studies (eg, anti-double stranded DNA or anti-Smith antibody), presence of hypocomplementemia, or widespread lesions (not localized to the head). Patients with marked photosensitivity and a picture otherwise suggestive of lupus may have negative ANA tests but are positive for antibodies against Ro/SSA or La/SSB (SCLE).

▶ Differential Diagnosis

The diagnosis is based on the clinical appearance confirmed by skin biopsy in all cases. In DLE, the scales are dry and “thumbtack-like” and can thus be distinguished from those of seborrheic dermatitis and psoriasis. Older lesions that have left depigmented scarring (classically in the concha of the ear) or areas of hair loss will also differentiate lupus from these diseases. Ten percent of patients with SLE have discoid skin lesions, and 5% of patients with discoid lesions have SLE. Medications (most commonly, hydrochlorothiazide, calcium channel blockers, ACE inhibitors, TNF inhibitors, and terbinafine) may induce SCLE with a positive Ro/SSA.

▶ Treatment

A. General Measures

Protect from sunlight. Use high-SPF (> 50) sunblock with UVB and UVA coverage daily. **Caution:** Do not use any form of radiation therapy. Avoid using drugs that are potentially photosensitizing when possible.

B. Local Treatment

For limited lesions, the following should be tried before systemic therapy: high-potency corticosteroid creams

applied each night and covered with airtight, thin, pliable plastic film (eg, Saran Wrap); or Cordran tape; or ultra-high-potency corticosteroid cream or ointment applied twice daily without occlusion.

C. Local Infiltration

Triamcinolone acetonide suspension, 2.5–10 mg/mL, may be injected into the lesions of DLE once a month.

D. Systemic Treatment

1. Antimalarials—Caution: These drugs should be used only when the diagnosis is secure because they have been associated with flares of psoriasis, which may be in the differential diagnosis. They may also cause ocular changes, and ophthalmologic evaluation is required at the onset of therapy and at regular intervals during treatment.

A. Hydroxychloroquine sulfate—0.2–0.4 g orally daily for several months may be effective and is often used prior to chloroquine. A minimum 3-month trial is recommended.

B. Chloroquine sulfate—250 mg daily may be effective in some cases where hydroxychloroquine is not.

C. Quinacrine (Atabrine)—100 mg daily may be the safest of the antimalarials, since eye damage has not been reported. It colors the skin yellow and is therefore not acceptable to some patients. It may be added to the other antimalarials for incomplete responses.

2. Isotretinoin—Isotretinoin, 1 mg/kg/d, is effective in hypertrophic DLE lesions and lesions of CLE or SCLE. Recurrences are prompt and predictable on discontinuation of therapy.

3. Thalidomide—Thalidomide is effective in refractory cases in doses of up to 300 mg daily. Monitor for neuropathy.

Both isotretinoin and thalidomide are teratogens and should be used with appropriate contraception and monitoring in women of childbearing age.

► Prognosis

The disease is persistent but not life-endangering unless systemic lupus is present. Treatment with antimalarials is effective in perhaps 60% of cases. Although the only morbidity may be cosmetic, this can be of overwhelming significance in more darkly pigmented patients with widespread disease. Scarring alopecia can be prevented or lessened with close attention and aggressive therapy. Over years, DLE tends to become inactive. Drug-induced SCLÉ usually resolves over months when the inciting medication is stopped.

CUTANEOUS T CELL LYMPHOMA (Mycosis Fungoides)

ESSENTIALS OF DIAGNOSIS

- ▶ Localized or generalized erythematous scaling patches and plaques.
- ▶ Pruritus.
- ▶ Lymphadenopathy.
- ▶ Distinctive histology.

► General Considerations

Mycosis fungoides is a cutaneous T cell lymphoma that begins on the skin and may involve only the skin for years or decades. Certain medications (including selective serotonin reuptake inhibitors) and photoallergy may produce eruptions clinically and histologically identical to those of mycosis fungoides.

► Clinical Findings

A. Symptoms and Signs

Localized or generalized erythematous patches or plaques are present usually on the trunk. Plaques are almost always over 5 cm in diameter. Pruritus is a frequent complaint. The lesions often begin as nondescript or nondiagnostic patches, and it is not unusual for the patient to have skin lesions for more than a decade before the diagnosis can be confirmed. In more advanced cases, tumors appear. Lymphadenopathy may occur locally or widely. Lymph node enlargement may be due to benign expansion of the node (dermatopathic lymphadenopathy) or by specific involvement with mycosis fungoides.

B. Laboratory Findings

The skin biopsy remains the basis of diagnosis, though at times numerous biopsies are required before the diagnosis can be confirmed. In more advanced disease, circulating malignant T cells (Sézary cells) can be detected in the blood (T cell gene rearrangement test). Eosinophilia may be present.

► Differential Diagnosis

Mycosis fungoides may be confused with psoriasis, a drug eruption, an eczematous dermatitis, or tinea corporis. Histologic examination can distinguish these conditions.

▶ Treatment

The treatment of mycosis fungoides is complex. Early and aggressive treatment has not proved to cure or prevent progression of the disease. Skin-directed therapies including topical corticosteroids, topical mechlorethamine, bexarotene gel, and UV phototherapy, are used initially. If the disease progresses, PUVA plus retinoids, PUVA plus interferon, extracorporeal photophoresis, bexarotene, α -interferon with or without retinoids, interleukin 12, denileukin, and total skin electron beam treatment are used.

▶ Prognosis

Mycosis fungoides is usually slowly progressive (over decades). Prognosis is better in patients with patch or plaque stage disease and worse in patients with erythroderma, tumors, and lymphadenopathy. Survival is not reduced in patients with limited patch disease. Elderly patients with limited patch and plaque stage disease commonly die of other causes. Overly aggressive treatment may lead to complications and premature demise.

EXFOLIATIVE DERMATITIS (Exfoliative Erythroderma)

ESSENTIAL OF DIAGNOSIS

- ▶ Scaling and erythema over most of the body.
- ▶ Itching, malaise, fever, chills, weight loss.

▶ General Considerations

Erythroderma describes generalized redness and scaling of the skin of > 30% BSA. A preexisting dermatosis is the cause of exfoliative dermatitis in two-thirds of cases, including psoriasis, atopic dermatitis, contact dermatitis, pityriasis rubra pilaris, and seborrheic dermatitis. Reactions to topical or systemic drugs account for perhaps 20–40% of cases and cancer (underlying lymphoma, solid tumors and,

most commonly, cutaneous T cell lymphoma) for 10–20%. Causation of the remainder is indeterminable. At the time of acute presentation, without a clear-cut prior history of skin disease or drug exposure, it may be impossible to make a specific diagnosis of the underlying condition, and diagnosis may require continued observation.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms may include itching, weakness, malaise, fever, and weight loss. Chills are prominent. Redness and scaling is widespread. Loss of hair and nails can occur. Generalized lymphadenopathy may be due to lymphoma or leukemia or may be reactive. The mucosae are spared.

B. Laboratory Findings

A skin biopsy is required and may show changes of a specific inflammatory dermatitis or cutaneous T cell lymphoma. Peripheral leukocytes may show clonal rearrangements of the T cell receptor in Sézary syndrome.

▶ Differential Diagnosis

It may be impossible to identify the cause of exfoliative erythroderma early in the course of the disease, so careful follow-up is necessary.

▶ Complications

Debility (protein loss) and dehydration may develop in patients with generalized inflammatory exfoliative erythroderma; or sepsis may occur.

▶ Treatment

A. Topical Therapy

Home treatment is with cool to tepid baths and application of mid-potency corticosteroids under wet dressings or with the use of an occlusive plastic suit. If the exfoliative erythroderma becomes chronic and is not manageable in an outpatient setting, the patient should be hospitalized. Keep the room at a constant warm temperature and provide the same topical treatment as for an outpatient.

B. Specific Measures

Stop all medications, if possible. Systemic corticosteroids may provide spectacular improvement in severe or fulminant exfoliative dermatitis, but long-term therapy should be avoided (see Chapter 26). In addition, systemic corticosteroids must be used with caution because some patients with erythroderma have psoriasis and could develop pustular psoriasis. For cases of psoriatic erythroderma and pityriasis rubra pilaris, acitretin, methotrexate, cyclosporine, or a TNF inhibitor may be indicated. Erythroderma secondary to lymphoma or leukemia requires specific topical or systemic chemotherapy. Suitable antibiotic drugs with coverage for *Staphylococcus* should be given when there is evidence of bacterial infection.

► Prognosis

Most patients recover completely or improve greatly over time but may require long-term therapy. Deaths are rare in the absence of cutaneous T cell lymphoma. A minority of patients will suffer from undiminished erythroderma for indefinite periods.

MISCELLANEOUS SCALING DERMATOSES

Isolated scaly patches may represent actinic (solar) keratoses, nonpigmented seborrheic keratoses, or Bowen or Paget disease.

1. Actinic Keratoses

Actinic keratoses are small (0.2–0.6 cm) macules or papules—flesh-colored, pink, or slightly hyperpigmented—that feel like sandpaper and are tender when the finger is drawn over them. They occur on sun-exposed parts of the body in persons of fair complexion. Actinic keratoses are considered premalignant, but only 1:1000 lesions per year progress to become squamous cell carcinomas.

Application of liquid nitrogen is a rapid and effective method of eradication. The lesions crust and disappear in 10–14 days. An alternative treatment is the use of fluorouracil cream. This agent may be rubbed into the lesions morning and night until they become first red and sore and then crusted and eroded (usually 2–3 weeks). Carac (0.5% fluorouracil) may be used once daily for a longer period (4 weeks to several months). Keratoses may clear with less irritation. Imiquimod 5% cream applied two to three times weekly for 3–6 weeks is the more costly alternative to topical fluorouracil (5FU). Photodynamic therapy can be effective in refractory cases and reduces the duration of treatment. Any lesions that persist should be evaluated for possible biopsy.

Akarsu S et al. Comparison of topical 3% diclofenac sodium gel and 5% imiquimod cream for the treatment of actinic keratoses. *Clin Exp Dermatol.* 2011 Jul;36(5):479–84. [PMID: 21418281]

2. Bowen Disease & Paget Disease

Bowen disease (intraepidermal squamous cell carcinoma) occurs either on both sun-exposed and non-sun-exposed

▲ **Figure 6-14.** Paget disease of the breast surrounding the nipple. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine.* McGraw-Hill, 2009.)

skin. The lesion is usually a small (0.5–3 cm), well-demarcated, slightly raised, pink to red, scaly plaque and may resemble psoriasis or a large actinic keratosis. These lesions may progress to invasive squamous cell carcinoma. Excision or other definitive treatment is indicated.

Extramammary Paget disease, a manifestation of intraepidermal carcinoma or underlying genitourinary or gastrointestinal cancer, resembles chronic eczema and usually involves apocrine areas such as the genitalia. Mammary Paget disease of the nipple, a unilateral or rarely bilateral red scaling plaque that may ooze, is associated with an underlying intraductal mammary carcinoma (Figure 6-14). While these lesions appear as red patches and plaques in fair skinned persons, in Asians, Hispanics, and other persons of color, hyperpigmentation may be prominent.

INTERTRIGO

Intertrigo is caused by the macerating effect of heat, moisture, and friction. It is especially likely to occur in obese persons and in humid climates. The symptoms are itching, stinging, and burning. The body folds develop fissures, erythema, and sodden epidermis, with superficial denudation. Candidiasis may complicate intertrigo. “Inverse psoriasis,” seborrheic dermatitis, tinea cruris, erythrasma, and candidiasis must be ruled out.

Maintain hygiene in the area, and keep it dry. Compresses may be useful acutely. Hydrocortisone 1% cream plus an imidazole or nystatin cream is effective. Recurrences are common.

VESICULAR DERMATOSES

HERPES SIMPLEX (Cold or Fever Sore; Genital Herpes)

ESSENTIALS OF DIAGNOSIS

- ▶ Recurrent small grouped vesicles on an erythematous base, especially in the orolabial and genital areas.
- ▶ May follow minor infections, trauma, stress, or sun exposure; regional lymph nodes may be swollen and tender.
- ▶ Viral cultures and direct fluorescent antibody tests are positive.

▶ General Considerations

Over 85% of adults have serologic evidence of herpes simplex type 1 (HSV-1) infections, most often acquired asymptotically in childhood. Occasionally, primary infections may be manifested as severe gingivostomatitis. Thereafter, the patient may have recurrent self-limited attacks, provoked by sun exposure, orofacial surgery, fever, or a viral infection.

About 25% of the United States population has serologic evidence of infection with herpes simplex type 2 (HSV-2). HSV-2 causes lesions whose morphology and natural history are similar to those caused by HSV-1 on the genitalia of both sexes. The infection is acquired by sexual contact. In monogamous heterosexual couples where one partner has HSV-2 infection, seroconversion of the noninfected partner occurs in 10% over a 1-year period. Up to 70% of such infections appeared to be transmitted during periods of asymptomatic shedding. Genital herpes may also be due to HSV-1.

▶ Clinical Findings

A. Symptoms and Signs

The principal symptoms are burning and stinging. Neuralgia may precede or accompany attacks. The lesions consist of small, grouped vesicles that can occur anywhere but which most often occur on the vermilion border of the lips (Figure 6-15), the penile shaft, the labia, the perianal skin, and the buttocks. Any erosion in the anogenital region can be due to HSV-2 (or HSV-1). Regional lymph nodes may be swollen and tender. The lesions usually crust and heal in 1 week. Herpes simplex is the most common cause of painful genital ulcerations in patients with HIV infection and other forms of immunosuppression.

B. Laboratory Findings

Lesions of herpes simplex must be distinguished from chancroid, syphilis, pyoderma, or trauma. Direct fluorescent antibody slide tests offer rapid, sensitive diagnosis. Viral culture may also be helpful. Herpes serology is not

▲ **Figure 6-15.** Herpes simplex type 1 vesicles at the vermilion border of the lip. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

used in the diagnosis of an acute genital ulcer. However, specific HSV-2 serology by Western blot assay or enzyme-linked immunosorbent assay (ELISA) can determine who is HSV-infected and potentially infectious. Such testing is very useful in couples in which only one partner reports a history of genital herpes.

▶ Complications

Complications include pyoderma, eczema herpeticum, herpetic whitlow, herpes gladiatorum (epidemic herpes in wrestlers transmitted by contact), proctitis, esophagitis, neonatal infection, keratitis, and encephalitis.

▶ Prevention

Sunscreens are useful adjuncts in preventing sun-induced recurrences. Prophylactic use of oral acyclovir may prevent recurrences. Acyclovir should be started at a dosage of 200 mg four times daily beginning 24 hours prior to ultraviolet light exposure, dental surgery, or orolabial cosmetic surgery. Comparable doses are 500 mg twice daily for valacyclovir and 250 mg twice daily for famciclovir.

▶ Treatment

A. Systemic Therapy

Three systemic agents are available for the treatment of herpes infections: acyclovir, its valine analog valacyclovir, and famciclovir. All three agents are very effective and, when used properly, virtually nontoxic. Only acyclovir is available for intravenous administration. In the immunocompetent, with the exception of severe orolabial herpes, only genital disease is treated. For first clinical episodes of herpes simplex, the dosage of acyclovir is 400 mg orally five times daily (or 800 mg three times daily); of valacyclovir, 1000 mg twice daily; and of famciclovir, 250 mg three times daily. The duration of treatment is from 7 to 10 days

depending on the severity of the outbreak. Most cases of recurrent herpes are mild and do not require therapy. In addition, pharmacotherapy of recurrent HSV is of limited benefit, with studies finding a reduction in the average outbreak by only 12–24 hours. To be effective, the treatment must be initiated by the patient at the first sign of recurrence. If treatment is desired, recurrent genital herpes outbreaks may be treated with 3 days of valacyclovir, 500 mg twice daily, 5 days of acyclovir, 200 mg five times a day, or 5 days of famciclovir, 125 mg twice daily. Valacyclovir, 2 g twice daily for 1 day, or famciclovir, 1 g once or twice in 1 day, are equally effective short-course alternatives, and can abort impending recurrences of both orolabial and genital herpes. The addition of a potent topical corticosteroid three times daily reduces the duration, size, and pain of orolabial herpes treated with an oral antiviral agent.

In patients with frequent or severe recurrences, suppressive therapy is most effective in controlling disease. Suppressive treatment will reduce outbreaks by 85% and reduces viral shedding by > 90%. This results in about a 50% reduced risk of transmission. The recommended suppressive doses, taken continuously, are acyclovir, 400 mg twice daily; valacyclovir, 500 mg once daily; or famciclovir, 125–250 mg twice daily. Long-term suppression appears very safe, and after 5–7 years a substantial proportion of patients can discontinue treatment. The use of condoms and patient education have proved effective in reducing genital herpes transmission in some studies and in others have not been beneficial. No single or combination intervention absolutely prevents transmission.

B. Local Measures

In general, topical therapy has only limited efficacy. It is strongly urged that 5% acyclovir ointment, if used at all, be limited to the restricted indications for which it has been approved, ie, initial herpes genitalis and mucocutaneous herpes simplex infections in immunocompromised patients. Penciclovir cream, to be applied at the first symptom every 2 hours while awake for 4 days for recurrent orolabial herpes, reduces the average attack duration from 5 days to 4.5 days.

► Prognosis

Aside from the complications described above, recurrent attacks last several days, and patients recover without sequelae.

HERPES ZOSTER (Shingles)

ESSENTIALS OF DIAGNOSIS

- Pain along the course of a nerve followed by grouped vesicular lesions.
- Involvement is unilateral; some lesions (< 20) may occur outside the affected dermatome.
- Lesions are usually on face or trunk.
- Direct fluorescent antibody positive, especially in vesicular lesions.

► General Considerations

Herpes zoster is an acute vesicular eruption due to the varicella-zoster virus. It usually occurs in adults. With rare exceptions, patients suffer only one attack. Dermatomal herpes zoster does not imply the presence of a visceral malignancy. Generalized disease, however, raises the suspicion of an associated immunosuppressive disorder such as HIV infection. HIV-infected patients are 20 times more likely to develop zoster, often before other clinical findings of HIV disease are present. A history of HIV risk factors and HIV testing when appropriate should be considered, especially in patients with zoster who are younger than 55 years.

► Clinical Findings

Pain usually precedes the eruption by 48 hours or more and may persist and actually increase in intensity after the lesions have disappeared. The lesions consist of grouped, tense, deep-seated vesicles distributed unilaterally along a dermatome (Figure 6–16). The most common distributions are on the trunk or face. Up to 20 lesions may be found outside the affected dermatomes, even in immunocompetent persons. Regional lymph glands may be tender and swollen.

► Differential Diagnosis

Since poison oak and poison ivy dermatitis can occur unilaterally, they must be differentiated at times from herpes zoster. Allergic contact dermatitis is pruritic; zoster is painful. One must differentiate herpes zoster from lesions of herpes simplex, which occasionally occurs in a dermatomal distribution. Doses of antivirals appropriate for zoster should be used in the absence of a clear diagnosis. Facial zoster may simulate erysipelas initially, but zoster is unilateral and shows vesicles after 24–48 hours. The pain of preeruptive herpes zoster may lead the clinician to diagnose migraine, myocardial infarction, acute abdomen, herniated disc, etc, depending on the dermatome involved.

► Complications

Sacral zoster may be associated with bladder and bowel dysfunction. Persistent neuralgia, anesthesia or scarring of the affected area, facial or other nerve paralysis, and

▲ **Figure 6-16.** Herpes zoster. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

encephalitis may occur. Postherpetic neuralgia is most common after involvement of the trigeminal region, and in patients over the age of 55. Early (within 72 hours after onset) and aggressive antiviral treatment of herpes zoster reduces the severity and duration of postherpetic neuralgia. Zoster ophthalmicus (V_1) can result in visual impairment.

► Prevention

An effective live herpes zoster vaccine (Zostavax) is available to prevent both herpes zoster and postherpetic neuralgia. It is approved for persons over the age of 50 and recommended in persons aged 60 and older, even in those who have had zoster.

► Treatment

A. General Measures

1. Immunocompetent host—Since early antiviral treatment of zoster reduces postherpetic neuralgia, those with a

risk of developing this complication should be treated, ie, those over age 50 and those with nontruncal eruption. In addition, younger patients with acute moderate to severe pain or rash may benefit from effective antiviral therapy. Treatment can be given with oral acyclovir, 800 mg five times daily; famciclovir, 500 mg three times daily; or valacyclovir, 1 g three times daily—all for 7 days (see Chapter 32). For reasons of increased bioavailability and ease of dosing schedule, the preferred agents are those given three times daily. Patients should maintain good hydration. The dose of antiviral should be adjusted for kidney function as recommended. Nerve blocks may be used in the management of initial severe pain. Ophthalmologic consultation is vital for involvement of the first branch of the trigeminal nerve, even if the patient has no ocular symptoms. Systemic corticosteroids are effective in reducing acute pain, improving quality of life, and returning patients to normal activities much more quickly. They do not increase the risk of dissemination in immunocompetent hosts. If not contraindicated, a tapering 3-week course of prednisone, starting at 60 mg/d, should be considered for its adjunctive benefit in immunocompetent patients. Oral corticosteroids do not reduce the prevalence, severity, or duration of postherpetic neuralgia beyond that achieved by effective antiviral therapy. Adequate analgesia should be given from the onset of zoster-associated pain, which might include opioids, tricyclic antidepressants, and gabapentin in patients with severe pain.

2. Immunocompromised host—Given the safety and efficacy of currently available antivirals, most immunocompromised patients with herpes zoster are candidates for antiviral therapy. The dosage schedule is as listed above, but treatment should be continued until the lesions have completely crusted and are healed or almost healed (up to 2 weeks). Because corticosteroids increase the risk of dissemination in immunosuppressed patients, they should not be used in these patients. Progression of disease may necessitate intravenous therapy with acyclovir, 10 mg/kg intravenously, three times daily. After 3–4 days, oral therapy may be substituted if there has been a good response to intravenous therapy. Adverse effects include decreased kidney function from crystallization, nausea and vomiting, and abdominal pain.

Foscarnet, administered in a dosage of 40 mg/kg two or three times daily intravenously, is indicated for treatment of acyclovir-resistant varicella-zoster virus infections.

B. Local Measures

Calamine or starch shake lotions may be of some help.

C. Postherpetic Neuralgia Therapy

The most effective treatment is prevention with vaccination of those at risk for developing zoster and early and aggressive antiviral therapy once zoster has occurred. Once established, postherpetic neuralgia may be treated with capsaicin ointment, 0.025–0.075%, or lidocaine (Lidoderm) topical patches. Chronic postherpetic neuralgia may be relieved by regional blocks (stellate ganglion, epidural,

local infiltration, or peripheral nerve), with or without corticosteroids added to the injections. Amitriptyline, 25–75 mg orally as a single nightly dose, is the first-line therapy beyond simple analgesics. Gabapentin, up to 3600 mg orally daily (starting at 300 mg orally three times daily), or duloxetine, up to 60–120 mg orally daily (starting at 30–60 mg orally daily) may be added for additional pain relief. Referral to a pain management clinic should be considered in moderate to severe cases and in those failing the above treatments.

► Prognosis

The eruption persists 2–3 weeks and usually does not recur. Motor involvement in 2–3% of patients may lead to temporary palsy.

POMPHOLYX; VESICULOBULLOUS HAND ECZEMA (Formerly Known as Dyshidrosis, Dyshidrotic Eczema)

ESSENTIALS OF DIAGNOSIS

- “Tapioca” vesicles of 1–2 mm on the palms, soles, and sides of fingers, associated with pruritus.
- Vesicles may coalesce to form multiloculated blisters.
- Scaling and fissuring may follow drying of the blisters.
- Appearance in the third decade, with lifelong recurrences.

► General Considerations

This is an extremely common form of hand dermatitis, preferably called pompholyx (Gr “bubble”) or vesiculobullous dermatitis of the palms and soles. Patients often have an atopic background and report flares with stress. Patients with widespread dermatitis due to any cause may develop pompholyx-like eruptions as a part of an autoeczematization response.

▲ **Figure 6–17.** Pompholyx (acute vesiculobullous hand eczema). (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

► Clinical Findings

Small clear vesicles stud the skin at the sides of the fingers and on the palms (Figure 6–17) or soles. They look like the grains in tapioca. They may be associated with intense itching. Later, the vesicles dry and the area becomes scaly and fissured.

► Differential Diagnosis

Unroofing the vesicles and examining the blister roof with a KOH preparation will reveal hyphae in cases of bullous tinea. Patients with inflammatory tinea pedis may have a vesicular dermatophytid of the palms. Always examine the feet of a patient with a hand eruption. Nonsteroidal anti-inflammatory drugs (NSAIDs) may produce an eruption very similar to that of dyshidrosis on the hands.

► Prevention

There is no known way to prevent attacks.

► Treatment

Topical and systemic corticosteroids help some patients dramatically. Since this is a chronic problem, systemic

corticosteroids are generally not appropriate therapy. A high-potency topical corticosteroid used early in the attack may help abort the flare and ameliorate pruritus. Topical corticosteroids are also important in treating the scaling and fissuring that are seen after the vesicular phase. It is essential that patients avoid anything that irritates the skin; they should wear cotton gloves inside vinyl gloves when doing dishes or other wet chores, use long-handled brushes instead of sponges, and use a hand cream after washing the hands. Patients respond to PUVA therapy and injection of botulinum toxin into the palms as for hyperhidrosis.

► Prognosis

For most patients, the disease is an inconvenience. For some, vesiculobullous hand eczema can be incapacitating.

PORPHYRIA CUTANEA TARDA

ESSENTIALS OF DIAGNOSIS

- Noninflammatory blisters on sun-exposed sites, especially the dorsal surfaces of the hands.
- Hypertrichosis, skin fragility.
- Associated liver disease.
- Elevated urine porphyrins.

► General Considerations

Porphyria cutanea tarda is the most common type of porphyria. Cases are sporadic or hereditary. The disease is associated with ingestion of certain medications (eg, estrogens), and liver disease from alcoholism or hepatitis C. In patients with liver disease, hemosiderosis is often present.

► Clinical Findings

A. Symptoms and Signs

Patients complain of painless blistering and fragility of the skin of the dorsal surfaces of the hands (Figure 6–18). Facial hypertrichosis and hyperpigmentation are common.

B. Laboratory Findings

Urinary uroporphyrins are elevated twofold to fivefold above coproporphyrins. Patients may also have abnormal liver function tests, evidence of hepatitis C infection, increased liver iron stores, and hemochromatosis gene mutations. Multiple triggering factors are often discovered.

▲ **Figure 6–18.** Porphyria cutanea tarda. (Courtesy of Lewis Rose, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine.* McGraw-Hill, 2009.)

► Differential Diagnosis

Skin lesions identical to those of porphyria cutanea tarda may be seen in patients who receive maintenance dialysis and in those who take certain medications (tetracyclines and NSAIDs, especially naproxen, and voriconazole). In this so-called pseudoporphyria, the biopsy results are identical to those associated with porphyria cutanea tarda, but urine porphyrins are normal.

► Prevention

Although the lesions are triggered by sun exposure, the wavelength of light triggering the lesions is beyond that absorbed by sunscreens, which for that reason are ineffective. Barrier sun protection with clothing is required.

► Treatment

Stopping all triggering medications and substantially reducing or stopping alcohol consumption may alone lead to improvement. Phlebotomy without oral iron supplementation at a rate of 1 unit every 2–4 weeks will gradually lead to improvement. Very low dose antimalarials (as low as 200 mg of hydroxychloroquine twice weekly), alone or in combination with phlebotomy, will increase the excretion of porphyrins, improving the skin disease. Treatment is continued until the patient is asymptomatic. Urine porphyrins may be monitored.

► Prognosis

Most patients improve with treatment. Sclerodermoid skin lesions may develop on the trunk, scalp, and face.

DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis is an uncommon disease manifested by pruritic papules, vesicles, and papulovesicles mainly on the elbows, knees, buttocks, posterior neck, and scalp. It appears to have its highest prevalence in

Scandinavia and is associated with HLA antigens -B8, -DR3, and -DQ2. The diagnosis is made by light microscopy, which demonstrates neutrophils at the dermal papillary tips. Direct immunofluorescence studies show granular deposits of IgA in the dermal papillae. Circulating antibodies to tissue transglutaminase are present in 90% of cases. NSAIDs may cause flares. Patients have gluten-sensitive enteropathy, but for the great majority it is subclinical. However, ingestion of gluten is the cause of the disease, and strict long-term avoidance of dietary gluten has been shown to decrease the dose of dapsone (usually 100–200 mg daily) required to control the disease and may even eliminate the need for treatment. Patients with dermatitis herpetiformis are at increased risk for development of gastrointestinal lymphoma, and this risk is reduced by a gluten-free diet.

WEEPING OR CRUSTED LESIONS

IMPETIGO

ESSENTIALS OF DIAGNOSIS

- ▶ Superficial blisters filled with purulent material that rupture easily.
- ▶ Crusted superficial erosions.
- ▶ Positive Gram stain and bacterial culture.

▶ General Considerations

Impetigo is a contagious and autoinoculable infection of the skin caused by staphylococci or streptococci.

▶ Clinical Findings

A. Symptoms and Signs

The lesions consist of macules, vesicles, bullae, pustules, and honey-colored gummy crusts that when removed leave denuded red areas (Figure 6–19). The face and other exposed parts are most often involved. **Ecthyma** is a deeper form of impetigo caused by staphylococci or streptococci, with ulceration and scarring. It occurs frequently on the extremities.

B. Laboratory Findings

Gram stain and culture confirm the diagnosis. In temperate climates, most cases are associated with *S aureus* infection.

▲ **Figure 6–19.** Bullous impetigo. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

Streptococcus species are more common in tropical infections. Community-associated methicillin-resistant *S aureus* (CA-MRSA) can be isolated from lesions of impetigo and ecthyma.

▶ Differential Diagnosis

The main differential diagnoses are acute allergic contact dermatitis and herpes simplex. Contact dermatitis may be suggested by the history or by linear distribution of the lesions, and culture should be negative for staphylococci and streptococci. Herpes simplex infection usually presents with grouped vesicles or discrete erosions and may be associated with a history of recurrences. Viral cultures are positive.

▶ Treatment

Soaks and scrubbing can be beneficial, especially in unroofing lakes of pus under thick crusts. Topical agents such as bacitracin, mupirocin, or retapamulin can be attempted for infections limited to small areas. Mupirocin and retapamulin are more expensive than systemic treatments. In most cases, systemic antibiotics are indicated. Cephalexin, 250 mg four times daily, is usually effective. Doxycycline, 100 mg twice daily, is a reasonable alternative. CA-MRSA may cause impetigo, and initial coverage for MRSA could include doxycycline, clindamycin, or trimethoprim-sulfamethoxazole (TMP-SMZ). About 50% of CA-MRSA cases are quinolone resistant. Recurrent impetigo is associated with nasal carriage of *S aureus* and is treated with rifampin, 600 mg daily for 5 days. Intranasal mupirocin ointment twice daily for 5 days clears the carriage of 40% of MRSA strains. Bleach baths (½ to 1 cup per 20 liters of bathwater for 15 minutes 3–5 times weekly) for all family members, and the use of dilute household bleach to clean showers and other bath surfaces may help reduce the spread. Individuals should not share towels if there is a case of impetigo in the household.

Geria AN et al. Impetigo update: new challenges in the era of methicillin resistance. *Cutis.* 2010 Feb;85(2):65–70. [PMID: 20349679]

CONTACT DERMATITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Erythema and edema, with pruritus, often followed by vesicles and bullae (in allergic contact dermatitis) in an area of contact with a suspected agent.
- ▶ Later, weeping, crusting, or secondary infection.
- ▶ A history of previous reaction to suspected contactant.
- ▶ Patch test with agent positive (in allergic contact dermatitis).

▶ General Considerations

Contact dermatitis (irritant or allergic) is an acute or chronic dermatitis that results from direct skin contact with chemicals or allergens. Eighty percent of cases are due to excessive exposure to or additive effects of primary or universal irritants (eg, soaps, detergents, organic solvents) and are called irritant contact dermatitis. This appears red and scaly but not vesicular. The most common causes of allergic contact dermatitis are poison ivy or poison oak; topically applied antimicrobials (especially bacitracin and neomycin), anesthetics (benzocaine); hair-care products; preservatives; jewelry (nickel); rubber; vitamin E; essential oils; propolis (from bees); and adhesive tape. Occupational exposure is an important cause of allergic contact dermatitis. Weeping and crusting are typically due to allergic and not irritant dermatitis.

▶ Clinical Findings

A. Symptoms and Signs

In allergic contact dermatitis, the acute phase is characterized by tiny vesicles and weepy and crusted lesions, whereas resolving or chronic contact dermatitis presents with scaling, erythema, and possibly thickened skin (Figure 6–20). Itching, burning, and stinging may be severe. The lesions, distributed on exposed parts or in bizarre asymmetric patterns, consist of erythematous macules, papules, and vesicles. The affected area is often hot and swollen, with exudation and crusting, simulating—and at times complicated by—infection. The pattern of the eruption may be diagnostic (eg, typical linear streaked vesicles on the extremities in poison oak or ivy dermatitis). The location will often suggest the cause: Scalp involvement suggests hair dyes or shampoos; face involvement, creams, cosmetics, soaps, shaving materials, nail polish; and neck involvement, jewelry, hair dyes.

B. Laboratory Findings

Gram stain and culture will rule out impetigo or secondary infection (impetiginization). If itching is generalized, then scabies should be considered. After the episode of allergic contact dermatitis has cleared, patch testing may be useful if the triggering allergen is not known.

▲ **Figure 6–20.** Contact dermatitis with linear pattern due to poison ivy. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

▶ Differential Diagnosis

Asymmetric distribution, blotchy erythema around the face, linear lesions, and a history of exposure help distinguish acute contact dermatitis from other skin lesions. The most commonly mistaken diagnosis is impetigo. Chronic allergic contact dermatitis must be differentiated from scabies, atopic dermatitis, pompholyx, and other eczemas.

▶ Prevention

Prompt and thorough removal of the causative oil by washing with liquid dishwashing soap (eg, Dial Ultra) may be effective if done within 30 minutes after exposure to poison oak or ivy. Goop and Tecnu are also effective but much more costly without increased efficacy. The three most effective over-the-counter barrier creams which are applied prior to exposure and prevent/reduce the severity of the dermatitis are Stokogard, Hollister Moisture Barrier, and Hydropel.

The mainstay of prevention is identification of the agent causing the dermatitis and avoidance of exposure or

use of protective clothing and gloves. In industry-related cases, prevention may be accomplished by moving or retraining the worker.

► Treatment

A. Overview

While local measures are important, severe or widespread involvement is difficult to manage without systemic corticosteroids because even the highest-potency topical corticosteroids seem not to work well on vesicular and weepy lesions. Localized involvement (except on the face) can often be managed solely with topical agents. Irritant contact dermatitis is treated by protection from the irritant and use of topical corticosteroids as for atopic dermatitis (described above). The treatment of allergic contact dermatitis is detailed below.

B. Local Measures

1. Acute weeping dermatitis—Compresses are most often used. It is unwise to scrub lesions with soap and water. Calamine lotion may be used between wet dressings, especially for involvement of intertriginous areas or when oozing is not marked. Lesions on the extremities may be bandaged with wet dressings for 30–60 minutes several times a day. High potency topical corticosteroids in gel or cream form (eg, fluocinonide, clobetasol, or halobetasol) may help suppress acute contact dermatitis and relieve itching. This treatment should be followed by tapering of the number of applications per day or use of a mid-potency corticosteroid such as triamcinolone 0.1% cream to prevent rebound of the dermatitis. A soothing formulation is 2 oz of 0.1% triamcinolone acetonide cream in 7.5 oz Sarna lotion (0.5% camphor, 0.5% menthol, 0.5% phenol) mixed by the patient.

2. Subacute dermatitis (subsiding)—Mid-potency (triamcinolone 0.1%) to high-potency corticosteroids (clobetasol, amcinonide, fluocinonide, desoximetasone) are the mainstays of therapy.

3. Chronic dermatitis (dry and lichenified)—High-potency to superpotency corticosteroids are used in ointment form.

C. Systemic Therapy

For acute severe cases, prednisone may be given orally for 12–21 days. Prednisone, 60 mg for 4–7 days, 40 mg for 4–7 days, and 20 mg for 4–7 days without a further taper is one useful regimen. Another is to dispense seventy-eight 5-mg pills to be taken 12 the first day, 11 the second day, and so on. The key is to use enough corticosteroid (and as early as possible) to achieve a clinical effect and to taper slowly enough to avoid rebound. A Medrol Dosepak (methylprednisolone) with 5 days of medication is inappropriate on both counts. (See Chapter 26.)

► Prognosis

Allergic contact dermatitis is self-limited if reexposure is prevented but often takes 2–3 weeks for full resolution.

Usatine RP et al. Diagnosis and management of contact dermatitis. *Am Fam Physician*. 2010 Aug 1;82(3):249–55. [PMID: 20672788]

PUSTULAR DISORDERS

ACNE VULGARIS

ESSENTIALS OF DIAGNOSIS

- Occurs at puberty, though onset may be delayed into the third or fourth decade.
- Open and closed comedones are the hallmark of acne vulgaris.
- The most common of all skin conditions.
- Severity varies from purely comedonal to papular or pustular inflammatory acne to cysts or nodules.
- Face and upper trunk may be affected.
- Scarring may be a sequela of the disease or picking and manipulating by the patient.

► General Considerations

Acne vulgaris is polymorphic. Open and closed comedones, papules, pustules, and cysts are found. The disease is activated by androgens in those who are genetically predisposed.

Acne vulgaris is more common and more severe in males. It does not always clear spontaneously when maturity is reached. Twelve percent of women and 3% of men over age 25 have acne vulgaris. This rate does not decrease until after age 44. The skin lesions parallel sebaceous activity. Pathogenic events include plugging of the infundibulum of the follicles, retention of sebum, overgrowth of the acne bacillus (*Propionibacterium acnes*) with resultant release of and irritation by accumulated fatty acids, and foreign body reaction to extrafollicular sebum. The mechanism of antibiotics in controlling acne is not clearly understood, but they may work because of their antibacterial or anti-inflammatory properties.

When a resistant case of acne is encountered in a woman, hyperandrogenism may be suspected. This may or may not be accompanied by hirsutism, irregular menses, or other signs of virilism. Polycystic ovary syndrome (PCOS) is the most common identifiable cause.

► Clinical Findings

There may be mild soreness, pain, or itching. The lesions occur mainly over the face, neck, upper chest, back, and shoulders. Comedones are the hallmark of acne vulgaris. Closed comedones are tiny, flesh-colored, noninflamed bumps that give the skin a rough texture or appearance. Open comedones typically are a bit larger and have black

▲ **Figure 6-21.** Acne vulgaris, severe nodular cystic form with scarring. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

material in them. Inflammatory papules, pustules, ectopic pores, acne cysts, and scarring are also seen (Figure 6-21).

Acne may have different presentations at different ages. Preteens often present with comedones as their first lesions. Inflammatory lesions in young teenagers are often found in the middle of the face, extending outward as the patient becomes older. Women in their third and fourth decades (often with no prior history of acne) commonly present with papular lesions on the chin and around the mouth.

► Differential Diagnosis

In adults, acne rosacea presents with papules and pustules in the middle third of the face, but telangiectasia, flushing, and the absence of comedones distinguish this disease from acne vulgaris. A pustular eruption on the face in patients receiving antibiotics or with otitis externa should be investigated with culture to rule out an uncommon gram-negative folliculitis. Acne may develop in patients who use systemic corticosteroids or topical fluorinated corticosteroids on the face. Acne may be exacerbated or caused by irritating creams or oils. Pustules on the face can also be caused by tinea infections. Lesions on the back are more problematic. When they occur alone, staphylococcal folliculitis, miliaria (“heat rash”) or, uncommonly, *Malassezia* folliculitis should be suspected. Bacterial culture, trial of an antistaphylococcal antibiotic, and observing

the response to therapy will help in the differential diagnosis. In patients with HIV infection, folliculitis is common and may be either staphylococcal folliculitis or eosinophilic folliculitis.

► Complications

Cyst formation, pigmentary changes in pigmented patients, severe scarring, and psychological problems may result.

► Treatment

A. General Measures

1. Education of the patient—When scarring seems out of proportion to the severity of the lesions, clinicians must suspect that the patient is manipulating the lesions. It is essential that the patient be educated in a supportive way about this complication. Anxiety and depression are often the underlying cause of young women excoriating minor acne. It is wise to let the patient know that at least 4–6 weeks will be required to see improvement and that old lesions may take months to fade. Therefore, improvement will be judged according to the number of new lesions forming after 6–8 weeks of therapy. Additional time will be required to see improvement on the back and chest, as these areas are slowest to respond. If hair pomades are used, they should contain glycerin and not oil. Avoid topical exposure to oils, cocoa butter (theobroma oil), and greases.

2. Diet—A low glycemic diet that results in weight loss has been reported to improve acne in males aged 18–25. This improvement was associated with a reduction in insulin resistance. Hyperinsulinemia has also been associated with acne in eumenorrheic women. The metabolic syndrome with insulin resistance can also be a feature of PCOS in women. This finding suggests a possible common pathogenic mechanism for acne in both adult women and men.

B. Comedonal Acne

Treatment of acne is based on the type and severity of lesions. Comedones require treatment different from that of pustules and cystic lesions. In assessing severity, take the sequelae of the lesions into account. An individual who gets only a few new lesions per month that scar or leave postinflammatory hyperpigmentation must be treated much more aggressively than a comparable patient whose lesions clear without sequelae. Soaps play little role in acne treatment, and unless the patient’s skin is exceptionally oily, a mild soap should be used to avoid irritation that will limit the usefulness of other topicals, all of which are themselves somewhat irritating. The agents effective in comedonal acne are listed in the order in which they should be tried.

1. Topical retinoids—Tretinoin is very effective for comedonal acne or for treatment of the comedonal component of more severe acne, but its usefulness is limited by irritation. Start with 0.025% cream (not gel) and have the patient use it at first twice weekly at night, then build up to

as often as nightly. A few patients cannot use even this low-strength preparation more than three times weekly but even that may cause improvement. A lentil-sized amount is sufficient to cover the entire face. To avoid irritation, have the patient wait 20 minutes after washing to apply. Adapalene gel 0.1% and reformulated tretinoin (Renova, Retin A Micro, Avita) are other options for patients irritated by standard tretinoin preparations. Some patients—especially teenagers—do best on 0.01% gel. Although the absorption of tretinoin is minimal, its use during pregnancy is contraindicated. Some patients report photosensitivity with tretinoin. Patients should be warned that they may flare in the first 4 weeks of treatment. Tazarotene gel (0.05% or 0.1%) (Tazorac) is another topical retinoid approved for treatment of psoriasis and acne, and may be used in patients intolerant of the other retinoids.

2. Benzoyl peroxide—Benzoyl peroxide products are available in concentrations of 2.5%, 4%, 5%, 8%, and 10%, but it appears that 2.5% is as effective as 10% and less irritating. In general, water-based and not alcohol-based gels should be used to decrease irritation. Benzoyl peroxide in combination with adapalene is available as a single formulation.

3. Antibiotics—Use of topical antibiotics (see below) has been demonstrated to decrease pustular and comedonal lesions.

C. Papular or Cystic Inflammatory Acne

Antibiotics are the mainstay for treatment of inflammatory acne. They may be used topically or orally. The oral antibiotics of choice are tetracycline and doxycycline. Minocycline is often effective in acne unresponsive or resistant to treatment with these antibiotics but it is more expensive. Rarely, other antibiotics such as TMP-SMZ (one double-strength tablet twice daily), clindamycin (150 mg twice daily), or a cephalosporin (cefadroxil or cephalexin) may be used. Topical clindamycin phosphate and erythromycin are also used (see below). Topicals are probably the equivalent of about 500 mg/d of tetracycline given orally, which is half the usual starting dose. Topical antibiotics are used in three situations: for mild papular acne that can be controlled by topicals alone, for patients who refuse or cannot tolerate oral antibiotics, or to wean patients under good control from oral to topical preparations. To decrease resistance, benzoyl peroxide should be used in combination with the topical antibiotic.

1. Mild acne—The first choice of topical antibiotics in terms of efficacy and relative lack of induction of resistant *P. acnes* is the combination of erythromycin or clindamycin with benzoyl peroxide topical gel. Clindamycin (Cleocin T) lotion (least irritating), gel, or solution, or one of the many brands of topical erythromycin gel or solution, may be used twice daily and the benzoyl peroxide in the morning. (A combination of erythromycin or clindamycin with benzoyl peroxide is available as a prescription item.) The addition of tretinoin 0.025% cream or 0.01% gel at night may increase improvement, since it works via a different mechanism.

2. Moderate acne—Tetracycline, 500 mg twice daily, doxycycline, 100 mg twice daily, and minocycline, 50–100 mg twice daily, are all effective though minocycline is more expensive. When initiating minocycline therapy, start at 100 mg in the evening for 4–7 days, then 100 mg twice daily, to decrease the incidence of vertigo. Plan a return visit in 6 weeks and at 3–4 months after that. If the patient's skin is quite clear, instructions should be given for tapering the dose by 250 mg for tetracycline, by 100 mg for doxycycline, or by 50 mg for minocycline every 6–8 weeks—while treating with topicals—to arrive at the lowest systemic dose needed to maintain clearing. In general, immediately lowering the dose to zero without other therapy results in prompt recurrence. Tetracycline, minocycline, and doxycycline are contraindicated in pregnancy, but oral erythromycin may be used.

It is important to discuss the issue of contraceptive failure when prescribing antibiotics for women taking oral contraceptives. Women may need to consider using barrier methods as well, and should report breakthrough bleeding. Oral contraceptives or spironolactone (50–200 mg daily) may be added as an antiandrogen in women with antibiotic-resistant acne or in women in whom relapse occurs after isotretinoin therapy.

3. Severe acne

A. ISOTRETINOIN—A vitamin A analog, isotretinoin is used for the treatment of severe cystic acne that has not responded to conventional therapy. A dosage of 0.5–1 mg/kg/d for 20 weeks for a cumulative dose of at least 120 mg/kg is usually adequate for severe cystic acne. Patients should be offered isotretinoin therapy before they experience significant scarring if they are not promptly and adequately controlled by antibiotics. The drug is *absolutely contraindicated during pregnancy* because of its teratogenicity; two serum pregnancy tests should be obtained before starting the drug in a female and every month thereafter. Sufficient medication for only 1 month should be dispensed. Two forms of effective contraception must be used. Informed consent must be obtained before its use and patients must be enrolled in a monitoring program (iPledge). Side effects occur in most patients, usually related to dry skin and mucous membranes (dry lips, nosebleed, and dry eyes). If headache occurs, pseudotumor cerebri must be considered. Depression has been reported. Hypertriglyceridemia will develop in about 25% of patients, hypercholesterolemia in 15%, and a lowering of high-density lipoproteins in 5%. Minor elevations in liver function tests may develop in some patients. Fasting blood sugar may be elevated. Miscellaneous adverse reactions include decreased night vision, musculoskeletal symptoms, dry skin, thinning of hair, exuberant granulation tissue in lesions, and bony hyperostoses (seen only with very high doses or with long duration of therapy). Moderate to severe myalgias rarely necessitate decreasing the dosage or stopping the drug. Inflammatory bowel disease has first appeared after acne treatment with both tetracyclines and isotretinoin at a rate of 1:1000 cases treated or less. Causality of this association has not been established. Young adults with severe acne who are

potential candidates for isotretinoin should be asked about any bowel symptoms prior to starting isotretinoin. Laboratory tests to be performed in all patients before treatment and after 4 weeks on therapy include complete blood cell count (CBC), cholesterol, triglycerides, and liver function studies.

Elevations of liver enzymes and triglycerides return to normal upon conclusion of therapy. The drug may induce long-term remissions in 40–60%, or acne may recur that is more easily controlled with conventional therapy. Occasionally, acne does not respond or promptly recurs after therapy, but it may clear after a second course.

B. INTRALESIONAL INJECTION—In otherwise moderate acne, intralesional injection of dilute suspensions of triamcinolone acetonide (2.5 mg/mL, 0.05 mL per lesion) will often hasten the resolution of deeper papules and occasional cysts.

C. LASER DERMABRASION—Cosmetic improvement may be achieved by excision and punch-grafting of deep scars and by abrasion of inactive acne lesions, particularly flat, superficial scars. The technique is not without untoward effects, since hyperpigmentation, hypopigmentation, grooving, and scarring have been known to occur. Dark-skinned individuals do poorly. Corrective surgery within 12 months after isotretinoin therapy may not be advisable. Active acne of all types can be treated with certain laser and photodynamic therapies. This can be considered when standard treatments are contraindicated or fail.

► Prognosis

Acne vulgaris eventually remits spontaneously, but when this will occur cannot be predicted. The condition may persist throughout adulthood and may lead to severe scarring if left untreated. Patients treated with antibiotics continue to improve for the first 3–6 months of therapy. Relapse during treatment may suggest the emergence of resistant *P. acnes*. The disease is chronic and tends to flare intermittently in spite of treatment. Remissions following systemic treatment with isotretinoin may be lasting in up to 60% of cases. Relapses after isotretinoin usually occur within 3 years and require a second course in up to 20% of patients.

ROSACEA

ESSENTIALS OF DIAGNOSIS

- ▶ A chronic facial disorder.
- ▶ A neurovascular component (erythema and telangiectasis and a tendency to flush easily).
- ▶ An acneiform component (papules and pustules) may also be present.
- ▶ A glandular component accompanied by hyperplasia of the soft tissue of the nose (rhinophyma).

► General Considerations

The pathogenesis of this disorder is not known. Topical corticosteroids applied to the lower face can induce rosacea-like conditions.

► Clinical Findings

Patients frequently report flushing or exacerbation of their rosacea due to heat or cold, hot drinks, spicy food, sunlight, exercise, alcohol, emotions, or menopausal flushing. The cheeks, nose, and chin—at times the entire face—may have a rosy hue. No comedones are seen. In its mildest form, erythema and dilated vessels are seen on the cheeks. Inflammatory papules may be superimposed on this background and may evolve to pustules (Figure 6–22). Associated seborrhea may be found. The patient often complains of burning or stinging with episodes of flushing. Patients may have associated ophthalmic disease, including blepharitis and keratitis, that often requires systemic antibiotic therapy.

► Differential Diagnosis

Rosacea is distinguished from acne by the presence of the neurovascular component and the absence of comedones. The rosy hue of rosacea and telangiectasis will pinpoint the diagnosis. Lupus is often misdiagnosed, but the presence of pustules excludes that diagnosis.

► Treatment

Educating patients to avoid the factors they know to produce exacerbations is important. Patients should wear a broad-spectrum sunscreen with UVA coverage; however, exquisite sensitivity to topical preparations may limit patient options. Zinc- or titanium-based sunscreens are better tolerated, and barrier protective silicones in the sun-block may enhance tolerance. Medical management is effective only for the inflammatory papules and pustules and the erythema that surrounds them. Rosacea is usually a lifelong condition, so maintenance therapy is required.

A. Local Therapy

Avoidance of triggers (especially alcohol) and sucking on an ice cube may be effective in reducing facial erythema and flushing. Metronidazole (available as creams, gels, or

▲ **Figure 6-22.** Rosacea. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

lotions), 0.75% applied twice daily or 1% applied once daily, is the topical treatment of choice. If metronidazole is not tolerated, topical clindamycin (solution, gel, or lotion) 1% applied twice daily is effective. Response is noted in 4–8 weeks. Sulfur-sodium sulfacetamide-containing topicals are helpful in patients only partially responsive to topical antibiotics. Benzoyl peroxide, as in acne vulgaris, may be helpful in reducing the pustular component. Topical retinoids can be carefully added for maintenance.

B. Systemic Therapy

Tetracycline, 250 or 500 mg orally twice daily on an empty stomach, should be used when topical therapy is inadequate. Minocycline or doxycycline, 50–100 mg orally daily to twice daily, is also effective. Metronidazole or amoxicillin, 250–500 mg orally twice daily, or rifaximin, 550 mg orally twice daily, may be used in refractory cases. Side effects are few, although metronidazole may produce a disulfiram-like effect when the patient ingests alcohol and it may cause neuropathy with long-term use. Isotretinoin may succeed where other measures fail. A dosage of 0.5 mg/kg/d orally for 12–28 weeks is recommended. See precautions above. Telangiectasias are benefitted by laser therapy, and phymatous overgrowth of the nose can be treated by surgical reduction.

► Prognosis

Rosacea tends to be a persistent process. With the regimens described above, it can usually be controlled adequately.

Scharschmidt TC et al. Neurogenic rosacea: a distinct clinical subtype requiring a modified approach to treatment. *Arch Dermatol.* 2011 Jan;147(1):123–6. [PMID: 21242409]
van Zuuren EJ et al. Interventions for rosacea. *Cochrane Database Syst Rev.* 2011 Mar 16;(3):CD003262. [PMID: 21412882]

FOLLICULITIS (Including Sycosis)

- ▶ Itching and burning in hairy areas.
- ▶ Pustules in the hair follicles.

► General Considerations

Folliculitis has multiple causes. It is frequently caused by staphylococcal infection and may be more common in the diabetic patient. When the lesion is deep-seated, chronic, and recalcitrant on the head and neck, it is called sycosis.

Gram-negative folliculitis, which may develop during antibiotic treatment of acne, may present as a flare of acne pustules or nodules. *Klebsiella*, *Enterobacter*, *Escherichia coli*, and *Proteus* have been isolated from these lesions.

“Hot tub folliculitis,” caused by *Pseudomonas aeruginosa*, is characterized by pruritic or tender follicular, pustular lesions occurring within 1–4 days after bathing in a contaminated hot tub, whirlpool, or public swimming pool. Rarely, systemic infections may result. Neutropenic patients should avoid these exposures.

Nonbacterial folliculitis may also be caused by friction and oils. Occlusion, perspiration, and rubbing, such as that resulting from tight jeans and other heavy fabrics on the upper legs can worsen this type of folliculitis.

Steroid acne may be seen during topical or systemic corticosteroid therapy.

A form of sterile folliculitis called eosinophilic folliculitis consisting of urticarial papules with prominent eosinophilic infiltration is common in patients with AIDS. It may appear first with institution of highly active antiretroviral therapy (HAART) and be mistaken for a drug eruption.

Pseudofolliculitis is caused by ingrowing hairs in the beard area. It occurs in men and women with tightly curled beard hair. In this entity, the papules and pustules are located at the side of and not in follicles. It may be treated by growing a beard, by using chemical depilatories, or by shaving with a foil-guard razor. Laser hair removal is dramatically beneficial in patients with pseudofolliculitis, requires limited maintenance, and can be done on patients of any skin color. Pseudofolliculitis is a true medical indication for such a procedure and should not be considered cosmetic.

► Clinical Findings

The symptoms range from slight burning and tenderness to intense itching. The lesions consist of pustules of hair follicles (Figure 6–23).

▲ **Figure 6-23.** Bacterial folliculitis. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

► Differential Diagnosis

It is important to differentiate bacterial from nonbacterial folliculitis. The history is important for pinpointing the causes of nonbacterial folliculitis, and a Gram stain and culture are indispensable. One must differentiate folliculitis from acne vulgaris or pustular miliaria (heat rash) and from infections of the skin such as impetigo or fungal infections. *Pseudomonas* folliculitis is often suggested by the history of hot tub use. Eosinophilic folliculitis in AIDS often requires biopsy for diagnosis.

► Complications

Abscess formation is the major complication of bacterial folliculitis.

► Prevention

Correct any predisposing local causes such as oils or friction. Be sure that the water in hot tubs and spas is treated properly. If staphylococcal folliculitis is persistent, treatment of nasal or perineal carriage with rifampin, 600 mg daily for 5 days, or with topical mupirocin ointment 2% twice daily for 5 days, may help. Prolonged oral clindamycin, 150–300 mg/d for 4–6 weeks, or oral TMP-SMZ given 1 week per month for 6 months can be effective in preventing recurrent staphylococcal folliculitis and furunculosis. Bleach baths (½ to 1 cup per 20 liters of bathwater for 15 minutes 3–5 times weekly) may reduce cutaneous

staphylococcal carriage and not contribute to antibiotic resistance. Control of blood glucose in diabetes may reduce the number of these infections.

► Treatment

A. Local Measures

Anhydrous ethyl alcohol containing 6.25% aluminum chloride (Xerac AC), applied to lesions and environs, may be helpful, especially for chronic frictional folliculitis of the buttocks. Topical antibiotics are generally ineffective if bacteria have invaded the hair follicle.

B. Specific Measures

Pseudomonas folliculitis will clear spontaneously in non-neutropenic patients if the lesions are superficial. It may be treated with ciprofloxacin, 500 mg twice daily for 5 days.

Systemic antibiotics are recommended for bacterial folliculitis due to other organisms. Extended periods of treatment (4–8 weeks or more) with antistaphylococcal antibiotics are required if infection has involved the scalp or densely hairy areas such as the axilla, beard, or groin.

Gram-negative folliculitis in acne patients may be treated with isotretinoin in compliance with all precautions discussed above (see Acne Vulgaris).

Eosinophilic folliculitis may be treated initially by the combination of potent topical corticosteroids and oral antihistamines. In more severe cases, treatment is with one of the following: topical permethrin (application for 12 hours every other night for 6 weeks); itraconazole, 200–400 mg daily; UVB or PUVA phototherapy; or isotretinoin, 0.5 mg/kg/d for up to 5 months. A remission may be induced by some of these therapies, but long-term treatment may be required.

► Prognosis

Bacterial folliculitis is occasionally stubborn and persistent, requiring prolonged or intermittent courses of antibiotics.

Hernandez C et al. Acute onset of facial pruritic papules in a patient with AIDS: AIDS-associated eosinophilic folliculitis. *Am Fam Physician.* 2009 Mar 15;79(6):511–2. [PMID: 19323365]

MILIARIA (Heat Rash)

ESSENTIALS OF DIAGNOSIS

- ▶ Burning, itching, superficial aggregated small vesicles, papules, or pustules on covered areas of the skin, usually the trunk.
- ▶ More common in hot, moist climates.
- ▶ Rare forms associated with fever and even heat prostration.

► General Considerations

Miliaria occurs most commonly on the trunk and intertriginous areas. A hot, moist environment is the most

frequent cause. Occlusive clothing required for certain occupations may increase the risk. Bedridden febrile patients are susceptible. Plugging of the ostia of sweat ducts occurs, with ultimate rupture of the sweat duct, producing an irritating, stinging reaction. Increase in numbers of resident aerobes, notably cocci, plays a role. Drugs that enhance sweat gland function (eg, clonidine, β -blockers, opiates) may contribute.

► Clinical Findings

The usual symptoms are burning and itching. The lesions consist of small, superficial, red, thin-walled, discrete vesicles (miliaria crystallina), papules (miliaria rubra), or vesicopustules or pustules (miliaria pustulosa). The reaction virtually always affects the back in a hospitalized patient.

► Differential Diagnosis

Miliaria is to be distinguished from drug eruption and folliculitis.

► Prevention

Use of an antibacterial preparation such as chlorhexidine prior to exposure to heat and humidity may help prevent the condition. Frequent turning or sitting of the hospitalized patient may reduce miliaria on the back.

► Treatment

The patient should keep cool and wear light clothing. Triamcinolone acetonide, 0.1% in Sarna lotion, or a mid-potency corticosteroid in a lotion or cream should be applied two to four times daily. Secondary infections (superficial pyoderma) are treated with appropriate antistaphylococcal antibiotics. Anticholinergic drugs given by mouth may be helpful in severe cases, eg, glycopyrrolate, 1 mg twice daily.

► Prognosis

Miliaria is usually a mild disorder, but severe forms (tropical anhidrosis and asthenia) result from interference with the heat-regulating mechanism.

Carter R 3rd et al. Patients presenting with miliaria while wearing flame resistant clothing in high ambient temperatures: a case series. *J Med Case Reports*. 2011 Sep 22;5(1):474. [PMID: 21939537]

MUCOCUTANEOUS CANDIDIASIS

ESSENTIALS OF DIAGNOSIS

- Severe pruritus of vulva, anus, or body folds.
- Superficial denuded, beefy-red areas with or without satellite vesicopustules.
- Whitish curd-like concretions on the oral and vaginal mucous membranes.
- Yeast and pseudohyphae on microscopic examination of scales or curd.

▲ **Figure 6-24.** Oral mucosal candidiasis. (Courtesy of Sol Silverman, Jr., DDS, Public Health Image Library, CDC.)

► General Considerations

Mucocutaneous candidiasis is a superficial fungal infection that may involve almost any cutaneous or mucous surface of the body. It is particularly likely to occur in diabetics, during pregnancy, and in obese persons. Systemic antibiotics, oral corticosteroids, and oral contraceptive agents may be contributory. Oral candidiasis may be the first sign of HIV infection (see Chapter 31).

► Clinical Findings

A. Symptoms and Signs

Itching may be intense. Burning is reported, particularly around the vulva and anus. The lesions consist of superficially denuded, beefy-red areas in the depths of the body folds such as in the groin and the intergluteal cleft, beneath the breasts, at the angles of the mouth, and in the umbilicus. The peripheries of these denuded lesions are superficially undermined, and there may be satellite vesicopustules. Whitish, curd-like concretions may be present on mucosal lesions (Figure 6-24). Paronychia may occur (Figure 6-25).

▲ **Figure 6-25.** Acute paronychia. (Courtesy of EJ Mayeaux, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

B. Laboratory Findings

Clusters of budding yeast and pseudohyphae can be seen under high power (400×) when skin scales or curd-like lesions have been cleared in 10% KOH. Culture can confirm the diagnosis.

► Differential Diagnosis

Intertrigo, seborrheic dermatitis, tinea cruris, “inverse psoriasis,” and erythrasma involving the same areas may mimic mucocutaneous candidiasis.

► Complications

Systemic invasive candidiasis with candidemia may be seen with immunosuppression and in patients receiving broad-spectrum antibiotic and hypertonic glucose solutions, as in hyperalimentation. There may or may not be clinically evident mucocutaneous candidiasis.

► Treatment

A. General Measures

Affected parts should be kept dry and exposed to air as much as possible. If possible, discontinue systemic antibiotics. For treatment of systemic invasive candidiasis, see Chapter 36.

B. Local Measures

1. Nails and paronychia—Apply clotrimazole solution 1% twice daily. Thymol 4% in ethanol applied once daily is an alternative.

2. Skin—Apply nystatin ointment or clotrimazole cream 1%, either with hydrocortisone cream 1%, twice daily. Gentian violet 0.5% solution is economical and highly effective in treating cutaneous candidiasis (and also mucosal disease), but the purple discoloration represents a cosmetic issue in some patients.

3. Vulvar and anal mucous membranes—For vaginal candidiasis, single-dose fluconazole (150 mg) is effective. Intravaginal clotrimazole, miconazole, terconazole, or nystatin may also be used. Long-term suppressive therapy may be required for recurrent or “intractable” cases. Non-*albicans* candidal species may be identified by culture in some refractory cases and may respond to oral itraconazole, 200 mg twice daily for 2–4 weeks.

4. Balanitis—This is most frequent in uncircumcised men, and *Candida* usually plays a role. Topical nystatin ointment is the initial treatment if the lesions are mildly erythematous or superficially erosive. Soaking with dilute aluminum acetate for 15 minutes twice daily may quickly relieve burning or itching. Chronicity and relapses, especially after sexual contact, suggest reinfection from a sexual partner who should be treated. Severe purulent balanitis is usually due to bacteria. If it is so severe that phimosis occurs, oral antibiotics—some with activity against anaerobes—are required; if rapid improvement does not occur, urologic consultation is indicated.

5. Mastitis—Lancinating breast pain and nipple dermatitis in breastfeeding women may be a manifestation of *Candida* colonization/infection of the breast ducts. Treatment with oral fluconazole, 200 mg daily can be dramatically effective. Topical gentian violet 0.5% is also useful in these cases.

► Prognosis

Cases of cutaneous candidiasis range from the easily cured to the intractable and prolonged.

Amir LH et al. The role of micro-organisms (*Staphylococcus aureus* and *Candida albicans*) in the pathogenesis of breast pain and infection in lactating women: study protocol. BMC Pregnancy Childbirth. 2011 Jul 22;11:54. [PMID: 21777483]

ERYTHEMAS

REACTIVE ERYTHEMAS

1. Urticaria & Angioedema

ESSENTIALS OF DIAGNOSIS

- ▶ Eruptions of evanescent wheals or hives.
- ▶ Itching is usually intense but may on rare occasions be absent.
- ▶ Special forms of urticaria have special features (dermatographism, cholinergic urticaria, solar urticaria, or cold urticaria).
- ▶ Most incidents are acute and self-limited over a period of 1–2 weeks.
- ▶ Chronic urticaria (episodes lasting > 6 weeks) may have an autoimmune basis.

► General Considerations

Urticaria can result from many different stimuli on an immunologic or nonimmunologic basis. The most common immunologic mechanism is mediated by IgE, as seen in the majority of patients with acute urticaria; another involves activation of the complement cascade. Some patients with chronic urticaria demonstrate autoantibodies directed against mast cell IgE receptors. ACE inhibitor and angiotensin receptor blocker therapy may be complicated by urticaria or angioedema. In general, extensive costly workups are not indicated in patients who have urticaria. A careful history and physical examination are more helpful.

► Clinical Findings

A. Symptoms and Signs

Lesions are itchy red swellings of a few millimeters to many centimeters (Figure 6–26). The morphology of the lesions

▲ **Figure 6-26.** Urticaria. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

may vary over a period of minutes to hours, resulting in geographic or bizarre patterns. Individual lesions in true urticaria last <24 hours, and often only 2–4 hours. Angioedema is involvement of deeper subcutaneous tissue with swelling of the lips, eyelids, palms, soles, and genitalia. Angioedema is no more likely than urticaria to be associated with systemic complications such as laryngeal edema or hypotension. In cholinergic urticaria, triggered by a rise in core body temperature (hot showers, exercise), wheals are 2–3 mm in diameter with a large surrounding red flare. Cold urticaria is acquired or inherited and triggered by exposure to cold and wind (see Chapter 37).

B. Laboratory Findings

Laboratory studies are not likely to be helpful in the evaluation of acute or chronic urticaria. The most common causes of acute urticaria are foods, infections, and medications. The cause of chronic urticaria is often not found. In patients with individual lesions that persist past 24 hours, skin biopsy may confirm neutrophilic urticaria or urticarial vasculitis. A functional ELISA test can detect patients with an autoimmune basis for their chronic urticaria.

► Differential Diagnosis

Papular urticaria resulting from insect bites persists for days. A central punctum can usually be seen. Streaked urticarial lesions may be seen in the 24–48 hours before blisters appear in acute allergic plant dermatitis, eg, poison ivy, oak, or sumac. Urticarial response to heat, sun, water, and pressure are quite rare. Urticarial vasculitis may be

seen as part of serum sickness, associated with fever and arthralgia. In this setting, a low serum complement level may be associated with severe systemic disease.

In hereditary angioedema, there is generally a positive family history and gastrointestinal or respiratory symptoms. Urticaria is not part of the syndrome, and lesions are not pruritic.

► Treatment

A. General Measures

A detailed search by history for a cause of acute urticaria should be undertaken, and treatment may then be tailored to include the provocative condition. The chief causes are medications—eg, aspirin, NSAIDs, morphine, and codeine; arthropod bites—eg, insect bites and bee stings (though the latter may cause anaphylaxis as well as angioedema); physical factors such as heat, cold, sunlight, and pressure; and, presumably, neurogenic factors, as in cholinergic urticaria induced by exercise, excitement, hot showers, etc. Other causes may include penicillins and other medications; inhalants such as feathers and animal danders; ingestion of shellfish, tomatoes, or strawberries; vaccines; external contactants, including various chemicals and cosmetics; and infections such as viral hepatitis (causing urticarial vasculitis).

B. Systemic Treatment

The mainstay of treatment initially includes H₁-antihistamines (see above). Initial therapy is hydroxyzine, 10 mg twice daily to 25 mg three times daily, or as a single nightly dose of 50–75 mg to reduce sedation. Cyproheptadine, 4 mg four times daily, may be especially useful for cold urticaria. “Nonsedating” or less sedating antihistamines are added if the generic sedating antihistamines are not effective. Options include fexofenadine, 60 mg twice daily (or 180 mg once daily); or cetirizine or loratadine, 10 mg daily. Higher doses of these second-generation antihistamines may be required to suppress urticaria (up to four times the standard recommended dose) than are required for allergic rhinitis. These high doses are safe and can be used in refractory cases.

Doxepin (a tricyclic antidepressant), 10–75 mg at bedtime, can be very effective in chronic urticaria. It has anticholinergic side effects.

H₂-antihistamines in combination with H₁-blockers may be helpful in patients with symptomatic dermatographism and to a lesser degree in chronic urticaria. UVB phototherapy can suppress some cases of chronic urticaria. If neutrophils are a significant component of the inflammatory infiltrate in chronic urticaria, dapsone may be useful.

A few patients with chronic urticaria may respond to elimination of salicylates and tartrazine (coloring agent). Asymptomatic foci of infection—sinusitis, vaginal candidiasis, cholecystitis, and intestinal parasites—may rarely cause chronic urticaria. Systemic corticosteroids in a dose of about 40 mg daily will usually suppress acute and chronic urticaria. However, the use of corticosteroids is rarely indicated, since properly selected combinations of

antihistamines with less toxicity are usually effective. Once corticosteroids are withdrawn, the urticaria virtually always returns if it had been chronic. Instead of instituting systemic corticosteroids, consultation should be sought from a dermatologist or allergist with experience in managing severe urticaria. Cyclosporine (3–5 mg/kg/d) and other immunosuppressives may be effective in severe cases of autoimmune chronic urticaria.

C. Local Treatment

Local treatment is rarely rewarding.

► Prognosis

Acute urticaria usually lasts only a few days to weeks. Half of patients whose urticaria persists for > 6 weeks will have it for years. Patients in whom angioedema develops with an ACE inhibitor may be switched to an angiotensin receptor blocker with caution (estimated cross reaction about 10%).

Weis M. Clinical review of hereditary angioedema: diagnosis and management. *Postgrad Med.* 2009 Nov;121(6):113–20. [PMID: 19940422]

2. Erythema Multiforme

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden onset of symmetric erythematous skin lesions with history of recurrence.
- ▶ May be macular, papular, urticarial, bullous, or purpuric.
- ▶ “Target” lesions with clear centers and concentric erythematous rings or “iris” lesions may be noted in erythema multiforme minor. These are rare in drug-associated erythema multiforme major.
- ▶ Erythema multiforme minor on extensor surfaces, palms, soles, or mucous membranes. Erythema multiforme major favors the trunk.
- ▶ Herpes simplex is the most common cause of erythema multiforme minor.
- ▶ Drugs are the most common cause of erythema multiforme major in adults.

► General Considerations

Erythema multiforme is an acute inflammatory skin disease that is divided clinically into minor and major types based on the clinical findings. Approximately 90% of cases of erythema multiforme minor follow outbreaks of herpes simplex, and so is now preferably termed “herpes-associated

erythema multiforme.” The term “erythema multiforme major” has been replaced by three terms: Stevens-Johnson syndrome (SJS), with < 10% BSA skin loss; toxic epidermal necrolysis (TEN) when there is > 30% BSA skin loss; and SJS/TEN overlap for cases with between 10% and 30% BSA denudation. The abbreviation SJS/TEN is often used to refer to these three variants of what is considered one syndrome. All these clinical scenarios are characterized by toxicity and involvement of two or more mucosal surfaces (often oral and conjunctival). They are most often caused by drugs, especially sulfonamides, NSAIDs, allopurinol, and anticonvulsants. In certain races, polymorphisms of antigen presenting major histocompatibility (MHC) loci increase the risk for the development of SJS/TEN. *Mycoplasma pneumoniae* may trigger a skin eruption closely resembling SJS and may be the cause of SJS in up to 50% of children in some series. Erythema multiforme may also present as chronic or recurring ulceration localized to the oral mucosa, with skin lesions present in only half of the cases. The exposure to drugs associated with SJS/TEN may be systemic or topical (eg, eyedrops).

► Clinical Findings

A. Symptoms and Signs

A classic target lesion, found most commonly in herpes-associated erythema multiforme, consists of three concentric zones of color change, most often found acrally on the hands and feet. Not all lesions will have this appearance (Figure 6–27). Drug-associated bullous eruptions in the SJS/TEN spectrum present with raised purpuric target-like lesions, with only two zones of color change and a central blister, or nondescript reddish or purpuric macules. Pain on eating, swallowing, and urination can occur if the appropriate mucosae are involved.

B. Laboratory Findings

Blood tests are not useful for diagnosis. Skin biopsy is diagnostic. Direct immunofluorescence studies are negative.

▲ **Figure 6–27.** Erythema multiforme. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

► Differential Diagnosis

Urticaria and drug eruptions are the chief entities that must be differentiated from erythema multiforme minor. Individual lesions of true urticaria should come and go within 24 hours and are usually responsive to antihistamines. In erythema multiforme major, the differential diagnosis includes autoimmune bullous diseases (including pemphigus and pemphigoid) and acute generalized exanthematous pustulosis. The presence of a blistering eruption requires biopsy and consultation for appropriate diagnosis and treatment.

► Complications

The tracheobronchial mucosa and conjunctiva may be involved in severe cases with resultant scarring. Ophthalmologic consultation is required if ocular involvement is present because vision loss is the major consequence of SJS/TEN.

► Treatment

A. General Measures

TEN is best treated in a burn unit, or hospital setting with similar support. Otherwise, patients need not be admitted unless mucosal involvement interferes with hydration and nutrition. Patients who begin to blister should be seen daily. Open lesions should be managed like second-degree burns. Immediate discontinuation of the inciting medication (before blistering occurs) is a significant predictor of outcome. Delay in establishing the diagnosis and inadvertently continuing the offending medication results in higher morbidity and mortality.

B. Specific Measures

The most important aspect of treatment is to stop the offending medication and to move patients with > 25–30% BSA involvement to an appropriate acute care environment. Nutritional and fluid support and high vigilance for infection are the most important aspects of care. Recent reviews of systemic treatments for SJS and TEN have been conflicting, but the largest series have failed to show statistically significant benefit with treatment. Some data support the use of high-dose corticosteroids. If corticosteroids are to be tried in more severe cases, they should be used early, before blistering occurs, and in moderate to high doses (prednisone, 100–250 mg) and stopped within days if there is no dramatic response. Intravenous immunoglobulin (IVIG) (1 g/kg/d for 4 days) has become standard of care at some centers for TEN cases and can be considered in cases with > 30% BSA involvement. It has not been proven to reduce mortality. Oral and topical corticosteroids are useful in the oral variant of erythema multiforme. Oral acyclovir prophylaxis of herpes simplex infections may be effective in preventing recurrent herpes-associated erythema multiforme minor.

C. Local Measures

Topical therapy is not very effective in this disease. For oral lesions, 1% diphenhydramine elixir mixed with Kaopectate or with 1% dyclonine may be used as a mouth rinse several times daily.

► Prognosis

Erythema multiforme minor usually lasts 2–6 weeks and may recur. SJS/TEN may be serious with a mortality of about 30% in cases with > 30% BSA involvement.

Harr T et al. Severe cutaneous adverse reactions: acute generalized exanthematous pustulosis, toxic epidermal necrolysis and Stevens-Johnson syndrome. *Med Clin North Am.* 2010 Jul;94(4):727–42. [PMID: 20609860]

3. Erythema Migrans (See also Chapter 34)

Erythema migrans is a unique cutaneous eruption that characterizes the localized or generalized early stage of Lyme disease (borreliosis). Three to 32 days (median: 7 days) after a tick bite, there is gradual expansion of redness around the papule representing the bite site (Figure 6–28). The advancing border is usually slightly raised, warm, red to bluish-red, and free of any scale. Centrally, the site of the

▲ **Figure 6–28.** Erythema migrans due to *Borrelia burgdorferi* (Lyme disease). (Courtesy of James Gathany, Public Health Image Library, CDC.)

bite may clear, leaving only a rim of peripheral erythema, or it may become indurated, vesicular, or necrotic. The annular erythema usually grows to a median diameter of 15 cm (range: 3–68 cm, but virtually always > 5 cm). It is accompanied by a burning sensation in half of patients; rarely, it is pruritic or painful. Multiple secondary annular lesions similar in appearance to the primary lesion but without indurated centers and generally of smaller size will develop in 20% of patients. In the southeastern United States, similar lesions are seen in patients who are not as ill and who tend to have classic central clearing of their lesions. These patients have negative Lyme serology tests. This condition has been called Southern tick-associated rash illness (STARI). This illness is transmitted by the lone-star tick; some cases are caused by *Borrelia lonestari*, for which the white tail deer is the animal reservoir. Systemic symptoms are uncommon in STARI and the skin lesions respond to the same antibiotic agents used for Lyme disease, suggesting that a spirochete (probably as yet unidentified *Borrelia* species) is causative in all these cases.

Without treatment, erythema migrans and the secondary lesions fade in a median of 28 days, though some may persist for months. Ten percent of untreated patients experience recurrences over the ensuing months. Treatment with systemic antibiotics (see Table 34–4) is necessary to prevent systemic involvement. However, only 60–70% of those with systemic involvement have experienced erythema migrans.

INFECTIOUS ERYTHEMAS

1. Erysipelas

ESSENTIALS OF DIAGNOSIS

- ▶ Edematous, spreading, circumscribed, hot, erythematous area, with or without vesicles or bullae.
- ▶ Central face frequently involved.
- ▶ Pain, chills, fever, and systemic toxicity may be striking.

▶ General Considerations

Erysipelas is a superficial form of cellulitis that occurs classically on the cheek, caused by β -hemolytic streptococci.

▶ Clinical Findings

A. Symptoms and Signs

The symptoms are pain, malaise, chills, and moderate fever. A bright red spot appears first, very often near a fissure at

the angle of the nose. This spreads to form a tense, sharply demarcated, glistening, smooth, hot plaque. The margin characteristically makes noticeable advances in days or even hours. The lesion is somewhat edematous and may pit slightly with the finger. Vesicles or bullae occasionally develop on the surface. The lesion does not usually become pustular or gangrenous and heals without scar formation. The disease may complicate any break in the skin that provides a portal of entry for the organism.

B. Laboratory Findings

Leukocytosis is almost invariably present; blood cultures may be positive.

▶ Differential Diagnosis

Erysipeloid is a benign bacillary infection producing cellulitis of the skin of the fingers or the backs of the hands in fishermen and meat handlers.

▶ Complications

Unless erysipelas is promptly treated, death may result from extension of the process and systemic toxicity, particularly in the elderly.

▶ Treatment

Place the patient at bed rest with the head of the bed elevated. Intravenous antibiotics effective against group A β -hemolytic streptococci and staphylococci are indicated for the first 48 hours in all but the mildest cases. A 7-day course is completed with penicillin VK, 250 mg, dicloxacillin, 250 mg, or a first-generation cephalosporin, 250 mg, orally four times a day. Alternatives in penicillin-allergic patients are clindamycin (250 mg twice daily orally for 7–14 days) or erythromycin (250 mg four times daily orally for 7–14 days), the latter only if the infection is known to be due to streptococci.

▶ Prognosis

With appropriate treatment, rapid improvement is expected. Recurrence is uncommon.

Pertel PE et al. The efficacy and safety of daptomycin vs. vancomycin for the treatment of cellulitis and erysipelas. *Int J Clin Pract.* 2009 Mar;63(3):368–75. [PMID: 19222623]

2. Cellulitis

ESSENTIALS OF DIAGNOSIS

- ▶ Edematous, expanding, erythematous, warm plaque with or without vesicles or bullae.
- ▶ Lower leg is frequently involved.
- ▶ Pain, chills, and fever are commonly present.
- ▶ Septicemia may develop.

▲ **Figure 6–29.** Erysipelas Cellulitis. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

▶ General Considerations

Cellulitis, a diffuse spreading infection of the dermis and subcutaneous tissue, is usually on the lower leg (Figure 6–29) and most commonly due to gram-positive cocci, especially group A β -hemolytic streptococci and *S aureus*. Rarely, gram-negative rods or even fungi can produce a similar picture. In otherwise healthy persons, the most common portal of entry for lower leg cellulitis is toe web intertrigo with fissuring, usually a complication of interdigital tinea pedis. Venous insufficiency can also predispose to lower leg cellulitis. Injection drug use and open ulcerations may also be complicated by cellulitis. Cellulitis in the diabetic foot may be a major problem and is often associated with neuropathy and hyperkeratotic nodules from ill-fitting shoes and abnormal weight bearing.

▶ Clinical Findings

A. Symptoms and Signs

Cellulitis begins as a small patch, which from its onset is tender. Swelling, erythema, and pain are often present. The

lesion expands over hours, so that from onset to presentation is usually 6 to 36 hours. As the lesion grows, the patient becomes more ill with progressive chills, fever, and malaise. If septicemia develops, hypotension may develop, followed by shock.

B. Laboratory Findings

Leukocytosis or at least a neutrophilia (left shift) is present from early in the course. Blood cultures may be positive. If a central ulceration, pustule, or abscess is present, culture may be of value. Aspiration of the advancing edge has a low yield (20%) and is usually not performed. Instead, if an unusual organism is suspected and there is no loculated site to culture, a full thickness skin biopsy taken before antibiotics are given can be useful. Part is cultured and part processed for histologic evaluation with Gram stain. This technique is particularly useful in the immunocompromised patient. If a primary source for the infection is identified (wound, leg ulcer, toe web intertrigo), cultures from these sites isolate the causative pathogen in half of cases and can be used to guide antibiotic therapy.

▶ Differential Diagnosis

Two potentially life threatening entities that can mimic cellulitis (ie, present with a painful, red, swollen lower extremity) include deep venous thrombosis and necrotizing fasciitis. The diagnosis of necrotizing fasciitis should be suspected in a patient who has a very toxic appearance, bullae, crepitus or anesthesia of the involved skin, overlying skin necrosis, and laboratory evidence of rhabdomyolysis (elevated creatine kinase [CK]) or disseminated intravascular coagulation. While these findings may be present with severe cellulitis and bacteremia, it is essential to rule out necrotizing fasciitis because rapid surgical debridement is essential. Other skin lesions that may resemble cellulitis include sclerosing panniculitis, an acute, exquisitely tender red plaque on the medial lower legs above the malleolus in patients with venous stasis or varicosities, and acute severe contact dermatitis on a limb, which produces erythema, vesiculation, and edema as seen in cellulitis, but with itching instead of pain.

▶ Treatment

Intravenous or parenteral antibiotics may be required for the first 2–5 days, with adequate coverage for *Streptococcus* and *Staphylococcus*. Hospitalization is required in cases with severe local symptoms and signs, hypotension, elevated serum creatinine, low serum bicarbonate, elevated creatine kinase, elevated white blood cell count with marked left shift, or elevated C-reactive protein. If CA-MRSA is suspected, therapy is vancomycin, clindamycin, or TMP-SMZ plus a β -lactam. In mild cases or following the initial parenteral therapy, dicloxacillin or cephalexin, 250–500 mg four times daily for 5–10 days, is usually adequate. If MRSA is suspected, use of TMP-SMZ, clindamycin, or the combination of doxycycline plus rifampin should be considered. In patients in whom intravenous treatment is not instituted, the first dose of oral antibiotic can be doubled to achieve rapid high blood levels.

BLISTERING DISEASES

PEMPHIGUS

ESSENTIALS OF DIAGNOSIS

- ▶ Relapsing crops of bullae.
- ▶ Often preceded by mucous membrane bullae, erosions, and ulcerations.
- ▶ Superficial detachment of the skin after pressure or trauma variably present (Nikolsky sign).
- ▶ Acantholysis on biopsy.
- ▶ Immunofluorescence studies are confirmatory.

▶ General Considerations

Pemphigus is an uncommon intraepidermal blistering disease occurring on skin and mucous membranes. It is caused by autoantibodies to adhesion molecules expressed in the skin and mucous membranes. The cause is unknown, and in the preantibiotic, presteroid era, the condition was usually fatal within 5 years. The bullae appear spontaneously and are tender and painful when they rupture. Drug-induced pemphigus from penicillamine, captopril, and others has been reported. There are several forms of pemphigus: **pemphigus vulgaris** and its variant, **pemphigus vegetans**; and the more superficially blistering **pemphigus foliaceus** and its variant, **pemphigus erythematosus**. All forms may occur at any age but most commonly in middle age. The vulgaris form begins in the mouth in over 50% of cases. The foliaceus form is especially apt to be associated with other autoimmune diseases, or it may be drug-induced. Paraneoplastic pemphigus, a unique form of the disorder, is associated with numerous types of benign and malignant neoplasms but most frequently non-Hodgkin lymphoma.

▶ Clinical Findings

A. Symptoms and Signs

Pemphigus is characterized by an insidious onset of flaccid bullae, crusts, and erosions in crops or waves (Figure 6–30). In pemphigus vulgaris, lesions often appear first on the oral mucous membranes. These rapidly become erosive. The scalp is another site of early involvement. Rubbing a cotton swab or finger laterally on the surface of uninvolved skin may cause easy separation of the epidermis (**Nikolsky sign**).

▲ **Figure 6–30.** Pemphigus. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

B. Laboratory Findings

The diagnosis is made by light microscopy and by direct and indirect immunofluorescence (IIF) microscopy. Autoantibodies to intercellular adhesion molecules can be detected with ELISA assays and have replaced the use of IIF in some centers.

▶ Differential Diagnosis

Blistering diseases include erythema multiforme, drug eruptions, bullous impetigo, contact dermatitis, dermatitis herpetiformis, and bullous pemphigoid, but flaccid blisters are not typical of these diseases, and acantholysis is not seen on biopsy. All of these diseases have clinical characteristics and different immunofluorescence test results that distinguish them from pemphigus.

Paraneoplastic pemphigus is clinically, histologically, and immunologically distinct from other forms of the disease. Oral erosions and erythematous plaques resembling erythema multiforme are seen. Survival rates are low because of the underlying malignancy.

▶ Complications

Secondary infection commonly occurs; this is a major cause of morbidity and mortality. Disturbances of fluid, electrolyte, and nutritional intake can occur as a result of painful oral ulcers.

▶ Treatment

A. General Measures

When the disease is severe, hospitalize the patient at bed rest and provide antibiotics and intravenous feedings as indicated. Anesthetic troches used before eating ease painful oral lesions.

B. Systemic Measures

Pemphigus requires systemic therapy as early in its course as possible. However, the main morbidity in this disease is

due to the side effects of such therapy. Initial therapy is with systemic corticosteroids: prednisone, 60–80 mg daily. In all but the most mild cases, a steroid-sparing agent is added from the beginning, since the course of the disease is long and the steroid-sparing agents take several weeks to exert their activity. Azathioprine (100–200 mg daily) or mycophenolate mofetil (1–1.5 g twice daily) is used most frequently, the latter seeming to be the most reliable and recommended for most cases. Rituximab may be given in refractory cases to diminish the amount of autoantibody production. If this fails, monthly IVIG at 2 g/kg intravenously over 3 days with rituximab is dramatically beneficial and has replaced high-dose corticosteroids plus cyclophosphamide and pulse intravenous corticosteroids as rescue therapy. Increased risk of thromboembolism is associated with IVIG therapy in these doses.

C. Local Measures

In patients with limited disease, skin and mucous membrane lesions should be treated with topical corticosteroids. Complicating infection requires appropriate systemic and local antibiotic therapy.

► Prognosis

The course tends to be chronic in most patients, though about one-third appear to experience remission. Infection is the most frequent cause of death, usually from *S aureus* septicemia.

Amagai M et al; Pemphigus Study Group. A randomized double-blind trial of intravenous immunoglobulin for pemphigus. *J Am Acad Dermatol.* 2009 Apr;60(4):595–603. [PMID: 19293008]

Meyer N et al. Geoepidemiologic considerations of autoimmune pemphigus. *Autoimmun Rev.* 2010 Mar;9(5):A379–82. [PMID: 19895907]

BULLOUS PEMPHIGOID

Many other autoimmune skin disorders are characterized by formation of bullae, or blisters. These include bullous pemphigoid, cicatricial pemphigoid, dermatitis herpetiformis, and pemphigoid gestationis.

Bullous pemphigoid is a relatively benign pruritic disease characterized by tense blisters in flexural areas, usually remitting in 5 or 6 years, with a course characterized by exacerbations and remissions. Most affected persons are over the age of 60 (often in their 70s or 80s), and men are affected twice as frequently as women. The appearance of blisters may be preceded by urticarial or edematous lesions for months. Oral lesions are present in about one-third of affected persons. The disease may occur in various forms, including localized, vesicular, vegetating, erythematous, erythrodermic, and nodular.

The diagnosis is made by biopsy and direct immunofluorescence examination. Light microscopy shows a subepidermal blister. With direct immunofluorescence, IgG

and C3 are found at the dermal-epidermal junction. If the patient has mild disease, ultrapotent corticosteroids may be adequate. Prednisone at a dosage of 0.75 mg/kg daily is often used to achieve rapid control of more widespread disease. Although slower in onset of action, tetracycline or erythromycin, 500 mg three times daily, alone or combined with nicotinamide—*not nicotinic acid or niacin!*—(up to 1.5 g/d), if tolerated, may control the disease in patients who cannot use corticosteroids or may allow decreasing or eliminating corticosteroids after control is achieved. Dapsone is particularly effective in mucous membrane pemphigoid. If these drugs are not effective, methotrexate, 5–25 mg weekly, or azathioprine, 50 mg one to three times daily, may be used as steroid-sparing agents. Mycophenolate mofetil (1 g twice daily) may be used in refractory cases.

PAPULES

WARTS

ESSENTIALS OF DIAGNOSIS

- Verrucous papules anywhere on the skin or mucous membranes, usually no larger than 1 cm in diameter.
- Prolonged incubation period (average 2–18 months). Spontaneous “cures” are frequent (50% at 2 years for common warts).
- “Recurrences” (new lesions) are frequent.

► General Considerations

Warts (common, plantar, and genital) are caused by human papillomaviruses (HPVs). Typing of HPV lesions is NOT a part of standard medical evaluation except in the case of genital dysplasia. Genital HPV types are divided into low-risk and high-risk depending on the likelihood of their association with cervical and anal cancer.

► Clinical Findings

There are usually no symptoms. Tenderness on pressure occurs with plantar warts; itching occurs with anogenital warts (Figure 6–31). Flat warts are most evident under oblique illumination. Periungual warts may be dry, fissured, and hyperkeratotic and may resemble hangnails or other nonspecific changes. Plantar warts resemble plantar corns or calluses.

▲ **Figure 6-31.** Condylomata acuminata, or genital warts, of the anal region due to human papillomavirus. (Public Health Image Library, CDC.)

► Differential Diagnosis

Some warty-looking lesions are actually hypertrophic actinic keratoses or squamous cell carcinomas. Some genital warty lesions may be due to secondary syphilis (condylomata lata). The lesions of molluscum contagiosum are pearly with a central dell. In AIDS, wart-like lesions may be caused by varicella zoster virus.

► Prevention

Administration of a vaccine against certain genital HPV types can prevent infection with these wart types and reduce cervical dysplasia. It is recommended for teenagers and young adults (see Chapters 1 and 18).

► Treatment

Treatment is aimed at inducing “wart-free” intervals for as long as possible without scarring, since no treatment can guarantee a remission or prevent recurrences. In immunocompromised patients, the goal is even more modest, ie, to control the size and number of lesions present.

A. Removal

For common warts of the hands, patients are usually offered liquid nitrogen or keratolytic agents. The former may work in fewer treatments but requires office visits and is painful.

1. Liquid nitrogen—Liquid nitrogen is applied to achieve a thaw time of 30–45 seconds. Two freeze-thaw cycles are given every 2–4 weeks for several visits. Scarring will occur if it is used incorrectly. Liquid nitrogen may cause permanent depigmentation in pigmented individuals. Cryotherapy is first-line physician applied surgical treatment for genital warts (condyloma acuminata).

2. Keratolytic agents and occlusion—Salicylic acid products may be used against common warts or plantar warts. They are applied then occluded. Plantar warts may be treated by applying a 40% salicylic acid plaster (Mediplast) after paring. The plaster may be left on for 5–6 days, then removed, the lesion pared down, and another plaster applied. Although it may take weeks or months to eradicate the wart, the method is safe and effective with almost no side effects. Chronic occlusion alone with water-impermeable tape (duct tape, adhesive tape) is less effective than cryotherapy.

3. Podophyllum resin—For genital warts, the purified active component of the podophyllum resin, podofilox, is applied by the patient twice daily 3 consecutive days a week for cycles of 4–6 weeks. It is less irritating and more effective than “physician-applied” podophyllum resin. After a single 4-week cycle, 45% of patients were wart-free; but of these, 60% relapsed at 6 weeks. Thus, multiple cycles of treatment are often necessary. Patients unable to obtain the take home podofilox may be treated in the clinician’s office by painting each wart carefully (protecting normal skin) every 2–3 weeks with 25% podophyllum resin (podophyllin) in compound tincture of benzoin. Pregnant patients should not be so treated. Podophyllin is ineffective for common warts and plantar warts.

4. Imiquimod—A 5% cream of this local interferon inducer has moderate activity in clearing external genital warts (EGWs). Treatment is once daily on 3 alternate days per week. Response may be slow, with patients who eventually cleared having responses at 8 weeks (44%) or 12 weeks (69%). There is a marked gender difference with respect to response, with 77% of women and 40% of men having complete clearing of their lesions. Once cleared, about 13% have recurrences in the short term.

In accidental exposure during pregnancy, there is less risk with imiquimod than with podophyllum resin (category B versus category X). Imiquimod is considerably more expensive than podophyllotoxin, but given the high rate of response in women and its safety, it appears to be the “patient-administered” treatment of choice for EGWs in women. In men, the more rapid response, lower cost, and similar efficacy make podophyllotoxin the initial treatment of choice, with imiquimod used for recurrences or refractory cases. Imiquimod has no demonstrated efficacy for—and should not be used to treat—plantar or common warts.

5. Operative removal—Plantar warts may be removed by blunt dissection. For genital warts, snip biopsy (scissors) removal followed by light electrocautery is more effective than cryotherapy, especially for patients with pedunculated or large lesions.

6. Laser therapy—The CO₂ laser can be effective for treating recurrent warts, periungual warts, plantar warts, and condylomata acuminata. It leaves open wounds that must fill in with granulation tissue over 4–6 weeks and is best reserved for warts resistant to all other modalities. Lasers with emissions of 585, 595, or 532 nm may also be used every 3–4 weeks to gradually ablate common or plantar

warts. This is no more effective than cryotherapy in controlled trials. For genital warts, it has not been shown that laser therapy is more effective than electrosurgical removal. Photodynamic therapy can be considered in refractory widespread flat and genital warts.

7. Other agents—Bleomycin diluted to 1 unit/mL may be injected into common and plantar warts. It has been shown to have a high cure rate. It should be used with caution on digital warts because of the potential complications of Raynaud phenomenon, nail loss, and terminal digital necrosis.

B. Immunotherapy

Squaric acid dibutylester may be effective. It is applied in a concentration of 0.2–2% directly to the warts from once weekly to five times weekly to induce a mild contact dermatitis. Between 60% and 80% of warts clear over 10–20 weeks. Injection of *Candida* antigen starting at 1:50 dilution and repeated every 3–4 weeks may be similarly effective in stimulating immunologic regression of common and plantar warts.

C. Physical Modalities

Soaking warts in hot (42.2°C) water for 10–30 minutes daily for 6 weeks has resulted in involution in some cases.

► Prognosis

There is a striking tendency to the development of new lesions. Warts may disappear spontaneously or may be unresponsive to treatment.

CALLOSITIES & CORNS OF FEET OR TOES

Callosities and corns are caused by pressure and friction due to faulty weight-bearing, orthopedic deformities, improperly fitting shoes, or neuropathies.

Tenderness on pressure and “after-pain” are the only symptoms. The hyperkeratotic well-localized overgrowths always occur at pressure points. Dermatoglyphics (finger-print lines) are preserved over the surface (not so in warts). When the surface is shaved with a 15 blade, a glassy core is found (which differentiates them from plantar warts, which have multiple capillary bleeding points or black dots when pared).

Treatment consists of correcting mechanical abnormalities that cause friction and pressure. Callosities may be removed by careful paring of the callus after a warm water soak or with keratolytic agents as found in various brands of corn pads.

Plantar hyperkeratosis of the heels can be treated successfully by using 20% urea (Ureacin 20) or 12% lactic acid (Amlactin) or combinations nightly and a pumice stone after soaking in water.

Callosities on diabetic feet, especially in the setting of hyposensate neuropathy, can be a major problem and the value of early podiatric management to prevent complications is very high.

Fujiwara Y et al. Beneficial effects of foot care nursing for people with diabetes mellitus: an uncontrolled before and after intervention study. *J Adv Nurs.* 2011 Sep;67(9):1952–62. [PMID: 21480962]

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum, caused by a poxvirus, presents as single or multiple dome-shaped, waxy papules 2–5 mm in diameter that are umbilicated (Figure 6–32). Lesions at first are firm, solid, and flesh-colored but upon reaching maturity become soft, whitish, or pearly gray and may suppurate. The principal sites of involvement are the face, lower abdomen, and genitals.

The lesions are autoinoculable and spread by wet skin-to-skin contact. In sexually active individuals, they may be confined to the penis, pubis, and inner thighs and are considered a sexually transmitted infection.

Molluscum contagiosum is common in patients with AIDS, usually with a helper T cell count < 100/mcL. Extensive lesions tend to develop over the face and neck as well as in the genital area.

▲ **Figure 6–32.** Molluscum contagiosum lesion on the back. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine.* McGraw-Hill, 2009.)

The diagnosis is easily established in most instances because of the distinctive central umbilication of the dome-shaped lesion. The best treatment is by curettage or applications of liquid nitrogen as for warts—but more briefly. When lesions are frozen, the central umbilication often becomes more apparent. Light electrosurgery with a fine needle is also effective. It has been estimated that individual lesions persist for about 2 months. They are difficult to eradicate in patients with AIDS unless immunity improves. However, in AIDS, with highly effective anti-retroviral treatment, molluscum do not need to be treated because they usually spontaneously clear.

Villa L et al. Molluscum contagiosum: a 20-year study in a sexually transmitted infections unit. *Sex Transm Dis.* 2010 Jul;37(7):423–4. [PMID: 20414149]

BASAL CELL CARCINOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Pearly papule, erythematous patch > 6 mm, or nonhealing ulcer, in sun exposed areas (face, trunk, lower legs).
- ▶ History of bleeding.
- ▶ Fair-skinned person with a history of sun exposure (often intense, intermittent).

▶ General Considerations

Basal cell carcinomas are the most common form of cancer. They occur on sun-exposed skin in otherwise normal fair-skinned individuals; ultraviolet light is the cause. The most common presentation is a papule or nodule that may have a central scab or erosion (Figure 6–33). Occasionally the nodules have stippled pigment (pigmented basal cell carcinoma). Intradermal nevi without pigment on the face of older white individuals may resemble basal cell carcinomas. Basal cell carcinomas grow slowly, attaining a size of 1–2 cm or more in diameter, usually only after years of growth. There is a waxy, “pearly” appearance, with telangiectatic vessels easily visible. It is the pearly or translucent quality of these lesions that is most diagnostic, a feature best appreciated if the skin is stretched. On the back and chest, basal cell carcinomas appear as reddish, somewhat shiny, scaly patches.

Clinicians should examine the whole skin routinely, looking for bumps, patches, and scabbed lesions. When examining the face, look at the eyelid margins and medial canthi, the nose and alar folds, the lips, and then around and behind the ears.

▶ Treatment

Lesions suspected to be basal cell carcinomas should be biopsied, by shave or punch biopsy. Therapy is then aimed at eradication with minimal cosmetic deformity, often by

▲ **Figure 6–33.** Nodular basal cell carcinoma of the nose. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine.* McGraw-Hill, 2009.)

excision and suturing with recurrence rates of 5% or less. The technique of three cycles of curettage and electrodesiccation depends on the skill of the operator and is not recommended for head and neck lesions. After 4–6 weeks of healing, it leaves a broad, hypopigmented, at times hypertrophic scar. Radiotherapy is effective and sometimes appropriate for older individuals (over age 65), but recurrent tumors after radiation therapy are more difficult to treat and may be more aggressive. Radiation therapy is the most expensive method to treat basal cell carcinoma and should only be used if other treatment options are not appropriate. Mohs surgery—removal of the tumor followed by immediate frozen section histopathologic examination of margins with subsequent reexcision of tumor-positive areas and final closure of the defect—gives the highest cure rates (98%) and results in least tissue loss. It is appropriate therapy for tumors of the eyelids, nasolabial folds, canthi, external ear, and temple; for recurrent lesions; or where tissue sparing is needed for cosmesis. Since up to half of patients with a basal cell carcinoma will develop a second lesion, patients with basal cell carcinomas must be monitored to detect new or recurrent lesions.

Muller FM et al. Randomized comparison of Mohs micrographic surgery and surgical excision for small nodular basal cell carcinoma: tissue-sparing outcome. *Dermatol Surg.* 2009 Sep;35(9):1349–54. [PMID: 19500127]

SQUAMOUS CELL CARCINOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Nonhealing ulcer or warty nodule.
- ▶ Skin damage due to long-term sun exposure.
- ▶ Common in fair-skinned organ transplant recipients.

Squamous cell carcinoma usually occurs subsequent to prolonged sun exposure on exposed parts in fair-skinned individuals who sunburn easily and tan poorly. It may arise from an actinic keratosis. The lesions appear as small red, conical, hard nodules that occasionally ulcerate (Figure 6–34). The frequency of metastasis is not precisely known, though metastatic spread is said to be less likely with squamous cell carcinoma arising out of actinic keratoses than with those that arise *de novo*. In actinically induced squamous cell cancers, rates of metastasis are estimated from retrospective studies to be 3–7%. Squamous cell carcinomas of the ear, lip, oral cavity, tongue, and genitalia have much higher rates of metastasis and require special management.

Examination of the skin and therapy are essentially the same as for basal cell carcinoma. The preferred treatment

of squamous cell carcinoma is excision. Electrodesiccation and curettage and x-ray radiation may be used for some lesions, and fresh tissue microscopically controlled excision (Mohs) is recommended for high-risk lesions (lips, temples, ears, nose) and for recurrent tumors. Follow-up for squamous cell carcinoma must be more frequent and thorough than for basal cell carcinoma, starting at every 3 months, with careful examination of lymph nodes. In addition, palpation of the lips is essential to detect hard or indurated areas that represent early squamous cell carcinoma. All such cases must be biopsied. Multiple squamous cell carcinomas are very common on the sun-exposed skin of organ transplant patients. The intensity of immunosuppression, not the use of any particular immunosuppressive agent, is the primary risk factor in determining the development of skin cancer after transplant. The tumors begin to appear after 5 years of immunosuppression. Voriconazole treatment appears to increase the risk of development of squamous cell carcinoma, especially in lung transplant patients. Regular dermatologic evaluation in at-risk organ transplant recipients is recommended. Biologic behavior of skin cancer in organ transplant recipients may be aggressive, and careful management is required. Other forms of immunosuppression such as chronic lymphocytic leukemia, HIV/AIDS, and chronic iatrogenic immunosuppression may also increase skin cancer risk and be associated with more aggressive skin cancer behavior.

VIOLACEOUS TO PURPLE PAPULES & NODULES

LICHEN PLANUS

ESSENTIALS OF DIAGNOSIS

- ▶ Pruritic, violaceous, flat-topped papules with fine white streaks and symmetric distribution.
- ▶ Lacy or erosive lesions of the buccal and vaginal mucosa; nail dystrophy.
- ▶ Commonly seen along linear scratch marks (Koebner phenomenon) on anterior wrists, penis, legs.
- ▶ Histopathologic examination is diagnostic.

► General Considerations

Lichen planus is an inflammatory pruritic disease of the skin and mucous membranes characterized by distinctive papules with a predilection for the flexor surfaces and trunk. The three cardinal findings are typical skin lesions, mucosal lesions, and histopathologic features of band-like infiltration of lymphocytes in the upper dermis. The most common drugs causing lichen planus-like reactions include sulfonamides, tetracycline, quinidine, NSAIDs, and hydrochlorothiazide. Hepatitis C infection is found with greater frequency in lichen planus patients than in controls. Allergy to mercury and other metal containing amalgams can trigger oral lesions identical to lichen planus.

► Clinical Findings

Itching is mild to severe. The lesions are violaceous, flat-topped, angulated papules, up to 1 cm in diameter, discrete or in clusters, with very fine white streaks (Wickham striae) on the flexor surfaces of the wrists and on the penis, lips, tongue as well as buccal, vaginal, esophageal, and anorectal mucous membranes. The papules may become bullous or eroded. The disease may be generalized (Figure 6–35).

▲ **Figure 6–35.** Lichen planus. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

Mucous membrane lesions have a lacy white network overlying them that may be confused with leukoplakia. The presence of oral and vaginal lichen planus in the same patient is common. Patients with both these mucous membranes involved are at much higher risk for esophageal lichen planus. The Koebner phenomenon (appearance of lesions in areas of trauma) may be seen.

A special form of lichen planus is the erosive or ulcerative variety, a major problem in the mouth or genitalia. Squamous cell carcinoma develops in 5% of patients with erosive oral or genital lichen planus and may occur in esophageal lichen planus.

► Differential Diagnosis

Lichen planus must be distinguished from similar lesions produced by medications (see above) and other papular lesions such as psoriasis, lichen simplex chronicus, graft-versus-host disease, and syphilis. Lichen planus on the mucous membranes must be differentiated from leukoplakia. Erosive oral lesions require biopsy and often direct immunofluorescence for diagnosis since lichen planus may simulate other erosive diseases.

► Treatment

A. Topical Therapy

Superpotent topical corticosteroids applied twice daily are most helpful for localized disease in nonflexural areas. Alternatively, high-potency corticosteroid cream or ointment may be used nightly under thin pliable plastic film.

Topical tacrolimus appears effective in oral and vaginal erosive lichen planus, but long-term therapy is required to prevent relapse. If tacrolimus is used, lesions must be observed carefully for development of cancer. Since absorption can occur through mucous membranes, serum tacrolimus levels should be checked at least once if widespread mucosal application (> 5–10 cm²) is used. If the erosive oral lichen planus lesions are adjacent to a metal containing amalgam, removal of the amalgam may result in clearing of the erosions.

B. Systemic Therapy

Corticosteroids (see Chapter 26) may be required in severe cases or in circumstances where the most rapid response to treatment is desired. Unfortunately, relapse almost always occurs as the corticosteroids are tapered, making systemic corticosteroid therapy an impractical option for the management of chronic lichen planus. NB-UVB, bath PUVA, oral PUVA, and the combination of an oral retinoid plus PUVA (re-PUVA) are all forms of phototherapy that can improve lichen planus. Hydroxychloroquine, 200 mg orally twice daily, can also be effective in mucosal lichen planus.

► Prognosis

Lichen planus is a benign disease, but it may persist for months or years and may be recurrent. Hypertrophic lichen planus and oral lesions tend to be especially persistent, and neoplastic degeneration has been described in chronically eroded lesions.

Farhi D et al. Pathophysiology, etiologic factors, and clinical management of oral lichen planus, part I: facts and controversies. *Clin Dermatol*. 2010 Jan–Feb;28(1):100–8. [PMID: 20082959]

KAPOSI SARCOMA

▶ General Considerations

Before 1980 in the United States, this rare malignant skin lesion was seen mostly in elderly men, had a chronic clinical course, and was rarely fatal. Kaposi sarcoma occurs endemically in an often aggressive form in young black men of equatorial Africa, but it is rare in American blacks. Kaposi sarcoma continues to occur largely in homosexual men with HIV infection as an AIDS-defining illness. Kaposi sarcoma may complicate immunosuppressive therapy, and stopping the immunosuppression may result in improvement. Human herpes virus 8 (HHV-8), or Kaposi sarcoma-associated herpes virus (KSHV), is universally present in all forms of Kaposi sarcoma.

Red or purple plaques or nodules on cutaneous or mucosal surfaces are characteristic. Marked edema may occur with few or no skin lesions. Kaposi sarcoma commonly involves the gastrointestinal tract and can be screened for by fecal occult blood testing. In asymptomatic patients, these lesions are not sought or treated. Pulmonary Kaposi sarcoma can present with shortness of breath, cough, hemoptysis, or chest pain; it may be asymptomatic, appearing only on chest radiograph. Bronchoscopy may be indicated. The incidence of AIDS-associated Kaposi sarcoma is diminishing; however, chronic Kaposi sarcoma can develop in patients with HIV infection, high CD4 counts, and low viral loads. In this setting, the Kaposi sarcoma usually resembles the endemic form, being indolent and localized. At times, however, it can be clinically aggressive.

▶ Treatment

For Kaposi sarcoma in the elderly, palliative local therapy with intralesional chemotherapy or radiation is usually all that is required. In the setting of iatrogenic immunosuppression, the treatment of Kaposi sarcoma is primarily reduction of doses of immunosuppressive medications. In AIDS-associated Kaposi sarcoma, the patient should first be given effective anti-HIV antiretrovirals because in most cases this treatment alone is associated with improvement. Other therapeutic options include cryotherapy or intralesional vinblastine (0.1–0.5 mg/mL) for cosmetically objectionable lesions; radiation therapy for accessible and space-occupying lesions; and laser surgery for certain intraoral and pharyngeal lesions. Systemic therapy is indicated in patients with

rapidly progressive skin disease (more than ten new lesions per month), with edema or pain, and with symptomatic visceral disease or pulmonary disease. Liposomal doxorubicin is highly effective in controlling these cases and has considerably less toxicity—and greater efficacy—than anthracycline monotherapy or combination chemotherapeutic regimens. α -Interferon may also be used. Paclitaxel and other taxanes can be effective even in patients who do not respond to anthracycline treatment.

Riva G et al. Immunological and inflammatory features of Kaposi's sarcoma and other Kaposi's sarcoma-associated herpesvirus/human herpesvirus 8-associated neoplasias. *AIDS Rev*. 2010 Jan–Mar;12(1):40–51. [PMID: 20216909]

PRURITUS (ITCHING)

Pruritus is a disagreeable sensation that provokes a desire to scratch. It is modulated by central factors, including anxiety, depression, and amphetamine and cocaine use. Many cases of pruritus are not mediated by histamine.

Dry skin is the first cause of itch that should be sought, since it is common and easily treated. Other causes include scabies, atopic dermatitis, insect bites, pediculosis, contact dermatitis, drug reactions, urticaria, psoriasis, lichen planus, lichen simplex chronicus, and fiberglass dermatitis.

Persistent pruritus not explained by cutaneous disease or association with a primary skin eruption should prompt a staged workup for systemic causes. Perhaps the most common cause of pruritus associated with systemic disease is uremia in conjunction with hemodialysis. This condition and to a lesser degree the pruritus of liver disease may be helped by phototherapy with ultraviolet B or PUVA. Naltrexone and nalmefene have been shown to relieve the pruritus of liver disease. Naltrexone is not effective in pruritus associated with advanced chronic kidney disease, but gabapentin may be effective. Endocrine disorders such as hypothyroidism or hyperthyroidism, psychiatric disturbances, lymphoma, leukemia, and other internal malignant disorders, iron deficiency anemia, and certain neurologic disorders may also cause pruritus. The treatment of chronic pruritus can be frustrating. Combinations of antihistamines, gabapentin, mirtazapine, and opioid antagonists can be attempted in refractory cases.

▶ Prognosis

Elimination of external factors and irritating agents may give complete relief. Pruritus accompanying a specific skin disease will subside when the skin disease is controlled. Pruritus accompanying serious internal disease may not respond to any type of therapy.

ANOGENITAL PRURITUS

ESSENTIALS OF DIAGNOSIS

- ▶ Itching, chiefly nocturnal, of the anogenital area.
- ▶ Examination is highly variable, ranging from no skin findings to excoriations and inflammation of any degree, including lichenification.

▶ General Considerations

Anogenital pruritus may be due to intertrigo, psoriasis, lichen simplex chronicus, or seborrheic or contact dermatitis (from soaps, colognes, douches, contraceptives, and perhaps scented toilet tissue), or it may be due to irritating secretions, as in diarrhea, leukorrhea, or trichomoniasis, or to local disease (candidiasis, dermatophytosis, erythrasma), and at times oxyuriasis (pinworms). Lichen sclerosus may at times be the cause. Erythrasma (Figure 6–36) is easily diagnosed by demonstration of coral-red fluorescence with Wood light; it is easily cured with erythromycin orally or topically.

In pruritus ani, hemorrhoids are often found, and leakage of mucus and bacteria from the distal rectum onto the perianal skin may be important in cases in which no other skin abnormality is found.

Many women experience pruritus vulvae. Pruritus vulvae does not usually involve the anal area, though anal itching may spread to the vulva. In men, pruritus of the scrotum is most commonly seen in the absence of pruritus ani. Up to one-third of causes of anogenital pruritus may be due to nerve impingements of the lumbosacral spine, so referral for evaluation of lumbosacral spine disease is appropriate if no skin disorder is identified, and topical therapy is ineffective.

Squamous cell carcinoma of the anus and extramammary Paget disease are rare causes of genital pruritus.

▶ Clinical Findings

A. Symptoms and Signs

The only symptom is itching. Physical findings are usually not present, but there may be erythema, fissuring, maceration, lichenification, excoriations, or changes suggestive of candidiasis or tinea.

B. Laboratory Findings

Urinalysis and blood glucose testing may lead to a diagnosis of diabetes mellitus. Microscopic examination or culture of tissue scrapings may reveal yeasts or fungi. Stool examination may show pinworms. Radiologic studies may demonstrate spinal cord disease.

▲ **Figure 6–36.** Erythrasma of the axilla. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine.* McGraw-Hill, 2009.)

▶ Differential Diagnosis

The etiologic differential diagnosis consists of *Candida* infection, parasitosis, local irritation from contactants or irritants, nerve impingement and other primary skin disorders of the genital area such as psoriasis, seborrhea, intertrigo, or lichen sclerosus et atrophicus.

▶ Prevention

Instruct the patient in proper anogenital hygiene after treating systemic or local conditions. If appropriate, physical therapy and exercises to support the lower spine are recommended.

▶ Treatment

A. General Measures

Treating constipation, preferably with high-fiber management (psyllium), may help. Instruct the patient to use very soft or moistened tissue or cotton after bowel movements and to clean the perianal area thoroughly with cool water if possible. Women should use similar precautions after urinating.

B. Local Measures

Pramoxine cream or lotion or hydrocortisone-pramoxine (Pramosone), 1% or 2.5% cream, lotion, or ointment, is helpful in managing pruritus in the anogenital area. The ointment or cream should be applied after a bowel movement. Topical doxepin cream 5% is similarly effective, but it may be sedating. The use of strong corticosteroids on the scrotum may lead to persistent severe burning upon withdrawal of the drug. Underclothing should be changed daily, and in men, the seam of their “boxers” should not rub against or contact the scrotum. Balneol Perianal Cleansing Lotion or Tucks premoistened pads, ointment, or cream may be very useful for pruritus ani. About one-third of patients with scrotal or anal pruritus will respond to capsaicin

0.006%. Treatment for underlying spinal neurologic disease may be required.

► Prognosis

Although benign, anogenital pruritus is often persistent and recurrent.

Markell KW et al. Pruritus ani: etiology and management. *Surg Clin North Am.* 2010 Feb;90(1):125–35. [PMID: 20109637]

SCABIES

ESSENTIALS OF DIAGNOSIS

- ▶ Generalized very severe itching.
- ▶ Pruritic burrows, vesicles and pustules, especially on finger webs and in wrist creases.
- ▶ Mites, ova, and brown dots of feces visible microscopically.
- ▶ Red papules or nodules on the scrotum and on the penile glans and shaft are pathognomonic.

► General Considerations

Scabies is caused by infestation with *Sarcoptes scabiei*. The infestation usually spares the head and neck (though even these areas may be involved in infants, in the elderly, and in patients with AIDS). Scabies is usually acquired by sleeping with or in the bedding of an infested individual or by other close contact. The entire household may be affected. Hospital-associated scabies is increasingly common, primarily in long-term care facilities. Index patients are usually elderly and immunosuppressed. When these patients are hospitalized, hospital-based epidemics can occur. These epidemics are difficult to eradicate since many health care workers become infected and spread the infestation to other patients.

► Clinical Findings

A. Symptoms and Signs

Itching is almost always present and can be quite severe. The lesions consist of more or less generalized excoriations with small pruritic vesicles, pustules, and “burrows” in the web spaces and on the heels of the palms, wrists (Figure 6–37), elbows, around the axillae, and on the breasts of women. The feet are a good place to identify burrows, since they may have been scratched off in other locations. The burrow appears as a short irregular mark, 2–3 mm long and the width of a hair. Characteristic nodular lesions may occur on the scrotum or penis and along the posterior axillary line.

B. Laboratory Findings

The diagnosis should be confirmed by microscopic demonstration of the organism, ova, or feces in a mounted specimen, examined with tap water. Best results are obtained when multiple lesions are scraped, choosing the

▲ **Figure 6–37.** Scabies. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

best unexcoriated lesions from interdigital webs, wrists, elbows, or feet. A No. 15 blade is used to scrape each lesion until it is flat. Pinpoint bleeding may result from the scraping. Patients with crusted/hyperkeratotic scabies must be evaluated for immunosuppression (especially HIV and HTLV-1 infections) if no iatrogenic cause of immunosuppression is present.

► Differential Diagnosis

Scabies must be distinguished from the various forms of pediculosis, from bedbug and flea bites, and from other causes of pruritus.

► Treatment & Prognosis

Treatment is aimed at killing scabies mites and controlling the dermatitis, which can persist for months after effective eradication of the mites. Bedding and clothing should be laundered or cleaned or set aside for 14 days in plastic bags. High heat (60°C) is required to kill the mites and ova. Unless treatment is aimed at all infected persons in a family or institutionalized group, reinfestations will probably occur.

Permethrin 5% cream is highly effective and safe in the management of scabies. Treatment consists of a single application for 8–12 hours, repeated in 1 week.

Pregnant patients should be treated only if they have documented scabies themselves. Permethrin 5% cream once for 12 hours—or 5% or 6% sulfur in petrolatum applied nightly for 3 nights from the collarbones down—may be used.

Patients will continue to itch for several weeks after treatment. Use of triamcinolone 0.1% cream will help resolve the dermatitis. Scabies in nursing home patients, institutionalized or mentally impaired (especially Down syndrome) patients, and AIDS patients may be much more difficult to treat.

Most failures in normal persons are related to incorrect use or incomplete treatment of the housing unit. In these cases, repeat treatment with permethrin once weekly for 2 weeks, with reeducation regarding the method and extent of application, is suggested. In immunocompetent individuals, ivermectin in a dose of 200 mcg/kg is effective in about 75% of cases with a single dose and 95% of cases with two doses 2 weeks apart. In immunosuppressed hosts

and those with crusted (hyperkeratotic) scabies, multiple doses of ivermectin (every 2 weeks for two or three doses) plus topical therapy with permethrin once weekly may be effective when topical treatment and oral therapy alone fail. Oral ivermectin can be very beneficial in mass treatment to eradicate infections in institutions or villages.

If secondary pyoderma is present, it is treated with systemic antibiotics. In areas where nephritogenic streptococcal strains are prevalent, infestation with scabies or exposure to scabies-infested dogs may be followed by acute post-streptococcal glomerulonephritis.

Persistent pruritic postscabietic papules may be treated with mid- to high-potency corticosteroids or with intralesional triamcinolone acetonide (2.5–5 mg/mL).

 Hay RJ. Scabies and pyodermas—diagnosis and treatment. *Dermatol Ther.* 2009 Nov–Dec;22(6):466–74. [PMID: 19889132]

PEDICULOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Pruritus with excoriation.
- ▶ Nits on hair shafts; lice on skin or clothes.
- ▶ Occasionally, sky-blue macules (maculae ceruleae) on the inner thighs or lower abdomen in pubic louse infestation.

▶ General Considerations

Pediculosis is a parasitic infestation of the skin of the scalp, trunk, or pubic areas. Body lice usually occur among people who live in overcrowded dwellings with inadequate hygiene facilities. Pubic lice may be sexually transmitted. Head lice may be transmitted by shared use of hats or combs. Adults contacting children with head lice frequently acquire the infestation.

There are three different varieties: (1) pediculosis pubis, caused by *Phthirus pubis* (pubic louse, “crabs”); (2) pediculosis corporis, caused by *Pediculus humanus* var *corporis* (body louse); and (3) pediculosis capitis, caused by *Pediculus humanus* var *capitis* (head louse).

Head and body lice are similar in appearance and are 3–4 mm long. The body louse can seldom be found on the body, because the insect comes onto the skin only to feed and must be looked for in the seams of the clothing. Trench fever, relapsing fever, and typhus are transmitted by the body louse in countries where those diseases are endemic.

▶ Clinical Findings

Itching may be very intense in body louse infestations, and scratching may result in deep excoriations, especially over the upper shoulders, posterior flanks, and neck. In some cases, only itching is present, with few excoriations seen. Pyoderma may be the presenting sign. Head lice can be found on the scalp or may be manifested as small nits

resembling pussy willow buds on the scalp hairs close to the skin. They are easiest to see above the ears and at the nape of the neck. Pubic louse infestations are occasionally generalized, particularly in hairy individuals; the lice may even be found on the eyelashes and in the scalp.

▶ Differential Diagnosis

Head louse infestation must be distinguished from seborrheic dermatitis, body louse infestation from scabies and bedbug bites, and pubic louse infestation from anogenital pruritus and eczema.

▶ Treatment

Body lice are treated by disposing of the infested clothing and addressing the patient’s social situation. For pubic lice, permethrin rinse 1% for 10 minutes and permethrin cream 5% applied for 8 hours are effective. Sexual contacts should be treated. Clothes and bedclothes should be washed and dried at high temperature if possible.

Permethrin 1% cream rinse (Nix) is a topical over-the-counter pediculicide and ovicide and is the treatment of choice for head lice. It is applied to the scalp and hair and left on for 8 hours before being rinsed off. Permethrin resistance of head lice is common. Malathion lotion 1% (Ovide) is very effective, but it is highly volatile and flammable, so application must be done in a well-ventilated room or out of doors. For involvement of eyelashes, petrolatum is applied thickly twice daily for 8 days, and remaining nits are then plucked off.

Scott GR et al; IUSTI/WHO. European guideline for the management of pediculosis pubis, 2010. *Int J STD AIDS.* 2011 Jun;22(6):304–5. [PMID: 21680662]

SKIN LESIONS DUE TO OTHER ARTHROPODS

ESSENTIALS OF DIAGNOSIS

- ▶ Localized rash with pruritus.
- ▶ Furuncle-like lesions containing live arthropods.
- ▶ Tender erythematous patches that migrate (“larva migrans”).
- ▶ Generalized urticaria or erythema multiforme in some patients.

▶ General Considerations

Some arthropods (eg, mosquitoes and biting flies) are readily detected as they bite. Many others are not because they are too small, because there is no immediate reaction, or because they bite during sleep. Reactions are allergic and may be delayed for hours to days. Patients are most apt to consult a clinician when the lesions are multiple and pruritus is intense.

Many persons will react severely only to their earliest contacts with an arthropod, thus presenting pruritic

lesions when traveling, moving into new quarters, etc. Body lice, fleas, bedbugs, and mosquitoes should be considered. Bedbug exposure typically occurs in hotels and in housing with inadequate hygiene but also may occur in stable domiciles. Spiders are often incorrectly believed to be the source of bites; they rarely attack humans, though the brown spider (*Loxosceles laeta*, *L. reclusa*) may cause severe necrotic reactions and death due to intravascular hemolysis, and the black widow spider (*Latrodectus mactans*) may cause severe systemic symptoms and death. (See also Chapter 38.) The majority of patient-diagnosed, physician-diagnosed, and even published cases of brown recluse spider bites (or loxoscelism) are incorrect, especially if made in areas where these spiders are not endemic. Many of these lesions are actually due to CA-MRSA.

In addition to arthropod bites, the most common lesions are venomous stings (wasps, hornets, bees, ants, scorpions) or bites (centipedes), furuncle-like lesions due to fly maggots or sand fleas in the skin, and a linear creeping eruption due to a migrating larva.

► Clinical Findings

The diagnosis may be difficult when the patient has not noticed the initial attack but suffers a delayed reaction. Individual bites are often in clusters and tend to occur either on exposed parts (eg, midges and gnats) or under clothing, especially around the waist or at flexures (eg, small mites or insects in bedding or clothing). The reaction is often delayed for 1–24 hours or more. Pruritus is almost always present and may be all but intolerable once the patient starts to scratch. Secondary infection may follow scratching. Urticarial wheals are common. Papules may become vesicular. The diagnosis is aided by searching for exposure to arthropods and by considering the patient's occupation and recent activities.

The principal arthropods are as follows:

- Fleas:** Fleas are bloodsucking ectoparasites that feed on dogs, cats, humans, and other species. Flea saliva produces papular urticaria in sensitized individuals. To break the life cycle of the flea, one must treat the home and pets, using quick-kill insecticides, residual insecticides, and a growth regulator.
- Bedbugs:** In crevices of beds or furniture; bites tend to occur in lines or clusters. Papular urticaria is a characteristic lesion of bedbug (*Cimex lectularius*) bites. Bedbugs are not restricted to any socioeconomic group and are a major health problem in some major metropolitan areas, especially in commercial and residential hotels.
- Ticks:** Usually picked up by brushing against low vegetation.
- Chiggers or red bugs:** These are larvae of trombiculid mites. A few species confined to particular regions and locally recognized habitats (eg, berry patches, woodland edges, lawns, brush turkey mounds in Australia, poultry farms) attack humans, often around the waist, on the ankles, or in flexures, raising intensely itching erythematous papules after a delay of many hours. The red chiggers may sometimes be seen in the center of papules that have not yet been scratched.
- Bird and rodent mites:** Larger than chiggers, bird mites infest birds and their nests. Bites are multiple anywhere on the body. Room air conditioning units may suck in bird mites and infest the inhabitants of the room. Rodent mites from mice or rats may cause similar effects. If the domicile has evidence of rodent activity, then rodent mite dermatitis should be suspected, as the mites are rarely found. Pet rodents or birds may be infested with mites, maintaining the infestation.
- Mites in stored products:** These are white and almost invisible and infest products such as copra, vanilla pods, sugar, straw, cottonseeds, and cereals. Persons who handle these products may be attacked, especially on the hands and forearms and sometimes on the feet.
- Caterpillars of moths with urticating hairs:** The hairs are blown from cocoons or carried by emergent moths, causing severe and often seasonally recurrent outbreaks after mass emergence. The gypsy moth is a cause in the eastern United States.
- Tungiasis:** Tungiasis is due to the burrowing flea known as *Tunga penetrans* and is found in Africa, the West Indies, and South and Central America. The female burrows under the skin, sucks blood, swells to 0.5 cm, and then ejects her eggs onto the ground. Ulceration, lymphangitis, gangrene, and septicemia may result, in some cases with lethal effect. Simple surgical removal is usually performed.

► Differential Diagnosis

Arthropods should be considered in the differential diagnosis of skin lesions showing any of the above symptoms.

► Prevention

Arthropod infestations are best prevented by avoidance of contaminated areas, personal cleanliness, and disinfection of clothing, bedclothes, and furniture as indicated. Chiggers and mites can be repelled by permethrin applied to the head and clothing. (It is not necessary to remove clothing.) Bedbugs are no longer repelled by permethrin. Aggressive cleaning, usually requiring removal of the affected occupant from the domicile, may be necessary to eradicate bedbug infestation in a residence.

► Treatment

Living arthropods should be removed carefully with tweezers after application of alcohol and preserved in alcohol for identification. In endemic Rocky Mountain spotted fever areas, ticks should not be removed with the bare fingers.

Corticosteroid lotions or creams are helpful. Topical antibiotics may be applied if secondary infection is suspected. Localized persistent lesions may be treated with intralesional corticosteroids.

Stings produced by many arthropods may be alleviated by applying papain powder (Adolph's Meat Tenderizer) mixed with water, or aluminum chloride hexahydrate (Xerac AC).

Extracts from venom sacs of bees, wasps, yellow jackets, and hornets are available for immunotherapy of patients at risk for anaphylaxis.

INFLAMMATORY NODULES

ERYTHEMA NODOSUM

ESSENTIALS OF DIAGNOSIS

- ▶ Painful red nodules without ulceration on anterior aspects of legs.
- ▶ Slow regression over several weeks to resemble contusions.
- ▶ Women are predominantly affected by a ratio of 10:1 over men.
- ▶ Some cases associated with infection, inflammatory bowel disease, or drug exposure.

▶ General Considerations

Erythema nodosum is a symptom complex characterized by tender, erythematous nodules that appear most commonly on the extensor surfaces of the lower legs. It usually lasts about 6 weeks and may recur. The disease may be associated with various infections—streptococcosis, primary coccidioidomycosis, other deep fungal infections, tuberculosis, *Yersinia pseudotuberculosis* and *Y enterocolitica* infection, diverticulitis, or syphilis. It may accompany sarcoidosis, Behçet disease, and inflammatory bowel disease. Erythema nodosum may be associated with pregnancy or with use of oral contraceptives.

▶ Clinical Findings

A. Symptoms and Signs

The subcutaneous swellings are exquisitely tender and may be preceded by fever, malaise, and arthralgia. They are most often located on the anterior surfaces of the legs below the knees but may occur on the arms, trunk, and face. The lesions, 1–10 cm in diameter, are at first pink to red; with regression, all the various hues seen in a contusion can be observed (Figure 6–38).

B. Laboratory Findings

Evaluation of patients presenting with acute erythema nodosum should include a careful history (including drug exposures) and physical examination for prior upper respiratory infection or diarrheal illness, symptoms of any deep fungal infection endemic to the area, a chest radiograph, a PPD, and two consecutive ASO/DNAse B titers at 2- to 4-week intervals. If no underlying cause is found, only a small percentage of patients will go on to develop a significant underlying illness (usually sarcoidosis) over the next year.

▲ **Figure 6–38.** Erythema nodosum. (Used, with permission, from Berger TG, Dept Dermatology, UCSF.)

▶ Differential Diagnosis

Erythema induratum from tuberculosis is seen on the posterior surfaces of the legs and may ulcerate. Lupus panniculitis presents as tender nodules on the buttocks and posterior arms that heal with depressed scars. In polyarteritis nodosa, the subcutaneous nodules are often associated with a fixed livedo. In the late stages, erythema nodosum must be distinguished from simple bruises and contusions.

▶ Treatment

First, the underlying cause should be identified and treated. Primary therapy is with NSAIDs in usual doses. Saturated solution of potassium iodide, 5–15 drops three times daily, results in prompt involution in many cases. Complete bed rest may be advisable if the lesions are painful. Systemic therapy directed against the lesions themselves may include corticosteroid therapy (see Chapter 26) unless contraindicated by associated infection.

► Prognosis

The lesions usually disappear after about 6 weeks, but they may recur.

Larsen S et al. Extraintestinal manifestations of inflammatory bowel disease: epidemiology, diagnosis, and management. *Ann Med.* 2010 Mar;42(2):97–114. [PMID: 20166813]

FURUNCULOSIS (Boils) & CARBUNCLES

ESSENTIALS OF DIAGNOSIS

- Extremely painful inflammatory swelling based on a hair follicle that forms an abscess.
- Predisposing condition (diabetes mellitus, HIV disease, injection drug use) sometimes present.
- Coagulase-positive *S aureus* is the causative organism.

► General Considerations

A furuncle (boil) is a deep-seated infection (abscess) caused by *S aureus* and involving the entire hair follicle and adjacent subcutaneous tissue. The most common sites of occurrence are the hairy parts exposed to irritation and friction, pressure, or moisture. Because the lesions are autoinoculable, they are often multiple. Diabetes mellitus (especially if using insulin injections), injection drug use, allergy injections, and HIV disease all increase the risk of staphylococcal infections by increasing the rate of carriage. Certain other exposures including hospitalization, athletic teams, prisons, military service, and homelessness may also increase the risk of infection.

A carbuncle consists of several furuncles developing in adjoining hair follicles and coalescing to form a conglomerate, deeply situated mass with multiple drainage points.

► Clinical Findings

A. Symptoms and Signs

Pain and tenderness may be prominent. The abscess is either rounded or conical. It gradually enlarges, becomes fluctuant, and then softens and opens spontaneously after a few days to 1–2 weeks to discharge a core of necrotic tissue and pus. The inflammation occasionally subsides before necrosis occurs. Infection of the soft tissue around the nails (paronychia) may be due to staphylococci when it is acute or *Candida* when chronic.

B. Laboratory Findings

There may be slight leukocytosis, but a white blood cell count is rarely required. Pus should be cultured to rule out MRSA or other bacteria. Culture of the anterior nares may

identify chronic staphylococcal carriage in cases of recurrent cutaneous infection.

► Differential Diagnosis

The most common entity in the differential is an inflamed epidermal inclusion cyst that suddenly becomes red, tender, and expands greatly in size over one to a few days. The history of a prior cyst in the same location, the presence of a clearly visible cyst orifice, and the extrusion of malodorous cheesy rather than purulent material helps in the diagnosis. Tinea profunda (deep dermatophyte infection of the hair follicle) may simulate recurrent furunculosis. Furuncle is also to be distinguished from deep mycotic infections, such as sporotrichosis; from other bacterial infections, such as anthrax and tularemia (rare); from atypical mycobacterial infections; and from acne cysts. Hidradenitis suppurativa (acne inversa) presents with recurrent tender sterile abscesses in the axillae and groin, on the buttocks, or below the breasts. The presence of old scars or sinus tracts plus negative cultures suggests this diagnosis.

► Complications

Serious and sometimes fatal complications of staphylococcal infection such as septicemia can occur.

► Prevention

Identifying and eliminating the source of infection is critical to prevent recurrences after treatment. The source individual may have chronic dermatitis or be an asymptomatic carrier. Local measures such as meticulous hand-washing; no sharing of towels and clothing; aggressive scrubbing of showers, bathrooms and surfaces with bleach; bleach baths ($1/2$ to 1 cup per 20 liters of bathwater for 15 minutes 3–5 times weekly) and isolation of infected patients who reside in institutions to prevent spread are all effective measures.

► Treatment

A. Specific Measures

Incision and drainage is recommended for all loculated suppurations and is the mainstay of therapy. Systemic antibiotics are usually given, although they offer little beyond adequate incision and drainage. Sodium dicloxacillin or cephalexin, 1 g daily in divided doses by mouth for 10 days, is usually effective. Doxycycline 100 mg twice daily, trimethoprim-sulfamethoxazole DS one tablet twice daily, and clindamycin 150–300 mg twice daily are effective in treating MRSA. Recurrent furunculosis may be effectively treated with a combination of cephalexin, 250–500 mg four times daily for 2–4 weeks, and rifampin, 300 mg twice daily for 5 days during this period. Chronic clindamycin, 150–300 mg daily for 1–2 months, may also cure recurrent furunculosis. Family members and intimate contacts may need evaluation for staphylococcal carrier state and perhaps concomitant treatment. Applications of topical 2% mupirocin to the nares, axillae, and anogenital areas twice daily for 5 days may eliminate the staphylococcal carrier state, although resistance is increasing.

B. Local Measures

Immobilize the part and avoid overmanipulation of inflamed areas. Use moist heat to help larger lesions “localize.” Use surgical incision and drainage *after* the lesions are “mature.” To incise and drain an acute staphylococcal paronychia, insert a flat metal spatula or sharpened hardwood stick into the nail fold where it adjoins the nail. This will release pus from a mature lesion.

► Prognosis

Recurrent crops may harass the patient for months or years.

Hansra NK et al. Cutaneous community-acquired and hospital-acquired methicillin-resistant *Staphylococcus aureus*. *Dermatol Ther*. 2011 Mar–Apr;24(2):263–72. [PMID: 21410616]

EPIDERMAL INCLUSION CYST

ESSENTIALS OF DIAGNOSIS

- ▶ Firm dermal papule or nodule.
- ▶ Overlying black comedone or “punctum.”
- ▶ Expressible foul-smelling cheesy material.
- ▶ May become red and drain, mimicking an abscess.

► General Considerations

Epidermal inclusion cysts (EICs) are common, benign growths of the upper portion of the hair follicle. They are common in Gardner syndrome and may be the first stigmata of the condition.

Epidermal inclusion cysts favor the face and trunk and may complicate nodulocystic acne vulgaris. Individual lesions range in size from 0.3 cm to several centimeters. An overlying pore or punctum is characteristic. Lateral pressure may lead to extrusion of a foul-smelling, cheesy material.

► Differential Diagnosis

EICs are distinguished from lipomas by being more superficial (in the dermis not the subcutaneous fat) and by their overlying punctum. Many other benign and malignant tumors may superficially resemble EICs, but all lack the punctum.

► Complications

EICs may rupture, creating an acute inflammatory nodule very similar to an abscess. Cultures of the expressed material will be sterile.

► Treatment

Treatment is not required if asymptomatic. Inflamed lesions may be treated with incision and drainage or intralesional

triamcinolone acetamide 5–10 mg/mL. For large or symptomatic cysts, surgical excision is curative.

Lin SH et al. Facial epidermal inclusion cysts are associated with smoking in men: a hospital-based case-control study. *Dermatol Surg*. 2010 Jun;36(6):894–8. [PMID: 20482735]

PHOTODERMATITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Painful or pruritic erythema, edema, or vesiculation on sun-exposed surfaces: the face, neck, hands, and “V” of the chest.
- ▶ Inner upper eyelids spared, as is the area under the chin.

► General Considerations

In most cases, photosensitivity is an acute or chronic skin reaction due to hypersensitivity to ultraviolet radiation. It is caused by certain drugs, by lupus erythematosus, and some inherited disorders including the porphyrias. Contact photosensitivity may occur with plants, perfumes, and sunscreens. Three percent of persons with atopic dermatitis, especially middle-aged women, are photosensitive.

Photodermatitis is manifested as phototoxicity—a tendency for the individual to sunburn more easily than expected—or, as photoallergy, a true immunologic reaction that often presents with dermatitis.

► Clinical Findings

A. Symptoms and Signs

The acute inflammatory skin reaction, if severe enough, is accompanied by pain, fever, gastrointestinal symptoms, malaise, and even prostration, but this is very rare. Signs include erythema, edema, and possibly vesiculation and oozing on exposed surfaces. Peeling of the epidermis and pigmentary changes often result. The key to diagnosis is localization of the rash to photoexposed areas, though these eruptions may become generalized with time to involve even photoprotected areas. The lower lip may be affected.

B. Laboratory Findings

Blood and urine tests are generally not helpful unless porphyria cutanea tarda is suggested by the presence of blistering, scarring, milia (white cysts 1–2 mm in diameter) and skin fragility of the dorsal hands, and facial hypertrichosis. Eosinophilia may be present in chronic photoallergic responses.

► Differential Diagnosis

The differential diagnosis is long. If a clear history of the use of a topical or systemic photosensitizer is not available and if the eruption is persistent, then a workup including biopsy

and light testing may be required. Photodermatitis must be differentiated from contact dermatitis that may develop from one of the many substances in suntan lotions and oils, as these may often have a similar distribution. Sensitivity to actinic rays may also be part of a more serious condition such as porphyria cutanea tarda or lupus erythematosus. These disorders are diagnosed by appropriate blood or urine tests. Phenothiazines, quinine or quinidine, griseofulvin, sulfonyleureas (especially hydrochlorothiazide), NSAIDs, and antibiotics (eg, some tetracyclines, quinolone, TMP-SMZ) may photosensitize the skin. Polymorphous light eruption (PMLE) is a very common idiopathic photodermatitis and often has its onset in the third to fourth decades except in Native Americans and Latinos, in whom it may present in childhood. PMLE is chronic in nature. Transitory periods of spontaneous remission do occur. The action spectrum of PMLE may also extend into the long ultraviolet wavelengths (UVA; 320–400 nm). Drug-induced photosensitivity is triggered by UVA.

► Complications

Some individuals continue to be chronic light reactors even when they apparently are no longer exposed to photosensitizing drugs.

► Prevention

While sunscreens are useful agents in general and should be used by persons with photosensitivity, patients may react to such low amounts of energy that sunscreens alone may not be sufficient. Sunscreens with an SPF of 30–60 and broad UVA coverage, containing dicamphor sulfonic acid (Mexoryl SX), avobenzone (Parasol 1789), titanium dioxide, and micronized zinc oxide, are especially useful in patients with photoallergic dermatitis. Photosensitivity due to porphyria is not prevented by sunscreens and requires barrier protection (clothing) to prevent outbreaks.

► Treatment

A. Specific Measures

Drugs should be suspected in cases of photosensitivity even if the particular medication (such as hydrochlorothiazide) has been used for months.

B. Local Measures

When the eruption is vesicular or weepy, treatment is similar to that of any acute dermatitis, using cooling and soothing wet dressing.

Sunscreens should be used as described above. Mid-potency to high-potency topical corticosteroids are of limited benefit in sunburn reactions but may help in PMLE and photoallergic reactions. Since the face is often involved, close monitoring for corticosteroid side effects is recommended.

C. Systemic Measures

Aspirin may have some value for fever and pain of acute sunburn. Systemic corticosteroids in doses as described for acute contact dermatitis may be required for severe

photosensitivity reactions. Otherwise, different photodermatoses are treated in specific ways.

Patients with severe photoallergy may require immunosuppressives, such as azathioprine, in the range of 50–300 mg/d, or cyclosporine, 3–5 mg/kg/d.

► Prognosis

The most common phototoxic sunburn reactions are usually benign and self-limited. PMLE and some cases of photoallergy can persist for years.

ULCERS

LEG ULCERS SECONDARY TO VENOUS INSUFFICIENCY

ESSENTIALS OF DIAGNOSIS

- Past history of varicosities, thrombophlebitis, or postphlebotic syndrome.
- Irregular ulceration, often on the medial aspect of the lower legs above the malleolus.
- Edema of the legs, varicosities, hyperpigmentation, and red and scaly areas (stasis dermatitis) and scars from old ulcers support the diagnosis.

► General Considerations

Patients at risk may have a history of venous insufficiency, either with obvious varicosities or with a past history of thrombophlebitis, or with immobility of the calf muscle group (paraplegics, etc). Red, pruritic patches of stasis dermatitis often precede ulceration. Because venous insufficiency plays a role in between 75% and 90% of lower leg ulcerations, testing of venous competence is a required part of a leg ulcer evaluation even when no changes of venous insufficiency are present.

► Clinical Findings

A. Symptoms and Signs

Classically, chronic edema is followed by a dermatitis, which is often pruritic. These changes are followed by hyperpigmentation, skin breakdown, and eventually sclerosis of the skin of the lower leg (Figure 6–39). The ulcer base may be clean, but it often has a yellow fibrin eschar that may require surgical removal. Ulcers that appear on the feet, toes, or above the knees should be approached with other diagnoses in mind.

▲ **Figure 6–39.** Venous stasis ulcer near the medial malleolus. (Courtesy of Maureen Sheehan, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

B. Laboratory Findings

Thorough evaluation of the patient's vascular system (including measurement of the ankle/brachial index [ABI]) is essential. If the ABI is < 0.7 , the patient should be referred to a vascular surgeon for surgical evaluation. Doppler and light rheography examinations as office procedures are usually sufficient (except in the diabetic) to elucidate the cause of most vascular cases of lower leg ulceration.

► Differential Diagnosis

The differential includes vasculitis, pyoderma gangrenosum, arterial ulcerations, infection, trauma, skin cancer, arachnid bites, and sickle cell anemia. When the diagnosis is in doubt, a punch biopsy from the border (not base) of the lesion may be helpful.

► Prevention

Compression stockings to reduce edema are the most important means of prevention. Compression should achieve a pressure of 30 mm Hg below the knee and 40 mm Hg at the ankle. The stockings should not be used in patients with arterial insufficiency with an ABI < 0.7 . Pneumatic sequential compression devices may be of great benefit when edema is refractory to standard compression dressings.

► Treatment

A. Local Measures

Clean the base of the ulcer with saline or cleansers such as Saf-Cleans. A curette or small scissors can be used to remove the yellow fibrin eschar; local anesthesia may be used if the areas are very tender.

The ulcer is treated with metronidazole gel to reduce bacterial growth and odor. Any red dermatitic skin is

treated with a medium- to high-potency corticosteroid ointment. The ulcer is then covered with an occlusive hydroactive dressing (DuoDerm, Hydrasorb or Cutinova) or a polyurethane foam (Allevyn) followed by an Unna zinc paste boot. This is changed weekly. The ulcer should begin to heal within weeks, and healing should be complete within 4–6 months. If the patient is diabetic, becaplermin (Regranex) may be applied to those ulcers that are not becoming smaller or developing a granulating base. Some ulcerations require grafting. Full- or split-thickness grafts often do not take, and pinch grafts (small shaves of skin laid onto the bed) may be effective. Cultured epidermal cell grafts may accelerate wound healing, but they are very expensive. They should be considered in refractory ulcers, especially those that have not healed after a year or more of conservative therapy. Manuka honey has been purported to accelerate wound healing, but comparative controlled trials of efficacy are lacking.

No topical intervention has evidence to suggest that it will improve healing of arterial leg ulcers.

B. Systemic Therapy

Pentoxifylline, 400 mg three times daily administered with compression dressings, is beneficial in accelerating healing of venous insufficiency leg ulcers. Zinc supplementation is occasionally beneficial in patients with low serum zinc levels. The diagnosis of cellulitis in the setting of a venous insufficiency ulcer can be very difficult. Surface cultures are of limited value. The diagnosis of cellulitis should be considered in the following settings: 1) expanding warmth and erythema surrounding the ulceration with or without 2) increasing pain of the ulceration. The patient may also report increased exudate from the ulceration, but this without the other cardinal findings of cellulitis does not confirm the diagnosis of cellulitis. If cellulitis accompanies the ulcer, systemic antibiotics are recommended: dicloxacillin, 250 mg orally four times a day, or levofloxacin, 500 mg once daily for 1–2 weeks is usually adequate. Routine use of antibiotics and treating bacteria isolated from a chronic ulcer without clinical evidence of infection is discouraged. If the ulcer fails to heal or there is a persistent draining tract in the ulcer, an underlying osteomyelitis should be sought.

► Prognosis

The combination of limited debridement, compression dressings or stockings, and newer moist dressings will heal the majority of venous stasis ulcers within months (average 18 months). These need to be applied at least 80% of the time to optimize ulcer healing. Topical growth factors, antibiotics, debriding agents, and xenografts and autografts can be considered in recalcitrant cases, but they are usually not required in most patients. The failure of venous insufficiency ulcerations to heal is most often related to not using the basic treatment methods consistently, rather than failure to use these specific modalities. Ongoing control of edema is essential to prevent recurrent ulceration. The use of compression stockings following ulcer healing is critical to prevent recurrence, with recurrence rates 2–20 times

higher if patients do not comply with compression stocking use. If the ABI is < 0.5 , the prognosis for healing is poor.

MISCELLANEOUS DERMATOLOGIC DISORDERS¹

PIGMENTARY DISORDERS

Although the color of skin may be altered by many diseases and agents, the vast majority of patients have either an increase or decrease in pigment secondary to some inflammatory disease such as acne or atopic dermatitis.

Other pigmentary disorders include those resulting from exposure to exogenous pigments such as carotenemia, argyria, and tattooing. Other endogenous pigmentary disorders are attributable to metabolic substances—including hemosiderin (iron)—in purpuric processes; or to homogentisic acid in ochronosis; and bile pigments.

► Classification

First, determine whether the disorder is hyperpigmentation or hypopigmentation, ie, an increase or decrease in normal skin colors. Each may be considered to be primary or to be secondary to other disorders.

A. Primary Pigmentary Disorders

1. Hyperpigmentation—The disorders in this category are nevoid, congenital or acquired, and include pigmented nevi, ephelides (juvenile freckles), and lentigines (senile freckles). Hyperpigmentation occurs also in arsenical melanosis or in association with Addison disease. **Melasma (chloasma)** occurs as patterned hyperpigmentation of the

▲ **Figure 6-40.** Vitiligo of the hands. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine.* McGraw-Hill, 2009.)

face, usually as a direct effect of estrogens. It occurs not only during pregnancy but also in 30–50% of women taking oral contraceptives, and rarely in men. One report suggests that such men have low testosterone and elevated luteinizing hormone levels.

2. Hypopigmentation and depigmentation—The disorders in this category are vitiligo, albinism, and piebaldism. In vitiligo, pigment cells (melanocytes) are destroyed (Figure 6-40). Vitiligo, present in approximately 1% of the population, may be associated with other autoimmune disorders such as autoimmune thyroid disease, pernicious anemia, diabetes mellitus, and Addison disease.

B. Secondary Pigmentary Disorders

Any damage to the skin (irritation, allergy, infection, excoriation, burns, or dermatologic therapy such as chemical peels and freezing with liquid nitrogen) may result in hyperpigmentation or hypopigmentation. Several disorders of clinical importance are described below.

1. Hyperpigmentation—The most common type of secondary hyperpigmentation occurs after another dermatologic condition, such as acne, and is most commonly seen in moderately complexioned persons (Asians, Hispanics, and light-skinned African Americans). It is called post-inflammatory hyperpigmentation.

Pigmentation may be produced by certain drugs, eg, chloroquine, chlorpromazine, minocycline, and amiodarone. Fixed drug eruptions to phenolphthalein in laxatives, to TMP-SMZ, to NSAIDs, and to tetracyclines, for example, are further causes.

2. Hypopigmentation—Leukoderma may complicate atopic dermatitis, lichen planus, psoriasis, DLE, and lichen simplex chronicus. Practitioners must exercise special care in using liquid nitrogen on any patient with olive or darker complexions, since doing so may result in

¹Hirsutism is discussed in Chapter 26.

hypopigmentation or depigmentation, at times permanent. Intralesional or intra-articular injections of high concentrations of corticosteroids may also cause localized temporary hypopigmentation.

► Differential Diagnosis

The evaluation of pigmentary disorders is helped by Wood's light, which accentuates epidermal pigmentation and highlights hypopigmentation. Depigmentation, as seen in vitiligo, enhances with Wood's light examination, whereas postinflammatory hypopigmentation does not.

► Complications

Actinic keratoses and skin cancers are more likely to develop in persons with vitiligo. Severe emotional trauma may occur in extensive vitiligo and other types of hypopigmentation and hyperpigmentation, particularly in naturally dark-skinned persons.

► Treatment & Prognosis

A. Hyperpigmentation

Therapeutic bleaching preparations generally contain hydroquinone. Hydroquinone has occasionally caused unexpected hypopigmentation, hyperpigmentation, or even secondary ochronosis and pigmented milia, particularly with prolonged use.

The role of exposure to ultraviolet light cannot be overstressed as a factor promoting or contributing to most disorders of hyperpigmentation, and such exposure should be minimized. Melasma, ephelides, and postinflammatory hyperpigmentation may be treated with varying success with 3–4% hydroquinone cream, gel, or solution and a sunscreen containing UVA photoprotectants (Avobenzone, Mexoryl, zinc oxide, titanium dioxide). Tretinoin cream, 0.025–0.05%, may be added. Superficial melasma responds well, but if there is predominantly dermal deposition of pigment (does *not* enhance with Wood's light), the prognosis is poor. Response to therapy may take months and requires avoidance of sunlight. Hyperpigmentation often recurs after treatment if the skin is exposed to ultraviolet light. Solar lentigines respond to liquid nitrogen application. Tretinoin, 0.1% cream and tazarotene 0.1% used over 10 months, will fade solar lentigines (liver spots), hyperpigmented facial macules in Asians, and postinflammatory hyperpigmentation in blacks. New laser systems for the removal of epidermal and dermal pigments are available, and referral should be considered for patients whose responses to medical treatment are inadequate.

B. Hypopigmentation

In secondary hypopigmentation, repigmentation may occur spontaneously. Cosmetics such as Covermark and Dermablend are highly effective for concealing disfiguring patches. Therapy of vitiligo is long and tedious, and the patient must be strongly motivated. If < 20% of the skin is involved (most cases), topical tacrolimus 0.1% twice daily is the first-line therapy. A superpotent corticosteroid may also be used, but local skin atrophy from prolonged use

may ensue. With 20–25% involvement, narrowband UVB or oral PUVA is best. Severe phototoxic response (sunburn) may occur with PUVA. The face and upper chest respond best, and the fingertips and the genital areas do not respond as well to treatment. Years of treatment may be required. Newer techniques of using epidermal autografts and cultured epidermis combined with PUVA therapy give hope for surgical correction of vitiligo.

Taïeb A et al. Clinical practice. Vitiligo. *N Engl J Med.* 2009 Jan 8;360(2):160–9. [PMID: 19129529]

BALDNESS (Alopecia)

► Baldness Due to Scarring (Cicatricial Alopecia)

Cicatricial baldness may occur following chemical or physical trauma, lichen planopilaris, bacterial or fungal infections, severe herpes zoster, chronic DLE, scleroderma, and excessive ionizing radiation. The specific cause is often suggested by the history, the distribution of hair loss, and the appearance of the skin, as in lupus erythematosus. Biopsy is useful in the diagnosis of scarring alopecia, but specimens must be taken from the active border and not from the scarred central zone.

Scarring alopecias are irreversible and permanent. It is important to diagnose and treat the scarring process as early in its course as possible.

► Baldness Not Associated with Scarring

Nonscarring alopecia may occur in association with various systemic diseases such as SLE, secondary syphilis, hyperthyroidism or hypothyroidism, iron deficiency anemia, and pituitary insufficiency. The only treatment necessary is prompt and adequate control of the underlying disorder and usually leads to regrowth of the hair.

Androgenetic (pattern) baldness, the most common form of alopecia, is of genetic predetermination. The earliest changes occur at the anterior portions of the calvarium on either side of the “widow's peak” and on the crown (vertex). The extent of hair loss is variable and unpredictable. Minoxidil 5% is available over the counter and can be specifically recommended for persons with recent onset (< 5 years) and smaller areas of alopecia. Approximately 40% of patients treated twice daily for a year will have moderate to dense growth. Finasteride (Propecia), 1 mg orally daily, has similar efficacy and may be additive to minoxidil. As opposed to minoxidil, finasteride is used only in males.

Hair loss or thinning of the hair in women results from the same cause as common baldness in men (androgenetic alopecia) and may be treated with topical minoxidil. A workup consisting of determination of serum testosterone, DHEAS, iron, total iron binding capacity, thyroid function tests, and a complete blood count will identify most other causes of hair thinning in premenopausal women. Women who complain of thin hair but show little evidence of alopecia need follow-up, because > 50% of the scalp hair can be lost before the clinician can perceive it.

Telogen effluvium is transitory increase in the number of hairs in the telogen (resting) phase of the hair growth cycle. This may occur spontaneously, may appear at the termination of pregnancy, may be precipitated by “crash dieting,” high fever, stress from surgery or shock, malnutrition, or may be provoked by hormonal contraceptives. Whatever the cause, telogen effluvium usually has a latent period of 2–4 months. The prognosis is generally good. The condition is diagnosed by the presence of large numbers of hairs with white bulbs coming out upon gentle tugging of the hair. Counts of hairs lost by the patient on combing or shampooing often exceed 150 per day, compared to an average of 70–100. In one study, a major cause of telogen effluvium was found to be iron deficiency, and the hair counts bore a clear relationship to serum iron levels. If iron deficiency is suspected, a serum ferritin should be obtained, and the value followed with supplementation.

Alopecia areata is of unknown cause but is believed to be an immunologic process. Typically, there are patches that are perfectly smooth and without scarring. Tiny hairs 2–3 mm in length, called “exclamation hairs,” may be seen. Telogen hairs are easily dislodged from the periphery of active lesions. The beard, brows, and lashes may be involved. Involvement may extend to all of the scalp hair (alopecia totalis) or to all scalp and body hair (alopecia universalis). Severe forms may be treated by systemic corticosteroid therapy, although recurrences follow discontinuation of therapy. Alopecia areata is occasionally associated with Hashimoto thyroiditis, pernicious anemia, Addison disease, and vitiligo.

Intralesional corticosteroids are frequently effective for alopecia areata. Triamcinolone acetonide in a concentration of 2.5–10 mg/mL is injected in aliquots of 0.1 mL at approximately 1- to 2-cm intervals, not exceeding a total dose of 30 mg per month for adults. Alternatively, anthralin 0.5% ointment, used daily, may help some patients. Alopecia areata is usually self-limiting, with complete regrowth of hair in 80% of patients with focal disease. Some mild cases are resistant to treatment, as are the extensive totalis and universalis types. Both topical diphencyprone and squaric acid dibutylester, have been used to treat persistent alopecia areata. The principle is to sensitize the skin, then intermittently apply weaker concentrations to produce and maintain a slight dermatitis. Hair regrowth in 3–6 months in some patients has been reported to be remarkable. Long-term safety and efficacy have not been established. Support groups for patients with extensive alopecia areata are very beneficial.

In **trichotillomania** (the pulling out of one’s own hair), the patches of hair loss are irregular and short growing hairs are always present, since they cannot be pulled out until they are long enough. The patches are often unilateral, occurring on the same side as the patient’s dominant hand. The patient may be unaware of the habit.

Alkhalifah A et al. Alopecia areata update: part II. Treatment. *J Am Acad Dermatol.* 2010 Feb;62(2):191–202. [PMID: 20115946]

NAIL DISORDERS

1. Morphologic Abnormalities of the Nails

► Classification

Acquired nail disorders may be classified as local or those associated with systemic or generalized skin diseases.

A. Local Nail Disorders

Onycholysis (distal separation of the nail plate from the nail bed, usually of the fingers) is caused by excessive exposure to water, soaps, detergents, alkalies, and industrial cleaning agents. Candidal infection of the nail folds and subungual area, nail hardeners, and drug-induced photosensitivity may cause onycholysis, as may hyperthyroidism, hypothyroidism, and psoriasis.

1. Distortion of the nail occurs as a result of chronic inflammation of the nail matrix underlying the eponychial fold. Such changes may also be caused by warts, tumors, or cysts, impinging on the nail matrix.
2. Discoloration and crumbly thickened nails are noted in dermatophyte infection and psoriasis.
3. Allergic reactions (to resins in undercoats and polishes or to nail glues) are characterized by onycholysis or by grossly distorted, hypertrophic, and misshapen nails.

B. Nail Changes Associated with Systemic or Generalized Skin Diseases

Beau lines (transverse furrows) may follow any serious systemic illness.

1. Atrophy of the nails may be related to trauma or to vascular or neurologic disease.
2. Clubbed fingers may be due to the prolonged hypoxemia associated with cardiopulmonary disorders (Figure 6–41). (See Chapter 9.)
3. Spoon nails may be seen in anemic patients.
4. Stippling or pitting of the nails is seen in psoriasis, alopecia areata, and hand eczema.
5. Nail hyperpigmentation may be caused by many chemotherapeutic agents, but especially the taxanes.

► Differential Diagnosis

Onychomycosis may cause nail changes identical to those seen in psoriasis. Careful examination for more characteristic lesions elsewhere on the body is essential to the diagnosis of the nail disorders. Cancer should be suspected (eg, Bowen disease or squamous cell carcinoma) as the cause of any persistent solitary subungual or periungual lesion.

► Complications

Toenail changes may lead to an ingrown nail—in turn often complicated by bacterial infection and occasionally by exuberant granulation tissue. Poor manicuring and

▲ **Figure 6-41.** Clubbing of the fingers in congenital heart disease. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

poorly fitting shoes may contribute to this complication. Cellulitis may result.

► Treatment & Prognosis

Treatment consists usually of careful debridement and manicuring and, above all, reduction of exposure to irritants (soaps, detergents, alkali, bleaches, solvents, etc). Longitudinal grooving due to temporary lesions of the matrix, such as warts, synovial cysts, and other impingements, may be cured by removal of the offending lesion.

2. Tinea Unguium (Onychomycosis)

Tinea unguium is a trichophyton infection of one or more (but rarely all) fingernails or toenails. The species most commonly found is *T rubrum*. “Saprophytic” fungi may rarely (< 5%) cause onychomycosis.

The nails are lusterless, brittle, and hypertrophic, and the substance of the nail is friable. Laboratory diagnosis is mandatory since only 50% of dystrophic nails are due to dermatophytosis. Portions of the nail should be cleared with 10% KOH and examined under the microscope for hyphae. Fungi may also be cultured. Periodic acid-Schiff stain of a histologic section of the nail plate will also demonstrate the fungus readily. Each technique is positive in only 50% of cases so several different tests may need to be performed.

Onychomycosis is difficult to treat because of the long duration of therapy required and the frequency of recurrences. Fingernails respond more readily than toenails. For toenails, treatment is limited to patients with discomfort, inability to exercise, and immune compromise.

In general, systemic therapy is required to effectively treat nail onychomycosis. Topical therapy has limited value

and the adjunctive value of surgical procedures is unproven. Efficacy of laser treatments is lacking, especially with regard to long-term cures. Fingernails can virtually always be cured and toenails are cured 35–50% of the time and are clinically improved about 75% of the time. In all cases, before treatment, the diagnosis should be confirmed. The costs of the various treatment options should be known and the most cost-effective treatment chosen. Drug interactions must be avoided. Ketoconazole, due to its higher risk for hepatotoxicity, is not recommended to treat any form of onychomycosis. For fingernails, ultramicrozoned griseofulvin 250 mg orally three times daily for 6 months can be effective. Alternative treatments are (in order of preference) oral terbinafine 250 mg daily for 6 weeks, oral itraconazole 400 mg daily for 7 days each month for 2 months, and oral itraconazole 200 mg daily for 2 months. Off-label use of fluconazole, 400 mg once weekly for 6 months, can also be effective, but there is limited evidence for this option. Once clear, fingernails usually remain free of disease for some years.

Onychomycosis of the toenails does not respond to griseofulvin therapy or topical treatments. The best treatment, which is also FDA approved, is oral terbinafine 250 mg daily for 12 weeks. Liver function tests and a complete blood count with platelets are performed monthly during treatment. Pulse oral itraconazole 200 mg twice daily for 1 week per month for 3 months is inferior to standard terbinafine treatments, but it is an acceptable alternative for those unable to take terbinafine. The courses of terbinafine or itraconazole may need to be repeated 6 months after the first treatment cycle if fungal cultures of the nail are still positive.

DERMATITIS MEDICAMENTOSA (Drug Eruption)

ESSENTIALS OF DIAGNOSIS

- ▶ Usually, abrupt onset of widespread, symmetric erythematous eruption.
- ▶ May mimic any inflammatory skin condition.
- ▶ Constitutional symptoms (malaise, arthralgia, headache, and fever) may be present.

► General Considerations

As is well recognized, only a minority of cutaneous drug reactions result from allergy. True allergic drug reactions

Table 6-3. Skin reactions due to systemic drugs.

Reaction	Appearance	Distribution and Comments	Common Offenders
Toxic erythema	Morbilloform, maculopapular, exanthematous reactions.	The most common skin reaction to drugs. Often more pronounced on the trunk than on the extremities. In previously exposed patients, the rash may start in 2-3 days. In the first course of treatment, the eruption often appears about the seventh to ninth days. Fever may be present.	Antibiotics (especially ampicillin and TMP-SMZ), sulfonamides and related compounds (including thiazide diuretics, furosemide, and sulfonyleurea hypoglycemic agents), and barbiturates.
SJS/TEN	Target-like lesions. Bullae may occur. Mucosal involvement.	Usually trunk and proximal extremities.	Sulfonamides, anticonvulsants, allopurinol and NSAIDs.
Erythema nodosum	Inflammatory cutaneous nodules.	Usually limited to the extensor aspects of the legs. May be accompanied by fever, arthralgias, and pain.	Oral contraceptives.
Allergic vasculitis	Inflammatory changes may present as urticaria that lasts over 24 hours, hemorrhagic papules ("palpable purpura"), vesicles, bullae, or necrotic ulcers.	Most severe on the legs.	Sulfonamides, phenytoin, propylthiouracil.
Exfoliative dermatitis and erythroderma	Red and scaly.	Entire skin surface.	Allopurinol, sulfonamides, isoniazid, anticonvulsants, or carbamazepine.
Photosensitivity: increased sensitivity to light, often of ultraviolet A wavelengths, but may be due to UVB or visible light as well	Sunburn, vesicles, papules in photodistributed pattern.	Exposed skin of the face, the neck, and the backs of the hands and, in women, the lower legs. Exaggerated response to ultraviolet light.	Sulfonamides and sulfonamide-related compounds (thiazide diuretics, furosemide, sulfonyleureas), tetracyclines, phenothiazines, sulindac, amiodarone, voriconazole, and NSAIDs.
Drug-related lupus erythematosus	May present with a photosensitive rash, annular lesions or psoriasis on upper trunk.	Less severe than systemic lupus erythematosus, sparing the kidneys and central nervous system. Recovery often follows drug withdrawal.	Diltiazem, etanercept, hydrochlorothiazide, infliximab, lisinopril, terbinafine.
Lichenoid and lichen planus-like eruptions	Pruritic, erythematous to violaceous polygonal papules that coalesce or expand to form plaques.	May be in photo- or nonphoto-distributed pattern.	Carbamazepine, furosemide, hydroxychloroquine, phenothiazines, β -blockers, quinidine, quinine, sulfonyleureas, tetracyclines, thiazides, and triprolidine.
Fixed drug eruptions	Single or multiple demarcated, round, erythematous plaques that often become hyperpigmented.	Recur at the same site when the drug is repeated. Hyperpigmentation, if present, remains after healing.	Numerous drugs, including antimicrobials, analgesics, barbiturates, cardiovascular drugs, heavy metals, antiparasitic agents, antihistamines, phenolphthalein, ibuprofen, and naproxen.
Urticaria	Red, itchy wheals that vary in size from < 1 cm to many centimeters. May be accompanied by angioedema.	Chronic urticaria is rarely caused by drugs.	Acute urticaria: penicillins, NSAIDs, sulfonamides, opioids, and salicylates. Angioedema is common in patients receiving ACE inhibitors and angiotensin receptor blockers.

(continued)

Table 6-3. Skin reactions due to systemic drugs. (continued)

Reaction	Appearance	Distribution and Comments	Common Offenders
Pigmentary changes	Flat hyperpigmented areas.	Forehead and cheeks (chloasma, melasma). The most common pigmentary disorder associated with drug ingestion. Improvement is slow despite stopping the drug.	Oral contraceptives are the usual cause.
	Blue-gray discoloration.	Light-exposed areas.	Chlorpromazine and related phenothiazines.
	Brown or blue-gray pigmentation.	Generalized.	Heavy metals (silver, gold, bismuth, and arsenic).
	Yellow color.	Generalized.	Quinacrine.
	Blue-black patches on the shins.		Minocycline, chloroquine.
	Blue-black pigmentation of the nails and palate and depigmentation of the hair.		Chloroquine.
	Slate-gray color.	Primarily in photoexposed areas.	Amiodarone.
	Brown discoloration of the nails.	Especially in more darkly pigmented patients.	Hydroxyurea.
Psoriasiform eruptions	Scaly red plaques.	May be located on trunk and extremities. Palms and soles may be hyperkeratotic. May cause psoriasiform eruption or worsen psoriasis.	Antimalarials, lithium, β -blockers, and tumor necrosis factor (TNF)-inhibitors.
Pityriasis rosea-like eruptions	Oval, red, slightly raised patches with central scale.	Mainly on the trunk.	Barbiturates, bismuth, captopril, clonidine, methopromazine, metoprolol, metronidazole, and tripeleminamine.

ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs; SJS/TEN, Stevens-Johnson syndrome/toxic epidermal necrolysis.

involve prior exposure, an “incubation” period, reactions to doses far below the therapeutic range, manifestations different from the usual pharmacologic effects of the drug, involvement of only a small portion of the population at risk, restriction to a limited number of syndromes (anaphylactic and anaphylactoid, urticarial, vasculitic, etc), and reproducibility.

Rashes are among the most common adverse reactions to drugs and occur in 2–3% of hospitalized patients. Amoxicillin, TMP-SMZ, and ampicillin or penicillin are the most common causes of urticarial and maculopapular reactions. Toxic epidermal necrolysis and Stevens-Johnson syndrome are most commonly produced by sulfonamides and anticonvulsants. Phenolphthalein, pyrazolone derivatives, tetracyclines, NSAIDs, TMP-SMZ, and barbiturates are the major causes of fixed drug eruptions.

► Clinical Findings

A. Symptoms and Signs

Drug eruptions are generally classified as “simple” or “complex.” Simple drug eruptions involve an exanthem, usually appear in the second week of drug therapy, and have no associated constitutional or laboratory findings. Antibiotics, including the penicillins and quinolones are the most common causes. Complex drug eruptions (also called drug-induced hypersensitivity syndromes) occur during the third week of treatment on average and have constitutional and laboratory findings. These may include fevers, chills, hematologic abnormalities (especially eosinophilia), and abnormal liver or kidney function. A mnemonic for complex eruptions is “DRESS” (DRUG Eruption with Eosinophilia and Systemic Symptoms). The most common

causes are the long-acting sulfonamides, allopurinol, and anticonvulsants. The use of anticonvulsants to treat bipolar disorder and chronic pain has led to an apparent increase in these reactions. In patients of certain races, polymorphisms of antigen presenting major histocompatibility (MHC) loci increases risk for the development of severe drug eruptions. Coexistent reactivation of Epstein-Barr virus, HHV-6, or cytomegalovirus is often present and may be important in the pathogenesis of these complex drug eruptions. Table 6–3 summarizes the types of skin reactions, their appearance and distribution, and the common offenders in each case.

B. Laboratory Findings

Routinely ordered blood work is of no value in the diagnosis of simple drug eruptions. In complex drug eruptions, the CBC, liver biochemical tests, and renal function tests should be monitored. Skin biopsies may be helpful in making the diagnosis.

► Differential Diagnosis

Observation after discontinuation, which may be a slow process, helps establish the diagnosis. Rechallenge, though of theoretical value, may pose a danger to the patient and is best avoided.

► Complications

Some cutaneous drug reactions may be associated with visceral involvement. The organ systems involved depend on the individual medication or drug class. Most common is an infectious mononucleosis-like illness and hepatitis associated with administration of anticonvulsants. Myocarditis may be a serious complication of drug-induced hypersensitivity syndrome. Months after recovering from DRESS, patients may suffer hypothyroidism.

► Treatment

A. General Measures

Systemic manifestations are treated as they arise (eg, anemia, icterus, purpura). Antihistamines may be of value in urticarial and angioneurotic reactions. Epinephrine 1:1000, 0.5–1 mL intravenously or subcutaneously, should be used as an emergency measure. In drug-induced hypersensitivity syndromes (DRESS), systemic corticosteroids

may be required, starting at about 1 mg/kg/d and tapering very slowly.

B. Local Measures

SJS/TEN with extensive blistering eruptions resulting in erosions and superficial ulcerations, which demand hospitalization and nursing care as for burn patients, develops in some DRESS patients.

► Prognosis

Drug rash usually disappears upon withdrawal of the drug and proper treatment. DRESS may be associated with autoimmune phenomena, including abnormal thyroid function. This can occur months after the hypersensitivity syndrome has resolved.

Disorders of the Eyes & Lids

Paul Riordan-Eva, FRCOphth

REFRACTIVE ERRORS

Refractive errors are the most common cause of reduced clarity of vision (visual acuity) and may be a readily treatable component of poor vision in patients with other diagnoses. In the normal state (**emmetropia**), objects at infinity are seen clearly. Focusing on objects nearer than infinity requires an increase in the refractive power of the crystalline lens by the process of accommodation. In farsightedness (**hyperopia**), objects at infinity are not seen clearly unless accommodation is used, and near objects may not be seen because accommodative capacity is finite. Farsightedness is corrected with plus (convex) lenses. In nearsightedness (**myopia**), the unaccommodated eye focuses on objects closer than infinity. The markedly nearsighted eye is able to focus on very near objects without glasses. Objects beyond this distance cannot be seen without the aid of corrective (minus, concave) lenses. **Astigmatism**, in which the refractive errors in the horizontal and vertical axes differ, is corrected with cylindrical lenses. **Presbyopia** is the natural loss of accommodative capacity with age. Persons with emmetropia usually notice inability to focus on objects at a normal reading distance at about age 45. Farsighted individuals experience symptoms at an earlier age. Presbyopia is corrected with plus lenses for near work.

Use of a pinhole will overcome most refractive errors and thus allows their identification as a cause of reduced visual acuity.

1. Contact Lenses

Contact lenses are used mostly for correction of refractive errors, for which they provide better optical correction than glasses, as well as for management of diseases of the cornea, conjunctiva, or lids. The major types of lenses are rigid (gas-permeable) and soft. Rigid lenses, which need to be removed each day, are more durable and easier to care for than soft lenses but are more difficult to tolerate. Usually removed each day, soft lenses are available for extended wear. Disposable soft lenses to be renewed daily, or less frequently (up to monthly), are available.

Contact lens care includes cleaning and sterilization whenever the lenses are to be reused and removal of

protein deposits as required. Sterilization is usually by chemical methods. For individuals developing reactions to preservatives in contact lens solutions, preservative-free systems are available.

The major risk from contact lens wear is bacterial, amebic, or fungal corneal infection, potentially a blinding condition. Such infections occur more commonly with soft lenses, particularly extended wear, for which there is at least a fivefold increase in risk of corneal ulceration compared with daily wear, and with certain contact lens solutions. Contact lens wearers should be made aware of the risks they face and ways to minimize them, such as avoiding overnight wear and maintaining meticulous lens hygiene, including not using tap water or saliva for lens cleaning. Whenever there is ocular discomfort or redness, contact lenses should be removed. Ophthalmologic care should be sought if symptoms persist.

► When to Refer

Any contact lens wearer with an acute painful red eye must be referred emergently to an ophthalmologist.

Cavanagh HD et al. Castroviejo Lecture 2009: 40 years in search of the perfect contact lens. *Cornea*. 2010 Oct;29(10):1075–85. [PMID: 20622672]

Jeng BH et al. Epidemiology of ulcerative keratitis in Northern California. *Arch Ophthalmol*. 2010 Aug;128(8):1022–8. [PMID: 20697003]

2. Surgical Correction

Various surgical techniques are available for the correction of refractive errors, particularly nearsightedness. Laser corneal refractive surgery reshapes the mid-portion (stroma) of the cornea with an excimer laser. Laser assisted in situ keratomileusis (LASIK), including femtosecond laser assisted LASIK (IntraLASIK), and the surface ablation techniques epithelial LASIK (Epi-LASIK), laser epithelial keratomileusis (also known as laser-assisted subepithelial keratectomy) (LASEK), and photorefractive keratectomy (PRK) differ according to how access to the stroma is achieved. LASIK is most commonly performed because postoperative visual recovery is rapid and there is little

postoperative discomfort, but it is contraindicated if the cornea is relatively thin. Approximately 16 million procedures have been performed worldwide with > 90% patient satisfaction after primary surgery. However, outcomes for individual cases are not completely predictable. It has been reported that repeated treatment is required in up to 15% of patients and serious complications occur in up to 5%. Other refractive surgery techniques are extraction of the clear crystalline lens with insertion of a single vision, multifocal or accommodative intraocular lens; insertion of an intraocular lens without removal of the crystalline lens (phakic intraocular lens); intrastromal corneal ring segments (INTACS); and conductive keratoplasty (CK). Topical atropine and pirenzepine, a selective muscarinic antagonist, and rigid contact lens wear during sleep (orthokeratology) are also being investigated for nearsightedness.

DISORDERS OF THE LIDS & LACRIMAL APPARATUS

1. Hordeolum

Hordeolum is a common staphylococcal abscess that is characterized by a localized red, swollen, acutely tender area on the upper or lower lid (Figure 7–1). Internal hordeolum is a meibomian gland abscess that usually

▲ **Figure 7-1.** External hordeolum (black arrow) and chalazion (white arrow), which developed from an internal hordeolum. (Courtesy of Richard P. Usatine, MD. Reproduced, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

points onto the conjunctival surface of the lid; external hordeolum or sty usually is smaller and on the margin.

Warm compresses are helpful. Incision may be indicated if resolution does not begin within 48 hours. An antibiotic ointment (bacitracin or erythromycin) applied to the eyelid every 3 hours may be beneficial during the acute stage. Internal hordeolum may lead to generalized cellulitis of the lid.

2. Chalazion

Chalazion is a common granulomatous inflammation of a meibomian gland that may follow an internal hordeolum (Figure 7–1). It is characterized by a hard, nontender swelling on the upper or lower lid with redness and swelling of the adjacent conjunctiva. If the chalazion is large enough to impress the cornea, vision will be distorted. Treatment is usually by incision and curettage but corticosteroid injection may also be effective.

Arbabi EM et al. Chalazion. *BMJ*. 2010 Aug 10;341:c4044. [PMID: 21155069]

3. Blepharitis

Blepharitis is a common chronic bilateral inflammatory condition of the lid margins. **Anterior blepharitis** involves the eyelid skin, eyelashes, and associated glands. It may be ulcerative, because of infection by staphylococci, or seborrheic in association with seborrhea of the scalp, brows, and ears. **Posterior blepharitis** results from inflammation of the meibomian glands. There may be bacterial infection, particularly with staphylococci, or primary glandular dysfunction, in which there is a strong association with acne rosacea.

► Clinical Findings

Symptoms are irritation, burning, and itching. In **anterior blepharitis**, the eyes are “red-rimmed,” and scales or granulations can be seen clinging to the lashes. In **posterior blepharitis**, the lid margins are hyperemic with telangiectasias; the meibomian glands and their orifices are inflamed, with dilation of the glands, plugging of the orifices, and abnormal secretions. The lid margin is frequently rolled inward to produce a mild entropion, and the tears may be frothy or abnormally greasy.

Blepharitis is a common cause of recurrent conjunctivitis. Both anterior and, more particularly, posterior blepharitis may be complicated by hordeola or chalazions; abnormal lid or lash positions, producing trichiasis; epithelial keratitis of the lower third of the cornea; marginal corneal infiltrates; and inferior corneal vascularization and thinning.

► Treatment

Anterior blepharitis is usually controlled by cleanliness of the lid margins, eyebrows, and scalp. Scales should be removed from the lids daily with a hot wash cloth or a damp cotton applicator and baby shampoo. In acute exacerbations, an antistaphylococcal antibiotic eye ointment such as bacitracin or erythromycin is applied daily to the

lid margins. Antibiotic sensitivity studies may be helpful in severe cases.

In **mild posterior blepharitis**, regular meibomian gland expression may be sufficient to control symptoms. Inflammation of the conjunctiva and cornea indicates a need for more active treatment, including long-term low-dose oral antibiotic therapy, usually with tetracycline (250 mg twice daily), doxycycline (100 mg daily), minocycline (50–100 mg daily) or erythromycin (250 mg three times daily), and possibly short-term topical corticosteroids, eg, prednisolone, 0.125% twice daily. Topical therapy with antibiotics such as ciprofloxacin 0.3% ophthalmic solution twice daily may be helpful but should be restricted to short courses.

Bernardes TF et al. Blepharitis. *Semin Ophthalmol.* 2010 May;25(3):79–83. [PMID: 20590417]

4. Entropion & Ectropion

Entropion (inward turning of usually the lower lid) occurs occasionally in older people as a result of degeneration of the lid fascia, or may follow extensive scarring of the conjunctiva and tarsus. Surgery is indicated if the lashes rub on the cornea. Botulinum toxin injections may also be used for temporary correction of the involutional lower eyelid entropion of older people.

Ectropion (outward turning of the lower lid) is common with advanced age. Surgery is indicated if there is excessive tearing, exposure keratitis, or a cosmetic problem.

Bedran EG et al. Ectropion. *Semin Ophthalmol.* 2010 May;25(3):59–65. [PMID: 20590414]

Pereira MG et al. Eyelid entropion. *Semin Ophthalmol.* 2010 May;25(3):52–8. [PMID: 20590413]

5. Tumors

Eyelid tumors are usually benign. Basal cell carcinoma is the most common malignant tumor. Squamous cell carcinoma, meibomian gland carcinoma, and malignant melanoma also occur. Surgery for any lesion involving the lid margin should be performed by an ophthalmologist or suitably trained plastic surgeon to avoid deformity of the lid. Otherwise, small lesions can often be excised by the nonophthalmologist. Histopathologic examination of eyelid tumors should be routine, since 2% of lesions thought to be benign clinically are found to be malignant. The Mohs technique of intraoperative examination of excised tissue is particularly valuable in ensuring complete excision so that the risk of recurrence is reduced.

Deprez M et al. Clinicopathological features of the eyelid skin tumors. A retrospective study of 5504 cases and review of literature. *Am J Dermatopathol.* 2009 May;31(3):256–62. [PMID: 19384066]

Murchison AP et al. Non-surgical treatments of primary, non-melanoma eyelid malignancies: a review. *Clin Experiment Ophthalmol.* 2011 Jan;39(1):65–83. [PMID: 21040309]

6. Dacryocystitis

Dacryocystitis is infection of the lacrimal sac usually due to congenital or acquired obstruction of the nasolacrimal system. It may be acute or chronic and occurs most often in infants and in persons over 40 years. It is usually unilateral. The usual infectious organisms are *Staphylococcus aureus* and β -hemolytic streptococci in acute dacryocystitis and *S epidermidis*, anaerobic streptococci, or *Candida albicans* in chronic dacryocystitis.

Acute dacryocystitis is characterized by pain, swelling, tenderness, and redness in the tear sac area; purulent material may be expressed. In chronic dacryocystitis, tearing and discharge are the principal signs, and mucus or pus may also be expressed.

Acute dacryocystitis responds well to systemic antibiotic therapy. Surgical relief of the underlying obstruction is usually done electively but may be performed urgently in acute cases. The chronic form may be kept latent with antibiotics, but relief of the obstruction is the only cure. In adults, the standard procedure for obstruction of the lacrimal drainage system is dacryocystorhinostomy, which involves surgical exploration of the lacrimal sac and formation of a fistula into the nasal cavity; if necessary, the procedure can be supplemented by nasolacrimal intubation. Laser-assisted endoscopic dacryocystorhinostomy and balloon dilation or probing of the nasolacrimal system are alternatives. Congenital nasolacrimal duct obstruction is common and often resolves spontaneously. It can be treated by probing of the nasolacrimal system and supplemented by nasolacrimal intubation or balloon catheter dilation, if necessary. Dacryocystorhinostomy is rarely required.

Anijeet D et al. Endonasal versus external dacryocystorhinostomy for nasolacrimal duct obstruction. *Cochrane Database Syst Rev.* 2011 Jan 19;(1):CD007097. [PMID: 21249688]

CONJUNCTIVITIS

Conjunctivitis is the most common eye disease. It may be acute or chronic. Most cases are due to viral or bacterial (including gonococcal and chlamydial) infection. Other causes include keratoconjunctivitis sicca, allergy, chemical irritants, and deliberate self-harm. The mode of transmission of infectious conjunctivitis is usually direct contact via fingers, towels, handkerchiefs, etc, to the fellow eye or to other persons. It may be through contaminated eye drops.

Conjunctivitis must be differentiated from acute uveitis, acute glaucoma, and corneal disorders (Table 7–1).

1. Viral Conjunctivitis

Adenovirus is the most common cause of viral conjunctivitis. There is usually bilateral disease with copious watery discharge, often with marked foreign body sensation, and a

Table 7-1. The inflamed eye: Differential diagnosis of common causes.

	Acute Conjunctivitis	Acute Anterior Uveitis (Iritis)	Acute Angle-Closure Glaucoma	Corneal Trauma or Infection
Incidence	Extremely common	Common	Uncommon	Common
Discharge	Moderate to copious	None	None	Watery or purulent
Vision	No effect on vision	Often blurred	Markedly blurred	Usually blurred
Pain	Mild	Moderate	Severe	Moderate to severe
Conjunctival injection	Diffuse; more toward fornices	Mainly circumcorneal	Mainly circumcorneal	Mainly circumcorneal
Cornea	Clear	Usually clear	Cloudy	Clarity change related to cause
Pupil size	Normal	Small	Moderately dilated	Normal or small
Pupillary light response	Normal	Poor	None	Normal
Intraocular pressure	Normal	Usually normal but may be low or elevated	Markedly elevated	Normal
Smear	Causative organisms	No organisms	No organisms	Organisms found only in corneal infection

follicular conjunctivitis. Infection spreads easily. Eye clinics and contaminated swimming pools are sometimes the source of infection. Epidemic keratoconjunctivitis, which may result in visual loss due to corneal subepithelial infiltrates, is usually caused by adenovirus types 8, 19, and 37. The disease lasts at least 2 weeks. Infection with adenovirus types 3, 4, 7, and 11 is typically associated with pharyngitis, fever, malaise, and preauricular adenopathy (pharyngoconjunctival fever). The disease usually lasts 10 days. Viral conjunctivitis may also be due to herpes simplex virus (HSV), when it is usually unilateral and may be associated with lid vesicles, and enterovirus 70 or coxsackievirus A24 that characteristically cause acute hemorrhagic conjunctivitis (see Chapter 32).

Except for HSV infection for which topical or systemic antivirals may be prescribed, there is no specific treatment. Cold compresses reduce discomfort and topical sulfonamides (or other antibiotics) can be prescribed to prevent secondary bacterial infection. The value of weak topical corticosteroids or topical cyclosporine for corneal infiltrates due to adenoviral infection is uncertain.

2. Bacterial Conjunctivitis

The organisms isolated most commonly in bacterial conjunctivitis are staphylococci, streptococci (particularly *S pneumoniae*), *Haemophilus* species, *Pseudomonas*, and *Moraxella*. All may produce a copious purulent discharge. There is no blurring of vision and only mild discomfort. In

severe (hyperpurulent) cases, examination of stained conjunctival scrapings and cultures is recommended, particularly to identify gonococcal infection.

The disease is usually self-limited, lasting about 10–14 days if untreated. Topical sulfonamide (eg, sulfacetamide, 10% ophthalmic solution or ointment three times a day) will usually clear the infection in 2–3 days but the need for antibacterial therapy is disputed. The use of topical fluoroquinolones is rarely justified for treatment of a generally self-limiting, benign infection.

Hutnik C et al. Bacterial conjunctivitis. *Clin Ophthalmol*. 2010 Dec 6;4:1451–7. [PMID: 21188158]

Tarabishy AB et al. Bacterial conjunctivitis: a review for internists. *Cleve Clin J Med*. 2008 Jul;75(7):507–12. [PMID: 18646586]

A. Gonococcal Conjunctivitis

Gonococcal conjunctivitis, usually acquired through contact with infected genital secretions, typically causes copious purulent discharge. It is an ophthalmologic emergency because corneal involvement may rapidly lead to perforation. The diagnosis should be confirmed by stained smear and culture of the discharge. A single 1-g dose of intramuscular ceftriaxone is usually adequate. (Fluoroquinolone resistance is common.) Topical antibiotics such as erythromycin and bacitracin may be added. Other sexually transmitted diseases, including chlamydiosis, syphilis, and HIV infection, should be considered.

B. Chlamydial Keratoconjunctivitis

1. Trachoma—Trachoma is the most common infectious cause of blindness worldwide, with approximately 40 million people affected and 1.3 million with profound vision

loss. Recurrent episodes of infection in childhood manifest as bilateral follicular conjunctivitis, epithelial keratitis, and corneal vascularization (pannus). Cicatrization of the tarsal conjunctiva leads to entropion and trichiasis in adulthood, with secondary central corneal scarring.

Immunologic tests or polymerase chain reaction on conjunctival samples will confirm the diagnosis but treatment should be started on the basis of clinical findings. Single-dose therapy with oral azithromycin, 20 mg/kg, is the preferred drug treatment but improvements in hygiene and living conditions probably have contributed more to the marked reduction in the prevalence of trachoma during the past 25 years. Local treatment is not necessary. Surgical treatment includes correction of eyelid deformities and corneal transplantation.

Evans JR et al. Antibiotics for trachoma. *Cochrane Database Syst Rev*. 2011 Mar 16;(3):CD001860. [PMID: 21412875]
Hu VH et al. Epidemiology and control of trachoma: systematic review. *Trop Med Int Health*. 2010 Jun;15(6):673–91. [PMID: 20374566]

2. Inclusion conjunctivitis—The agent of inclusion conjunctivitis is a common cause of genital tract disease in adults. The eye is usually involved following contact with genital secretions. The disease starts with acute redness, discharge, and irritation. The eye findings consist of follicular conjunctivitis with mild keratitis. A nontender preauricular lymph node can often be palpated. Healing usually leaves no sequelae. Diagnosis can be rapidly confirmed by immunologic tests or polymerase chain reaction on conjunctival samples. Treatment is with a single-dose of azithromycin, 1 g orally. Before treatment, all cases should be assessed for genital tract infection so that management can be adjusted accordingly, and other venereal diseases sought.

3. Dry Eyes (Keratoconjunctivitis Sicca)

This is a common disorder, particularly in older women. Hypofunction of the lacrimal glands, causing loss of the aqueous component of tears, may be due to aging, hereditary disorders, systemic disease (eg, Sjögren syndrome), or systemic drugs. Excessive evaporation of tears may be due to environmental factors (eg, a hot, dry, or windy climate) or abnormalities of the lipid component of the tear film, as in blepharitis. Mucin deficiency may be due to vitamin A deficiency, or conjunctival scarring from trachoma, Stevens-Johnson syndrome and related conditions, mucous membrane pemphigoid, burns, or topical drugs or their preservatives.

► Clinical Findings

The patient complains of dryness, redness, or foreign body sensation. In severe cases, there is persistent marked discomfort, with photophobia, difficulty in moving the eyelids, and often excessive mucus secretion. In many cases, inspection reveals no abnormality, but on slit-lamp examination there are subtle abnormalities of tear film stability and reduced volume of the tear film meniscus along the lower lid. In more severe cases, damaged corneal and conjunctival cells stain with 1% rose bengal. In the most severe cases,

there is marked conjunctival injection, loss of the normal conjunctival and corneal luster, epithelial keratitis that may progress to frank ulceration, and mucous strands. Schirmer test, which measures the rate of production of the aqueous component of tears, may be helpful.

► Treatment

Aqueous deficiency can be treated with various types of artificial tears. The simplest preparations are physiologic (0.9%) or hypo-osmotic (0.45%) solutions of sodium chloride, which can be used as frequently as every half-hour, but in most cases are needed only three or four times a day. More prolonged duration of action can be achieved with drop preparations containing methylcellulose, polyvinyl alcohol, or polyacrylic acid (carbomers) or by using petrolatum ointment or a hydroxypropyl cellulose (Lacrisert) insert. Such mucomimetics are particularly indicated when there is mucin deficiency. If there is tenacious mucus, mucolytic agents (eg, acetylcysteine, 20% one drop six times daily) may be helpful. Autologous serum eye drops are used for severe dry eyes. Presumably due to its effects on ocular surface and lacrimal gland inflammation, cyclosporine (0.05% ophthalmic emulsion [Restasis] twice a day) has been shown to be beneficial in moderate and severe dry eyes with few adverse effects even in individuals treated for up to 4 years.

Lacrimal punctal occlusion by canalicular plugs or surgery is useful in severe cases. Blepharitis is treated as described above. Associated blepharospasm may benefit from botulinum toxin injections.

Artificial tear preparations are generally very safe and without side effects. Preservatives included in some preparations to maintain sterility are potentially toxic and allergenic and may cause keratitis and cicatrizing conjunctivitis in frequent users. The development of such reactions may be misinterpreted by both the patient and the clinician as a worsening of the dry eye state requiring more frequent use of the artificial tears and leading in turn to further deterioration, rather than being recognized as a need to change to a preservative-free preparation.

Akpek EK et al. Treatment of Sjögren's syndrome-associated dry eye: an evidence-based review. *Ophthalmology*. 2011 Jul; 118(7):1242–52. [PMID: 21459453]

4. Allergic Eye Disease

Allergic eye disease is common and takes a number of different forms but all are expressions of atopy, which may also manifest as atopic asthma, atopic dermatitis, or allergic rhinitis.

► Clinical Findings

Symptoms include itching, tearing, redness, stringy discharge and, occasionally, photophobia and visual loss.

Allergic conjunctivitis is a benign disease, occurring usually in late childhood and early adulthood. It may be seasonal (hay fever), developing usually during the spring or summer, or perennial. Clinical signs are limited to conjunctival hyperemia and edema (chemosis), the latter at times being marked and sudden in onset. **Vernal keratoconjunctivitis** also tends to occur in late childhood and early adulthood. It is usually seasonal, with a predilection for the spring. Large “cobblestone” papillae are noted on the upper tarsal conjunctiva. There may be lymphoid follicles at the limbus. **Atopic keratoconjunctivitis** is a more chronic disorder of adulthood. Both the upper and the lower tarsal conjunctivas exhibit a fine papillary conjunctivitis with fibrosis, resulting in forniceal shortening and entropion with trichiasis. Staphylococcal blepharitis is a complicating factor. Corneal involvement, including refractory ulceration, is frequent during exacerbations of both vernal and atopic keratoconjunctivitis. The latter may be complicated by herpes simplex keratitis.

► Treatment

A. Mild and Moderately Severe Allergic Eye Disease

Treatments include topical histamine H_1 -receptor antagonist (Table 7-2), such as levocabastine hydrochloride 0.05% or emedastine difumarate 0.05%, or ketorolac tromethamine 0.5%, a nonsteroidal anti-inflammatory agent, four times daily. Ketotifen 0.025% two to four times daily and bepotastine 1.5% twice daily, have histamine H_1 -receptor antagonist, mast cell stabilizer, and eosinophil inhibitor activity. Olopatadine, 0.2% once daily or 0.1% twice daily; azelastine, 0.05% twice daily; and epinastine, 0.05% twice daily reduce symptoms by similar mechanisms. Topical mast cell stabilizers, such as cromolyn sodium 4% or lodoxamide tromethamine 0.1%, applied four times daily, or nedocromil sodium 2%, applied twice daily, produce longer-term prophylaxis but the therapeutic response may be delayed. Topical vasoconstrictors and antihistamines are of limited efficacy in allergic eye disease and may produce rebound hyperemia and follicular conjunctivitis. Systemic antihistamines (eg, loratadine 10 mg orally daily) may be useful in prolonged atopic keratoconjunctivitis. In allergic conjunctivitis, specific allergens may be avoidable. In vernal keratoconjunctivitis, a cooler climate often provides significant benefit.

B. Acute Exacerbations and Severe Allergic Eye Disease

Topical corticosteroids (Table 7-2) are essential to the control of acute exacerbations of both vernal and atopic keratoconjunctivitis. Corticosteroid-induced side effects, including cataracts, glaucoma, and exacerbation of herpes simplex keratitis, are major problems but may be attenuated by the ester corticosteroid, loteprednol 0.5%. Topical cyclosporine or tacrolimus is also effective. Systemic corticosteroid or other immunosuppressant therapy and even plasmapheresis may be required in severe atopic keratoconjunctivitis.

PINGUECULA & PTERYGIUM

Pinguecula is a yellow elevated conjunctival nodule, more commonly on the nasal side, in the area of the palpebral fissure. It is common in persons over age 35 years. Pterygium is a fleshy, triangular encroachment of the conjunctiva onto the nasal side of the cornea and is usually associated with constant exposure to wind, sun, sand, and dust (Figure 7-2). Pinguecula and pterygium are often bilateral.

Pingueculae rarely grow but may become inflamed (pingueculitis). Pterygia become inflamed and may grow. No treatment is usually required for inflammation of pinguecula or pterygium, but artificial tears are often beneficial, and short courses of topical nonsteroidal anti-inflammatory agents or weak corticosteroids (prednisolone, 0.125% three times a day) may be necessary.

The indications for excision of pterygium are growth that threatens vision by encroaching on the visual axis, marked induced astigmatism, or severe ocular irritation. Recurrence is common and often more aggressive than the primary lesion.

CORNEAL ULCER

Corneal ulcers are most commonly due to infection by bacteria, viruses, fungi, or amebas. Noninfectious causes—all of which may be complicated by infection—include neurotrophic keratitis (resulting from loss of corneal sensation), exposure keratitis (due to inadequate eyelid closure), severe dry eyes, severe allergic eye disease, and various inflammatory disorders that may be purely ocular or part of a systemic vasculitis. Delayed or ineffective treatment of corneal infection may lead to devastating consequences with corneal scarring or intraocular infection. Prompt referral is essential.

Patients complain of pain, photophobia, tearing, and reduced vision. The eye is red, with predominantly circumferential injection, and there may be purulent or watery discharge. The corneal appearance varies according to the organisms involved.

Table 7-2. Topical ophthalmic agents.

Agent	Cost/Size ¹	Recommended Regimen	Indications
Antibacterial Agents²			
Bacitracin 500 units/g ointment (various) ³	\$57.46/3.5 g	Refer to package insert (instructions vary)	Ocular surface infection involving lid, conjunctiva, or cornea.
Cefazolin 10% (fortified) solution	Compounding pharmacy		
Chloramphenicol 1% ointment ⁴	Compounding pharmacy		
Chloramphenicol 0.5% solution ⁴	Compounding pharmacy		
Ciprofloxacin HCl 0.3% solution (Ciloxan)	\$47.30/5 mL		
Ciprofloxacin HCl 0.3% ointment	\$119.40/3.5 g		
Erythromycin 0.5% ointment (various) ⁵	\$19.00/3.5 g		
Fusidic acid 1% in gel (Fucithalamic)	Not available in United States		
Gatifloxacin 0.3% solution (Zymarid)	\$107.23/2.5 mL		
Gentamicin sulfate 0.3% solution (various)	\$17.93/5 mL		
Gentamicin sulfate 0.3% ointment (various)	\$18.03/3.5 g		
Levofloxacin 0.5% solution (various), 1.5% solution (Iquix)	\$91.98/5 mL		
Moxifloxacin 0.5% solution (Vigamox)	\$102.12/3 mL		
Norfloxacin 0.3% solution	Compounding pharmacy		
Ofloxacin 0.3% solution (Ocuflox)	\$13.75/5 mL		
Polymyxin B/Trimethoprim sulfate 10,000 U/mL/1 mg/mL (Polytrim) ⁶	\$17.42/10 mL		
Sulfacetamide sodium 10% solution (various)	\$16.54/15 mL	1 or 2 drops every 1-3 hours	
Sulfacetamide sodium 10% ointment (various)	\$65.86/3.5 g	Apply small amount (0.5 inch) into lower conjunctival sac once to four times daily and at bedtime	
Tobramycin 0.3% solution (various)	\$18.60/5 mL		
Tobramycin 1.5% (fortified) solution	Compounding pharmacy		
Tobramycin 0.3% ointment (Tobrex)	\$97.92/3.5 g		
Antifungal Agents			
Amphotericin 0.1-0.5% solution	Compounding pharmacy		
Natamycin 5% suspension (Natacyn)	\$260.28/15 mL	1 drop every 1-2 hours	Fungal ocular infections.
Voriconazole 1% solution	Compounding pharmacy		
Antiviral Agents			
Acyclovir 3% ointment (Zovirax)	Not available in United States	5 times daily	Herpes simplex virus keratitis.
Ganciclovir 0.15% gel (Zirgan)	214.00/5 g	5 times daily	

(continued)

Table 7-2. Topical ophthalmic agents. (continued)

Agent	Cost/Size ¹	Recommended Regimen	Indications
Trifluridine 1% solution (Viroptic)	\$167.76/7.5 mL	1 drop onto cornea every 2 hours while awake for a maximum daily dose of 9 drops until resolution occurs; then an additional 7 days of 1 drop every 4 hours while awake (minimum five times daily)	
Anti-inflammatory Agents			
Antihistamines⁷			
Azelastine HCl 0.05% ophthalmic solution (Optivar)	\$158.35/6 mL	1 drop two to four times daily (up to 6 weeks)	Allergic eye disease.
Bepotastine besilate 1.5% solution (Bepreve)	\$238.96/10 mL	1 drop twice daily	
Emedastine difumarate 0.05% solution (Emadine)	\$95.40/5 mL	1 drop four times daily	
Epinastine HCl 0.05% ophthalmic solution (Elestat)	\$130.24/5 mL	1 drop twice daily (up to 8 weeks)	
Levocabastine HCl 0.05% ophthalmic solution (Livostin)	Discontinued	1 drop four times daily (up to 2 weeks)	
Mast cell stabilizers			
Cromolyn sodium 4% solution (Crolom)	\$37.20/10 mL	1 drop four to six times daily	Allergic eye disease.
Ketotifen fumarate 0.025% solution (Zaditor)	\$11.70/5 mL	1 drop two to four times daily	
Lodoxamide tromethamine 0.1% solution (Alomide)	\$123.12/10 mL	1 or 2 drops four times daily (up to 3 months)	
Nedocromil sodium 2% solution (Alocril)	\$109.81/5 mL	1 drop twice daily	
Olopatadine hydrochloride 0.1% solution (Patanol)	\$140.64/5 mL	1 drop twice daily	
Nonsteroidal anti-inflammatory agents⁸			
Bromfenac 0.09% solution (Xibrom)	\$155.00/2.5 mL	1 drop to operated eye twice daily beginning 24 hours after cataract surgery and continuing through first 2 postoperative weeks	Treatment of postoperative inflammation following cataract extraction.
Diclofenac sodium 0.1% solution (Voltaren)	\$17.50/5 mL	1 drop to operated eye four times daily beginning 24 hours after cataract surgery and continuing through first 2 postoperative weeks.	Treatment of postoperative inflammation following cataract extraction and laser corneal surgery.
Flurbiprofen sodium 0.03% solution (various)	\$6.98/2.5 mL	1 drop every half hour beginning 2 hours before surgery; 1 drop to operated eye four times daily beginning 24 hours after cataract surgery	Inhibition of intraoperative miosis. Treatment of cystoid macular edema and inflammation after cataract surgery.
Ketorolac tromethamine 0.5% solution (Acular)	\$33.60/5 mL	1 drop four times daily	Treatment of allergic eye disease, postoperative inflammation following cataract extraction and laser corneal surgery.

(continued)

Table 7-2. Topical ophthalmic agents. (continued)

Agent	Cost/Size ¹	Recommended Regimen	Indications
Nepafenac 0.1% suspension (Nevanac)	\$153.72/3 mL	1 drop to operated eye three times daily beginning 24 hours after cataract surgery and continuing through first 2 postoperative weeks	Treatment of postoperative inflammation following cataract extraction.
Corticosteroids⁹			
Dexamethasone sodium phosphate 0.1% solution (various)	\$20.34/5 mL	1 or 2 drops as often as indicated by severity; use every hour during the day and every 2 hours during the night in severe inflammation; taper off as inflammation decreases	Treatment of steroid-responsive inflammatory conditions of anterior segment.
Dexamethasone sodium phosphate 0.05% ointment	Compounding pharmacy	Apply thin coating on lower conjunctival sac three or four times daily	
Fluorometholone 0.1% suspension (various) ¹⁰	\$16.01/10 mL	1 or 2 drops as often as indicated by severity; use every hour during the day and every 2 hours during the night in severe inflammation; taper off as inflammation decreases	
Fluorometholone 0.25% suspension (FML Forte) ¹⁰	\$51.72/10 mL		
Fluorometholone 0.1% ointment (FML S.O.P.)	\$46.79/3.5 g	Apply thin coating on lower conjunctival sac three or four times daily	
Loteprednol etabopate 0.5% (Lotemax)	\$252.02/10 mL	1 or 2 drops four times daily	
Prednisolone acetate 0.12% suspension (Pred Mild)	\$42.62/10 mL	1 or 2 drops as often as indicated by severity of inflammation; use every hour during the day and every 2 hours during the night in severe inflammation; taper off as inflammation decreases	
Prednisolone sodium phosphate 0.125% solution	Compounding pharmacy		
Prednisolone acetate 1% suspension (various)	\$16.32/10 mL		
Prednisolone sodium phosphate 1% solution (various)	\$57.55/10 mL		
Rimexolone 1% suspension (Vexol)	\$88.74/10 mL		
Immunomodulator			
Cyclosporine 0.05% emulsion (Restasis) 0.4 mL/container	\$154.42/30 containers	1 drop twice daily	Dry eyes and severe allergic eye disease.
Agents for Glaucoma and Ocular Hypertension			
Sympathomimetics			
Apraclonidine HCl 0.5% solution (Iopidine)	\$77.10/5 mL	1 drop three times daily	Reduction of intraocular pressure. Expensive. Reserve for treatment of resistant cases.
Apraclonidine HCl 1% solution (Iopidine)	\$19.95/unit dose	1 drop 1 hour before and immediately after anterior segment laser surgery	To control or prevent elevations of intraocular pressure after laser trabeculoplasty or iridotomy.

(continued)

Table 7-2. Topical ophthalmic agents. (continued)

Agent	Cost/Size ¹	Recommended Regimen	Indications
Brimonidine tartrate 0.2% solution (Alphagan)	\$18.13/5 mL	1 drop two or three times daily	Reduction of intraocular pressure.
β-Adrenergic blocking agents			
Betaxolol HCl 0.5% solution (Betoptic) and 0.25% suspension (Betoptic S) ¹²	0.5%: \$123.28/10 mL 0.25%: \$176.04/10 mL	1 drop twice daily	Reduction of intraocular pressure.
Carteolol HCl 1% and 2% solution (Various, Teoptic ¹³)	1%: \$37.07/10 mL 2%	1 drop twice daily	
Levobunolol HCl 0.25% and 0.5% solution (Betagan) ¹⁴	0.5%: \$32.25/10 mL	1 drop once or twice daily	
Metipranolol HCl 0.3% solution (OptiPranolol) ¹⁴	\$41.06/10 mL	1 drop twice daily	
Timolol 0.25% and 0.5% solution (Betimol) ¹⁴	0.5%: \$97.56/10 mL	1 drop once or twice daily	
Timolol maleate 0.25% and 0.5% solution (Timoptic) and 0.25% and 0.5% gel (Timoptic-XE, Timoptic GFS) ¹⁴	0.5% solution: \$32.35/10 mL 0.5% gel: \$43.68/5 mL	1 drop once or twice daily	
Miotics			
Pilocarpine HCl (various) ¹⁵ 1-4%, 6%, 8%, and 10%	2%: \$66.15/15 mL	1 drop three or four times daily	Reduction of intraocular pressure, treatment of acute or chronic angle-closure glaucoma, and pupillary constriction.
Pilocarpine HCl 4% gel (Pilopine HS)	\$95.64/4 g	Apply 0.5-inch ribbon in lower conjunctival sac at bedtime	
Carbonic anhydrase inhibitors			
Brimonidine 1% suspension (Azopt)	\$129.36/10 mL	1 drop three times daily	Reduction of intraocular pressure.
Dorzolamide HCl 2% solution (Trusopt)	\$83.75/10 mL	1 drop three times daily	
Prostaglandin analogs			
Bimatoprost 0.03% solution (Lumigan)	\$107.76/2.5 mL	1 drop once daily at night	Reduction of intraocular pressure.
Latanoprost 0.005% solution (Xalatan)	\$114.56/2.5 mL	1 drop once or twice daily at night	Reduction of intraocular pressure.
Tafloprost 0.0015% solution (Zioptan)	\$116.40/30 Units	1 drop once daily at night	
Travoprost 0.004% solution (Travatan)	\$107.04/2.5 mL	1 drop once daily at night	
Unoprostone isopropyl 0.15% solution (Rescula)	Not available in United States	1 drop twice daily	
Combined preparations			
Azarga (brinzolamide 1% and timolol 0.5%)	Not available in United States	1 drop twice daily	Reduction of intraocular pressure.
Combigan (brimonidine 0.2% and timolol 0.5%)	\$194.74/10 mL	1 drop twice daily	
Cosopt (dorzolamide 2% and timolol 0.5%)	\$153.67/10 mL	1 drop twice daily	
DuoTrav (travoprost 0.004% and timolol 0.5%)	Not available in United States	1 drop daily	

(continued)

Table 7-2. Topical ophthalmic agents. (continued)

Agent	Cost/Size ¹	Recommended Regimen	Indications
Ganfort (bimatoprost 0.03% and timolol 0.5%)	Not available in United States	1 drop daily in the morning	
Xalacom (latanoprost 0.005% and timolol 0.5%)	Not available in United States	1 drop daily in the morning	

¹Average wholesale price (AWP, for AB-rated generic when available) for quantity listed. Source: *Red Book Online, 2012*, Thomson Reuters (Healthcare) Inc. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.

²Many combination products containing antibacterials or antifungals and corticosteroids are available.

³Little efficacy against gram-negative organisms (except *Neisseria*).

⁴Aplastic anemia has been reported with prolonged ophthalmic use.

⁵Also indicated for prophylaxis of neonatal conjunctivitis due to *Neisseria gonorrhoeae* or *Chlamydia trachomatis*.

⁶No gram-positive coverage.

⁷May produce rebound hyperemia and local reactions.

⁸Cross-sensitivity to aspirin and other nonsteroidal anti-inflammatory drugs.

⁹Long-term use increases intraocular pressure, causes cataracts and predisposes to bacterial, herpes simplex virus, and fungal keratitis.

¹⁰Less likely to elevate intraocular pressure.

¹¹Macular edema occurs in 30% of patients.

¹²Cardioselective (β_1) β -blocker.

¹³Teoptic is not available in the United States.

¹⁴Nonselective (β_1 and β_2) β -blocker. Monitor all patients for systemic side effects, particularly exacerbation of asthma.

¹⁵Decreased night vision, headaches possible.

► When to Refer

Any patient with an acute painful red eye and corneal abnormality should be referred emergently to an ophthalmologist.

1. Bacterial Keratitis

Bacterial keratitis usually pursues an aggressive course. Precipitating factors include contact lens wear—especially overnight wear—and corneal trauma, including refractive surgery. The pathogens most commonly isolated are *Pseudomonas aeruginosa*, *Pneumococcus*, *Moraxella* species,

▲ **Figure 7-2.** A medial pterygium extending to the cornea. (Courtesy of Paul D. Corneau. Reproduced, with permission from, Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

and staphylococci. The cornea is hazy, with a central ulcer and adjacent stromal abscess. Hypopyon is often present. The ulcer is scraped to recover material for Gram stain and culture prior to starting treatment with high-concentration topical antibiotic drops applied hourly day and night for at least the first 48 hours. Fluoroquinolones such as levofloxacin 0.5%, ofloxacin 0.3%, norfloxacin 0.3%, or ciprofloxacin 0.3% are commonly used as first-line agents as long as local prevalence of resistant organisms is low (Table 7-2). The fourth-generation fluoroquinolones (moxifloxacin 0.5% and gatifloxacin 0.3%) may be preferable because they are also active against mycobacteria. Gram-positive cocci can also be treated with a cephalosporin such as fortified cefazolin 10%; and gram-negative bacilli can be treated with an aminoglycoside such as fortified tobramycin 1.5%. If no organisms are seen on Gram stain, these two agents can be used together in areas where resistance to fluoroquinolones is common. Adjunctive topical corticosteroid therapy should only be prescribed by an ophthalmologist.

► When to Refer

Any patient with suspected bacterial keratitis must be referred emergently to an ophthalmologist.

2. Herpes Simplex Keratitis

Herpes simplex keratitis is an important cause of ocular morbidity. The ability of the virus to colonize the trigeminal ganglion leads to recurrences that may be precipitated by fever, excessive exposure to sunlight, or immunodeficiency.

The dendritic (branching) ulcer is the most characteristic manifestation. More extensive (“geographic”) ulcers also occur, particularly if topical corticosteroids have been used. These ulcers are most easily seen after instillation of fluorescein and examination with a blue light. Such epithelial disease in itself does not lead to corneal scarring. It responds well to simple debridement and patching. More rapid healing can be achieved by the addition of topical antivirals, such as trifluridine drops, ganciclovir gel, or acyclovir ointment (Table 7–2), or oral antivirals, such as acyclovir, 400 mg five times daily. Long-term oral acyclovir, 400 mg twice daily, or valacyclovir, 500 mg once daily, reduces the rate of recurrent epithelial disease, particularly in atopic individuals.

Stromal herpes simplex keratitis produces increasingly severe corneal opacity with each recurrence. Topical antivirals alone are insufficient to control stromal disease, so topical corticosteroids are used as well but they may enhance viral replication, exacerbating epithelial disease; steroid dependence is common. Oral acyclovir, 200–400 mg five times a day, is often helpful in the treatment of severe herpetic keratitis. The role of topical cyclosporine is being determined. Severe stromal scarring may require corneal grafting, but the overall outcome is relatively poor. **Caution:** For patients with known or possible herpetic disease, topical corticosteroids should be prescribed only with ophthalmologic supervision.

► When to Refer

Any patient with a history of herpes simplex keratitis and an acute red eye should be referred urgently to an ophthalmologist.

3. Herpes Zoster Ophthalmicus

Herpes zoster frequently involves the ophthalmic division of the trigeminal nerve. It presents with malaise, fever, headache, and periorbital burning and itching. These symptoms may precede the eruption by a day or more. The rash is initially vesicular, quickly becoming pustular and then crusting. Involvement of the tip of the nose or

the lid margins predicts involvement of the eye. Ocular signs include conjunctivitis, keratitis, episcleritis, and anterior uveitis, often with elevated intraocular pressure. Recurrent anterior segment inflammation, neurotrophic keratitis, and posterior subcapsular cataract are long-term complications. Optic neuropathy, cranial nerve palsies, acute retinal necrosis, and cerebral angiitis occur infrequently. HIV infection is an important risk factor for herpes zoster ophthalmicus and increases the likelihood of complications.

High-dose oral acyclovir (800 mg five times a day), valacyclovir (1g three times a day), or famciclovir (250–500 mg three times a day) started within 72 hours after the appearance of the rash reduces the incidence of ocular complications but not of postherpetic neuralgia. Anterior uveitis requires treatment with topical corticosteroids and cycloplegics. Neurotrophic keratitis is an important cause of long-term morbidity.

► When to Refer

Any patient with herpes zoster ophthalmicus and ocular symptoms or signs should be referred urgently to an ophthalmologist.

4. Fungal Keratitis

Fungal keratitis tends to occur after corneal injury involving plant material or in an agricultural setting, in eyes with chronic ocular surface disease, and increasingly in contact lens wearers. It is usually an indolent process, with the cornea characteristically having multiple stromal abscesses and relatively little epithelial loss. Intraocular infection is common. Corneal scrapings should be cultured on media suitable for fungi whenever the history or corneal appearance is suggestive of fungal disease. Diagnosis is often delayed and treatment is difficult. Natamycin 5%, amphotericin 0.1–0.5%, and voriconazole 1% are the most commonly used topical agents. Systemic imidazoles may be helpful. Corneal grafting is often required.

5. Acanthamoeba Keratitis

Acanthamoeba infection is an important cause of keratitis in contact lens wearers. Although severe pain with perineural and ring infiltrates in the corneal stroma is characteristic, earlier forms with changes confined to the corneal epithelium are identifiable. Diagnosis is facilitated by confocal microscopy. Culture requires specialized media. Treatment is hampered by the organism's ability to encyst within the corneal stroma. Topical biguanides are probably the only effective primary treatment. Topical corticosteroids may be beneficial. Corneal grafting may be required after resolution of infection to restore vision. Systemic anti-inflammatory therapy is helpful if there is scleral involvement.

ACUTE ANGLE-CLOSURE GLAUCOMA

ESSENTIALS OF DIAGNOSIS

- ▶ Older age group, particularly farsighted individuals.
- ▶ Rapid onset of severe pain and profound visual loss with “halos around lights.”
- ▶ Red eye, cloudy cornea, dilated pupil.
- ▶ Hard eye to palpation.

▶ General Considerations

Primary acute angle-closure glaucoma occurs only with closure of a preexisting narrow anterior chamber angle, for which the predisposing factors are age, owing to enlargement of the crystalline lens; farsightedness; and inheritance, being particularly prevalent among Asians and Inuits. It may be precipitated by pupillary dilation and thus can occur from sitting in a darkened theater, during times of stress, following nonocular administration of anticholinergic or sympathomimetic agents (eg, nebulized bronchodilators, atropine for preoperative medication, antidepressants, bowel or bladder antispasmodics, nasal decongestants, or tocolytics) or, rarely, from pharmacologic mydriasis (see Precautions in Management of Ocular Disorders, below). Secondary acute angle-closure glaucoma may occur in anterior uveitis, dislocation of the lens, or topiramate therapy. Symptoms are the same as in primary acute angle-closure glaucoma, but differentiation is important because of differences in management. Chronic angle-closure glaucoma is particularly common in eastern Asia. It presents in the same way as open-angle glaucoma (see below).

▶ Clinical Findings

Patients with acute glaucoma usually seek treatment immediately because of extreme pain and blurred vision, though there are subacute cases. The blurred vision is associated with halos around lights. Nausea and abdominal pain may occur. The eye is red, the cornea cloudy, and the pupil moderately dilated and nonreactive to light. Intraocular pressure is usually over 50 mm Hg, producing a hard eye on palpation.

▶ Differential Diagnosis

Acute glaucoma must be differentiated from conjunctivitis, acute uveitis, and corneal disorders (Table 7–1).

▶ Treatment

A. Primary

Initial treatment in primary angle-closure glaucoma is reduction of intraocular pressure. A single 500-mg intravenous dose of acetazolamide, followed by 250 mg orally four times a day, is usually sufficient. Osmotic diuretics such as oral glycerin and intravenous urea or mannitol—the dosage of all three being 1–2 g/kg—may be necessary if there is no response to acetazolamide. Laser therapy to the

peripheral iris (iridoplasty) or anterior chamber paracentesis is also effective. Once the intraocular pressure has started to fall, topical 4% pilocarpine, 1 drop every 15 minutes for 1 hour and then four times a day, is used to reverse the underlying angle closure. The definitive treatment is laser peripheral iridotomy or surgical peripheral iridectomy. Cataract extraction is a possible alternative. If it is not possible to control the intraocular pressure medically, glaucoma drainage surgery as for uncontrolled open-angle glaucoma (see below) may be required.

All patients with primary acute angle-closure should undergo prophylactic laser peripheral iridotomy to the unaffected eye, unless that eye has already undergone cataract or glaucoma surgery. Whether prophylactic laser peripheral iridotomy should be undertaken in asymptomatic patients with narrow anterior chamber angles is uncertain and mainly influenced by the risk of the more common chronic angle-closure (see below).

B. Secondary

In secondary acute angle-closure glaucoma, systemic acetazolamide is also used, with or without osmotic agents. Further treatment is determined by the cause.

► Prognosis

Untreated acute angle-closure glaucoma results in severe and permanent visual loss within 2–5 days after onset of symptoms. Affected patients need to be observed for development of chronic glaucoma.

► When to Refer

Any patient with suspected acute angle-closure glaucoma must be referred emergently to an ophthalmologist.

CHRONIC GLAUCOMA

ESSENTIALS OF DIAGNOSIS

- No symptoms in early stages.
- Insidious progressive bilateral loss of peripheral vision, resulting in tunnel vision but preserved visual acuities.
- Pathologic cupping of the optic disks.
- Intraocular pressure is usually elevated.

► General Considerations

Chronic glaucoma is characterized by gradually progressive excavation (“cupping”) and pallor of the optic disk with loss of vision progressing from slight constriction of the peripheral fields to complete blindness. In chronic open-angle glaucoma, primary or secondary, the intraocular pressure is elevated due to reduced drainage of aqueous fluid through the trabecular meshwork. In chronic angle-closure glaucoma, flow of aqueous fluid into the anterior chamber angle is obstructed. In normal-tension glaucoma, intraocular pressure is not elevated but the same pattern of optic nerve damage occurs, probably due to vascular insufficiency.

Primary open-angle glaucoma is bilateral. There is an increased prevalence in first-degree relatives of affected individuals and in diabetic patients. In blacks, it is more frequent, occurs at an earlier age, and results in more severe optic nerve damage. Secondary open-angle glaucoma may result from uveitis; ocular trauma; or corticosteroid therapy, whether it is topical, systemic, inhaled, or administered by nasal spray.

In the United States, it is estimated that 2% of people over 40 years of age have glaucoma, affecting more than 2 million individuals and being three times more prevalent in blacks. At least 25% of cases are undetected. Over 90% of cases are of the open-angle type. Worldwide, about 4.5 million people are bilaterally blind from chronic open-angle glaucoma and 4 million, of which approximately 50% live in China, are bilaterally blind from chronic angle-closure glaucoma.

► Clinical Findings

Because initially there are no symptoms, chronic glaucoma is often suspected at a routine eye test. Diagnosis requires consistent and reproducible abnormalities in at least two of three parameters—optic disk, visual field, and intraocular pressure. Optic disk cupping is identified as an absolute increase or an asymmetry between the two eyes of the ratio

of the diameter of the optic cup to the diameter of the whole optic disk (cup-disk ratio, Figure 7–3). (Cup-disk ratio greater than 0.5 or 0.2 or more asymmetry between eyes is suggestive.) Visual field abnormalities initially develop in the paracentral region, followed by constriction of the peripheral visual field. Central vision remains good until late in the disease. The normal range of intraocular pressure is 10–21 mm Hg.

In many individuals, elevated intraocular pressure is not associated with optic disk or visual field abnormalities (**ocular hypertension**). Treatment to reduce intraocular pressure is justified if there is a moderate to high risk of progression to glaucoma, determined by several factors, including age, optic disk appearance, level of intraocular

pressure, and corneal thickness. A significant proportion of eyes with primary open-angle glaucoma have normal intraocular pressure when it is first measured, and only repeated measurements identify the abnormally high pressure. In normal-tension glaucoma, intraocular pressure is always within the normal range.

There are many causes of optic disk abnormalities or visual field changes that mimic glaucoma, and visual field testing may prove unreliable in some patients, particularly in the older age group. The diagnosis of glaucoma is not always straightforward, hampering the effectiveness of screening programs.

▶ Prevention

All persons over age 50 years should have intraocular pressure measurement and optic disk examination every 3–5 years. In persons with diabetes and in individuals with a family history of glaucoma, annual examination is indicated. Regular ophthalmic screening should be considered in patients taking long-term oral or combined intranasal and inhaled corticosteroid therapy.

▶ Treatment

A. Medications

The prostaglandin analogs (latanoprost 0.005%, bimatoprost 0.03%, travoprost 0.004%, and tafluprost 0.0015% once daily at night, and unoprostone 0.15% twice daily) are commonly used as first-line therapy because of their efficacy, their lack of systemic side effects, as well as the convenience of once-daily dosing (except unoprostone) (Table 7–2). All may produce conjunctival hyperemia, permanent darkening of the iris and eyebrow color, and increased eyelash growth. Latanoprost has been associated with reactivation of uveitis and macular edema. Tafluprost is not available in the United States.

Topical β -adrenergic blocking agents such as timolol 0.25% or 0.5%, carteolol 1%, levobunolol 0.5%, and metipranolol 0.3% solutions twice daily or timolol 0.25% or 0.5% gel once daily may be used alone or in combination with a prostaglandin analog. They are contraindicated in patients with reactive airway disease or heart failure. Betaxolol, 0.25% or 0.5%, a β -receptor selective blocking agent, is theoretically safer in reactive airway disease but less effective at reducing intraocular pressure. Brimonidine 0.2%, a selective α_2 -agonist, and dorzolamide 2% or brinzolamide 1%, topical carbonic anhydrase inhibitors, also can be used in addition to a prostaglandin analog or a β -blocker (twice daily) or as initial therapy when prostaglandin analogs and β -blockers are contraindicated (brimonidine twice daily, dorzolamide and brinzolamide three times daily). All three are associated with allergic reactions. Combination drops Xalacom (latanoprost 0.005% and timolol 0.5%), Ganfort (bimatoprost 0.03% and timolol 0.5%), and DuoTrav (travoprost 0.004% and timolol 0.5%), each used once daily, and Cosopt (dorzolamide 2% and timolol 0.5%), Azarga (brinzolamide 1% and timolol 0.5%), and Combigan (brimonidine 0.2% and timolol 0.5%), each used twice daily improve compliance when multiple medications are required.

▲ **Figure 7-3.** A: Normal eye with a normal optic cup-to-disk ratio of 0.4. B: Glaucoma with an increased optic cup-to-disk ratio of 0.8. (Courtesy of Paul D. Corneau. Reproduced, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Apraclonidine, 0.5–1%, another α_2 -agonist, can be used three times a day to postpone the need for surgery in patients receiving maximal medical therapy, but long-term use is limited by drug reactions. It is more commonly used to control acute rises in intraocular pressure such as after laser therapy. Pilocarpine 1–4%, epinephrine, 0.5–1%, and the prodrug dipivefrin, 0.1%, are rarely used because of adverse effects. Oral carbonic anhydrase inhibitors (eg, acetazolamide) may still be used on a long-term basis if topical therapy is inadequate and surgical or laser therapy is inappropriate.

Formulations of topical agents without preservative or not including benzalkonium chloride as the preservative are becoming available.

B. Laser Therapy and Surgery

Laser trabeculoplasty is used as an adjunct to topical therapy to defer surgery and is also advocated as primary treatment. Surgery is generally undertaken when intraocular pressure is inadequately controlled by medical and laser therapy, but it may also be used as primary treatment. Trabeculectomy remains the standard procedure. Adjunctive treatment with subconjunctival mitomycin or fluorouracil is used perioperatively or postoperatively in difficult cases. Viscocanalostomy and deep sclerectomy with collagen implant—two alternative procedures that avoid a full-thickness incision into the eye—may be as effective as trabeculectomy but are more difficult to perform.

In chronic angle-closure glaucoma, laser peripheral iridotomy or surgical peripheral iridectomy may be helpful. In patients with asymptomatic narrow anterior chamber angles, which includes about 10% of Chinese adults, prophylactic laser peripheral iridotomy can be performed to reduce the risk of acute and chronic angle-closure glaucoma. However, there are concerns about the efficacy of such treatment and the risk of cataract progression and corneal decompensation. In the United States, about 1% of people over age 35 years have narrow anterior chamber angles, but acute and chronic angle-closure are sufficiently uncommon that prophylactic therapy is not generally advised.

► Prognosis

Untreated chronic glaucoma that begins at age 40–45 years will probably cause complete blindness by age 60–65. Early diagnosis and treatment can preserve useful vision throughout life. In primary open-angle glaucoma—and if treatment is required in ocular hypertension—the aim is to reduce intraocular pressure to a level that will adequately reduce progression of visual field loss. In eyes with marked visual field or optic disk changes, intraocular pressure must be reduced to less than 16 mm Hg. In normal-tension glaucoma with progressive visual field loss, it is necessary to achieve even lower intraocular pressure such that surgery is often required.

► When to Refer

All patients with suspected chronic glaucoma should be referred to an ophthalmologist.

UVEITIS

ESSENTIALS OF DIAGNOSIS

- Usually immunologic but possibly infective or neoplastic.
- Acute nongranulomatous anterior uveitis: pain, redness, photophobia, and visual loss.
- Granulomatous anterior uveitis: blurred vision in a mildly inflamed eye.
- Posterior uveitis: gradual loss of vision in a quiet eye.

► General Considerations

Intraocular inflammation (uveitis) is classified into acute or chronic, and nongranulomatous or granulomatous according to the clinical signs, or by its distribution—anterior or posterior uveitis, predominantly affecting the anterior or posterior segments of the eye, or panuveitis, in which both segments are affected equally. The common types are acute nongranulomatous anterior uveitis, granulomatous anterior uveitis, and posterior uveitis.

In most cases, the pathogenesis of uveitis is primarily immunologic, but infection may be the cause, particularly in immunodeficiency states. The systemic disorders associated with acute nongranulomatous anterior uveitis are the HLA-B27-related conditions ankylosing spondylitis, reactive

arthritis, psoriasis, ulcerative colitis, and Crohn disease. Behçet syndrome produces both anterior uveitis, with recurrent hypopyon but little discomfort, and posterior uveitis, characteristically with branch retinal vein occlusions. Both herpes simplex and herpes zoster infections may cause non-granulomatous anterior uveitis as well as retinitis (acute retinal necrosis), which has a very poor prognosis.

Diseases producing granulomatous anterior uveitis also tend to be causes of posterior uveitis. These include sarcoidosis, toxoplasmosis, tuberculosis, syphilis, Vogt-Koyanagi-Harada syndrome (bilateral uveitis associated with alopecia, poliosis [depigmented eyelashes, eyebrows, or hair], vitiligo, and hearing loss), and sympathetic ophthalmia following penetrating ocular trauma. In toxoplasmosis, there may be evidence of previous episodes of retinochoroiditis. Syphilis characteristically produces a “salt and pepper” fundus but may present with a wide variety of clinical manifestations. The other principal pathogens responsible for ocular inflammation in HIV infection (see below) are cytomegalovirus (CMV), herpes simplex and herpes zoster viruses, mycobacteria, *Cryptococcus*, *Toxoplasma*, and *Candida*.

Autoimmune retinal vasculitis and pars planitis (intermediate uveitis) are idiopathic conditions that produce posterior uveitis.

► Clinical Findings

Anterior uveitis is characterized by inflammatory cells and flare within the aqueous. In severe cases, there may be hypopyon (layered collection of white cells) and fibrin within the anterior chamber. Cells may also be seen on the corneal endothelium as keratic precipitates (KPs). In granulomatous uveitis, these are large “mutton-fat” KPs, and iris nodules may be seen. In nongranulomatous uveitis, the KPs are smaller and iris nodules are not seen. The pupil is usually small, and with the development of posterior synechiae (adhesions between the iris and anterior lens capsule), it also becomes irregular.

Nongranulomatous anterior uveitis tends to present acutely with unilateral pain, redness, photophobia, and visual loss. Granulomatous anterior uveitis is more indolent, causing blurred vision in a mildly inflamed eye.

In **posterior uveitis**, there are cells in the vitreous. Inflammatory lesions may be present in the retina or choroid. Fresh lesions are yellow, with indistinct margins, and there may be retinal hemorrhages, whereas older lesions have more definite margins and are commonly pigmented. Retinal vessel sheathing may occur adjacent to such lesions or more diffusely. In severe cases, vitreous opacity precludes visualization of retinal details.

Posterior uveitis tends to present with gradual visual loss in a relatively quiet eye. Bilateral involvement is common. Visual loss may be due to vitreous haze and opacities, inflammatory lesions involving the macula, macular edema, retinal vein occlusion or, rarely, associated optic neuropathy.

► Differential Diagnosis

Retinal detachment, intraocular tumors, and central nervous system lymphoma may all masquerade as uveitis.

► Treatment

Anterior uveitis usually responds to topical corticosteroids. Occasionally, periocular corticosteroid injections or even systemic corticosteroids may be required. Dilation of the pupil is important to relieve discomfort and prevent posterior synechiae. **Posterior uveitis** more commonly requires systemic, periocular or intravitreal corticosteroid therapy and occasionally systemic immunosuppression with agents such as azathioprine, tacrolimus, cyclosporine, mycophenolate, or methotrexate. The value of biologic therapies is being evaluated. Pupillary dilation is not usually necessary.

If an infectious cause is identified, specific antimicrobial therapy may be indicated. In general, the prognosis for anterior uveitis, particularly the nongranulomatous type, is better than that for posterior uveitis.

► When to Refer

- Any patient with suspected acute uveitis should be referred urgently to an ophthalmologist or emergently if visual loss or pain is severe.
- Any patient with suspected chronic uveitis should be referred to an ophthalmologist, urgently if there is more than mild visual loss.

► When to Admit

Patients with severe uveitis, particularly those requiring intravenous therapy, may require hospital admission.

CATARACT

ESSENTIALS OF DIAGNOSIS

- ▶ Gradually progressive blurred vision.
- ▶ No pain or redness.
- ▶ Lens opacities (may be grossly visible).

▶ General Considerations

Cataract is opacity of the crystalline lens. It is the leading cause of blindness worldwide, but access to treatment and quality of outcome are still limited in many areas. Cataracts are usually bilateral. They may be congenital (owing to intrauterine infections such as rubella and CMV, or inborn errors of metabolism such as galactosemia); traumatic; or secondary to systemic disease (diabetes, myotonic dystrophy, atopic dermatitis), systemic or inhaled corticosteroid treatment, or uveitis; but senile cataract is by far the most common type. Most persons over age 60 have some degree of lens opacity. Cigarette smoking increases the risk of cataract formation.

▶ Clinical Findings

The predominant symptom is progressive blurring of vision. Glare, especially in bright light or when driving at night; change of focusing, particularly development of nearsightedness; and monocular double vision may also occur.

Even in its early stages, a cataract can be seen through a dilated pupil with an ophthalmoscope or slit lamp. As the cataract matures, the retina will become increasingly more difficult to visualize, until finally the fundus reflection is absent and the pupil is white.

▶ Treatment

In adults, functional visual impairment is the prime criterion for surgery. The cataract is usually removed by one of the techniques in which the posterior lens capsule remains (extracapsular), thus providing support for a prosthetic intraocular lens that dispenses with the need for heavy cataract glasses or contact lenses. Laser treatment may be required subsequently if the posterior capsule opacifies. Ultrasonic fragmentation (phacoemulsification) of the lens nucleus and foldable intraocular lenses allow cataract surgery to be performed through a small incision without the need for sutures, thus reducing the postoperative complication rate and accelerating visual rehabilitation. Multifocal and accommodative intraocular lenses reduce the need for both distance and near vision correction.

Management of congenital cataract is complicated by additional technical difficulties during surgery, changes in the optics of the eye with growth influencing choice of intraocular lens power, and treatment of associated amblyopia.

▶ Prognosis

In the developed world, cataract surgery in adults improves visual acuity in 95% of cases, whereas in less developed

areas the outcome is less good, in part due to uncorrected refractive error. In the other 5%, there is preexisting retinal damage or operative or postoperative complications. Treatment with α_1 -antagonists, particularly with tamsulosin for benign prostatic hyperplasia, or with risperidone for psychiatric disease increases the risk of intraoperative (floppy iris syndrome) and postoperative complications.

▶ When to Refer

Patients with cataracts should be referred to an ophthalmologist when their visual impairment adversely affects their everyday activities.

RETINAL DETACHMENT

ESSENTIALS OF DIAGNOSIS

- ▶ Curtain spreading across field of vision or sudden onset of visual loss in one eye.
- ▶ No pain or redness.
- ▶ Detachment seen by ophthalmoscopy.

▶ General Considerations

Most cases of retinal detachment are due to development of a retinal tear (rhegmatogenous retinal detachment). This is usually spontaneous, is related to changes in the vitreous, and generally occurs in persons over 50 years of age. Nearsightedness and cataract extraction are the two most common predisposing causes. Retinal tear may also be caused by penetrating or blunt ocular trauma. Once there is a tear in the retina, fluid vitreous is able to pass through the tear behind the sensory retina. This, combined with vitreous traction and the pull of gravity, results in progressive detachment.

Tractional retinal detachment occurs when there is preretinal fibrosis, such as in association with proliferative retinopathy secondary to diabetic retinopathy or retinal vein

occlusion. Serous retinal detachment results from accumulation of subretinal fluid, such as in neovascular age-related macular degeneration or secondary to choroidal tumors.

► Clinical Findings

Rhegmatogenous retinal detachment usually starts in the superior temporal area and spreads rapidly, causing visual field loss that starts inferiorly and expands upwards. Central vision remains intact until the macula becomes detached. On ophthalmoscopic examination, the retina is seen hanging in the vitreous like a gray cloud. One or more retinal tears will usually be found on further examination.

In traction retinal detachment, there is irregular retinal elevation with fibrosis. With serous retinal detachment, the retina is dome-shaped and the subretinal fluid may shift position with changes in posture.

► Treatment

Treatment of rhegmatogenous retinal detachments is directed at closing the retinal tears. A permanent adhesion between the neurosensory retina, the retinal pigment epithelium, and the choroid is produced in the region of the tears by laser photocoagulation to the retina or cryotherapy to the sclera. Indentation of the sclera with a silicone sponge or buckle; subretinal fluid drainage via an incision in the sclera; or injection of an expansile gas into the vitreous cavity, possibly following intraocular surgery to remove the vitreous (pars plana vitrectomy) may be required to achieve apposition of the neurosensory retina to the retinal pigment epithelium while the adhesion is developing. Certain types of uncomplicated retinal detachment may be treated by pneumatic retinopexy, in which an expansile gas is injected into the vitreous cavity followed by positioning of the patient's head to facilitate reattachment of the retina. Once the retina is repositioned, the tear is sealed by laser photocoagulation or cryotherapy; these two methods are also used to seal retinal tears without associated detachment.

In complicated retinal detachments—particularly those in which fibroproliferative tissue has developed on the surface of the retina or within the vitreous cavity, ie, traction retinal detachments—retinal reattachment can be accomplished only by pars plana vitrectomy, direct manipulation of the retina, and internal tamponade of the retina with air, expansile gases, or even silicone oil. (The presence of an expansile gas within the eye is a contraindication to air travel, mountaineering at high altitude, and nitrous oxide anesthesia. Such gases persist in the globe for weeks after surgery.) Treatment of serous retinal detachments is determined by the underlying cause.

► Prognosis

About 80% of uncomplicated rhegmatogenous retinal detachments can be cured with one operation; an additional 15% will need repeated operations; and the remainder never reattach. The visual prognosis is worse if the macula is detached or if the detachment is of long duration. Without treatment, retinal detachment often becomes total within 6 months. Spontaneous detachments are ultimately bilateral in up to 25% of cases.

► When to Refer

All cases of retinal detachment must be referred urgently to an ophthalmologist, emergently if central vision is good because this indicates that the macula has not detached. During transportation, the patient's head is positioned so that the detached portion of the retina will fall back with the aid of gravity.

VITREOUS HEMORRHAGE

Patients with vitreous hemorrhage complain of sudden visual loss, abrupt onset of floaters that may progressively increase in severity or, occasionally, “bleeding within the eye.” Visual acuity ranges from 20/20 (6/6) to light perception only. The eye is not inflamed, and the clue to diagnosis is the inability to see fundal details clearly despite the presence of a clear lens. Causes of vitreous hemorrhage include diabetic retinopathy, retinal tears (with or without detachment), retinal vein occlusions, neovascular age-related macular degeneration, blood dyscrasias, trauma, and subarachnoid hemorrhage. In all cases, examination by an ophthalmologist is essential. Retinal tears and detachments necessitate urgent treatment (see above).

► When to Refer

All patients with suspected vitreous hemorrhage must be referred urgently to an ophthalmologist.

AGE-RELATED MACULAR DEGENERATION

ESSENTIALS OF DIAGNOSIS

- Older age group.
- Acute or chronic deterioration of central vision in one or both eyes.
- Distortion or abnormal size of images.
- No pain or redness.
- Macular abnormalities seen by ophthalmoscopy.

► General Considerations

In developed countries, age-related macular degeneration is the leading cause of permanent visual loss in the older population. The exact cause is unknown, but the prevalence increases with each decade over age 50 years (to almost 30% by age 75), and there is an association with genetically determined variations in the complement pathway. Other associated factors are race (usually white), sex (slight female predominance), family history, and cigarette smoking.

Age-related macular degeneration is classified into atrophic (“dry,” “geographic”) and neovascular (“wet,” “exudative”). Although both are progressive and usually bilateral, they differ in manifestations, prognosis, and management.

► Clinical Findings

The precursor to age-related macular degeneration is age-related maculopathy, characterized by retinal drusen. Hard drusen appear ophthalmoscopically as discrete yellow deposits. Soft drusen are larger, paler, and less distinct. Large, confluent soft drusen are particularly associated with neovascular age-related macular degeneration.

Atrophic degeneration is characterized by gradually progressive bilateral visual loss of moderate severity due to atrophy and degeneration of the outer retina and retinal pigment epithelium. In **neovascular degeneration**, choroidal new vessels grow between the retinal pigment epithelium and Bruch membrane, leading to accumulation of serous fluid, hemorrhage, and fibrosis. The onset of visual loss is more rapid and more severe in neovascular degeneration than in atrophic degeneration. The two eyes are frequently affected sequentially over a period of a few years. Neovascular disease accounts for about 90% of all cases of legal blindness due to age-related macular degeneration. Macular degeneration results in loss of central vision only. Peripheral fields and hence navigational vision are maintained, though these may become impaired by cataract formation for which surgery may be helpful.

► Treatment

In the Age-Related Eye Disease Study (AREDS), oral treatment with antioxidants (vitamin A [beta-carotene], vitamin C and vitamin E), and zinc and copper reduced the risk of disease progression in patients with moderate age-related maculopathy or severe disease in one eye, but there are concerns about long-term adverse effects and adherence to treatment is poor. Lack of disease progression has also been found to be associated with high dietary consumption of other carotenoids, lutein and zeaxanthin, and omega-3 long-chain polyunsaturated fatty acids, and with dietary supplementation with a combination of folic acid, vitamin B₆ and vitamin B₁₂ in women. Laser retinal photocoagulation results in regression of drusen but does not reduce the risk of disease progression.

Inhibitors of vascular endothelial growth factors (VEGF), including ranibizumab, pegaptanib, and bevacizumab, reverse the choroidal neovascularization, resulting in stabilization and less frequently improvement in vision in neovascular degeneration. They have to be administered by

intravitreal injection. Initial trials involved monthly injections for 2 years. Current studies are determining whether it is feasible to initially treat monthly for 3 months and then only when there is evidence of reactivation of disease. Treatment is well tolerated with minimal adverse effects, although there is a small risk of intraocular infection and inflammation, retinal detachment, or traumatic cataract.

There is no specific treatment for atrophic degeneration, but—as with the neovascular form—patients may benefit from low vision aids.

► When to Refer

Older patients developing sudden visual loss due to macular disease—particularly paracentral distortion or scotoma with preservation of central acuity—should be referred urgently to an ophthalmologist.

CENTRAL & BRANCH RETINAL VEIN OCCLUSIONS

ESSENTIALS OF DIAGNOSIS

- Sudden monocular loss of vision.
- No pain or redness.
- Widespread or sectoral retinal hemorrhages.

► General Considerations

All patients with retinal vein occlusion should be screened for diabetes, systemic hypertension, hyperlipidemia, and glaucoma. In younger patients, antiphospholipid antibodies, inherited thrombophilia, and hyperhomocysteinemia should be considered. Rarely, hyperviscosity syndromes, including myeloproliferative disorders, are associated with retinal vein occlusions and particularly should be considered in bilateral disease.

► Clinical Findings

A. Symptoms and Signs

The visual impairment in central retinal vein occlusion is commonly first noticed upon waking. Ophthalmoscopic signs include widespread retinal hemorrhages, retinal venous dilation and tortuosity, retinal cotton-wool spots, and optic disk swelling.

Branch retinal vein occlusions may present in a variety of ways. Sudden loss of vision may occur at the time of occlusion if the fovea is involved or some time afterward from vitreous hemorrhage due to retinal new vessels. More gradual visual loss may occur with development of macular edema. In acute branch retinal vein occlusion, the retinal abnormalities (hemorrhages, venous dilation and tortuosity, and cotton-wool spots) are confined to the area drained by the obstructed vein. Check blood pressure in all patients.

B. Laboratory Findings

Obtain screening studies for diabetes and hyperlipidemia. In younger patients, consider obtaining antiphospholipid antibodies, lupus anticoagulant, tests for inherited thrombophilia, and plasma homocysteine levels. Very high paraproteins, found on serum protein electrophoresis (particularly IgM), can cause hyperviscosity.

► Complications

If central retinal vein occlusion is associated with widespread retinal ischemia, manifesting as poor visual acuity (20/200 (6/60) or worse), florid retinal abnormalities, and extensive areas of capillary closure on fluorescein angiography, there is a high risk of development of neovascular (rubeotic) glaucoma, typically within first 3 months.

Branch retinal vein occlusion may be complicated by peripheral retinal neovascularization or chronic macular edema.

► Treatment

Eyes at risk of neovascular glaucoma following ischemic central retinal vein occlusion can be treated by panretinal laser photocoagulation either prophylactically or as soon as there is evidence of neovascularization, the latter approach necessitating frequent monitoring. Regression of iris neovascularization has been achieved with intravitreal injections of bevacizumab, an inhibitor of VEGF. In branch retinal vein occlusion complicated by retinal neovascularization, the ischemic retina should be laser photocoagulated.

Retinal laser photocoagulation may be indicated in chronic macular edema due to branch but not central retinal vein occlusion. Intravitreal injection of a VEGF inhibitor, ranibizumab, bevacizumab, or pegaptanib, is beneficial in chronic macular edema due to either branch or nonischemic central retinal vein occlusion. Intravitreal triamcinolone improves vision in chronic macular edema due to nonischemic central retinal vein occlusion, whereas an intravitreal implant containing dexamethasone is beneficial in both central and branch retinal vein occlusion.

Improvement in vision has been reported after vitrectomy with direct injection of tissue plasminogen activator into the retinal venous system or incision of the sclera at the edge of the optic disk (radial optic neurotomy). Improvement has also been reported after isovolemic hemodilution in central retinal vein occlusion and after vitrectomy alone or combined with surgical incision of the retinal vascular adventitia (arteriovenous sheathotomy) and injection of tissue plasminogen activator in branch retinal vein occlusion. However, the overall value of each technique remains uncertain.

► Prognosis

In central retinal vein occlusion, severity of visual loss initially is a good guide to visual outcome. Initial visual acuity of 20/60 (6/18) or better indicates a good prognosis. Visual prognosis is poor for eyes with neovascular glaucoma.

Visual outcome in branch retinal vein occlusion is determined by the severity of macular damage from hemorrhage, ischemia, or edema.

► When to Refer

All patients with retinal vein occlusion should be referred urgently to an ophthalmologist.

CENTRAL & BRANCH RETINAL ARTERY OCCLUSIONS

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden monocular loss of vision.
- ▶ No pain or redness.
- ▶ Widespread or sectoral retinal pallid swelling.

▶ General Considerations

In patients 50 years of age or older with central retinal artery occlusion, giant cell arteritis must be considered (see Ischemic Optic Neuropathy and Chapter 20). Carotid and cardiac sources of emboli must be sought in central and in branch retinal artery occlusion in particular, even if no retinal emboli are identified on ophthalmoscopy, so that appropriate treatment can be given to reduce the risk of stroke (see Chapters 12 and 14). Migraine, oral contraceptives, systemic vasculitis, congenital or acquired thrombophilia, and hyperhomocysteinemia should be considered in young patients. Internal carotid artery dissection should be considered when there is neck pain or a recent history of neck trauma. Diabetes, hyperlipidemia, and systemic hypertension should be considered in all patients.

▶ Clinical Findings

A. Symptoms and Signs

Central retinal artery occlusion presents as sudden profound monocular visual loss. Visual acuity is usually reduced to counting fingers or worse, and visual field is restricted to an island of vision in the temporal field. Ophthalmoscopy reveals pallid swelling of the retina, most obvious in the posterior segment, with a cherry-red spot at the fovea. The retinal arteries are attenuated, and “box-car” segmentation of blood in the veins may be seen. Occasionally, emboli are seen in the central retinal artery or its branches. The retinal swelling subsides over a period of 4–6 weeks, leaving a pale optic disk and attenuated arterioles with otherwise a relatively normal retinal appearance but thinning of the inner retina is detectable by optical coherence tomography.

Branch retinal artery occlusion may also present with sudden loss of vision if the fovea is involved, but more commonly sudden loss of visual field is the presenting complaint. Fundal signs of retinal swelling and adjacent cotton-wool spots are limited to the area of retina supplied by the occluded artery.

Evaluate all patients for arrhythmia, particularly atrial fibrillation, as well as cardiac murmurs. In addition, measure the patient’s blood pressure and identify risk factors for cardiac source of emboli. Clinical features of giant cell arteritis, which generally occurs in patients 50 years or older, include jaw claudication (which is very specific), headache, scalp tenderness, general malaise, weight loss,

symptoms of polymyalgia rheumatica, and tenderness, thickening, or absence of pulse of the superficial temporal arteries. Table 20–14 lists the clinical manifestations of vasculitis.

B. Laboratory Findings

Screen for diabetes and hyperlipidemia in all patients. Erythrocyte sedimentation rate and C-reactive protein are usually markedly elevated in giant cell arteritis but one or both may be normal. Consider screening for other types of vasculitis (see Table 20–13). In younger patients, consider obtaining antiphospholipid antibodies, lupus anticoagulant, tests for inherited thrombophilia and a plasma homocysteine level.

C. Imaging

Obtain duplex ultrasonography of the carotid arteries, ECG, and echocardiography, with transesophageal studies (if necessary), to identify carotid and cardiac sources of emboli and, when indicated, obtain CT or MR angiography for internal carotid artery dissection.

▶ Treatment

If the patient is seen within a few hours after onset, emergency treatment—including laying the patient flat, ocular massage, high concentrations of inhaled oxygen, intravenous acetazolamide, and anterior chamber paracentesis—may influence the visual outcome. Studies of early thrombolysis, particularly by local intra-arterial injection but also intravenously, have shown good results in central retinal artery occlusion not due to giant cell arteritis but the former method has a high incidence of adverse effects.

In giant cell arteritis, there is risk—highest in the first few days—of involvement of the other eye. When the diagnosis is suspected, high-dose corticosteroids (oral prednisolone 1–1.5 mg/kg/d, if necessary preceded by intravenous hydrocortisone 250–500 mg stat, or methylprednisolone 0.5–1 g/d for 1–3 days followed by oral prednisolone, especially in patients with bilateral visual loss) must be instituted immediately, possibly together with low-dose aspirin (~81 mg/d orally). The patient must be monitored closely to ensure that treatment is adequate. A temporal artery biopsy should be performed promptly, and if necessary, assistance should be sought from a rheumatologist.

▶ When to Refer

- Patients with central retinal artery occlusion should be referred emergently to an ophthalmologist.
- Patients with branch retinal artery occlusion should be referred urgently.

▶ When to Admit

Patients with visual loss due to giant cell arteritis may require emergency admission for high-dose corticosteroid

therapy and close monitoring to ensure that treatment is adequate.

TRANSIENT MONOCULAR BLINDNESS

ESSENTIALS OF DIAGNOSIS

- ▶ Monocular loss of vision usually lasting a few minutes with complete recovery.

Transient monocular blindness may be caused by retinal emboli from ipsilateral carotid disease or the heart. The visual loss is characteristically described as a curtain passing vertically across the visual field with complete monocular visual loss lasting a few minutes and a similar curtain effect as the episode passes (amaurosis fugax; also called “fleeting blindness”). Emboli are rarely seen on ophthalmoscopy. Other causes of temporary ocular

ischemia are giant cell arteritis, antiphospholipid syndrome, and severe occlusive carotid disease; in the last case, the visual loss characteristically occurs on exposure to bright light. More transient episodes of visual loss, lasting only a few seconds to 1 minute and affecting one or both eyes, occur in patients with raised intracranial pressure. In young patients, there is a benign form of transient visual loss that has been ascribed to choroidal or retinal vascular spasm.

▶ Diagnostic Studies

Clinical assessment and investigations are the same as for retinal artery occlusion (see above).

▶ Treatment

To reduce the risk of stroke, all patients with transient monocular blindness due to retinal emboli from ipsilateral carotid disease should be treated with oral aspirin (~ 81 mg daily), or another antiplatelet drug, and their vascular risk factors should be controlled. Patients with 70–99% stenosis and possibly those with 50–69% stenosis should be considered for early carotid endarterectomy or possibly angioplasty with stenting, but surgery is less likely to be necessary than in patients with cerebral hemispheric events (see Chapter 12).

In younger patients with the benign variant of transient monocular blindness, calcium channel blockers, such as slow-release nifedipine, 60 mg/d, may be effective.

▶ When to Refer

In all cases of episodic visual loss, early ophthalmologic consultation is advisable.

RETINAL DISORDERS ASSOCIATED WITH SYSTEMIC DISEASES

1. Diabetic Retinopathy

ESSENTIALS OF DIAGNOSIS

- ▶ Present in about 40% of diagnosed diabetic patients.
- ▶ Present in up to 20% of type 2 diabetic patients at diagnosis.
- ▶ Background retinopathy: mild retinal abnormalities without visual loss.
- ▶ Maculopathy: macular edema, exudates, or ischemia.
- ▶ Proliferative retinopathy: new retinal vessels.

▶ General Considerations

In the United States, diabetic retinopathy is present in about 40% of diagnosed diabetic patients. It is the leading cause of new blindness among adults aged 20–65 years; the number of affected individuals aged 65 years or older is particularly increasing. Retinopathy increases in prevalence and severity with increasing duration and poorer control of diabetes. In type 1 diabetes, retinopathy is not detectable for at least 3 years after diagnosis. In type 2 diabetes, retinopathy is present in up to 20% of patients at diagnosis and may be the presenting feature. It is broadly classified as **nonproliferative**, comprising **background retinopathy** and **maculopathy**, or **proliferative**. Maculopathy and proliferative retinopathy may coexist, particularly in severe disease.

▶ Clinical Findings

Nonproliferative retinopathy manifests as dilation of veins, microaneurysms, retinal hemorrhages, retinal edema, and hard exudates. In **background retinopathy**, the abnormalities are mild and do not cause any impairment of visual acuity. Pre-proliferative retinopathy is characterized by marked vascular abnormalities and retinal hemorrhages.

Maculopathy manifests as edema, exudates, or ischemia involving the macula (Figure 7–4). Assessment requires stereoscopic examination of the retina, retinal imaging with optical coherence tomography, and sometimes fluorescein angiography. Visual acuity is a poor guide to the presence of treatable maculopathy—hence the need for regular ophthalmologic follow-up. Maculopathy is the most common cause of legal blindness in type 2 diabetes.

Proliferative retinopathy is characterized by neovascularization, arising from either the optic disk or the major vascular arcades. Vitreous hemorrhage is a common sequela. Proliferation into the vitreous of blood vessels, with their associated fibrous component, may lead to tractional retinal detachment. Without treatment, the visual prognosis with proliferative retinopathy is generally much worse than that with nonproliferative retinopathy.

▶ **Figure 7–4.** Diabetic exudative maculopathy. (Courtesy of Victor Chong. Reproduced, with permission, from Riordan-Eva P, Cunningham ET Jr. *Vaughan & Asbury's General Ophthalmology*, 18th edition, McGraw-Hill, 2011.)

▶ Screening

Adult and adolescent patients with diabetes should undergo at least yearly screening by fundal photography, preferably after pupil dilation (mydriasis), or by slit-lamp examination after pupil dilation. (Failure to identify diabetic retinopathy by direct ophthalmoscopy is common, particularly if the pupils are not dilated. Non-mydriatic fundal photography, possibly with centralized screening by telemedicine, may increase rates of participation.) More frequent monitoring is required in women during pregnancy and in those planning pregnancy. Patients with type 2 diabetes mellitus should be screened shortly after diagnosis.

▶ Treatment

Treatment includes optimizing blood glucose, blood pressure, renal function, and serum lipids, although such measures are probably more important in preventing the development of retinopathy than in influencing its subsequent course.

Macular edema and exudates, but not ischemia, may respond to laser photocoagulation, intravitreal corticosteroid or VEGF inhibitor, or vitrectomy.

Proliferative retinopathy is usually treated by panretinal laser photocoagulation, preferably before vitreous hemorrhage or tractional detachment has occurred. Regression of neovascularization can also be achieved by intravitreal injection of a VEGF inhibitor. Determining whether panretinal laser photocoagulation should be undertaken for pre-proliferative retinopathy may be helped by assessing the degree of retinal ischemia on fluorescein angiography.

Vitreotomy is necessary for removal of persistent vitreous hemorrhage, to improve vision and allow panretinal laser photocoagulation for the underlying retinal neovascularization, for treatment of tractional retinal detachment involving the macula, and for management of rapidly progressive proliferative disease.

Proliferative diabetic retinopathy, especially after successful laser treatment, is not a contraindication to treatment with thrombolytic agents, aspirin, or warfarin unless there has been recent vitreous or pre-retinal hemorrhage.

▶ When to Refer

- All diabetic patients with sudden loss of vision or retinal detachment should be referred emergently to an ophthalmologist.
- Proliferative retinopathy or maculopathy requires urgent referral to an ophthalmologist.
- Pre-proliferative retinopathy or unexplained reduction of visual acuity requires early referral to an ophthalmologist.

2. Hypertensive Retinopathy

Systemic hypertension affects both the retinal and choroidal circulations. The clinical manifestations vary according to the degree and rapidity of rise in blood pressure and the underlying state of the ocular circulation. The most florid disease occurs in young patients with abrupt elevations of blood pressure, such as may occur in pheochromocytoma, malignant hypertension, or preeclampsia-eclampsia.

Chronic hypertension accelerates the development of atherosclerosis. The retinal arterioles become more tortuous and narrow and develop abnormal light reflexes (“silver-wiring” and “copper-wiring”). There is increased venous compression at the retinal arteriovenous crossings (“arteriovenous nicking”), an important factor predisposing to branch retinal vein occlusions. Flame-shaped hemorrhages occur in the nerve fiber layer of the retina.

Acute elevations of blood pressure result in loss of autoregulation in the retinal circulation, leading to the breakdown of endothelial integrity and occlusion of precapillary arterioles and capillaries. These pathologic changes are manifested as cotton-wool spots, retinal hemorrhages, retinal edema, and retinal exudates, often in a stellate appearance at the macula (see Figure 11–2). In the choroid, vasoconstriction and ischemia result in serous retinal detachments and retinal pigment epithelial infarcts. These infarcts later develop into pigmented lesions that may be focal, linear, or wedge-shaped. The abnormalities in the choroidal circulation may also affect the optic nerve head, producing ischemic optic neuropathy with optic disk swelling. Malignant hypertensive retinopathy was the term previously used to describe the constellation of clinical signs resulting from the combination of abnormalities in the retinal, choroidal, and optic disk circulation. When there is such severe disease, there is likely to be permanent retinal, choroidal, or optic nerve damage. Precipitous reduction of blood pressure may exacerbate such damage.

3. Blood Dyscrasias

In conditions characterized by severe thrombocytopenia or anemia, various types of hemorrhages occur in both the retina and choroid and may lead to visual loss. If the

macula is uninvolved, normal vision is usually regained after resolution of the hemorrhages.

Sickle cell retinopathy is particularly common in hemoglobin SC disease but may also occur with other hemoglobin S variants. Manifestations include “salmon-patch” preretinal/intraretinal hemorrhages, “black sunbursts” resulting from intraretinal hemorrhage, and new vessels. Severe visual loss is rare. Retinal laser photocoagulation reduces the frequency of vitreous hemorrhage from new vessels. Surgery is occasionally needed for persistent vitreous hemorrhage or tractional retinal detachment.

Elagouz M et al. Sickle cell disease and the eye: old and new concepts. *Surv Ophthalmol*. 2010 Jul 8;55(4):359–77. [PMID: 20452638]

4. AIDS

Cotton-wool spots, retinal hemorrhages, and microaneurysms are the most common ophthalmic abnormalities in AIDS patients.

CMV retinitis occurs when CD4 counts are below 50/mcL (or $0.05 \times 10^6/L$). It is characterized by progressively enlarging yellowish-white patches of retinal opacification, which are accompanied by retinal hemorrhages; they usually begin adjacent to the major retinal vascular arcades (Figure 7–5). Patients are often asymptomatic until there is involvement of the fovea or optic nerve or until retinal detachment develops.

Choices for initial therapy are (1) valganciclovir 900 mg orally twice daily for 3 weeks; (2) ganciclovir 5 mg/kg intravenously twice a day, foscarnet 60 mg/kg intravenously three times a day, or cidofovir 5 mg/kg intravenously once weekly, for 2–3 weeks; or (3) local administration, using either intravitreal injection of ganciclovir or foscarnet, or the sustained-release ganciclovir intravitreal implant. Major

side effects are neutropenia and thrombocytopenia with systemic ganciclovir and nephrotoxicity with foscarnet and cidofovir. Doses of both ganciclovir and foscarnet are adjusted in patients with renal failure. Oral probenecid and intravenous hydration are used to minimize nephrotoxicity from cidofovir. All available agents are virostatic. Maintenance therapy can be conducted with lower-dose therapy (oral valganciclovir 900 mg once daily, intravenous ganciclovir 5 mg/kg/d, intravenous foscarnet 90 mg/kg/d, or intravenous cidofovir 5 mg/kg once every 2 weeks) or with intravitreal therapy. Local therapy tends to be more effective than systemic therapy and avoids systemic side effects, but there is a risk of intraocular complications, and the incidence of retinitis in the fellow eye and of extraocular CMV infection is higher. Unresponsive disease or reactivation during maintenance therapy can be managed by changing to a different agent or by use of combination therapy. Retinal detachment, either due to retinitis or as a complication of intravitreal therapy, requires vitrectomy and intravitreal silicone oil. Pharmacologic prophylaxis against CMV retinitis in patients with low CD4 counts or high CMV burdens has not been found to be worthwhile.

In all patients with CMV retinitis, highly active antiretroviral therapy (HAART) needs to be instituted or adjusted. This may lead to the immune reconstitution inflammatory syndrome (IRIS), of which the immune recovery uveitis may lead to visual loss, predominantly due to cystoid macular edema. If the CD4 count is maintained above 100/mcL ($0.1 \times 10^6/L$), it may be possible to discontinue maintenance anti-CMV therapy.

Other ophthalmic manifestations of opportunistic infections occurring in AIDS patients include herpes simplex retinitis, toxoplasmic and candidal chorioretinitis, herpes zoster ophthalmicus, and various entities due to syphilis or tuberculosis. Kaposi sarcoma of the conjunctiva (see Chapter 31) and orbital lymphoma may also be seen on rare occasions.

ISCHEMIC OPTIC NEUROPATHY

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden painless visual loss with signs of optic nerve dysfunction.
- ▶ Optic disc swelling in anterior ischemic optic neuropathy.

Anterior ischemic optic neuropathy—due to inadequate perfusion of the posterior ciliary arteries that supply the anterior portion of the optic nerve—produces sudden visual loss, usually with an altitudinal field defect, and optic disk swelling. In older patients, it is often caused by giant cell arteritis, which necessitates emergency high-dose systemic corticosteroid treatment to prevent visual loss in the other eye. (See Central & Branch Retinal Artery Occlusions, above and Polymyalgia Rheumatica & Giant Cell Arteritis, Chapter 20.) The predominant factor predisposing to nonarteritic anterior ischemic optic neuropathy is a congenitally crowded optic disk. Other causative factors include systemic hypertension, diabetes mellitus, hyperlipidemia, systemic vasculitis, inherited or acquired thrombophilia, and possibly ingestion of sildenafil, interferon-alpha therapy, and sleep apnea. Rarely, an optic neuropathy that can be difficult to differentiate from nonarteritic anterior optic neuropathy can develop in patients taking amiodarone.

Ischemic optic neuropathy, usually involving the retrobulbar optic nerve and thus not causing any optic disk swelling (**posterior ischemic optic neuropathy**), may occur after severe blood loss or nonocular surgery, particularly prolonged lumbar spine surgery in the prone position.

▶ When to Refer

Patients with ischemic optic neuropathy should be referred urgently to an ophthalmologist.

▶ When to Admit

Patients with ischemic optic neuropathy due to giant cell arteritis may require emergency admission for high-dose corticosteroid therapy and close monitoring to ensure that treatment is adequate.

OPTIC NEURITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Subacute unilateral visual loss with signs of optic nerve dysfunction.
- ▶ Pain exacerbated by eye movements.
- ▶ Optic disc usually normal in acute stage but subsequently develops pallor.

▶ General Considerations

Inflammatory optic neuropathy (optic neuritis) is strongly associated with demyelinating disease, particularly multiple sclerosis but also acute disseminated encephalomyelitis. It also occurs in sarcoidosis; as a component of neuromyelitis optica (Devic syndrome); with viral infections (including measles, mumps, influenza and those caused by the varicella zoster virus); with various autoimmune disorders, particularly systemic lupus erythematosus; and by spread of inflammation from the meninges, orbital tissues, or paranasal sinuses.

▶ Clinical Findings

Optic neuritis in demyelinating disease is characterized by unilateral loss of vision, which usually develops over a few days. Vision ranges from 20/30 (6/9) to no perception of light. Commonly there is pain in the region of the eye, particularly on eye movements. Field loss is usually a central scotoma, but a wide range of monocular field defects is possible. There is marked loss of color vision and a relative afferent pupillary defect. In about two-thirds of cases, the optic nerve is normal during the acute stage (retrobulbar optic neuritis). In the remainder, the optic disk is swollen (papillitis) with occasional flame-shaped peripapillary hemorrhages. Visual acuity usually improves within 2–3 weeks and returns to 20/40 (6/12) or better in 95% of previously

unaffected eyes. Optic atrophy subsequently develops if there has been destruction of sufficient optic nerve fibers. Any patient with presumed demyelinating optic neuritis in which visual recovery does not occur or there are other atypical features, including continuing deterioration of vision or persisting pain after 2 weeks, should undergo further investigation, including CT or MRI of the head and orbits to exclude a lesion compressing the optic nerve.

► Treatment

In acute demyelinating optic neuritis, intravenous methylprednisolone (1 g daily for 3 days followed by a tapering course of oral prednisolone) has been shown to accelerate visual recovery, although in clinical practice, the oral taper is not often prescribed. Use in an individual patient is determined by the degree of visual loss, the state of the fellow eye, and the patient's visual requirements.

Optic neuritis due to sarcoidosis, neuromyelitis optica, herpes zoster, or systemic lupus erythematosus generally has a poorer prognosis, requires more prolonged corticosteroid therapy, and may necessitate long-term immunosuppression.

► Prognosis

Among patients with a first episode of clinically isolated optic neuritis, multiple sclerosis will develop in 50% within 15 years but the visual and neurologic prognosis is good. The major risk factors are female gender and multiple white matter lesions on brain MRI. In patients with multiple cerebral white matter lesions, long-term interferon therapy reduces the risk of subsequent development of multiple sclerosis by 25% at 5 years, although the effect on long-term disability remains uncertain and some patients do not respond. Other disease-modifying drugs are available.

► When to Refer

All patients with optic neuritis should be referred urgently for ophthalmologic or neurologic assessment.

OPTIC DISK SWELLING

Optic disk swelling may result from intraocular disease, orbital and optic nerve lesions, severe hypertensive retin-ochoroidopathy, or raised intracranial pressure, the last necessitating urgent imaging to exclude an intracranial mass or cerebral venous sinus occlusion. Intraocular causes include central retinal vein occlusion, posterior uveitis, and posterior scleritis. Optic nerve lesions causing disk swelling include optic neuritis; anterior ischemic optic neuropathy; optic disk drusen; optic nerve sheath meningioma; and nerve infiltration by sarcoidosis, leukemia, or lymphoma. Any orbital lesion causing nerve compression may produce disk swelling.

Papilledema (optic disk swelling due to raised intracranial pressure) is usually bilateral and most commonly produces enlargement of the blind spot without loss of acuity (Figure 7–6). Chronic papilledema, as in idiopathic intra-cranial hypertension and cerebral venous sinus occlusion, or severe acute papilledema may be associated with visual field loss and occasionally with profound loss of acuity. All patients with chronic papilledema must be monitored carefully—especially their visual fields—and cerebrospinal fluid shunt or optic nerve sheath fenestration should be considered in those with progressive visual failure not controlled by medical therapy (weight loss where appropriate and acetazolamide).

Optic disk drusen and congenitally crowded optic disks, which are associated with farsightedness, cause optic

▲ Figure 7-6. Severe acute papilledema.

disk elevation that may be mistaken for swelling (pseudopapilledema). Exposed optic disk drusen may be obvious clinically or can be demonstrated by their autofluorescence. Buried drusen are best detected by orbital ultrasound or CT scanning. Other family members may be similarly affected.

OCULAR MOTOR PALSIES

In complete **third nerve paralysis**, there is ptosis with a divergent and slightly depressed eye. Extraocular movements are restricted in all directions except laterally (preserved lateral rectus function). Intact fourth nerve (superior oblique) function is detected by the presence of inward rotation on attempted depression of the eye.

Pupillary involvement (dilated pupil that does not constrict to light) is an important sign differentiating “surgical,” including traumatic, from “medical” causes of isolated third nerve palsy. Compressive lesions of the third nerve—eg, aneurysm of the posterior communicating artery and uncus herniation due to a supratentorial mass lesion—characteristically have pupillary involvement. Patients with painful acute isolated third nerve palsy and pupillary involvement should be assumed to have a posterior communicating artery aneurysm until this has been excluded. Pituitary apoplexy is a rarer cause. Medical causes of isolated third nerve palsy include diabetes mellitus, hypertension, and giant cell arteritis.

Fourth nerve paralysis causes upward deviation of the eye with failure of depression on adduction. In acquired cases, there is vertical and torsional diplopia that are most apparent on looking down. Trauma is a major cause of acquired—particularly bilateral—fourth nerve palsy, but posterior fossa tumor and medical causes such as in third nerve palsies should also be considered. Similar clinical features are seen in congenital cases due to developmental anomaly of the nerve, muscle or tendon.

Sixth nerve paralysis causes convergent squint in the primary position with failure of abduction of the affected eye, producing horizontal diplopia that increases on gaze to the affected side and on looking into the distance. It is an important sign of raised intracranial pressure. Sixth nerve palsy may also be due to trauma, neoplasms,

brainstem lesions, or medical causes such as in third nerve palsy.

An intracranial or intraorbital mass lesion should be considered in any patient with an isolated ocular motor palsy. In patients with isolated ocular motor nerve palsies presumed to be due to medical causes, brain MRI is generally only necessary if recovery has not begun within 3 months, although some authors suggest that it should be undertaken in all cases.

Ocular motor nerve palsies occurring in association with other neurologic signs may be due to lesions in the brainstem, the cavernous sinus, or in the orbit. Lesions around the cavernous sinus involve the upper divisions of the trigeminal nerve, the ocular motor nerves, and occasionally the optic chiasm. Orbital apex lesions involve the optic nerve and the ocular motor nerves.

Myasthenia gravis and dysthyroid eye disease should also be considered in the differential diagnosis of disordered extraocular movements.

▶ When to Refer

- Any patient with recent onset isolated third nerve palsy, particularly if there is pupillary involvement or pain, must be referred emergently for neurologic assessment and possible CT, MR, or catheter angiography for intracranial aneurysm.
- All patients with recent onset double vision should be referred urgently to an ophthalmologist or neurologist, particularly if there is multiple cranial nerve dysfunction or other neurologic abnormalities.

▶ When to Admit

Patients with double vision due to giant cell arteritis may require emergency admission for high-dose corticosteroid therapy and close monitoring to ensure that treatment is adequate.

DYSTHYROID EYE DISEASE

Dysthyroid eye disease is a syndrome of clinical and orbital imaging abnormalities caused by deposition of mucopolysaccharides and infiltration with chronic inflammatory cells of the orbital tissues, particularly the extraocular muscles. It usually occurs in association with autoimmune hyperthyroidism, when it is known as Graves disease. However clinical or laboratory evidence of thyroid dysfunction and thyroid autoantibodies may not be detectable at presentation or even on long-term follow-up. Radioiodine therapy and cigarette smoking increase its severity.

Clinical Findings

The primary clinical features are proptosis, lid retraction and lid lag, conjunctival chemosis and episcleral inflammation, and extraocular muscle dysfunction. Resulting symptoms are cosmetic abnormalities, surface irritation, which usually responds to artificial tears, and diplopia, which should be treated conservatively (eg, with prisms) in the active stages of the disease and only by surgery when the disease has been static for at least 6 months. The important complications are corneal exposure and optic nerve compression, both of which may lead to marked visual loss. The primary imaging features are enlargement of the extraocular muscles, usually affecting both orbits.

Treatment

Treatment options for optic nerve compression or severe corneal exposure are intravenous pulse methylprednisolone therapy (eg, 1 g daily for 3 days, repeated weekly for 3 weeks), oral prednisolone 80–100 mg/d, radiotherapy, or surgery (usually consisting of extensive removal of bone from the medial, inferior, and lateral walls of the orbit), either singly or in combination.

The optimal management of moderately severe dysthyroid eye disease without visual loss is controversial. Systemic corticosteroids and radiotherapy have not been shown to provide definite long-term benefit. Peribulbar corticosteroid injections have been advocated. Surgical decompression may be justified in patients with marked proptosis. Lateral tarsorrhaphy may be used for moderately severe corneal exposure. Other procedures are particularly useful for correcting lid retraction but should not be undertaken until the orbital disease is quiescent and orbital decompression or extraocular muscle surgery has been undertaken. Oral selenium seems to be beneficial in mild disease. Establishing and maintaining euthyroidism are important in all cases.

When to Refer

All patients with dysthyroid eye disease should be referred to an ophthalmologist, urgently if there is reduced vision.

ORBITAL CELLULITIS

Orbital cellulitis is characterized by fever, proptosis, restriction of extraocular movements, and swelling with redness of the lids. Immediate treatment with intravenous antibiotics is necessary to prevent optic nerve damage and spread of infection to the cavernous sinuses, meninges, and brain. Infection of the paranasal sinuses is the usual underlying cause; examples of infecting organisms include *S pneumoniae*, other streptococci, *H influenzae* and, less commonly, *S aureus*. Penicillinase-resistant penicillin, such as nafcillin, is recommended, possibly together with metronidazole or clindamycin to treat anaerobic infections (Table 30–5). If trauma is the underlying cause, a cephalosporin, such as cefazolin or ceftriaxone, should be added to ensure coverage for *S aureus* and group A β -hemolytic streptococci. Vancomycin or clindamycin may be required if there is concern about methicillin-resistant *S aureus* (MRSA). For patients with penicillin hypersensitivity, vancomycin, levofloxacin, and metronidazole are recommended. The response to antibiotics is usually excellent, but abscess formation may necessitate surgical drainage. In immunocompromised patients, zygomycosis must be considered.

When to Refer

All patients with suspected orbital cellulitis must be referred emergently to an ophthalmologist.

OCULAR TRAUMA

1. Conjunctival & Corneal Foreign Bodies

If a patient complains of “something in my eye” and gives a consistent history, a foreign body is usually present on the cornea or under the upper lid even though it may not be visible. Visual acuity should be tested before treatment is instituted, as a basis for comparison in the event of complications.

After a local anesthetic (eg, proparacaine, 0.5%) is instilled, the eye is examined with a hand flashlight, using oblique illumination, and loupe. Corneal foreign bodies may be made more apparent by the instillation of sterile fluorescein. They are then removed with a sterile wet cotton-tipped applicator or hypodermic needle. Polymyxin-bacitracin ophthalmic ointment should be instilled. It is not necessary to patch the eye.

Steel foreign bodies usually leave a diffuse rust ring. This requires excision of the affected tissue and is best done under local anesthesia using a slit lamp. **Caution:** Anesthetic drops should not be given to the patient for self-administration.

If there is no infection, a layer of corneal epithelial cells will line the crater within 24 hours. The intact corneal epithelium forms an effective barrier to infection, but once it is disturbed the cornea becomes extremely susceptible to infection. Early infection is manifested by a white necrotic area around the crater and a small amount of gray exudate.

In the case of a foreign body under the upper lid, a local anesthetic is instilled and the lid is everted by grasping the lashes gently and exerting pressure on the mid portion of the outer surface of the upper lid with an applicator. If a foreign body is present, it can easily be removed by passing a wet sterile cotton-tipped applicator across the conjunctival surface.

► When to Refer

Urgent referral to an ophthalmologist should be arranged if a corneal foreign body cannot be removed or if there is suspicion of corneal infection.

Yagci A et al. Topical anesthetic abuse keratopathy: a commonly overlooked health care problem. *Cornea.* 2011 May;30(5):571–5. [PMID: 21490529]

2. Intraocular Foreign Body

Intraocular foreign body requires emergency treatment by an ophthalmologist. Patients giving a history of “something hitting the eye”—particularly while hammering on metal or using grinding equipment—must be assessed for this possibility, especially when no corneal foreign body is seen, a corneal or scleral wound is apparent, or there is marked visual loss or media opacity. Such patients must be treated as for corneal laceration (see below) and referred without delay. Intraocular foreign bodies significantly increase the risk of intraocular infection.

► When to Refer

Patients with suspected intraocular foreign body must be referred emergently to an ophthalmologist.

Bhagat N et al. Post-traumatic infectious endophthalmitis. *Surv Ophthalmol.* 2011 May–Jun;56(3):214–51. [PMID: 21397289]

3. Corneal Abrasions

A patient with a corneal abrasion complains of severe pain and photophobia. There is often a history of trauma to the eye, commonly involving a fingernail, piece of paper, or contact lens. Visual acuity is recorded, and the cornea and conjunctiva are examined with a light and loupe to rule out a foreign body. If an abrasion is suspected but cannot be seen, sterile fluorescein is instilled into the conjunctival sac: the area of corneal abrasion will stain a deeper green than the surrounding cornea.

Treatment includes polymyxin-bacitracin ophthalmic ointment, mydriatic (cyclopentolate 1%), and analgesics either topical or oral nonsteroidal anti-inflammatory agents. Padding the eye is probably not helpful for small abrasions. Recurrent corneal erosion may follow corneal abrasions.

4. Contusions

Contusion injuries of the eye and surrounding structures may cause ecchymosis (“black eye”), subconjunctival hemorrhage, edema or rupture of the cornea, hemorrhage into the anterior chamber (hyphema), rupture of the root of the iris (iridodialysis), paralysis of the pupillary sphincter, paralysis of the muscles of accommodation, cataract, dislocation of the lens, vitreous hemorrhage, retinal hemorrhage and edema (most common in the macular area), detachment of the retina, rupture of the choroid, fracture of the orbital floor (“blowout fracture”), or optic nerve injury. Many of these injuries are immediately obvious; others may not become apparent for days or weeks. The possibility of globe injury must always be considered in patients with facial injury, particularly if there is an orbital fracture. Patients with moderate to severe contusions should be seen by an ophthalmologist.

▲ **Figure 7-7.** Severe ocular injury with total hyphema. (Courtesy of James Augsburger; Reproduced, with permission, from Riordan-Eva P, Cunningham ET Jr. *Vaughn & Asbury's General Ophthalmology*, 18th edition, McGraw-Hill, 2011.)

Any injury causing hyphema involves the danger of secondary hemorrhage, which may cause intractable glaucoma with permanent visual loss (Figure 7–7). The patient should be advised to rest until complete resolution has occurred. Daily ophthalmologic assessment is essential. Aspirin and any drugs inhibiting coagulation increase the risk of secondary hemorrhage and are to be avoided. Sick cell anemia or trait adversely affects outcome.

► When to Refer

Patients with moderate or severe ocular contusion should be referred to an ophthalmologist, emergently if there is hyphema.

 Wei LA et al. Pediatric orbital floor fractures. *J AAPOS*. 2011 Apr;15(2):173–80. [PMID: 21596296]

5. Lacerations

A. Lids

If the lid margin is lacerated, the patient should be referred for specialized care, since permanent notching may result.

Lacerations of the lower eyelid near the inner canthus often sever the lower canaliculus, for which canalicular intubation is likely to be required. Lid lacerations not involving the margin may be sutured like any skin laceration.

Murchison AP et al. Management of eyelid injuries. *Facial Plast Surg*. 2010 Dec;26(6):464–81. [PMID: 21086233]
 Priel A et al. Medial canthal degloving injuries: the triad of telecanthus, ptosis, and lacrimal trauma. *Plast Reconstr Surg*. 2011 Oct;128(4):300e–5e. [PMID: 21921742]
 Tint NL et al. Eyelid avulsion repair with bi-canalicular silicone stenting without medial canthal tendon reconstruction. *Br J Ophthalmol*. 2011 Oct;95(10):1389–92. [PMID: 21775766]

B. Conjunctiva

In lacerations of the conjunctiva, sutures are not necessary. To prevent infection, sulfonamides or other antibiotics are instilled into the eye until the laceration is healed.

C. Cornea or Sclera

Patients with suspected corneal or scleral lacerations must be seen promptly by an ophthalmologist (Figure 7–8). Manipulation is kept to a minimum, since pressure may result in extrusion of the intraocular contents. The eye is bandaged lightly and covered with a metal shield that rests on the orbital bones above and below. The patient should be instructed not to squeeze the eye shut and to remain still. The eye is routinely imaged by radiography, and CT scanning if necessary, to identify and localize any metallic intraocular foreign body. MRI is contraindicated because of the risk of movement of the foreign body in the magnetic field. Endophthalmitis occurs in over 5% of open globe injuries.

► When to Refer

Patients with suspected globe laceration must be referred emergently to an ophthalmologist.

▲ **Figure 7-8.** Corneal laceration with extrusion of iris. (Courtesy of James Augsburger. Reproduced, with permission, from Riordan-Eva P, Cunningham ET Jr. *Vaughn & Asbury's General Ophthalmology*, 18th edition, McGraw-Hill, 2011.)

Patel SN et al. Diagnostic value of clinical examination and radiographic imaging in identification of intraocular foreign bodies in open globe injury. *Eur J Ophthalmol*. 2011 May 17. [Epub ahead of print] [PMID: 21607931]

ULTRAVIOLET KERATITIS (Actinic Keratitis)

Ultraviolet burns of the cornea are usually caused by use of a sunlamp without eye protection, exposure to a welding arc, or exposure to the sun when skiing (“snow blindness”). There are no immediate symptoms, but about 6–12 hours later the patient complains of agonizing pain and severe photophobia. Slit-lamp examination after instillation of sterile fluorescein shows diffuse punctate staining of both corneas.

Treatment consists of binocular patching and instillation of 1–2 drops of 1% cyclopentolate (to relieve the discomfort of ciliary spasm). All patients recover within 24–48 hours without complications. Local anesthetics should not be prescribed because they delay corneal epithelial healing.

Yagci A et al. Topical anesthetic abuse keratopathy: a commonly overlooked health care problem. *Cornea*. 2011 May;30(5):571–5. [PMID: 21490529]

CHEMICAL CONJUNCTIVITIS & KERATITIS

Chemical burns are treated by copious irrigation of the eyes with tap water, saline solution, or buffering solution if available as soon as possible after exposure. Neutralization of an acid with an alkali or vice versa generates heat and may cause further damage. Alkali injuries are more serious and require prolonged irrigation, since alkalies are not precipitated by the proteins of the eye as are acids. It is important to remove any retained particulate matter such as is typically present in injuries involving cement and building plaster. This may require double eversion of the upper lid. The pupil should be dilated with 1% cyclopentolate, 1 drop twice a day, to relieve discomfort and prophylactic topical antibiotics should be started. In moderate to severe injuries, intensive topical corticosteroids and topical and systemic vitamin C are also necessary. Complications include mucus deficiency, scarring of the cornea and conjunctiva, symblepharon (adhesions between the tarsal and bulbar conjunctiva), tear duct obstruction, and secondary

infection. It can be difficult to assess severity of chemical burns without slit-lamp examination.

TREATMENT OF OCULAR DISORDERS

Table 7–2 lists commonly used ophthalmic drugs and their indications and costs.

PRECAUTIONS IN MANAGEMENT OF OCULAR DISORDERS

1. Use of Local Anesthetics

Unsupervised self-administration of local anesthetics is dangerous because the patient may further injure an anesthetized eye without knowing it. The drug may also interfere with the normal healing process.

Yagci A et al. Topical anesthetic abuse keratopathy: a commonly overlooked health care problem. *Cornea*. 2011 May;30(5):571–5. [PMID: 21490529]

2. Pupillary Dilation

Dilating the pupil can very occasionally precipitate acute glaucoma if the patient has a narrow anterior chamber angle and should be undertaken with caution if the anterior chamber is obviously shallow (readily determined by oblique illumination of the anterior segment of the eye). A

short-acting mydriatic such as tropicamide should be used and the patient warned to report immediately if ocular discomfort or redness develops. Angle closure is more likely to occur if pilocarpine is used to overcome pupillary dilation than if the pupil is allowed to constrict naturally.

3. Corticosteroid Therapy

Repeated use of local corticosteroids presents several hazards: herpes simplex (dendritic) keratitis, fungal infection, open-angle glaucoma, and cataract formation. Furthermore, perforation of the cornea may occur when corticosteroids are used for herpes simplex keratitis. Topical nonsteroidal anti-inflammatory agents are being used increasingly. The potential for causing or exacerbating systemic hypertension, diabetes mellitus, gastritis, osteoporosis, or glaucoma must always be borne in mind when systemic corticosteroids are prescribed, such as for uveitis or giant cell arteritis.

Razeghinejad MR et al. Steroid-induced iatrogenic glaucoma. *Ophthalmic Res.* 2011 Jul 13;47(2):66–80. [PMID: 21757964]

4. Contaminated Eye Medications

Ophthalmic solutions are prepared with the same degree of care as fluids intended for intravenous administration, but once bottles are opened there is always a risk of contamination, particularly with solutions of tetracaine, proparacaine, fluorescein, and any preservative-free preparations. The most dangerous is fluorescein, as this solution is frequently contaminated with *P aeruginosa*, which can rapidly destroy the eye. Sterile fluorescein filter paper strips are recommended for use in place of fluorescein solutions.

Whether in plastic or glass containers, eye solutions should not remain in use for long periods after the bottle is opened. Four weeks after opening is an absolute maximal time to use a solution containing preservatives before discarding. Preservative-free preparations should be kept refrigerated and discarded within 1 week after opening.

If the eye has been injured accidentally or by surgical trauma, it is of the greatest importance to use freshly opened bottles of sterile medications or single-use eye-dropper units.

5. Toxic & Hypersensitivity Reactions to Topical Therapy

In patients receiving long-term topical therapy, local toxic or hypersensitivity reactions to the active agent or preservatives may develop, especially if there is inadequate tear secretion. Preservatives in contact lens cleaning solutions may produce similar problems. Burning and soreness are exacerbated by drop instillation or contact lens insertion; occasionally, fibrosis and scarring of the conjunctiva and cornea may occur.

An antibiotic instilled into the eye can sensitize the patient to that drug and cause an allergic reaction upon subsequent systemic administration.

6. Systemic Effects of Ocular Drugs

The systemic absorption of certain topical drugs (through the conjunctival vessels and lacrimal drainage system) must be considered when there is a systemic medical contraindication to the use of the drug. Ophthalmic solutions of the nonselective β -blockers, eg, timolol, may worsen bradycardia, congestive heart failure, or asthma. Phenylephrine eye drops may precipitate hypertensive crises and angina. Also to be considered are adverse interactions between systemically administered and ocular drugs. Using only 1 or 2 drops at a time and a few minutes of nasolacrimal occlusion or eyelid closure ensure maximum efficacy and decrease systemic side effects of topical agents.

ADVERSE OCULAR EFFECTS OF SYSTEMIC DRUGS

Systemically administered drugs produce a wide variety of adverse effects on the visual system. Table 7–3 lists the major examples.

 Razeghinejad MR et al. Non-steroidal drug-induced glaucoma. *Eye (Lond).* 2011 Aug;25(8):971–80. [PMID: 21637303]

Table 7–3. Adverse ophthalmic effects of systemic drugs.

Drug	Possible Side Effects
Respiratory drugs	
Anticholinergic bronchodilators	Angle-closure glaucoma due to mydriasis, blurring of vision due to cycloplegia, dry eyes.
Oxygen	Retinopathy of prematurity.
Sympathomimetic bronchodilators and decongestants	Angle-closure glaucoma due to mydriasis.
Cardiovascular system drugs	
α_2 -Antagonists (terazosin, doxazosin)	Complications during (floppy-iris syndrome) and after cataract surgery.

(continued)

Table 7-3. Adverse ophthalmic effects of systemic drugs. (continued)

Drug	Possible Side Effects
Amiodarone	Corneal deposits (vortex keratopathy), optic neuropathy, thyroid ophthalmopathy.
Carbonic anhydrase inhibitors (acetazolamide)	Stevens-Johnson syndrome, near-sightedness, angle-closure glaucoma due to ciliary body swelling.
Digitalis	Disturbance of color vision, photopsia.
Phosphodiesterase type 5 inhibitors (eg, sildenafil)	Disturbance of color vision, ischemic optic neuropathy.
Statins	Extraocular muscle paralysis (myasthenic syndrome).
Thiazides	Xanthopsia (yellow vision), near-sightedness.
Gastrointestinal drugs	
Anticholinergic agents	Angle-closure glaucoma due to mydriasis, blurring of vision due to cycloplegia, dry eyes.
Urinary tract drugs	
α_2 -Antagonists (tamsulosin, alfuzosin, terazosin, doxazosin)	Complications during (floppy-iris syndrome) and after cataract surgery.
Central nervous system drugs	
Amphetamines	Widening of palpebral fissure, blurring of vision due to mydriasis, elevated intraocular pressure.
Anticholinergic agents including preoperative medications	Angle-closure glaucoma due to mydriasis, blurring of vision due to cycloplegia, dry eyes.
Diazepam	Nystagmus.
Haloperidol	Capsular cataract.
Lithium carbonate	Proptosis, oculozytic crisis, nystagmus.
Monoamine oxidase inhibitors	Nystagmus.
Morphine	Miosis.
Neostigmine	Nystagmus, miosis.
Paroxetine	Angle-closure glaucoma.
Phenothiazines	Pigmentary deposits in conjunctiva, cornea, lens, and retina, oculozytic crisis.
Phenytoin	Nystagmus.
Risperidone	Complications during (floppy-iris syndrome) and after cataract surgery.
Thioridazine	Corneal and lens deposits, retinopathy, oculozytic crisis.
Topiramate	Angle-closure glaucoma due to ciliary body swelling, near-sightedness.
Tricyclic agents	Angle-closure glaucoma due to mydriasis, blurring of vision due to cycloplegia.
Vigabatrin	Visual field constriction.
Obstetric drugs	
Sympathomimetic tocolytics	Angle-closure glaucoma due to mydriasis.
Hormonal agents	
Female sex hormones	Retinal artery occlusion, retinal vein occlusion, papilledema, cranial nerve palsies, ischemic optic neuropathy.
Tamoxifen	Crystalline retinal and corneal deposits, optic neuropathy.
Immunomodulators	
Alpha-interferon	Retinopathy, keratoconjunctivitis, dry eyes, optic neuropathy.
Corticosteroids	Cataract (posterior subcapsular); susceptibility to viral (herpes simplex), bacterial, and fungal infections; steroid-induced glaucoma.
Cyclosporine	Posterior reversible leukoencephalopathy.
Tacrolimus	Optic neuropathy, posterior reversible leukoencephalopathy.

(continued)

Table 7-3. Adverse ophthalmic effects of systemic drugs. (continued)

Drug	Possible Side Effects
Antibacterials	
Chloramphenicol	Optic neuropathy.
Ethambutol	Optic neuropathy.
Fluoroquinolones	Diplopia.
Isoniazid	Optic neuropathy.
Linezolid	Optic neuropathy.
Streptomycin	Optic neuropathy, Stevens-Johnson syndrome.
Sulfonamides	Stevens-Johnson syndrome, near-sightedness, angle-closure glaucoma due to ciliary body swelling.
Tetracycline, doxycycline, minocycline	Papilledema.
Antimalarial agents	
Chloroquine, hydroxychloroquine	Retinal degeneration principally involving the macula, keratopathy.
Quinine	Retinal toxicity, pupillary abnormalities.
Amebicides	
Iodochlorhydroxyquin	Optic neuropathy.
Chemotherapeutic agents	
Chlorambucil	Optic neuropathy.
Cisplatin	Optic neuropathy
Fluorouracil	Lacrimal obstruction.
Vincristine	Optic neuropathy.
Chelating agents	
Deferoxamine	Retinopathy, optic neuropathy, lens opacity.
Penicillamine	Ocular pemphigoid, optic neuropathy, extraocular muscle paralysis (myasthenic syndrome).
Oral hypoglycemic agents	
Chlorpropamide	Refractive error, Stevens-Johnson syndrome, optic neuropathy.
Vitamins	
Vitamin A	Papilledema.
Vitamin D	Band-shaped keratopathy.
Antirheumatic agents	
Gold salts	Deposits in the cornea, conjunctiva, and lens.
Indomethacin	Corneal deposits.
Penicillamine	Ocular pemphigoid, optic neuropathy, extraocular muscle paralysis (myasthenic syndrome).
Phenylbutazone	Retinal hemorrhages.
Salicylates	Subconjunctival and retinal hemorrhages, nystagmus.
Dermatologic agents	
Retinoids (isotretinoin, tretinoin, acitretin, and etretinate)	Papilledema, blepharoconjunctivitis, corneal opacities, decreased contact lens tolerance, decreased dark adaptation, teratogenic ocular abnormalities.
Bisphosphonates	
Alendronate	Scleritis, episcleritis, uveitis.
Pamidronate	Scleritis, episcleritis, uveitis.

Ear, Nose, & Throat Disorders

Lawrence R. Lustig, MD, &
Joshua S. Schindler, MD

DISEASES OF THE EAR

HEARING LOSS

ESSENTIALS OF DIAGNOSIS

- ▶ Three main types of hearing loss: conductive, sensory, and neural.
- ▶ Most commonly due to cerumen impaction, transient eustachian tube dysfunction associated with upper respiratory tract infection, or age-related hearing loss.

▶ Classification & Epidemiology

Table 8–1 categorizes hearing loss as normal, mild, moderate, severe, and profound and outlines the vocal equivalent as well as the decibel range.

A. Conductive Hearing Loss

Conductive hearing loss results from dysfunction of the external or middle ear. There are four mechanisms, each resulting in impairment of the passage of sound vibrations to the inner ear: (1) obstruction (eg, cerumen impaction), (2) mass loading (eg, middle ear effusion), (3) stiffness effect (eg, otosclerosis), and (4) discontinuity (eg, ossicular disruption). Conductive losses in adults are most commonly due to cerumen impaction or transient eustachian tube dysfunction associated with upper respiratory tract infection. Persistent conductive losses usually result from chronic ear infection, trauma, or otosclerosis. Conductive hearing loss is often correctable with medical or surgical therapy—or in some cases both.

B. Sensory Hearing Loss

Sensory and neural causes of hearing loss are difficult to differentiate due to testing methodology, thus often referred to as ‘sensorineural.’ Sensory hearing loss results

from deterioration of the cochlea, usually due to loss of hair cells from the organ of Corti. Sensorineural losses in adults are common. The most common form is a gradually progressive, predominantly high-frequency loss with advancing age (presbycusis). Additional common causes include excessive noise exposure, head trauma, and systemic diseases. An individual’s genetic make-up influences all of these causes of hearing loss. Sensory hearing loss is usually not correctable with medical or surgical therapy but often may be prevented or stabilized. An exception is a sudden sensory hearing loss, which may respond to corticosteroids if delivered within several weeks of onset.

Rauch SD et al. Oral vs intratympanic corticosteroid therapy for idiopathic sudden sensorineural hearing loss: a randomized trial. *JAMA*. 2011 May 25;305(20):2071–9. [PMID: 21610239]

Shearer AE et al. Deafness in the genomics era. *Hear Res*. 2011 Dec;282(1–2):1–9. [PMID: 22016077]

C. Neural Hearing Loss

Neural hearing loss occurs with lesions involving the eighth nerve, auditory nuclei, ascending tracts, or auditory cortex. It is the least common clinically recognized cause of hearing loss. Causes include acoustic neuroma, multiple sclerosis, and auditory neuropathy.

Manchaiah VK et al. The genetic basis of auditory neuropathy spectrum disorder (ANSD). *Int J Pediatr Otorhinolaryngol*. 2011 Feb;75(2):151–8. [PMID: 21176974]

▶ Evaluation of Hearing (Audiology)

In a quiet room, the hearing level may be estimated by having the patient repeat aloud words presented in a soft whisper, a normal spoken voice, or a shout. A 512-Hz tuning fork is useful in differentiating conductive from

Table 8-1. Hearing loss classification.

Classification	Vocal Equivalent	Decibel (dB) Range
Normal	Soft whisper	0-20 dB
Mild	Soft spoken voice	20-40 dB
Moderate	Normal spoken	40-60 dB
Severe	Loud spoken voice	60-80 dB
Profound	Shout	>80 dB

sensorineural losses. In the **Weber test**, the tuning fork is placed on the forehead or front teeth. In conductive losses, the sound appears louder in the poorer-hearing ear, whereas in sensorineural losses it radiates to the better side. In the **Rinne test**, the tuning fork is placed alternately on the mastoid bone and in front of the ear canal. In conductive losses > 25dB, bone conduction exceeds air conduction; in sensorineural losses, the opposite is true.

Formal audiometric studies are performed in a sound-proofed room. Pure-tone thresholds in decibels (dB) are obtained over the range of 250–8000 Hz for both air and bone conduction. Conductive losses create a gap between the air and bone thresholds, whereas in sensorineural losses both air and bone thresholds are equally diminished. Speech discrimination measures the clarity of hearing, reported as percentage correct (90–100% is normal). The site of the lesion responsible for sensorineural loss (cochlea versus central auditory system) may be determined with auditory brainstem-evoked responses; however, an MRI scan is preferred for its better sensitivity and specificity in the evaluation of central lesions.

Every patient who complains of a hearing loss should be referred for audiologic evaluation unless the cause is easily remediable (eg, cerumen impaction, otitis media). Because idiopathic sudden sensorineural hearing loss requires treatment (corticosteroids) within a limited several week time period, any new-onset hearing loss without obvious ear pathology needs an immediate audiometric referral. Routine audiologic screening is recommended for adults who have been exposed to potentially injurious levels of noise or in those who have reached the age of 65, after which screening evaluations may be done every few years.

▶ Hearing Rehabilitation

Patients with hearing loss not correctable by medical therapy may benefit from hearing amplification. Contemporary hearing aids are comparatively free of distortion and have been miniaturized to the point where they often may be contained entirely within the ear canal or lie inconspicuously behind the ear. To optimize the benefit, a hearing aid

must be carefully selected to conform to the nature of the hearing loss. Digitally programmable hearing aids are widely available and allow optimization of speech intelligibility and improved performance in difficult listening circumstances. Aside from hearing aids, many assistive devices are available to improve comprehension in individual and group settings, to help with hearing television and radio programs, and for telephone communication.

For patients with conductive loss or unilateral profound sensorineural loss, the bone-anchored hearing aid uses an oscillating post drilled into the mastoid, directly stimulating the ipsilateral cochlea (for conductive losses) or contralateral ear (profound unilateral sensorineural loss).

For patients with severe to profound sensory hearing loss, the cochlear implant—an electronic device that is surgically implanted into the cochlea to stimulate the auditory nerve—offers socially beneficial auditory rehabilitation to most adults with acquired deafness and children with congenital or genetic deafness. New trends in cochlear implantation include its use for patients with only partial deafness, preserving residual hearing and allowing both acoustic and electrical hearing in the same ear, as well as bilateral cochlear implantation.

DISEASES OF THE AURICLE

Disorders of the auricle are for the most part dermatologic. Skin cancers due to sun exposure are common and may be treated with standard techniques. Traumatic auricular hematoma must be recognized and drained to prevent significant cosmetic deformity (cauliflower ear) or canal blockage resulting from dissolution of supporting cartilage. Similarly, cellulitis of the auricle must be treated promptly to prevent development of perichondritis and its resultant deformity. Relapsing polychondritis is a rheumatologic disorder often associated with recurrent, frequently bilateral, painful episodes of auricular erythema and edema. Treatment with corticosteroids may help forestall cartilage dissolution. Respiratory compromise may occur as a result of progressive involvement of the cartilaginous tracheobronchial tree. Chondritis and perichondritis may be differentiated from auricular cellulitis by sparing of involvement of the lobule, which does not contain cartilage.

DISEASES OF THE EAR CANAL

1. Cerumen Impaction

Cerumen is a protective secretion produced by the outer portion of the ear canal. In most persons, the ear canal is self-cleansing. Recommended hygiene consists of cleaning the external opening with a washcloth over the index finger without entering the canal itself. In most cases, cerumen impaction is self-induced through ill-advised attempts at cleaning the ear. It may be relieved with detergent ear drops (eg, 3% hydrogen peroxide; 6.5% carbamide peroxide), mechanical removal, suction, or irrigation. Irrigation is performed with water at body temperature to avoid a vestibular caloric response. The stream should be directed at the posterior ear canal wall adjacent to the cerumen plug. Irrigation should be performed only when the tympanic membrane is known to be intact.

Use of jet irrigators designed for cleaning teeth (eg, WaterPik) for wax removal should be avoided since they may result in tympanic membrane perforations. Following professional irrigation, the ear canal should be thoroughly dried (eg, by instilling isopropyl alcohol or using a hair blow-dryer on low-power setting) to reduce the likelihood of inducing external otitis. Specialty referral for cleaning under microscopic guidance is indicated when the impaction is frequently recurrent, has not responded to routine measures, or if the patient has a history of chronic otitis media or tympanic membrane perforation.

Roland PS et al. Clinical practice guideline: cerumen impaction. *Otolaryngol Head Neck Surg.* 2008 Sep;139(3 Suppl 2):S1–S21. [PMID: 18707628]

2. Foreign Bodies

Foreign bodies in the ear canal are more frequent in children than in adults. Firm materials may be removed with a loop or a hook, taking care not to displace the object medially toward the tympanic membrane; microscopic guidance is helpful. Aqueous irrigation should not be performed for organic foreign bodies (eg, beans, insects), because water may cause them to swell. Living insects are best immobilized before removal by filling the ear canal with lidocaine.

Burton M et al. Foreign body in the external auditory canal. *Ear Nose Throat J.* 2009 Jul;88(7):988. [PMID: 19623522]

3. External Otitis

ESSENTIALS OF DIAGNOSIS

- ▶ Painful erythema and edema of the ear canal skin.
- ▶ Often with purulent exudate
- ▶ May evolve into osteomyelitis of the skull base, often called malignant external otitis, particularly in the diabetic or immunocompromised patient.

▶ General Considerations

External otitis presents with otalgia, frequently accompanied by pruritus and purulent discharge. There is often a history of recent water exposure (ie, swimmer's ear) or mechanical trauma (eg, scratching, cotton applicators). External otitis is usually caused by gram-negative rods (eg, *Pseudomonas*, *Proteus*) or fungi (eg, *Aspergillus*), which grow in the presence of excessive moisture. Persistent external otitis in the diabetic or immunocompromised patient may evolve into osteomyelitis of the skull base, often called **malignant external otitis**. Usually caused by *Pseudomonas aeruginosa*, osteomyelitis begins in the floor of the ear canal and may extend into the middle fossa floor, the clivus, and even the contralateral skull base.

▶ Clinical Findings

Examination reveals erythema and edema of the ear canal skin, often with a purulent exudate. Manipulation of the auricle often elicits pain. Because the lateral surface of the tympanic membrane is ear canal skin, it is often erythematous. However, in contrast to acute otitis media, it moves normally with pneumatic otoscopy. When the canal skin is very edematous, it may be impossible to visualize the tympanic membrane. **Malignant external otitis** usually presents with persistent foul aural discharge, granulations in the ear canal, deep otalgia, and in advanced cases, progressive cranial nerve palsies involving nerves VI, VII, IX, X, XI, or XII. Diagnosis is confirmed by the demonstration of osseous erosion on CT and radionuclide scanning.

▶ Treatment

Fundamental to the treatment of external otitis is protection of the ear from additional moisture and avoidance of further mechanical injury by scratching. In cases of swimmer's ear, acidification with a drying agent (ie, a 50/50 mixture of isopropyl alcohol/white vinegar) after getting moisture into the ear is often helpful. When infected, acidic otic antibiotic drops that contain either an aminoglycoside or fluoroquinolone antibiotic, with or without corticosteroids, are usually effective (eg, neomycin sulfate, polymyxin B sulfate, and hydrocortisone). Purulent debris filling the ear canal should be gently removed to permit entry of the topical medication. Drops should be used abundantly (five or more drops three or four times a day) to penetrate the depths of the canal. When substantial edema of the canal wall prevents entry of drops into the ear canal, a wick is placed to facilitate entry of the medication. In recalcitrant cases—particularly when cellulitis of the periauricular tissue has developed—oral fluoroquinolones (eg, ciprofloxacin, 500 mg twice daily for 1 week) are the drugs of choice because of their effectiveness against *Pseudomonas* species. Any case of persistent otitis externa in an immunocompromised or diabetic individual must be referred for specialty evaluation.

Treatment of **malignant external otitis** is medical, requiring prolonged antipseudomonal antibiotic administration, often for several months. Although intravenous therapy is often required (eg, ciprofloxacin 200–400 mg

every 12 hours), selected patients may be treated with oral ciprofloxacin (500–1000 mg twice daily), which has proved effective against many of the causative *Pseudomonas* strains. To avoid relapse, antibiotic therapy should be continued, even in the asymptomatic patient, until gallium scanning indicates a marked reduction in the inflammatory process. Surgical debridement of infected bone is reserved for cases of deterioration despite medical therapy.

4. Pruritus

Pruritus of the external auditory canal, particularly at the meatus, is a common problem. While it may be associated with external otitis or with dermatologic conditions such as seborrheic dermatitis and psoriasis, most cases are self-induced either from excoriation or by overly zealous ear cleaning. To permit regeneration of the protective cerumen blanket, patients should be instructed to avoid use of soap and water or cotton swabs in the ear canal and avoid any scratching. Patients with excessively dry canal skin may benefit from application of mineral oil, which helps counteract dryness and repel moisture. When an inflammatory component is present, topical application of a corticosteroid (eg, 0.1% triamcinolone) may be beneficial. Symptomatic reduction of pruritus may also be obtained by use of oral antihistamines (eg, diphenhydramine, 25 mg orally at bedtime).

Acar B et al. New treatment strategy and assessment questionnaire for external auditory canal pruritus: topical pimecrolimus therapy and Modified Itch Severity Scale. *J Laryngol Otol.* 2010 Feb;124(2):147–51. [PMID: 19922703]
 Garvey C et al. A review of common dermatologic disorders of the external ear. *J Am Acad Audiol.* 2008 Mar;19(3):226–32. [PMID: 18672650]

5. Exostoses & Osteomas

Bony overgrowths of the ear canal are a frequent incidental finding and occasionally have clinical significance. Clinically, they present as skin-covered bony mounds in the medial ear canal obscuring the tympanic membrane to a variable degree. Solitary osteomas are of no significance as long as they do not cause obstruction or infection. Multiple exostoses, which are generally acquired from repeated exposure to cold water (eg, “surfer’s ear”) often progress and require surgical removal.

King JF et al. Laterality of exostosis in surfers due to evaporative cooling effect. *Otol Neurotol.* 2010 Feb;31(2):345–51. [PMID: 19806064]

6. Neoplasia

The most common neoplasm of the ear canal is squamous cell carcinoma (SCC). When an apparent otitis externa does not resolve on therapy, a malignancy should be suspected and biopsy performed. This disease carries a very high 5-year mortality rate because the tumor tends to invade the lymphatics of the cranial base and must be treated with wide surgical resection and radiation therapy. Adenomatous tumors, originating from the ceruminous glands, generally follow a more indolent course.

Chang CH et al. Treatments and outcomes of malignant tumors of external auditory canal. *Am J Otolaryngol.* 2009 Jan–Feb; 30(1):44–8. [PMID: 19027512]
 Prabhu R et al. Squamous cell carcinoma of the external auditory canal: long-term clinical outcomes using surgery and external-beam radiotherapy. *Am J Clin Oncol.* 2009 Aug; 32(4):401–4. [PMID: 19398900]

DISEASES OF THE EUSTACHIAN TUBE

1. Eustachian Tube Dysfunction

ESSENTIALS OF DIAGNOSIS

- ▶ Aural fullness.
- ▶ Fluctuating hearing.
- ▶ Discomfort with barometric pressure change.
- ▶ At risk for serous otitis media.

The tube that connects the middle ear to the nasopharynx—the eustachian tube—provides ventilation and drainage for the middle ear cleft. It is normally closed, opening only during swallowing or yawning. When eustachian tube function is compromised, air trapped within the middle ear becomes absorbed and negative pressure results. The most common causes of eustachian tube dysfunction are diseases associated with edema of the tubal lining, such as viral upper respiratory tract infections and allergy. The patient usually reports a sense of fullness in the ear and mild to moderate impairment of hearing. When the tube is only partially blocked, swallowing or yawning may elicit a popping or crackling sound. Examination may reveal retraction of the tympanic membrane and decreased mobility on pneumatic otoscopy. Following a viral illness, this disorder is usually transient, lasting days to weeks. Treatment with systemic and intranasal decongestants (eg, pseudoephedrine, 60 mg orally every 4 hours; oxymetazoline, 0.05% spray every 8–12 hours) combined with autoinflation by forced exhalation against closed nostrils may hasten relief. Autoinflation should not be recommended to patients with active intranasal infection, since this maneuver may precipitate middle ear infection. Allergic patients

may also benefit from desensitization or intranasal corticosteroids (eg, beclomethasone dipropionate, two sprays in each nostril twice daily for 2–6 weeks). Air travel, rapid altitudinal change, and underwater diving should be avoided during an active phase of the disease.

Conversely, an overly patent eustachian tube, termed “patulous eustachian tube,” is a relatively uncommon problem, though may be quite distressing. Typical complaints include fullness in the ear and autophony, an exaggerated ability to hear oneself breathe and speak. A patulous eustachian tube may develop during rapid weight loss, or it may be idiopathic. In contrast to a hypofunctioning eustachian tube, the aural pressure is often made worse by exertion and may diminish during an upper respiratory tract infection. Although physical examination is usually normal, respiratory excursions of the tympanic membrane may occasionally be detected during vigorous breathing. Treatment includes avoidance of decongestant products, insertion of a ventilating tube to reduce the outward stretch of the eardrum during phonation, and, rarely, surgical narrowing of the eustachian tube.

Bartlett C et al. Simple mass loading of the tympanic membrane to alleviate symptoms of patulous eustachian tube. *J Otolaryngol Head Neck Surg.* 2010 Jun;39(3):259–68. [PMID: 20470670]

Caffier PP et al. Impact of laser eustachian tuboplasty on middle ear ventilation, hearing, and tinnitus in chronic tube dysfunction. *Ear Hear.* 2011 Feb;32(1):132–9. [PMID: 20585250]

Daudia A et al. Long-term middle-ear ventilation with subannular tubes. *J Laryngol Otol.* 2010 Sep;124(9):945–9. [PMID: 20403228]

2. Serous Otitis Media

ESSENTIALS OF DIAGNOSIS

- ▶ Blocked eustachian tube remains for a prolonged period.
- ▶ Resultant negative pressure will result in transudation of fluid.

Prolonged eustachian tube dysfunction with resultant negative middle ear pressure may cause a transudation of fluid. This condition, known as serous otitis media, is especially common in children because their eustachian tubes are narrower and more horizontal in orientation than those in adults. Serous otitis media is less common in adults, in whom it usually occurs after an upper respiratory tract infection, with barotraumas, or with chronic allergic rhinitis. In any adult with persistent unilateral serous otitis media, nasopharyngeal carcinoma must be excluded. The tympanic membrane in serous otitis media is dull and hypomobile, occasionally accompanied by air bubbles in the middle ear and conductive hearing loss. The treatment of serous otitis media is similar to that for eustachian tube dysfunction. A short course of oral corticosteroids (eg, prednisone, 40 mg/d for 7 days) has been advocated by some clinicians, as have oral antibiotics (eg, amoxicillin,

250 mg three times daily for 7 days)—or even a combination of the two. The role of these regimens remains controversial, but they are probably of little lasting benefit.

When medication fails to bring relief after several months, a ventilating tube placed through the tympanic membrane may restore hearing and alleviate the sense of aural fullness. Endoscopically guided laser expansion of the nasopharyngeal orifice of the eustachian tube may improve function in recalcitrant cases.

Campbell RG et al. Management of otitis media with effusion in children with primary ciliary dyskinesia: a literature review. *Int J Pediatr Otorhinolaryngol.* 2009 Dec;73(12):1630–8. [PMID: 19796826]

Skoner AR et al. Allergic rhinitis, histamine, and otitis media. *Allergy Asthma Proc.* 2009 Sep–Oct;30(5):470–81. [PMID: 19843400]

3. Barotrauma

Persons with poor eustachian tube function (eg, congenital narrowness or acquired mucosal edema) may be unable to equalize the barometric stress exerted on the middle ear by air travel, rapid altitudinal change, or underwater diving. The problem is generally most acute during airplane descent, since the negative middle ear pressure tends to collapse and block the eustachian tube. Several measures are useful to enhance eustachian tube function and avoid otic barotrauma. The patient should be advised to swallow, yawn, and autoinflate frequently during descent, which may be painful if the eustachian tube collapses. Systemic decongestants (eg, pseudoephedrine, 60–120 mg) should be taken several hours before anticipated arrival time so that they will be maximally effective during descent. Topical decongestants such as 1% phenylephrine nasal spray should be administered 1 hour before arrival.

For acute negative middle ear pressure that persists on the ground, treatment includes decongestants and attempts at autoinflation. Myringotomy (creation of a small eardrum perforation) provides immediate relief and is appropriate in the setting of severe otalgia and hearing loss. Repeated episodes of barotrauma in persons who must fly frequently may be alleviated by insertion of ventilating tubes.

Underwater diving may represent an even a greater barometric stress to the ear than flying. The problem occurs most commonly during the descent phase, when pain develops within the first 15 feet if inflation of the middle ear via the eustachian tube has not occurred. Divers must descend slowly and equilibrate in stages to avoid the development of severely negative pressures in the tympanum that may result in hemorrhage (hemotympanum) or perilymphatic fistula. In the latter, the oval or round window ruptures, resulting in sensory hearing loss and acute vertigo. Emesis due to acute labyrinthine dysfunction can be very dangerous during an underwater dive. Sensory hearing loss or vertigo, which develops during the ascent phase of a saturation dive, may be the first (or only) symptom of decompression sickness. Immediate recompression will return intravascular gas bubbles to solution and restore the inner ear microcirculation. Patients should be

warned to avoid diving when they have upper respiratory infections or episodes of nasal allergy. Tympanic membrane perforation is an absolute contraindication to diving, as the patient will experience an unbalanced thermal stimulus to the semicircular canals and may experience vertigo, disorientation, and even emesis.

Duplessis C et al. Exploiting otoacoustic emission testing to identify clinical and subclinical inner ear barotrauma in divers: potential risk factor for sensorineural hearing loss. *J Otolaryngol Head Neck Surg.* 2009 Feb;38(1):67–76. [PMID: 19344615]

DISEASES OF THE MIDDLE EAR

1. Acute Otitis Media

ESSENTIALS OF DIAGNOSIS

- ▶ Otolgia, often with an upper respiratory tract infection.
- ▶ Erythema and hypomobility of tympanic membrane.

▶ General Considerations

Acute otitis media is a bacterial infection of the mucosally lined air-containing spaces of the temporal bone. Purulent material forms not only within the middle ear cleft but also within the pneumatized mastoid air cells and petrous apex. Acute otitis media is usually precipitated by a viral upper respiratory tract infection that causes eustachian tube obstruction. This results in accumulation of fluid and mucus, which becomes secondarily infected by bacteria. The most common pathogens both in adults and in children are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Streptococcus pyogenes*.

▶ Clinical Findings

Acute otitis media is most common in infants and children, although it may occur at any age. Presenting symptoms and signs include otalgia, aural pressure, decreased hearing, and often fever. The typical physical findings are erythema and decreased mobility of the tympanic membrane. Occasionally, bullae will be seen on the tympanic membrane.

Rarely, when middle ear empyema is severe, the tympanic membrane can bulge outward. In such cases, tympanic membrane rupture is imminent. Rupture is accompanied by a sudden decrease in pain, followed by the onset of otorrhea. With appropriate therapy, spontaneous healing of the tympanic membrane occurs in most cases. When perforation persists, chronic otitis media may evolve. Mastoid tenderness often accompanies acute otitis media and is due to the presence of pus within the mastoid air cells. This alone does not indicate suppurative (surgical) mastoiditis. Frank swelling over the mastoid bone or the

association of cranial neuropathies or central findings indicates severe disease requiring urgent care.

▶ Treatment

The treatment of acute otitis media is specific antibiotic therapy, often combined with nasal decongestants. The first-choice oral antibiotic treatment is amoxicillin (20–40 mg/kg/d) or erythromycin (50 mg/kg/d) plus sulfonamide (150 mg/kg/d) for 10 days. Alternatives useful in resistant cases are cefaclor (20–40 mg/kg/d) or amoxicillin-clavulanate (20–40 mg/kg/d) combinations.

Tympanocentesis for bacterial (aerobic and anaerobic) and fungal culture may be performed by any experienced physician. A 20-gauge spinal needle bent 90 degrees to the hub attached to a 3-mL syringe is inserted through the inferior portion of the tympanic membrane. Interposition of a pliable connecting tube between the needle and syringe permits an assistant to aspirate without inducing movement of the needle. Tympanocentesis is useful for otitis media in immunocompromised patients and when infection persists or recurs despite multiple courses of antibiotics.

Surgical drainage of the middle ear (myringotomy) is reserved for patients with severe otalgia or when complications of otitis (eg, mastoiditis, meningitis) have occurred.

Recurrent acute otitis media may be managed with long-term antibiotic prophylaxis. Single daily oral doses of sulfamethoxazole (500 mg) or amoxicillin (250 or 500 mg) are given over a period of 1–3 months. Failure of this regimen to control infection is an indication for insertion of ventilating tubes.

Coco A et al. Management of acute otitis media after publication of the 2004 AAP and AAFP clinical practice guideline. *Pediatrics.* 2010 Feb;125(2):214–20. [PMID: 20100746]

Gunasekera H et al. Management of children with otitis media: a summary of evidence from recent systematic reviews. *J Paediatr Child Health.* 2009 Oct;45(10):554–62. [PMID: 19751382]

2. Chronic Otitis Media

ESSENTIALS OF DIAGNOSIS

- ▶ Chronic otorrhea with or without otalgia.
- ▶ Tympanic membrane perforation with conductive hearing loss.
- ▶ Often amenable to surgical correction.

▶ General Considerations

Chronic infection of the middle ear and mastoid generally develops as a consequence of recurrent acute otitis media, although it may follow other diseases and trauma. Perforation of the tympanic membrane is usually present. This may be accompanied by mucosal changes such as polypoid degeneration and granulation tissue and osseous changes such as osteitis and sclerosis. The bacteriology of chronic otitis media differs from that of acute otitis media. Common organisms include *P aeruginosa*, *Proteus* species, *Staphylococcus aureus*, and mixed anaerobic infections.

► Clinical Findings

The clinical hallmark of chronic otitis media is purulent aural discharge. Drainage may be continuous or intermittent, with increased severity during upper respiratory tract infection or following water exposure. Pain is uncommon except during acute exacerbations. Conductive hearing loss results from destruction of the tympanic membrane or ossicular chain, or both.

► Treatment

The medical treatment of chronic otitis media includes regular removal of infected debris, use of earplugs to protect against water exposure, and topical antibiotic drops for exacerbations. The activity of ciprofloxacin against *Pseudomonas* may help dry a chronically discharging ear when given in a dosage of 500 mg orally twice a day for 1–6 weeks.

Definitive management is surgical in most cases. Tympanic membrane repair may be accomplished with temporalis muscle fascia. Successful reconstruction of the tympanic membrane may be achieved in about 90% of cases, often with elimination of infection and significant improvement in hearing. When the mastoid air cells are involved by irreversible infection, they should be exenterated at the same time through a mastoidectomy.

Hartzell LD et al. Timing of tympanoplasty in children with chronic otitis media with effusion. *Curr Opin Otolaryngol Head Neck Surg.* 2010 Dec;18(6):550–3. [PMID: 21045692]
 Morris PS et al. Acute and chronic otitis media. *Pediatr Clin North Am.* 2009 Dec;56(6):1383–99. [PMID: 19962027]

► Complications of Otitis Media

A. Cholesteatoma

Cholesteatoma is a special variety of chronic otitis media (Figure 8–1). The most common cause is prolonged eustachian tube dysfunction, with resultant chronic negative middle ear pressure that draws inward the upper flaccid portion of the tympanic membrane. This creates a squamous epithelium-lined sac, which—when its neck becomes obstructed—may fill with desquamated keratin and become chronically infected. Cholesteatomas typically erode bone, with early penetration of the mastoid and destruction of the ossicular chain. Over time they may erode into the inner ear, involve the facial nerve, and on rare occasions spread intracranially. Otoscopic examination may reveal an epitympanic retraction pocket or a marginal tympanic membrane perforation that exudes keratin debris, or granulation tissue. The treatment of cholesteatoma is surgical marsupialization of the sac or its complete removal. This may require the creation of a “mastoid bowl” in which the ear canal and mastoid are joined into a large common cavity that must be periodically cleaned.

B. Mastoiditis

Acute suppurative mastoiditis usually evolves following several weeks of inadequately treated acute otitis media. It is characterized by postauricular pain and erythema accompanied by a spiking fever. CT scan reveals coalescence of the mastoid air cells due to destruction of their bony septa. Initial treatment consists of intravenous antibiotics directed against the most common offending organisms (eg, cefazolin 0.5–1.5 g every 6–8 hours), and myringotomy for culture and drainage. Failure of medical therapy indicates the need for surgical drainage (mastoidectomy).

Groth A et al. Acute mastoiditis in children in Sweden 1993–2007—no increase after new guidelines. *Int J Pediatr Otorhinolaryngol.* 2011 Dec;75(12):1496–501. [PMID: 21945244]
 Osborn AJ et al. Decisions regarding intracranial complications from acute mastoiditis in children. *Curr Opin Otolaryngol Head Neck Surg.* 2011 Sep 15. [Epub ahead of print] [PMID: 21926622]

C. Petrous Apicitis

The medial portion of the petrous bone between the inner ear and clivus may become a site of persistent infection when the drainage of its pneumatic cell tracts becomes blocked. This may cause foul discharge, deep ear and retro-orbital pain, and sixth nerve palsy (Gradenigo syndrome); meningitis may be a complication. Treatment is with prolonged antibiotic therapy (based on culture results) and surgical drainage via petrous apicectomy.

Wanna GB et al. Contemporary management of intracranial complications of otitis media. *Otol Neurotol*. 2010 Jan;31(1):111–7. [PMID: 19887978]

D. Facial Paralysis

Facial palsy may be associated with either acute or chronic otitis media. In the acute setting, it results from inflammation of the seventh nerve in its middle ear segment, perhaps mediated through bacterially secreted neurotoxins. Treatment consists of myringotomy for drainage and culture, followed by intravenous antibiotics (based on culture results). The use of corticosteroids is controversial. The prognosis is excellent, with complete recovery in most cases.

Facial palsy associated with chronic otitis media usually evolves slowly due to chronic pressure on the seventh nerve in the middle ear or mastoid by cholesteatoma. Treatment requires surgical correction of the underlying disease. The prognosis is less favorable than for facial palsy associated with acute otitis media.

Lorch M et al. Facial nerve palsy: etiology and approach to diagnosis and treatment. *Pediatr Emerg Care*. 2010 Oct;26(10):763–9. [PMID: 20930602]

Yonamine FK et al. Facial paralysis associated with acute otitis media. *Braz J Otorhinolaryngol*. 2009 Mar–Apr;75(2):228–30. [PMID: 19575108]

E. Sigmoid Sinus Thrombosis

Trapped infection within the mastoid air cells adjacent to the sigmoid sinus may cause septic thrombophlebitis. This is heralded by signs of systemic sepsis (spiking fevers, chills), at times accompanied by signs of increased intracranial pressure (headache, lethargy, nausea and vomiting, papilledema). Diagnosis can be made noninvasively by magnetic resonance venography. Primary treatment is with intravenous antibiotics (based on culture results). Surgical drainage with ligation of the internal jugular vein may be indicated when embolization is suspected.

Thorne MC et al. Suppurative complications of acute otitis media: changes in frequency over time. *Arch Otolaryngol Head Neck Surg*. 2009 Jul;135(7):638–41. [PMID: 19620582]

F. Central Nervous System Infection

Otogenic meningitis is by far the most common intracranial complication of ear infection. In the setting of acute suppurative otitis media, it arises from hematogenous spread of bacteria, most commonly *H influenzae* and *S pneumoniae*. In chronic otitis media, it results either from passage of infections along preformed pathways such as the petrosquamous suture line or from direct extension of disease through the dural plates of the petrous pyramid.

Epidural abscesses arise from direct extension of disease in the setting of chronic infection. They are usually asymptomatic but may present with deep local pain, headache, and low-grade fever. They are often discovered as an incidental finding at surgery. Brain abscess may arise in the

temporal lobe or cerebellum as a result of septic thrombophlebitis adjacent to an epidural abscess. The predominant causative organisms are *S aureus*, *S pyogenes*, and *S pneumoniae*. Rupture into the subarachnoid space results in meningitis and often death. (See Chapter 30.)

Wanna GB et al. Contemporary management of intracranial complications of otitis media. *Otol Neurotol*. 2010 Jan;31(1):111–7. [PMID: 19887978]

3. Otosclerosis

Otosclerosis is a progressive disease with a marked familial tendency that affects the bony otic capsule. Lesions involving the footplate of the stapes result in increased impedance to the passage of sound through the ossicular chain, producing conductive hearing loss. This may be treated either through the use of a hearing aid or surgical replacement of the stapes with a prosthesis (stapedectomy). When otosclerotic lesions impinge on the cochlea ('cochlear otosclerosis'), permanent sensory hearing loss occurs. Some evidence suggests that hearing loss associated with cochlear otosclerosis may be stabilized by treatment with oral sodium fluoride over prolonged periods of time (Floral—8.3 mg sodium fluoride and 364 mg calcium carbonate—two tablets orally each morning).

Cruise AS et al. Sodium fluoride in otosclerosis treatment: review. *J Laryngol Otol*. 2010 Jun;124(6):583–6. [PMID: 20163750]

Kisilevsky VE et al. Results of stapedotomy in otosclerosis with severe and profound hearing loss. *J Otolaryngol Head Neck Surg*. 2010 Jun;39(3):244–52. [PMID: 20470668]

Markou K et al. An overview of the etiology of otosclerosis. *Eur Arch Otorhinolaryngol*. 2009 Jan;266(1):25–35. [PMID: 18704474]

4. Trauma to the Middle Ear

Tympanic membrane perforation may result from impact injury or explosive acoustic trauma (Figure 8–2). Spontaneous healing occurs in most cases. Persistent perforation may result from secondary infection brought on by exposure to water. Patients should be advised to wear earplugs while swimming or bathing during the healing period. Hemorrhage behind an intact tympanic membrane (hemotympanum) may follow blunt trauma or extreme barotrauma. Spontaneous resolution over several weeks is the usual course. When a conductive hearing loss > 30 dB persists for more than 3 months following trauma, disruption of the ossicular chain should be suspected. Middle ear exploration with reconstruction of the ossicular chain, combined with repair of the tympanic membrane when required, will usually restore hearing.

Mick P et al. Penetrating and blast ear trauma: 7-year review of two pediatric practices. *J Otolaryngol Head Neck Surg*. 2008 Dec;37(6):774–6. [PMID: 19128702]

▲ **Figure 8-2.** Traumatic perforation of the left tympanic membrane. (Courtesy of William Clark, MD; used with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger, J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

5. Middle Ear Neoplasia

Primary middle ear tumors are rare. Glomus tumors arise either in the middle ear (glomus tympanicum) or in the jugular bulb with upward erosion into the hypotympanum (glomus jugulare). They present clinically with pulsatile tinnitus and hearing loss. A vascular mass may be visible behind an intact tympanic membrane. Large glomus jugulare tumors are often associated with multiple cranial neuropathies, especially involving nerves VII, IX, X, XI, and XII. Treatment usually requires surgery, radiotherapy, or both. Pulsatile tinnitus thus warrants magnetic resonance angiography and venography to rule out a vascular mass.

Alaani A et al. The crucial role of imaging in determining the approach to glomus tympanicum tumours. *Eur Arch Otorhinolaryngol*. 2009 Jun;26(6):827–31. [PMID: 18841375]

EARACHE

Earache can be caused by a variety of otologic problems, but external otitis and acute otitis media are most the common. Differentiation of the two should be apparent by pneumatic otoscopy (see above relevant sections on otitis externa and otitis media). Pain out of proportion to the physical findings may be due to herpes zoster oticus, especially when vesicles appear in the ear canal or concha. Persistent pain and discharge from the ear suggest osteomyelitis of the skull base or cancer, and patients with these complaints should be referred for specialty evaluation.

Nonotologic causes of otalgia are numerous. The sensory innervation of the ear is derived from the trigeminal, facial, glossopharyngeal, vagal, and upper cervical nerves.

Because of this rich innervation, referred otalgia is quite frequent. Temporomandibular joint dysfunction is a common cause of referred ear pain. Pain is exacerbated by chewing or psychogenic grinding of the teeth (bruxism) and may be associated with dental malocclusion. Management includes soft diet, local heat to the masticatory muscles, massage, nonsteroidal anti-inflammatory medications, and dental referral. Repeated episodes of severe lancinating otalgia may occur in glossopharyngeal neuralgia. Treatment with carbamazepine (100–300 mg orally every 8 hours) often confers substantial symptomatic relief. Severe glossopharyngeal neuralgia, which is refractory to medical management, may respond to microvascular decompression of the ninth cranial nerve. Infections and neoplasia that involve the oropharynx, hypopharynx, and larynx frequently cause otalgia. Persistent earache demands specialty referral to exclude cancer of the upper aerodigestive tract.

Neilan RE et al. Otalgia. *Med Clin North Am*. 2010 Sep;94(5):961–71. [PMID: 20736106]

DISEASES OF THE INNER EAR

1. Sensory Hearing Loss

Diseases of the cochlea result in sensory hearing loss, a condition that is usually irreversible. Most cochlear diseases result in bilateral symmetric hearing loss. The presence of unilateral or asymmetric sensorineural hearing loss suggests a lesion proximal to the cochlea. Lesions affecting the eighth cranial nerve and central auditory system are discussed in the section on neural hearing loss. The primary goals in the management of sensory hearing loss are prevention of further losses and functional improvement with amplification and auditory rehabilitation.

A. Presbycusis

Presbycusis, or age-related hearing loss, is the most frequent cause of sensory hearing loss and is progressive, predominantly high-frequency, and symmetrical. It is difficult to separate the various etiologic factors (eg, noise trauma, drug exposure) that may contribute to presbycusis, but genetic predisposition and prior noise exposure appear to play an important role. Most patients notice a loss of speech discrimination that is especially pronounced in noisy environments. About 25% of people between the ages of 65 and 75 years and almost 50% of those over 75 experience hearing difficulties.

Ko J. Presbycusis and its management. *Br J Nurs*. 2010 Feb 11–24;19(3):160–5. [PMID: 20220659]

Schneider JM et al. Role of general practitioners in managing age-related hearing loss. *Med J Aust*. 2010 Jan 4;192(1):20–3. [PMID: 20047543]

Sprinzel GM et al. Current trends in treating hearing loss in elderly people: a review of the technology and treatment options—a mini-review. *Gerontology*. 2010;56(3):351–8. [PMID: 20090297]

B. Noise Trauma

Noise trauma is the second most common cause of sensory hearing loss. Sounds exceeding 85 dB are potentially injurious to the cochlea, especially with prolonged exposures. The loss typically begins in the high frequencies (especially 4000 Hz) and progresses to involve the speech frequencies with continuing exposure. Among the more common sources of injurious noise are industrial machinery, weapons, and excessively loud music. Personal music devices (eg, MP3 and CD players) used at excessive loudness levels may also be potentially injurious. Monitoring noise levels in the workplace by regulatory agencies has led to preventive programs that have reduced the frequency of occupational losses. Individuals of all ages, especially those with existing hearing losses, should wear earplugs when exposed to moderately loud noises and specially designed earmuffs when exposed to explosive noises.

Henderson E et al. Prevalence of noise-induced hearing-threshold shifts and hearing loss among US youths. *Pediatrics.* 2011 Jan;127(1):e39–46. [PMID: 21187306]

C. Physical Trauma

Head trauma has effects on the inner ear similar to those of severe acoustic trauma. Some degree of sensory hearing loss may occur following simple concussion and is frequent after skull fracture. Deployment of air bags during an automobile accident has also been associated with hearing loss.

Mick P et al. Penetrating and blast ear trauma: 7-year review of two pediatric practices. *J Otolaryngol Head Neck Surg.* 2008 Dec;37(6):774–6. [PMID: 19128702]

D. Ototoxicity

Ototoxic substances may affect both the auditory and vestibular systems. The most commonly used ototoxic medications are aminoglycosides; loop diuretics; and several antineoplastic agents, notably cisplatin. These medications may cause irreversible hearing loss even when administered in therapeutic doses. When using these medications, it is important to identify high-risk patients such as those with preexisting hearing losses or kidney disease. Patients simultaneously receiving multiple ototoxic agents are at particular risk owing to ototoxic synergy. Useful measures to reduce the risk of ototoxic injury include serial audiometry and monitoring of serum peak and trough levels and substitution of equivalent nonototoxic drugs whenever possible. Efforts are underway to develop strategies, known as ototoxic chemoprotection, using drugs that shield the inner ear from damage during ototoxic exposure.

It is possible for topical agents that enter the middle ear to be absorbed into the inner ear via the round window. When the tympanic membrane is perforated, use of potentially

ototoxic ear drops (eg, neomycin, gentamicin) is best avoided.

Konrad-Martin D et al. Evaluation of audiometric threshold shift criteria for ototoxicity monitoring. *J Am Acad Audiol.* 2010 May;21(5):301–14. [PMID: 20569665]

E. Sudden Sensory Hearing Loss

Idiopathic sudden loss of hearing in one ear may occur at any age, but typically, it occurs in persons over age 20 years. The cause is unknown; however, one hypothesis is that it results from a viral infection or a sudden vascular occlusion of the internal auditory artery. Prognosis is mixed, with many patients suffering permanent deafness in the involved ear while others have complete recovery. Prompt treatment with corticosteroids has been shown to improve the odds of recovery. A common regimen is oral prednisone, 1 mg/kg/d, followed by a tapering dose over a 10-day period. Intratympanic administration of corticosteroids alone or in association with oral corticosteroids is increasingly being used for this problem and has been associated with an equal or more favorable prognosis in some reports. Because treatment appears to be most effective as close to the onset of the loss as possible, and appears not to be effective after 6 weeks, a prompt audiogram should be obtained in all patients who present with sudden hearing loss without obvious middle ear pathology.

F. Hereditary Hearing Loss

Sensory hearing loss with onset during adult life often runs in families. The mode of inheritance may be either autosomal dominant or recessive. The age at onset, the rate of progression of hearing loss, and the audiometric pattern (high-frequency, low-frequency, or flat) can often be predicted by studying family members. Great strides have been made in identifying the molecular genetic errors associated with hereditary hearing loss. The connexin-26 mutation, the most common cause of genetic deafness, may be tested clinically. Hearing loss is also frequently found in hereditary mitochondrial disorders. Progress is being made toward the development of methods to restore lost hair cells in genetic and other forms of deafness via gene therapy or stem cell–mediated techniques.

 Shearer AE et al. Deafness in the genomics era. *Hear Res.* 2011 Dec;282(1–2):1–9. [PMID: 22016077]

G. Autoimmune Hearing Loss

Sensory hearing loss may be associated with a wide array of systemic autoimmune disorders such as systemic lupus erythematosus, granulomatosis with polyangiitis (formerly Wegener granulomatosis), and Cogan syndrome (hearing loss, keratitis, aortitis). The loss is most often bilateral and progressive. The hearing level often fluctuates, with periods of deterioration alternating with partial or even complete remission. The tendency is for the gradual evolution of permanent hearing loss, which usually stabilizes with some remaining auditory function but occasionally proceeds to complete deafness. Vestibular dysfunction, particularly dysequilibrium and postural instability, may accompany the auditory symptoms. A syndrome resembling Ménière disease may also occur with intermittent attacks of severe vertigo.

In many cases, the autoimmune pattern of audiovestibular dysfunction presents in the absence of recognized systemic autoimmune disease. Use of laboratory tests to screen for autoimmune disease (eg, antinuclear antibody, rheumatoid factor, erythrocyte sedimentation rate) may be informative. Specific tests of immune reactivity against inner ear antigens (anticochlear antibodies, lymphocyte transformation tests) are currently of interest for research purposes only, demonstrating limited clinical value to date. Responsiveness to oral corticosteroid treatment is helpful in making the diagnosis and constitutes first-line therapy. If stabilization of hearing becomes dependent on long-term corticosteroid use, steroid-sparing immunosuppressive regimens may become necessary.

Alexander TH et al. Safety of high-dose corticosteroids for the treatment of autoimmune inner ear disease. *Otol Neurotol.* 2009 Jun;30(4):443–8. [PMID: 19395984]
 Buniel MC et al. Immunosuppressive therapy for autoimmune inner ear disease. *Immunotherapy.* 2009 May;1(3):425–34. [PMID: 19885385]

2. Tinnitus

Tinnitus is the perception of abnormal ear or head noises. Persistent tinnitus often, though not always, indicates the presence of sensory hearing loss. Intermittent periods of mild, high-pitched tinnitus lasting seconds to minutes are common in normal-hearing persons. When severe and persistent, tinnitus may interfere with sleep and the ability to concentrate, resulting in considerable psychological distress.

The most important treatment of tinnitus is avoidance of exposure to excessive noise, ototoxic agents, and other factors that may cause cochlear damage. Masking the tinnitus with music or through amplification of normal

sounds with a hearing aid may also bring some relief. Among the numerous drugs that have been tried, oral antidepressants (eg, nortriptyline at an initial dosage of 50 mg orally at bedtime) have proved to be the most effective. Habituation techniques, such as tinnitus retraining therapy, and masking techniques may prove beneficial in those with refractory symptoms. Transcranial magnetic stimulation of the central auditory system has been shown to improve symptoms in some patients. Progress is also being made toward implantable brain stimulators to treat tinnitus.

Pulsatile tinnitus—often described by the patient as listening to one’s own heartbeat—should be distinguished from tonal tinnitus. Although often ascribed to conductive hearing loss, this symptom may be far more serious and may indicate a vascular abnormality such as glomus tumor, venous sinus stenosis, carotid vaso-occlusive disease, arteriovenous malformation, or aneurysm. Magnetic resonance angiography and venography should be considered to establish the diagnosis.

In contrast, a staccato “clicking” tinnitus may result from middle ear muscle spasm, sometimes associated with palatal myoclonus. The patient typically perceives a rapid series of popping noises, lasting seconds to a few minutes, accompanied by a fluttering feeling in the ear.

Adjajian P et al. The mechanisms of tinnitus: perspectives from human functional neuroimaging. *Hear Res.* 2009 Jul;253(1–2):15–31. [PMID: 19364527]

 Meng Z et al. Repetitive transcranial magnetic stimulation for tinnitus. *Cochrane Database Syst Rev.* 2011 Oct 5;(10):CD007946. [PMID: 21975776]

3. Hyperacusis

Excessive sensitivity to sound may occur in normal-hearing individuals either in association with ear disease, following noise trauma, in patients susceptible to migraines, or for psychological reasons. Patients with cochlear dysfunction commonly experience “recruitment,” an abnormal sensitivity to loud sounds despite a reduced sensitivity to softer ones. Fitting hearing aids and other amplification devices to patients with recruitment requires use of compression circuitry to avoid uncomfortable overamplification. For normal-hearing individuals with hyperacusis, use of an earplug in noisy environments may be beneficial, though attempts should be made at habituation.

Gu JW et al. Tinnitus, diminished sound-level tolerance, and elevated auditory activity in humans with clinically normal hearing sensitivity. *J Neurophysiol.* 2010 Dec;104(6):3361–70. [PMID: 20881196]
 Meeus OM et al. Correlation between hyperacusis measurements in daily ENT practice. *Int J Audiol.* 2010 Jan;49(1):7–13. [PMID: 20053152]

4. Vertigo

ESSENTIALS OF DIAGNOSIS

- ▶ Either a sensation of motion when there is no motion or an exaggerated sense of motion in response to movement.
- ▶ Duration of vertigo episodes and association with hearing loss is the key to diagnosis.
- ▶ Must differentiate peripheral from central etiologies of vestibular dysfunction.
- ▶ **Peripheral:** Onset is sudden; often associated with tinnitus and hearing loss; horizontal nystagmus may be present.
- ▶ **Central:** Onset is gradual; no associated auditory symptoms.
- ▶ Evaluation includes audiogram and electronystagmography (ENG) or videonystagmography (VNG) and MRI.

▶ General Considerations

Vertigo can be caused by either a peripheral and central etiology, or both (Table 8–2).

▶ Clinical Findings

A. Symptoms and Signs

Vertigo is the cardinal symptom of vestibular disease. It is either a sensation of motion when there is no motion or an exaggerated sense of motion in response to a given bodily movement. While vertigo is typically experienced as a distinct “spinning” sensation, it may also present as a sense of tumbling or of falling forward or backward. It should be distinguished from imbalance, light-headedness, and syncope, all of which are nonvestibular in origin (Table 8–3).

1. Peripheral vestibular disease—Peripheral vestibulopathy usually causes vertigo of sudden onset, may be so severe that the patient is unable to walk or stand, and is frequently accompanied by nausea and vomiting. Tinnitus and hearing loss may be associated and provide strong support for a peripheral (ie, otologic) origin.

A thorough history will often narrow down, if not confirm the diagnosis. Critical elements of the history include the duration of the discrete vertiginous episodes (seconds, minutes to hours, or days), and associated symptoms. Triggers should also be sought, including diet (eg, high salt in the case of Ménière disease), stress, fatigue, and bright lights (eg, migraine-associated dizziness).

The physical examination of the patient with vertigo includes evaluation of the ears, eye motion in response to head turning and observation for nystagmus, cranial nerve examination, and Romberg testing. In acute peripheral lesions, nystagmus is usually horizontal with a rotatory component; the fast phase usually beats away from the diseased side. Visual fixation tends to inhibit nystagmus

Table 8–2. Causes of vertigo.

Peripheral causes
Vestibular neuritis/labyrinthitis
Ménière disease
Benign positional vertigo
Ethanol intoxication
Inner ear barotrauma
Semicircular canal dehiscence
Central causes

Hyperviscosity syndromes
Waldenström macroglobulinemia
Endocrinopathies
Hypothyroidism
Pendred syndrome

except in very acute peripheral lesions or with central nervous system disease. Dix-Hallpike testing (quickly lowering the patient to the supine position with the head extending over the edge and placed 30 degrees lower than the body, turned either to the left or right) will elicit a delayed onset (~10 sec) fatiguable nystagmus in cases of benign positional vertigo. Nonfatigable nystagmus in this position indicates a central etiology for the dizziness.

Since visual fixation often suppresses observed nystagmus, many of these maneuvers are performed with Frenzel goggles, which prevent visual fixation, and often bring out subtle forms of nystagmus. The Fukuda test, in which the patient consistently rotates when walking in place with eyes closed, can also demonstrate vestibular asymmetry.

2. Central disease—In contrast to peripheral forms of vertigo, dizziness arising from central etiologies (Table 8–2) tends to develop gradually and then become progressively more severe and debilitating. Nystagmus is not always present but can occur in any direction and may be dissociated in the two eyes. The associated nystagmus is often nonfatigable, vertical rather than horizontal in orientation, without latency, and unsuppressed by visual fixation. ENG is useful in documenting these characteristics. The evaluation of central audiovestibular dysfunction requires imaging of the brain with MRI.

Episodic vertigo can occur in patients with diplopia from external ophthalmoplegia and is maximal when the patient looks in the direction where the separation of images is greatest. Cerebral lesions involving the temporal cortex may also produce vertigo, which is sometimes the initial symptom of a seizure. Finally, vertigo may be a feature of a number of systemic disorders and can occur as a side effect of certain anticonvulsant, antibiotic, hypnotic, analgesic, and tranquilizing drugs or of alcohol.

B. Laboratory Findings

Laboratory investigations such as audiologic evaluation, caloric stimulation, ENG, VNG, vestibular-evoked myogenic potentials (VEMPs), and MRI are indicated in patients with persistent vertigo or when central nervous system disease is suspected. These studies will help distinguish between central and peripheral lesions and to identify causes requiring specific therapy. ENG consists of objective recording of the nystagmus induced by head and body movements, gaze, and caloric stimulation. It is helpful in quantifying the degree of vestibular hypofunction. Computer-driven rotary chairs and posturography platforms offer additional diagnostic modalities from specialized centers.

Ahmed MF et al. Caloric test versus rotational sinusoidal harmonic acceleration and step-velocity tests in patients with and without suspected peripheral vestibulopathy. *Otol Neurotol.* 2009 Sep;30(6):800–5. [PMID: 19623096]

▶ Vertigo Syndromes Due to Peripheral Lesions

A. Endolymphatic Hydrops (Ménière Syndrome)

The cause of Ménière syndrome is unknown. Distention of the endolymphatic compartment of the inner ear is a pathologic finding and thought to be part of the pathogenesis of the disorder. Although a precise cause of hydrops cannot be established in most cases, two known causes are syphilis and head trauma. The classic syndrome consists of episodic vertigo, with discrete vertigo spells lasting 20 minutes to several hours in association with fluctuating low-frequency sensorineural hearing loss, tinnitus (usually low-tone and “blowing” in quality), and a sensation of unilateral aural pressure (Table 8–3). These symptoms in the absence of hearing fluctuations suggests migraine-associated dizziness. Symptoms wax and wane as the endolymphatic pressure rises and falls. Caloric testing commonly reveals loss or impairment of thermally induced nystagmus on the involved side. Primary treatment involves a low salt diet and diuretics (eg, acetazolamide). In refractory cases, patients may undergo intratympanic corticosteroid injections, endolymphatic sac decompression or vestibular ablation either through transtympanic gentamicin, vestibular nerve section, or surgical labyrinthectomy.

Herraiz C et al. Transtympanic steroids for Ménière’s disease. *Otol Neurotol.* 2010 Jan;31(1):162–7. [PMID: 19924013]
 Pullens B et al. Surgery for Ménière’s disease. *Cochrane Database Syst Rev.* 2010 Jan 20;(1):CD005395. [PMID: 20091573]

B. Labyrinthitis

Patients with labyrinthitis suffer from acute onset of continuous, usually severe vertigo lasting several days to a

Table 8–3. Common vestibular disorders: differential diagnosis based on classic presentations.

Duration of Typical Vestiginous Episodes	Auditory Symptoms Present	Auditory Symptoms Absent
Seconds	Perilymphatic fistula	Positioning vertigo (cupulolithiasis), vertebrobasilar insufficiency, migraine-associated vertigo
Hours	Endolymphatic hydrops (Ménière syndrome, syphilis)	Migraine-associated vertigo
Days	Labyrinthitis, labyrinthine concussion, autoimmune inner ear disease	Vestibular neuronitis, migraine-associated vertigo
Months	Acoustic neuroma, ototoxicity	Multiple sclerosis, cerebellar degeneration

week, accompanied by hearing loss and tinnitus. During a recovery period that lasts for several weeks, the vertigo gradually improves. Hearing may return to normal or remain permanently impaired in the involved ear. The cause of labyrinthitis is unknown. Treatment consists of antibiotics if the patient is febrile or has symptoms of a bacterial infection, and supportive care. Vestibular suppressants are useful during the acute phase of the attack (eg, diazepam or meclizine) but should be discontinued as soon as feasible to avoid long-term dysequilibrium from inadequate compensation.

Newman-Toker DE et al. Disconnect between charted vestibular diagnoses and emergency department management decisions: a cross-sectional analysis from a nationally representative sample. *Acad Emerg Med.* 2009 Oct;16(10):970–7. [PMID: 19799573]

Post RE. Dizziness: a diagnostic approach. *Am Fam Physician.* 2010 Aug 15;82(4):361–8. [PMID: 20704166]

C. Benign Paroxysmal Positioning Vertigo

Patients suffering from recurrent spells of vertigo, lasting under several minutes per spell, associated with changes in head position (often provoked by rolling over in bed), usually have benign paroxysmal positioning vertigo. The term “positioning vertigo” is more accurate than “positional vertigo” because it is provoked by changes in head position rather than by the maintenance of a particular posture.

The typical symptoms of positioning vertigo occur in clusters that persist for several days. There is a brief (10–15 sec) latency period following a head movement before symptoms develop, and the acute vertigo subsides within 10–60 seconds, though the patient may remain imbalanced for several hours. Constant repetition of the positional change leads to habituation. Since some central nervous system disorders can mimic BPPV (eg, vertebrobasilar insufficiency), recurrent cases warrant MRI scanning of the head. In central lesions, there is no latent period, fatigability, or habituation of the symptoms and signs. Treatment of BPPV involves physical therapy protocols (eg, the Epley maneuver or Brandt-Daroff exercises), based on the theory that peripheral positioning vertigo results from free-floating otoconia within a semicircular canal.

Bhattacharyya N et al. American Academy of Otolaryngology-Head and Neck Surgery Foundation. Clinical practice guideline: benign paroxysmal positional vertigo. *Otolaryngol Head Neck Surg.* 2008 Nov;139(5 Suppl 4):S47–81. [PMID: 18973840]

Marom T et al. Revisiting benign paroxysmal positional vertigo pathophysiology. *Am J Otolaryngol.* 2009 Jul–Aug;30(4):250–5. [PMID: 19563936]

D. Vestibular Neuronitis

In vestibular neuronitis, a paroxysmal, usually single attack of vertigo occurs without accompanying impairment of auditory function and will persist for several days to a week before gradually clearing. During the acute phase, examination reveals nystagmus and absent responses to caloric stimulation on one or both sides. The cause of the disorder

is unclear though presumed to be viral. Treatment consists of supportive care, including diazepam or meclizine during the acute phases of the vertigo only, followed by vestibular therapy if the patient does not completely compensate.

Post RE. Dizziness: a diagnostic approach. *Am Fam Physician.* 2010 Aug 15;82(4):361–8. [PMID: 20704166]

E. Traumatic Vertigo

The most common cause of vertigo following head injury is labyrinthine concussion. Symptoms generally diminish within several days but may linger for a month or more. Basilar skull fractures that traverse the inner ear usually result in severe vertigo lasting several days to a week and deafness in the involved ear. Chronic posttraumatic vertigo may result from cupulolithiasis. This occurs when traumatically detached statoconia (otoconia) settle on the ampulla of the posterior semicircular canal and cause an excessive degree of cupular deflection in response to head motion. Clinically, this presents as episodic positioning vertigo. Treatment consists of supportive care and vestibular suppressant medication (diazepam or meclizine) during the acute phase of the attack, and vestibular therapy.

Scherer MR et al. Traumatic brain injury and vestibular pathology as a comorbidity after blast exposure. *Phys Ther.* 2009 Sep;89(9):980–92. [PMID: 19628578]

F. Perilymphatic Fistula

Leakage of perilymphatic fluid from the inner ear into the tympanic cavity via the round or oval window is often discussed as a cause of vertigo and sensory hearing loss but is actually very rare. Most cases result from either physical injury (eg, blunt head trauma, hand slap to ear); extreme barotrauma during airlift, scuba diving, etc; or vigorous Valsalva maneuvers (eg, during weight lifting). Treatment may require middle ear exploration and window sealing with a tissue graft; however, this is seldom indicated without a clear-cut history of a precipitating traumatic event.

Al Felasi M et al. Perilymphatic fistula of the round window. *Eur Ann Otorhinolaryngol Head Neck Dis.* 2011 Jun;128(3):139–41. [PMID: 21288793]

G. Cervical Vertigo

Position receptors located in the facets of the cervical spine are important physiologically in the coordination of head and eye movements. Cervical proprioceptive dysfunction is a common cause of vertigo triggered by neck movements. This disturbance often commences after neck injury, particularly hyperextension. An association also exists with degenerative cervical spine disease. Although symptoms vary, vertigo may be triggered by assuming a particular head position as opposed to moving to a new head position (the latter typical of labyrinthine dysfunction). Diagnosis may often be confused with migraine-associated vertigo, which is also associated with head movement. Management

consists of neck movement exercises to the extent permitted by orthopedic considerations.

Schikora N et al. Influence of cervical spine stabilization via Stiff Neck on the postural system in healthy patients: compensation or decompensation of the postural system? *Eur Arch Otorhinolaryngol.* 2010 Oct;267(10):1623–8. [PMID: 20443016]

H. Migrainous Vertigo

Episodic vertigo is frequently associated with a migraine type of headache. Head trauma may also be a precipitating feature. The vertigo may be temporally related to the headache and last up to several hours, although the vertigo may also occur in the absence of any headache. It may appear identical to Ménière disease but without associated hearing loss or tinnitus. Accompanying symptoms may include head pressure, visual and motion sensitivity, auditory sensitivity, and photosensitivity. Symptoms typically worsen with lack of sleep and anxiety or stress. There is often a history of motion intolerance (easily carsick as a child) and there may be a familial tendency. Food triggers may also be common, including caffeine, chocolate, and alcohol among others. Treatment includes dietary and lifestyle changes (improved sleep pattern, avoidance of stress) and antimigraine prophylactic medication.

Felisati G et al. Migraine and vertigo: two diseases with the same pathogenesis? *Neurol Sci.* 2010 Jun;31(Suppl 1):S107–9. [PMID: 20464597]

Fotuhi M et al. Vestibular migraine: a critical review of treatment trials. *J Neurol.* 2009 May;256(5):711–6. [PMID: 19252785]

Jeong SH et al. Vestibular dysfunction in migraine: effects of associated vertigo and motion sickness. *J Neurol.* 2010 Jun; 257(6):905–12. [PMID: 20041331]

I. Superior Semicircular Canal Dehiscence

Deficiency in the bony covering of the superior semicircular canal may be associated with vertigo triggered by loud noise exposure, straining, and an apparent conductive hearing loss. Diagnosis is with coronal high-resolution CT scan and VEMPs. Surgically sealing the dehiscent canal can improve symptoms.

Chi FL et al. Variety of audiologic manifestations in patients with superior semicircular canal dehiscence. *Otol Neurotol.* 2010 Jan;31(1):2–10. [PMID: 20050265]

Phillips DJ et al. Diagnosis and outcomes of middle cranial fossa repair for patients with superior semicircular canal dehiscence syndrome. *J Clin Neurosci.* 2010 Mar;17(3):339–41. [PMID: 20074960]

► Vertigo Syndromes Due to Central Lesions

Central nervous system causes of vertigo include brainstem vascular disease, arteriovenous malformations, tumor of the brainstem and cerebellum, multiple sclerosis, and vertebrobasilar migraine (Table 8–2). Vertigo of central origin often becomes unremitting and disabling. The associated

nystagmus is often nonfatigable, vertical rather than horizontal in orientation, without latency, and unsuppressed by visual fixation. ENG is useful in documenting these characteristics. There are commonly other signs of brainstem dysfunction (eg, cranial nerve palsies; motor, sensory, or cerebellar deficits in the limbs) or of increased intracranial pressure. Auditory function is generally spared. The underlying cause should be treated.

Kutz JW Jr. The dizzy patient. *Med Clin North Am.* 2010 Sep;94(5):989–1002. [PMID: 20736108]

Lempert T et al. Management of common central vestibular disorders. *Curr Opin Otolaryngol Head Neck Surg.* 2010 Oct;18(5):436–40. [PMID: 20639762]

DISEASES OF THE CENTRAL AUDITORY & VESTIBULAR SYSTEMS (Table 8–3)

Lesions of the eighth cranial nerve and central audiovestibular pathways produce neural hearing loss and vertigo. One characteristic of neural hearing loss is deterioration of speech discrimination out of proportion to the decrease in pure tone thresholds. Another is auditory adaptation, wherein a steady tone appears to the listener to decay and eventually disappear. Auditory evoked responses are useful in distinguishing cochlear from neural losses and may give insight into the site of lesion within the central pathways.

The evaluation of central audiovestibular disorders usually requires imaging of the internal auditory canal, cerebellopontine angle, and brain with enhanced MRI.

1. Vestibular Schwannoma (Acoustic Neuroma)

Eighth cranial nerve schwannomas are among the most common intracranial tumors. Most are unilateral, but about 5% are associated with the hereditary syndrome, neurofibromatosis type 2, in which bilateral eighth nerve tumors may be accompanied by meningiomas and other intracranial and spinal tumors. These benign lesions arise within the internal auditory canal and gradually grow to involve the cerebellopontine angle, eventually compressing the pons and resulting in hydrocephalus. Their typical auditory symptoms are unilateral hearing loss with a deterioration of speech discrimination exceeding that predicted by the degree of pure tone loss. Nonclassic presentations, such as sudden unilateral hearing loss, are fairly common. Any individual with a unilateral or asymmetric sensorineural hearing loss should be evaluated for an intracranial mass lesion. Vestibular dysfunction more often takes the form of continuous dysequilibrium than episodic vertigo. Other lesions of the cerebellopontine angle such as meningioma and epidermoids may have similar audiovestibular manifestations. Diagnosis is made by enhanced MRI. Treatment consists of observation, microsurgical excision, or stereotactic radiotherapy, depending on such factors as patient age, underlying health, and size of the tumor at presentation. Bevacizumab (vascular endothelial growth

factor blocker) has recently shown promise for treatment of tumors in patients with neurofibromatosis type 2.

Gal TJ et al. Current epidemiology and management trends in acoustic neuroma. *Otolaryngol Head Neck Surg.* 2010 May;142(5):677–81. [PMID: 20416455]

Plotkin SR et al. Hearing improvement after bevacizumab in patients with neurofibromatosis type 2. *N Engl J Med.* 2009 Jul 23;361(4):358–67. [PMID: 19587327]

Tan M et al. Trends in the management of vestibular schwannomas at Johns Hopkins 1997–2007. *Laryngoscope.* 2010 Jan;120(1):144–9. [PMID: 19877188]

Whitehouse K et al. Vestibular schwannomas—when should conservative management be reconsidered? *Br J Neurosurg.* 2010 Apr;24(2):185–90. [PMID: 19886818]

2. Vascular Compromise

Vertebrobasilar insufficiency is a common cause of vertigo in the elderly. It is often triggered by changes in posture or extension of the neck. Reduced flow in the vertebrobasilar system may be demonstrated noninvasively through magnetic resonance angiography. Empiric treatment is with vasodilators and aspirin.

Vascular loops that impinge upon the brainstem root entry zone of cranial nerves have been shown to cause dysfunction. Widely recognized examples are hemifacial spasm and tic douloureux. It has been suggested that hearing loss, tinnitus, and disabling positioning vertigo may result from a vascular loop abutting the eighth cranial nerve, although this is controversial.

Karatas M. Vascular vertigo: epidemiology and clinical syndromes. *Neurologist.* 2011 Jan;17(1):1–10. [PMID: 21192184]

Otto V et al. Treatment of vertebrobasilar insufficiency-associated vertigo with a fixed combination of cinnarizine and dimenhydrinate. *Int Tinnitus J.* 2008;14(1):57–67. [PMID: 18616088]

3. Multiple Sclerosis

Patients with multiple sclerosis may suffer from episodic vertigo and chronic imbalance. Hearing loss in this disease is most commonly unilateral and of rapid onset. Spontaneous recovery may occur.

Bovo R et al. Vertigo and autoimmunity. *Eur Arch Otorhinolaryngol.* 2010 Jan;267(1):13–9. [PMID: 19834724]

Peyvandi A et al. Neuro-otologic manifestations of multiple sclerosis. *Arch Iran Med.* 2010 May;13(3):188–92. [PMID: 20433222]

OTOLOGIC MANIFESTATIONS OF AIDS

The otologic manifestations of AIDS are protean. The pinna and external auditory canal may be affected by Kaposi sarcoma as well as persistent and potentially invasive fungal infections, particularly due to *Aspergillus fumigatus*. The most common middle ear manifestation of AIDS is serous otitis media due to eustachian tube dysfunction arising from adenoidal hypertrophy (HIV lymphadenopathy), recurrent mucosal viral infections, or an obstructing nasopharyngeal tumor (eg, lymphoma). For middle ear effusions, ventilating tubes are seldom helpful and may

trigger profuse watery otorrhea. Acute otitis media is usually caused by the typical bacterial organisms that occur in nonimmunocompromised patients, although *Pneumocystis jiroveci* otitis has been reported. Sensorineural hearing loss is common and in some cases appears to result from viral central nervous system infection. In cases of progressive hearing loss, it is important to evaluate for cryptococcal meningitis and syphilis. Acute facial paralysis due to herpes zoster infection (Ramsay Hunt syndrome) is quite common and follows a clinical course similar to that in nonimmunocompromised patients. Treatment is primarily with high-dose acyclovir (see Chapters 6 and 32). Corticosteroids may also be effective.

DISEASES OF THE NOSE & PARANASAL SINUSES

INFECTIONS OF THE NOSE & PARANASAL SINUSES

1. Acute Viral Rhinosinusitis (Common Cold)

ESSENTIALS OF DIAGNOSIS

- ▶ Clear rhinorrhea, hyposmia, and nasal congestion.
- ▶ Associated symptoms, including malaise, headache, and cough.
- ▶ Erythematous, engorged nasal mucosa on examination without intranasal purulence.
- ▶ Symptoms last < 4 weeks and typically < 10 days.
- ▶ Symptoms are self-limited.

▶ Clinical Findings

The nonspecific symptoms of the ubiquitous common cold are present in the early phases of many diseases that affect the upper aerodigestive tract. Because there are numerous serologic types of rhinoviruses, adenoviruses, and other viruses, patients remain susceptible throughout life. These infections, while generally quite benign and self-limited, have been implicated in the development or exacerbation of more serious conditions, such as acute bacterial sinusitis, acute otitis media, asthma and cystic fibrosis exacerbation, and bronchitis. Nasal congestion, decreased sense of smell, watery rhinorrhea, and sneezing accompanied by general malaise, throat discomfort and, occasionally, headache are typical in viral infections. Nasal examination usually shows erythematous, edematous mucosa and a watery discharge. The presence of purulent nasal discharge suggests bacterial rhinosinusitis.

▶ Treatment

Despite ongoing research into viral chemotherapy, at this time, there are no effective antiviral therapies for either the prevention or treatment of viral rhinitis. There is a common misperception among patients that antibiotics are

helpful. Zinc for the treatment of viral rhinitis has been controversial. A 2011 meta-analysis of randomized controlled trials demonstrated no benefit in five studies that used < 75 mg of zinc acetate daily, but significant reduction in duration of cold symptoms was noted in all three studies that used zinc acetate in daily doses of over 75 mg. The effect with zinc salts other than acetate was also significant at doses > 75 mg/d, but not as high as the zinc acetate lozenge studies (20% vs 42%). Buffered hypertonic saline (3–5%) nasal irrigation has been shown to improve symptoms and reduce the need for nonsteroidal anti-inflammatory drugs. Other supportive measures, such as oral decongestants (pseudoephedrine, 30–60 mg every 4–6 hours or 120 mg twice daily), may provide some relief of rhinorrhea and nasal obstruction. Nasal sprays, such as oxymetazoline or phenylephrine, are rapidly effective but should not be used for more than a few days to prevent rebound congestion. Withdrawal of the drug after prolonged use leads to **rhinitis medicamentosa**, an almost addictive need for continuous usage. Treatment of rhinitis medicamentosa requires mandatory cessation of the sprays, and this is often extremely frustrating for patients. Topical intranasal corticosteroids (eg, flunisolide, 2 sprays in each nostril twice daily), intranasal anticholinergic (ipratropium 0.06% nasal spray, 2–3 sprays every 8 hours as needed) or a short tapering course of oral prednisone may help during the process of withdrawal.

► Complications

Other than eustachian tube dysfunction or transient middle ear effusion, complications of viral rhinitis are unusual. Secondary acute bacterial rhinosinusitis may occur and is suggested by persistence of symptoms beyond 10 days, accompanied both by purulent green or yellow nasal secretions and unilateral facial or tooth pain. (See Acute Bacterial Rhinosinusitis below.)

While the symptoms of influenza A/H1N1 (swine flu) are much the same as other respiratory viruses, certain persons (including children younger than 5 years, adults older than 65 years, pregnant women, patients with underlying respiratory or immune disorders, and adolescents younger than 19 years receiving aspirin therapy) are at particular risk for the development of hypoxia and acute respiratory distress syndrome (ARDS). Mortality in those in whom ARDS developed was > 17%. Diagnosis of influenza A/H1N1 is confirmed by nasopharyngeal, oropharyngeal, or endobronchial swab or aspirate and identification of the virus by reverse transcriptase-polymerase chain reaction (RT-PCR). Treatment with oseltamivir or zanamivir has been effective, but up to date diagnosis, treatment, and containment guidelines should be sought from the Centers for Disease Control and Prevention at www.cdc.gov/h1n1flu/ if the diagnosis is suspected.

Sullivan SJ et al. 2009 H1N1 Influenza. *Mayo Clin Proc.* 2010 Jan;85(1):64–76. [PMID: 20007905]

2. Acute Bacterial Rhinosinusitis (Sinusitis)

ESSENTIALS OF DIAGNOSIS

- ▶ Purulent yellow-green nasal discharge or expectoration.
- ▶ Facial pain or pressure over the affected sinus or sinuses.
- ▶ Nasal obstruction.
- ▶ Acute onset of symptoms (between 1 and 4 weeks duration).
- ▶ Associated symptoms, including cough, malaise, fever, and headache.

► General Considerations

Acute sinus infections are uncommon compared with viral rhinitis, but they still affect nearly 20 million Americans annually, accounting for over 2 billion dollars in health care expenditures for sinusitis annually. Such infections are often associated with inflammation of the mucosal of the nasal cavity near the drainage pores of the sinuses. To acknowledge this inflammation as a major component of the disease and to differentiate it from such processes as allergic or acute viral rhinitis, otolaryngologists prefer the term “bacterial rhinosinusitis.”

Acute bacterial rhinosinusitis usually is a result of impaired mucociliary clearance and obstruction of the osteomeatal complex, or sinus “pore.” Edematous mucosa causes obstruction of the complex, resulting in the accumulation of mucous secretion in the sinus cavity that becomes secondarily infected by bacteria. The largest of these osteomeatal complexes is deep to the middle turbinate in the middle meatus. This complex is actually a confluence of complexes draining the maxillary, ethmoid, and frontal sinuses. The sphenoid drains from a separate complex between the septum and superior turbinate.

The typical pathogens of bacterial sinusitis are the same as those that cause acute otitis media: *S pneumoniae*, other streptococci, *H influenzae* and, less commonly, *S aureus* and *Moraxella catarrhalis*. Pathogens vary regionally in both prevalence and drug resistance. It should be kept in mind that about 25% of healthy asymptomatic individuals may, if sinus aspirates are cultured, harbor such bacteria as well. Understanding of the anatomy, pathogenesis and microbiology of acute bacterial rhinosinusitis can help the clinician afford the most expeditious and cost-effective diagnosis and treatment while avoiding serious complications.

► Clinical Findings

A. Symptoms and Signs

There are no agreed upon criteria for the diagnosis of acute bacterial rhinosinusitis in adults. All study groups note a number of major symptoms, including purulent nasal drainage, nasal obstruction or congestion, facial pain/pressure, altered smell, cough, and fever. Minor symptoms

include headache, otalgia, halitosis, dental pain, and fatigue. Many of the more specific signs and symptoms may be related to the affected sinuses. It is important to note that studies have demonstrated no correlation between patient reports of “sinus headache” and presence of sinusitis on CT scan. Bacterial rhinosinusitis can be distinguished from viral rhinitis by persistence of symptoms more than 10 days after onset or worsening of symptoms within 10 days after initial improvement. Acute infections are defined as those lasting less than 4 weeks, with subacute infections lasting between 4 weeks and 12 weeks.

Acute maxillary sinusitis is the most common form of acute bacterial rhinosinusitis because the maxillary is the largest sinus with a single drainage pathway that is easily obstructed. Unilateral facial fullness, pressure and tenderness over the cheek are common symptoms, but may not be present in many cases. Pain may refer to the upper incisor and canine teeth via branches of the trigeminal nerve, which traverse the floor of the sinus. Purulent nasal drainage should be noted with nasal airway obstruction or facial pain (pressure). Maxillary sinusitis may result from dental infection, and teeth that are tender should be carefully examined for signs of abscess. Removal of the diseased tooth or drainage of the periapical abscess typically resolves the sinus infection.

Acute ethmoiditis in adults is often accompanied by maxillary sinusitis and symptoms are similar to those described above. Localized ethmoid sinusitis may present with pain and pressure over the high lateral wall of the nose between the eyes that may radiate to the orbit.

Sphenoid sinusitis is usually seen in the setting of pansinusitis, or infection of all the paranasal sinuses on at least one side. The patient may complain of a headache “in the middle of the head” and often points to the vertex.

Acute frontal sinusitis may cause pain and tenderness of the forehead. This is most easily elicited by palpation of the orbital roof just below the medial end of the eyebrow.

Hospital-associated sinusitis is a form of acute bacterial rhinosinusitis that may present without any symptoms in the head and neck. It is a common source of fever in critically ill patients and is often associated with prolonged presence of a nasogastric or, rarely, nasotracheal tube causing inflammation of the nasal mucosa and osteomeatal complex obstruction. Pansinusitis on the side of the tube is common on imaging studies.

B. Imaging

It is usually possible to make the diagnosis of acute bacterial rhinosinusitis on clinical grounds alone. Although more sensitive than clinical examination, routine radiographs are not cost-effective and are not recommended by the Agency for Health Care Policy and Research or American Association of Otolaryngology Guidelines in the routine diagnosis of acute bacterial rhinosinusitis. They may, however, be helpful when clinically based criteria are difficult to evaluate, when the patient does not respond to appropriate therapy, or when symptoms of more serious infection are noted.

When necessary, noncontrast, screening coronal CT scans are more cost-effective and provide more information than conventional sinus films. CT provides a rapid and

effective means to assess all of the paranasal sinuses, identify areas of greater concern (such as bony dehiscence, periosteal elevation or maxillary tooth root exposure within the sinus), and speed appropriate therapy.

CT scans are reasonably sensitive but are not specific. Swollen soft tissue and fluid may be difficult to distinguish when opacification of the sinus is present from other conditions, such as chronic rhinosinusitis, nasal polyposis, or mucus retention cysts. Sinus abnormalities can be seen in most patients with an upper respiratory infection, while bacterial rhinosinusitis develops in only 2%.

If malignancy, intracranial extension or opportunistic infection is suspected, MRI with gadolinium should be ordered instead of, or in addition to, CT. MRI will distinguish tumor from fluid, inflammation, and inspissated mucus far better than CT, as well as better delineating tumor extent with respect to adjacent structures such as the orbit, skull base, and palate. Bone destruction can be demonstrated as well by MRI as by CT.

► Treatment

All patients with acute bacterial rhinosinusitis should have careful evaluation of pain. Nonsteroidal anti-inflammatory drugs are generally recommended. Sinus symptoms may be improved with oral or nasal decongestants (or both)—eg, oral pseudoephedrine, 30–120 mg per dose, up to 240 mg/d; nasal oxymetazoline, 0.05%, or xylometazoline, 0.05–0.1%, one or two sprays in each nostril every 6–8 hours for up to 3 days. All clinical practice guidelines recommend using intranasal corticosteroids (eg, fluticasone, 100 mcg each nostril twice daily) in the first 5 days of symptoms that could be acute bacterial rhinosinusitis or acute viral rhinitis. However, this use has not been approved in the United States by the Food and Drug Administration.

Eighty percent of patients with acute bacterial rhinosinusitis improve symptomatically within 2 weeks without antibiotic therapy. However, antibiotics may be considered when symptoms last more than 10–14 days or when symptoms (including fever, facial pain, and swelling of the face) are severe. Administration of antibiotics does, however, reduce the incidence of clinical failure by 50% and, coupled with clinical criteria-based diagnosis, represents the most cost-effective treatment strategy. Double-blinded studies exist to support numerous antibiotic choices. A summary of national guidelines for the treatment of acute sinusitis can be found in Table 8–4. Selection of antibiotics is usually empiric and based on a number of factors including regional patterns of antibiotic resistance, antibiotic allergy, cost, and patient tolerance. Unless the patient is allergic to penicillin, amoxicillin should be used as the first-line agent. Treatment is usually for 7–10 days, although longer courses are sometimes required to prevent relapses. Macrolide therapy has been recommended as first-line therapy in patients with penicillin allergy, and tetracycline have also been used.

Multidrug resistant *S pneumoniae* prevalence is growing in many urban areas of the United States as are β -lactamase β -lactam inhibitor producing strains of *H influenzae* and *M catarrhalis*. In such regions, guidelines call for empiric use of amoxicillin-clavulanate or second- or third-generation cephalosporins. Fluoroquinolones are reserved for treatment

Table 8-4. Oral antibiotic regimens for acute sinusitis.

Drug	Dose	Duration	Notes
First-line therapy			
Amoxicillin	1000 mg three times daily	7-10 days	
Trimethoprim-sulfamethoxazole	160 mg-800 mg twice daily	7-10 days	Suitable in penicillin allergy
Doxycycline	200 mg once daily × 1 day, 100 mg twice daily thereafter	7-10 days	Suitable in penicillin allergy
Amoxicillin-clavulanate ¹	1000/62.5 mg ER 2 tablets twice daily	10 days	If no improvement after 3 days on first-line therapy
First-line therapy after recent antibiotic use²			
Levofloxacin	500 mg once daily	10 days	
Amoxicillin-clavulanate	875/125 mg twice daily	10 days	
Second-line therapy			
Amoxicillin-clavulanate	1000/62.5 mg ER 2 tablets twice daily	10 days	If no improvement after 3 days on first-line therapy
Moxifloxacin	400 mg once daily	10 days	If no improvement after 3 days on first-line therapy

¹In communities where there is multidrug resistant *S pneumoniae* and β -lactamase β -lactam inhibitor producing strains of *H influenzae* and *M catarrhalis*.

²Within last 4-6 weeks.

failures or for patients with a recent history of antibiotic therapy for another infection. Recurrent sinusitis or sinusitis that does not appear to respond clinically warrants CT imaging and evaluation by a specialist.

Hospital-associated infections in critically ill patients are treated differently from community-acquired infections. Broad-spectrum antibiotic coverage for bacteria including *P aeruginosa*, *S aureus* (including methicillin-resistant strains) and anaerobes must be considered. Removal of the nasogastric tube and improved nasal hygiene (nasal saline sprays, humidification of supplemental nasal oxygen, and nasal decongestants) are critical interventions and often curative in mild cases without aggressive antibiotic use. Endoscopic or transantral cultures may help direct medical therapy in complicated cases.

► Complications

Local complications of acute bacterial rhinosinusitis include orbital cellulitis and abscess, osteomyelitis, intracranial extension and cavernous sinus thrombosis.

Any change in the ocular examination in a patient with acute bacterial rhinosinusitis necessitates immediate CT imaging. Orbital complications typically occur by extension of ethmoid sinusitis through the lamina papyracea, a thin layer of bone that comprises the medial orbital wall. Extension in this area may cause orbital cellulitis leading to proptosis, gaze restriction, and orbital pain. Select cases are responsive to intravenous antibiotics with or without corticosteroids and should be managed in close conjunction with an ophthalmologist or otolaryngologist, or both. Extension through the lamina papyracea can also lead to subperiosteal abscess formation (orbital abscess). Such abscesses cause marked proptosis, ophthalmoplegia and

pain with medial gaze. While some of these abscesses will respond to antibiotics, such findings should prompt an immediate referral to a specialist for consideration of decompression and evacuation. Failure to intervene quickly may lead to permanent visual impairment and a “frozen globe.”

Osteomyelitis requires prolonged antibiotics as well as removal of necrotic bone. The frontal sinus is most commonly affected, with bone involvement suggested by a tender puffy swelling of the forehead (Pott puffy tumor). Following treatment, secondary cosmetic reconstructive procedures may be necessary.

Intracranial complications of sinusitis can occur either through hematogenous spread, as in cavernous sinus thrombosis and meningitis, or by direct extension, as in epidural and intraparenchymal brain abscesses. Fortunately, they are rare today. Cavernous sinus thrombosis is heralded by ophthalmoplegia, chemosis, and visual loss. The diagnosis is most commonly confirmed by MRI and, when identified early, it typically responds to intravenous antibiotics. Frontal epidural and intracranial abscesses are often clinically silent, but may present with altered mental status, persistent fever, or severe headache.

► When to Refer

Failure of acute bacterial rhinosinusitis to resolve after an adequate course of oral antibiotics may necessitate referral to an otolaryngologist for evaluation. Endoscopic cultures may direct further treatment choices. Nasal endoscopy and CT scan are indicated when symptoms persist longer than 4-12 weeks. Any patients with suspected extension of disease outside the sinuses should be evaluated urgently by an otolaryngologist and imaging.

▶ When to Admit

- Facial swelling and erythema indicative of facial cellulitis.
- Proptosis.
- Vision change or gaze abnormality indicative of orbital cellulitis.
- Abscess or cavernous sinus involvement.
- Mental status changes suggestive of intracranial extension.
- Immunocompromised status.
- Failure to respond to appropriate first-line treatment for acute bacterial rhinosinusitis or symptoms persisting longer than 4 weeks.

3. Nasal Vestibulitis & *S aureus* Nasal Colonization

Inflammation of the nasal vestibule may result from folliculitis of the hairs that line this orifice and is usually the result of nasal manipulation or hair trimming. Systemic antibiotics effective against *S aureus* (such as dicloxacillin, 250 mg orally four times daily for 7–10 days) are indicated. Topical mupirocin or bacitracin (applied two or three times daily) may be a helpful addition and may prevent future occurrences. If recurrent, the addition of rifampin (10 mg/kg orally twice daily for the last 4 days of treatment) may eliminate the *S aureus* carrier state. If a furuncle exists, it should be incised and drained, preferably intranasally. Adequate treatment of these infections is important to prevent retrograde spread of infection through valveless veins into the cavernous sinus and intracranial structures.

S aureus is the leading nosocomial pathogen in the world, and nasal carriage is a well-defined risk factor in the development and spread of nosocomial infections. While the vast majority of patients have no vestibulitis symptoms, screening methods (including nasal swabs and PCR-based assays) have demonstrated rates of *S aureus* nasal colonization at around 30% and methicillin-resistant *S aureus* colonization in patients in the intensive care unit to be as high as 11%. Elimination of the carrier state is challenging, but

studies of mupirocin (2% topical nasal application twice daily) have demonstrated efficacy in reducing surgical and catheter/hardware infections. Consensus screening and treatment recommendations are not yet available.

van Rijen M et al. Mupirocin ointment for preventing *Staphylococcus aureus* infections in nasal carriers. *Cochrane Database Syst Rev.* 2008 Oct 8;(4):CD006216. [PMID: 18843708]

4. Invasive Fungal Sinusitis

Invasive fungal sinusitis is rare and includes both rhinocerebral mucormycosis (*Mucor*, *Absidia*, and *Rhizopus sp.*) and other invasive fungal infections, such as *Aspergillus*. The fungus spreads rapidly through vascular channels and may be lethal if not detected early. Patients with mucormycosis almost invariably have a contributing factor that results in some degree of immunocompromise, such as diabetes mellitus, long-term corticosteroid therapy, or end-stage renal disease. Mucormycosis is more common, however, in patients who are profoundly immunocompromised for the treatment of hematologic malignancies. Occasional cases have been reported in patients with AIDS though *Aspergillus sp.* is more common in this setting. The initial symptoms may be similar to those of acute bacterial rhinosinusitis, although facial pain is often more severe. Nasal drainage is typically clear or straw-colored, rather than purulent, and visual symptoms may be noted at presentation in the absence of significant nasal findings. On examination, the classic finding of mucormycosis is a black eschar on the middle turbinate. This finding is not universal and may be inapparent if the infection is deep or high within the nasal bones. Often the mucosa appears normal or simply pale and dry. Early diagnosis requires suspicion of the disease and nasal biopsy with silver stains, revealing broad nonseptate hyphae within tissues and necrosis with vascular occlusion. Because CT or MRI may initially show only soft tissue changes, biopsy and ultimate debridement should be based on the clinical setting rather than radiographic demonstration of bony destruction or intracranial changes.

Invasive fungal sinusitis represents a medical and surgical emergency. Once recognized, prompt wide surgical debridement and amphotericin B by intravenous infusion are indicated for patients with reversible immune deficiency. Lipid-based amphotericin B (Ambisome) may be used in patients who have kidney disease or in those in whom it develops secondary to nephrotoxic doses of non-lipid amphotericin. Other antifungals, including voriconazole and caspofungin, may be appropriate therapy depending on the speciation of the organism. There is evidence that suggests that iron chelator therapy may also be a useful adjunct. While necessary for any possibility of cure, surgical management often results in tremendous disfigurement and functional deficits. Even with early diagnosis and immediate appropriate intervention, the prognosis is guarded and often results in the loss of at least one eye. In persons with diabetes, the mortality rate is about

20%. If kidney disease is present or develops, mortality is over 50%; in the setting of AIDS or hematologic malignancy with neutropenia, mortality approaches 100%.

ALLERGIC RHINITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Clear rhinorrhea, sneezing, tearing, eye irritation, and pruritus.
- ▶ Associated symptoms, including cough, bronchospasm, eczematous dermatitis.
- ▶ Environmental allergen exposure with presence of allergen specific IgE.

▶ General Considerations

Allergic rhinitis is very common in the United States. Population studies have reported the prevalence as between 14% and 40% among Americans, with most consensus panels agreeing on 20%. Allergic rhinitis adversely affects school and work performance, costing about \$6 billion annually in the United States. These costs may be underestimated as epidemiology studies consistently show an association with asthma. Seasonal allergic rhinitis is most commonly caused by pollens and spores. Flowering shrub and tree pollens are most common in the spring, flowering plants and grasses in the summer, and ragweed and molds in the fall. Dust, household mites, air pollution, and pet dander may produce year-round symptoms, termed “perennial rhinitis.”

Allergic rhinitis is caused by exposure to an airborne allergen in a predisposed individual. Activation of both humoral (B-cell) and cytotoxic (T-cell) immune responses with subsequent allergen-specific IgE responses causes release of inflammatory mediators. The response is increased as antigen is passed to regional lymph nodes for greater T-cell activation. Interleukin and cytokine release causes specific activation of mast cells, eosinophils, plasma cells, basophils and other T-cells. Many of these circulating cells then migrate into the nasal and ocular epithelium where they contribute directly to symptoms through proinflammatory mediators, including histamine, prostaglandins, and kinins.

▶ Clinical Findings

The symptoms of “hay fever” are similar to those of viral rhinitis but are usually persistent and may show seasonal

variation. Nasal symptoms are often accompanied by eye irritation, pruritus, conjunctival erythema, and excessive tearing. Many patients will note a strong family history of atopy or allergy.

The clinician should be careful to distinguish allergic rhinitis from nonallergic or vasomotor rhinitis. **Vasomotor rhinitis** is caused by increased sensitivity of the vidian nerve and is a common cause of clear rhinorrhea in the elderly. Often patients will report that they have troubling rhinorrhea in response to numerous nasal stimuli, including warm or cold air, odors or scents, light, or particulate matter.

On physical examination, the mucosa of the turbinates is usually pale or violaceous because of venous engorgement. This is in contrast to the erythema of viral rhinitis. Nasal polyps, which are yellowish boggy masses of hypertrophic mucosa, are associated with long-standing allergic rhinitis.

▶ Treatment

A. Intranasal Corticosteroids

Intranasal corticosteroid sprays have revolutionized the treatment of allergic rhinitis. Evidence-based literature reviews show that these are more effective—and frequently less expensive—than nonsedating antihistamines. Patients should be reminded that there may be a delay in onset of relief of 2 or more weeks. Corticosteroid sprays may also shrink hypertrophic nasal mucosa and nasal polyps, thereby providing an improved nasal airway and osteomeatal complex drainage. Because of this effect, intranasal corticosteroids are critical in treating allergy in patients prone to recurrent acute bacterial rhinosinusitis or chronic rhinosinusitis. There are many available preparations, including beclomethasone (42 mcg/spray twice daily per nostril), flunisolide (25 mcg/spray twice daily per nostril), mometasone furoate (200 mcg once daily per nostril), budesonide (100 mcg twice daily per nostril) and fluticasone propionate (200 mcg once daily per nostril). All intranasal corticosteroids are considered equally effective. Probably the most critical factor is compliance with regular use and proper introduction into the nasal cavity. In order to deliver medication to the region of the middle meatus, proper application involves holding the bottle straight up with the head tilted forward and pointing the bottle toward the ipsilateral ear when spraying. Side effects are limited and the most annoying is epistaxis. Some experts believe that this is related to incorrect delivery of the drug to the nasal septum.

B. Antihistamines

Treatment of allergic and perennial rhinitis has improved in recent years. Antihistamines offer temporary, but immediate, control of many of the most troubling symptoms of allergic rhinitis. Over-the-counter antihistamines include nonsedating loratadine (10 mg orally once daily) and minimally sedating cetirizine (10 mg orally once daily). Brompheniramine or chlorpheniramine (4 mg orally

every 6–8 hours, or 8–12 mg orally every 8–12 hours as a sustained-release tablet) and clemastine (1.34–2.68 mg orally twice daily) may be less expensive, although usually associated with some drowsiness. Prescription oral H₁-receptor antagonists include fexofenadine (60 mg twice daily or 120 mg once daily) and desloratadine (5 mg once daily). Fexofenadine appears to be nonsedating; desloratadine is minimally sedating. Also shown to be effective in randomized trials are ebastine (10–20 mg orally once daily) and misolastine (10 mg orally once daily). The H₁-receptor antagonist antihistamine nasal spray azelastine (1–2 sprays per nostril daily) has also been shown to be effective in a randomized trial. Topical nasal sprays are particularly useful in patients who experience side effects, mostly xerostomia and sedation, of oral antihistamines. Many patients who find initial benefit from an antihistamine complain that allergy symptoms eventually return after several months of use. In such patients, typically with perennial allergy problems, antihistamine tolerance seems to develop and alternating effective antihistamines periodically can control symptoms over the long term.

C. Adjunctive Treatment Measures

In addition to intranasal corticosteroid sprays and antihistamines, including H₁-receptor antagonists, the literature supports the use of antileukotriene medications such as montelukast (10 mg/d orally) alone or with cetirizine (10 mg/d orally) or loratadine (10 mg/d orally). There are proinflammatory effects of cysteinyl leukotrienes in upper airway disease, including allergic rhinitis, and hyperplastic polyposis, and sinusitis. Improved nasal rhinorrhea, sneezing, and congestion are seen with the use of leukotriene receptor antagonists, often in conjunction with antihistamines. Cromolyn sodium and sodium nedocromil are also useful adjunct agents for allergic rhinitis. They work by stabilizing mast cells and preventing proinflammatory mediator release. They are not absorbed by the gastrointestinal tract but do function topically and have very few side effects. The most useful form of cromolyn is probably the ophthalmologic preparation; the nasal preparation is not nearly as effective as inhaled corticosteroids. Intranasal cromolyn is cleared rapidly and must be administered four times daily for continued relief of symptoms.

Intranasal anticholinergic agents, such as ipratropium bromide 0.03% or 0.06% sprays (42–84 mcg per nostril three times daily), may be helpful adjuncts when rhinorrhea is a major symptom. Ipratropium nasal sprays are not as effective as intranasal corticosteroids for treating allergic rhinitis but are useful for treating **vasomotor rhinitis**.

Avoiding or reducing exposure to airborne allergens is the most effective means of alleviating symptoms of allergic rhinitis. Depending on the allergen, this can be extremely difficult. Maintaining an allergen-free environment by covering pillows and mattresses with plastic covers, substituting synthetic materials (foam mattress, acrylics) for animal products (wool, horsehair), and removing dust-collecting household fixtures (carpets, drapes, bedspreads,

wicker) is worth the attempt to help more troubled patients. Air purifiers and dust filters may also aid in maintaining an allergen-free environment. Nasal saline irrigations are a useful adjunct in the treatment of allergic rhinitis to mechanically flush the allergens from the nasal cavity. Though debated, there is no clear benefit to hypertonic saline over commercially available normal saline preparations (eg, Ayr or Ocean Spray). When symptoms are extremely bothersome, a search for offending allergens may prove helpful. This can either be done by serum radioallergen sorbent test (RAST) testing or skin testing by an allergist.

In some cases, allergic rhinitis symptoms are inadequately relieved by medication and avoidance measures. Often, such patients have a strong family history of atopy and may also have lower respiratory manifestations such as allergic asthma. Referral to an allergist may be appropriate for consideration of immunotherapy. This treatment course is quite involved, with proper identification of offending allergens, progressively increasing doses of allergen(s) and eventual maintenance dose administration over a period of 3–5 years. Immunotherapy has been proven to reduce circulating IgE levels in patients with allergic rhinitis and reduce the need for allergy medications. While oral allergen exposure is actively being investigated, currently the primary mode of allergen exposure is by subcutaneous injection. Treatments are given at a suitable medical facility with monitoring following treatment because of the risk of anaphylaxis during dose escalation. Local reactions are common and usually self-limited.

OLFACTORY DYSFUNCTION

ESSENTIALS OF DIAGNOSIS

- ▶ Subjective diminished smell or taste sensation.
- ▶ Lack of objective nasal obstruction.
- ▶ Objective decrease in olfaction demonstrated by testing.

► General Considerations

Odorant molecules traverse the nasal vault to reach the cribriform area and become soluble in the mucus overlying the exposed dendrites of receptor cells. Anatomic blockage of the nasal cavity with subsequent airflow disruption is the most common cause of olfactory dysfunction (hyposmia or anosmia). Polyps, septal deformities, and nasal tumors may be the cause. Transient olfactory dysfunction often accompanies the common cold, nasal allergies, and perennial rhinitis through changes in the nasal and olfactory epithelium. About 20% of olfactory dysfunction is idiopathic, although it often follows a viral illness. Central nervous system neoplasms, especially those that involve the olfactory groove or temporal lobe, may affect olfaction and must be considered in patients with no other explanation for their hyposmia or other neurologic signs. Head trauma accounts for < 5% of cases of hyposmia but is more commonly associated with anosmia. Absent, diminished, or distorted smell or taste has been reported in a wide variety of endocrine, nutritional, and nervous disorders. In particular, olfactory dysfunction in Parkinson disease and Alzheimer disease has been the subject of research. A great many medications have also been implicated in altering olfaction.

► Clinical Findings

Evaluation of olfactory dysfunction should include a thorough history of systemic illnesses and medication use as well as a physical examination focusing on the nose and nervous system. Nasal obstruction (from polyps, trauma, foreign bodies or nasal masses) can cause functional hyposmia and should be excluded before concluding that the disruption of olfaction is primary. Most clinical offices are not set up to test olfaction, but such tests may at times be worthwhile if only to assess whether a patient possesses any sense of smell at all. The University of Pennsylvania Smell Identification Test (UPSIT) is available commercially and is a simple, self-administered “scratch-and-sniff” test that is useful in differentiating hyposmia, anosmia, and malingering. Odor threshold can be tested at regional specialty centers using increasing concentrations of various odorants.

► Treatment

There is no specific treatment for primary disruption of olfaction. While some disturbances spontaneously resolve, little evidence supports the use of large doses of vitamin A and zinc to patients with transient olfactory dysfunction. The degree of hyposmia is the greatest predictor of recovery, with less severe hyposmia recovering at a much higher rate. In permanent hyposmia, counseling should be offered about seasoning foods with spices (eg, pepper) that stimulate the trigeminal as well as olfactory chemoreceptors, abuse of table salt as a seasoning, and safety issues such as the use of smoke alarms and electric rather than gas home appliances.

EPISTAXIS

ESSENTIALS OF DIAGNOSIS

- Bleeding from the unilateral anterior nasal cavity most commonly.
- Most cases may be successfully treated by direct pressure on the bleeding site for 15 minutes. When this is inadequate, topical sympathomimetics and various nasal tamponade methods are usually effective.
- Posterior, bilateral, or large volume epistaxis should be triaged immediately to a specialist in a critical care setting.

► General Considerations

Epistaxis is an extremely common problem in the primary care setting. Predisposing factors include nasal trauma (nose picking, foreign bodies, forceful nose blowing), rhinitis, drying of the nasal mucosa from low humidity or supplemental nasal oxygen, deviation of the nasal septum, hypertension, atherosclerotic disease, hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome), inhaled nasal cocaine or other drug use, and alcohol use. Anticoagulation or antiplatelet medications may be associated with a higher incidence of epistaxis, more frequent recurrence of epistaxis, and greater difficulty controlling bleeding, but they do not cause epistaxis. Bleeding is most common in the anterior septum where a confluence of veins creates a superficial venous plexus (Kiesselbach plexus).

► Clinical Findings

It is important in all patients with epistaxis to consider underlying causes of the bleeding. Laboratory assessment of bleeding parameters may be indicated, especially in recurrent cases. Once the acute episode has passed, careful examination of the nose and paranasal sinuses to rule out neoplasia and hereditary hemorrhagic telangiectasia is wise.

Patients presenting with epistaxis often have higher blood pressures than control patients, but in many cases, blood pressure returns to normal following treatment of acute bleeding. Repeat evaluation for clinically significant hypertension and treatment should be performed following control of epistaxis and removal of any packing.

► Treatment

Most cases of anterior epistaxis may be successfully treated by direct pressure on the site by compression of the nares continuously for 15 min. Venous pressure is reduced in the sitting position, and slight leaning forward lessens the swallowing of blood. Short-acting topical nasal decongestants (eg, phenylephrine, 0.125–1% solution, one or two sprays), which act as vasoconstrictors, may also be helpful. When the bleeding does not readily subside, the nose should be examined, using good illumination and suction, in an attempt to locate the bleeding site. Topical 4% cocaine applied either as a spray or on a cotton strip serves both as an anesthetic and a vasoconstrictor. If cocaine is unavailable, a topical decongestant (eg, oxymetazoline) and a topical anesthetic (eg, tetracaine or lidocaine) provide similar results. When visible, the bleeding site may be cauterized with silver nitrate, diathermy, or electrocautery. A supplemental patch of Surgicel or Gelfoam may be helpful with a moisture barrier, such as petroleum-based ointment, to prevent drying and crusting.

Occasionally, a site of bleeding may be inaccessible to direct control, or attempts at direct control may be unsuccessful. In such cases there are a number of alternatives. When the site of bleeding is anterior, a hemostatic sealant, pneumatic nasal tamponade, or anterior packing may suffice. There are a number of ways to do this, such as with several feet of lubricated iodoform packing systematically placed in the floor of the nose and then the vault of the nose, or with various manufactured products designed for nasal tamponade.

About 5% of nasal bleeding originates in the **posterior nasal cavity**. Such bleeds are more commonly associated with atherosclerotic disease and hypertension. If an anteriorly placed pneumatic nasal tamponade is unsuccessful, it may be necessary to consult an otolaryngologist for a pack to occlude the choana before placing a pack anteriorly. In emergency settings, double balloon packs (Epistat) may facilitate rapid control of bleeding with little or no mucosal trauma. Because such packing is uncomfortable, bleeding may persist, and vasovagal syncope is quite possible, hospitalization for monitoring and stabilization is indicated. Opioid analgesics are needed to reduce the considerable discomfort and elevated blood pressure caused by a posterior pack.

Surgical management of epistaxis, through ligation of the nasal arterial supply (internal maxillary artery and ethmoid arteries) is an alternative to posterior nasal packing. Endovascular embolization of the internal maxillary artery or facial artery is also quite effective and can allow very specific control of hemorrhage. Such alternatives are necessary when packing fails to control life-threatening hemorrhage. On very rare occasions, ligation of the external carotid artery may be necessary.

After control of epistaxis, the patient is advised to avoid straining and vigorous exercise for several days. Nasal saline should be applied to the packing frequently to keep the packing moist. Avoidance of hot or spicy foods and tobacco is also advisable, since these may cause nasal vasodilation. Avoiding nasal trauma, including nose picking, is

an obvious necessity. Lubrication with petroleum jelly or bacitracin ointment and increased home humidity may also be useful ancillary measures. Finally, antistaphylococcal antibiotics (eg, cephalexin, 500 mg orally four times daily, or clindamycin, 150 mg orally four times daily) are indicated to reduce the risk of toxic shock syndrome developing while the packing remains in place (at least 5 days).

► When to Refer

- Patients with recurrent epistaxis, large volume epistaxis, and episodic epistaxis with associated nasal obstruction should be referred to an otolaryngologist for endoscopic evaluation and possible imaging.
- Those with ongoing bleeding beyond 15 minutes should be taken to a local emergency department if the clinician is not prepared to manage acute epistaxis.

NASAL TRAUMA

The nasal pyramid is the most frequently fractured bone in the body. Fracture is suggested by crepitation or palpably mobile bony segments. Epistaxis and pain are common, as are soft tissue hematomas (“black eye”). It is important to make certain that there is no palpable step-off of the infraorbital rim, which would indicate the presence of a zygomatic complex fracture. Radiologic confirmation may at times be helpful but is not necessary in uncomplicated nasal fractures. It is also important to assess for possible concomitant additional facial, pulmonary, or intracranial injuries when the circumstances of injury are suggestive, as in the case of automobile and motorcycle accidents.

Treatment is aimed at maintaining long-term nasal airway patency and cosmesis. Closed reduction, using topical 4% cocaine and locally injected 1% lidocaine, should be attempted within 1 week of injury. In the presence of marked nasal swelling, it is best to wait several days for the edema to subside before undertaking reduction. Persistent functional or cosmetic defects may be repaired by delayed reconstructive nasal surgery.

Intranasal examination should be performed in all cases to rule out septal hematoma, which appears as a widening of the anterior septum, visible just posterior to the columella. The septal cartilage receives its only nutrition from its closely adherent mucoperichondrium. An untreated subperichondrial hematoma will result in loss of the nasal cartilage with resultant saddle nose deformity. Septal hematomas may become infected, with *S aureus* most commonly, and should be drained with an incision in the inferior mucoperichondrium on both sides.

Packing for 2–5 days is often helpful to help prevent re-formation of the hematoma. Antibiotics with

antistaphylococcal efficacy (eg, cephalexin, 500 mg four times daily, or clindamycin, 150 mg four times daily) should be given for 3–5 days or the duration of the packing to reduce the risk of toxic shock syndrome and the drained fluid sent for culture.

TUMORS & GRANULOMATOUS DISEASE

1. Benign Nasal Tumors

A. Nasal Polyps

Nasal polyps are pale, edematous, mucosally covered masses commonly seen in patients with allergic rhinitis, but compelling evidence argues against a purely allergic pathogenesis. They may result in chronic nasal obstruction and a diminished sense of smell. In patients with nasal polyps and a history of asthma, aspirin should be avoided as it may precipitate a severe episode of bronchospasm, known as **triad asthma** (Samter triad). Such patients may have an immunologic salicylate sensitivity. The presence of polyps in children should suggest the possibility of cystic fibrosis.

Initial treatment with topical nasal corticosteroids (see Allergic Rhinitis section for specific drugs) for 1–3 months is usually successful for small polyps and may reduce the need for operation. A short course of oral corticosteroids (eg, prednisone, 6-day course using 21 5-mg tablets: 30 mg on day 1 and tapering by 5 mg each day) may also be of benefit. When polyps are massive or medical management is unsuccessful, polyps may be removed surgically. In healthy persons, this is a minor outpatient procedure. In recurrent cases or when surgery itself is associated with increased risk (such as in patients with asthma), a more complete procedure, such as ethmoidectomy, may be advisable. In recurrent polyposis, it may be necessary to remove polyps from the ethmoid, sphenoid, and maxillary sinuses to provide longer-lasting relief. Intranasal corticosteroid should be continued following polyp removal to prevent recurrence, and the clinician should consider allergen testing to determine the offending allergen and avoidance measures.

Williams AN et al. The clinical effectiveness of aspirin desensitization in chronic rhinosinusitis. *Curr Allergy Asthma Rep*. 2008 May;8(3):245–52. [PMID: 18589844]

B. Inverted Papilloma

Inverted papillomas are benign tumors caused by human papillomavirus (HPV) that usually arise on the lateral nasal wall. They present with unilateral nasal obstruction and occasionally hemorrhage. They are often easily seen on anterior rhinoscopy as cauliflower-like growths in or around the middle meatus. Because SCC is seen in about 10% of inverted or schneiderian papillomas, complete excision is strongly recommended. This usually requires a medial maxillectomy, but in selected cases an endoscopic approach may be possible. Because recurrence rates for inverted papilloma are reported to be as high as 20%, subsequent clinical and radiologic follow-up is imperative. All excised tissue (not just a portion) should be carefully reviewed by the pathologist to be sure no carcinoma is present.

Reh DD et al. The role of endoscopic sinus surgery in the management of sinonasal inverted papilloma. *Curr Opin Otolaryngol Head Neck Surg*. 2009 Feb;17(1):6–10. [PMID: 19225300]

C. Juvenile Angiofibroma

These highly vascular tumors arise in the nasopharynx, typically in adolescent males. Initially, they cause nasal obstruction and hemorrhage. Any adolescent male with recurrent epistaxis should be evaluated for an angiofibroma. *The clinician should take great care when considering a biopsy because these masses can bleed profusely.* Although benign, these tumors expand locally from the sphenopalatine foramen to the pterygopalatine fossa at the pterygoid canal and extend to the pterygoid base, the greater wing of the sphenoid, the nasal cavity, and the paranasal sinuses. They may involve the skull base, usually extradurally, and extend into the superior clivus. Treatment consists of preoperative embolization followed by surgical excision via an approach appropriate for the tumor extent. Small angiofibromas that do not involve the infratemporal fossa may be resected endoscopically. Extensive ones may require skull base approaches. Recurrences are not uncommon and should be resected if possible. Unresectable recurrences that do not appear to grow significantly may be followed radiologically with serial MR scans in expectation of possible eventual involution stabilization or involution of tumor. Low-dose (30 Gy) irradiation may be helpful in nonresectable, continually growing tumors.

2. Malignant Nasopharyngeal & Paranasal Sinus Tumors

Though rare, malignant tumors of the nose, nasopharynx, and paranasal sinuses are quite problematic because they tend to remain asymptomatic until late in their course. SCC is the most common cancer found in the sinuses and nasopharynx. It is especially common in the nasopharynx, where it obstructs the eustachian tube and results in serous otitis media. Nasopharyngeal carcinoma (poorly differentiated SCC, nonkeratinizing SCC, or lymphoepithelioma) is usually associated with elevated IgA antibody to the viral capsid antigen of the Epstein-Barr virus (EBV). It is particularly common in patients of southern Chinese descent. Adenocarcinomas, mucosal melanomas, sarcomas, and non-Hodgkin lymphomas are less commonly encountered neoplasms of this area.

Early symptoms are nonspecific, mimicking those of rhinitis or sinusitis. Unilateral nasal obstruction, otitis media, and discharge are common, with pain and recurrent hemorrhage often clues to the diagnosis of cancer. Any adult with persistent unilateral nasal symptoms or new otitis media should be thoroughly evaluated with nasal endoscopy and nasopharyngoscopy. A high index of suspicion remains a key to early diagnosis of these tumors. Patients often present with advanced symptoms such as proptosis, expansion of a cheek, or ill-fitting maxillary dentures. Malar hypesthesia, due to involvement of the infraorbital nerve, is common in maxillary sinus tumors. Biopsy is necessary for definitive diagnosis, and MRI is the best imaging study to delineate the extent of disease and plan appropriate surgery and radiation.

Treatment depends on the tumor type and the extent of disease. Nasopharyngeal carcinoma at this time is best treated by concomitant radiation and cisplatin followed by adjuvant chemotherapy with cisplatin and fluorouracil—this protocol significantly decreases local, nodal, and distant failures and increased progression-free and overall survival. Locally recurrent nasopharyngeal carcinoma may in selected cases be treated with repeat irradiation protocols or surgery with moderate success and a high degree of concern about local wound healing. Other SCCs are best treated—when resectable—with a combination of surgery and irradiation. Numerous protocols investigating the role of chemotherapy are under evaluation. Cranial base surgery appears to be an effective modality in improving the overall prognosis in paranasal sinus malignancies eroding the ethmoid roof. More centers are capable of performing such resections endoscopically using image navigation. Although the prognosis is poor for advanced tumors, the results of treating resectable tumors of paranasal sinus origin have improved with the wider use of skull base resections and intensity-modulated radiation therapy. Cure rates are often 45–60%.

3. Sinonasal Inflammatory Disease (Granulomatosis with Polyangiitis & Sarcoidosis)

The nose and paranasal sinuses are involved in over 90% of cases of granulomatosis with polyangiitis (formerly Wegener granulomatosis). It is often not realized that involvement at these sites is more common than involvement of lungs or kidneys. Examination shows bloodstained crusts and friable mucosa. Biopsy, when positive, shows necrotizing granulomas and vasculitis. Other recognized sites of granulomatosis with polyangiitis (formerly Wegener granulomatosis) in the head and neck include the subglottis and the middle ear.

Sarcoidosis also commonly involves the paranasal sinuses and is clinically similar to other chronic sinonasal inflammatory processes. Sinonasal symptoms, including rhinorrhea, nasal obstruction, and hyposmia or anosmia may precede diagnosis of sarcoidosis in other organ systems. Clinically, the turbinates appear engorged with small white granulomas. Biopsy shows classic noncaseating granulomas. Notably, patients with sinonasal involvement generally have more trouble managing sarcoidosis in other organ systems.

Polymorphic reticulosis (midline malignant reticulosis, idiopathic midline destructive disease, lethal midline granuloma)—as the multitude of apt descriptive terms suggest—is not well understood but appears to be a nasal T-cell or NK cell lymphoma. In contrast to granulomatosis with polyangiitis (formerly Wegener granulomatosis), involvement is limited to the mid face, and there may be extensive bone destruction. Many destructive lesions of the mucosa and nasal structures labeled as polymorphic reticulosis are in fact non-Hodgkin lymphoma of either NK cell or T cell origin. Immunophenotyping, especially for CD56 expression, is essential in the histologic evaluation. Even when apparently localized, these lymphomas have a poor prognosis, with progression and death within a year the rule.

For treatment of granulomatosis with polyangiitis (formerly Wegener granulomatosis), see Chapter 20.

DISEASES OF THE ORAL CAVITY & PHARYNX

LEUKOPLAKIA, ERYTHROPLAKIA, ORAL LICHEN PLANUS, & ORAL CANCER

ESSENTIALS OF DIAGNOSIS

- ▶ **Leukoplakia**—A white lesion that cannot be removed by rubbing the mucosal surface.
- ▶ **Erythroplakia**—Similar to leukoplakia except that it has a definite erythematous component.
- ▶ **Oral Lichen Planus**—Most commonly presents as lacy leukoplakia but may be erosive; definitive diagnosis requires biopsy.
- ▶ **Oral Cancer**—Early lesions appear as leukoplakia or erythroplakia; more advanced lesions will be larger, with invasion into tongue such that a mass lesion is palpable. Ulceration may be present.

Leukoplakic regions range from small to several centimeters in diameter (Figure 8–3). Histologically, they are often hyperkeratoses occurring in response to chronic irritation (eg, from dentures, tobacco, lichen planus); about 2–6%, however, represent either dysplasia or early invasive SCC. Distinguishing between **erythroplakia** and **leukoplakia** is important because about 90% of cases of erythroplakia are either dysplasia or carcinoma. **SCC** accounts for 90% of oral cancer. Alcohol and tobacco use are the major epidemiologic risk factors.

The differential diagnosis may include oral candidiasis, necrotizing sialometaplasia, pseudoepitheliomatous hyperplasia, median rhomboid glossitis, and vesiculoerosive

▲ **Figure 8–3.** Leukoplakia with moderate dysplasia on the lateral border of the tongue. (Courtesy of Ellen Eisenberg, DMD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger, J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

inflammatory disease such as erosive lichen planus. This should not be confused with the brown-black gingival melanin pigmentation—diffuse or speckled—common in nonwhites, blue-black embedded fragments of dental amalgam, or other systemic disorders associated with general pigmentation (neurofibromatosis, familial polyposis, Addison disease). Intraoral melanoma is extremely rare and carries a dismal prognosis.

Any area of **erythroplakia**, enlarging area of **leukoplakia**, or a lesion that has submucosal depth on palpation should have an incisional biopsy or an exfoliative cytologic examination. Ulcerative lesions are particularly suspicious and worrisome. Specialty referral should be sought early both for diagnosis and treatment. A systematic intraoral examination—including the lateral tongue, floor of the mouth, gingiva, buccal area, palate, and tonsillar fossae—and palpation of the neck for enlarged lymph nodes should be part of any general physical examination, especially in patients over the age of 45 who smoke tobacco or drink immoderately. Indirect or fiberoptic examination of the nasopharynx, oropharynx, hypopharynx, and larynx by an otolaryngologist, head and neck surgeon, or radiation oncologist should also be considered for such patients when there is unexplained or persistent throat or ear pain, oral or nasal bleeding, or oral erythroplakia. Fine-needle aspiration (FNA) biopsy may expedite the diagnosis if an enlarged lymph node is found. To date, there are no approved therapies for reversing or stabilizing leukoplakia or erythroplakia.

Oral lichen planus is a relatively common (0.5–2% of the population) chronic inflammatory autoimmune disease that may be difficult to diagnose clinically because of its numerous distinct phenotypic subtypes. For example, the reticular pattern may mimic candidiasis or hyperkeratosis, while the erosive pattern may mimic SCC. Management begins with distinguishing it from other oral lesions. Exfoliative cytology or a small incisional or excisional biopsy is indicated, especially if SCC is suspected. Therapy is aimed at managing pain and discomfort. Corticosteroids have been used widely both locally and systemically. Cyclosporines and retinoids have also been used. Many think there is a low rate (1%) of SCC arising within lichen planus (in addition to the possibility of clinical misdiagnosis).

Hairy leukoplakia occurs on the lateral border of the tongue and is a common early finding in HIV infection (see Chapter 31). It often develops quickly and appears as slightly raised leukoplakic areas with a corrugated or “hairy” surface (Figure 8–4). Clinical response following administration of zidovudine or acyclovir has been reported, and treatment is under active investigation.

Early detection of **SCC** is the key to successful management (Figure 8–5). Lesions < 4 mm in depth have a low propensity to metastasize. Most patients in whom the tumor is detected before it is 2 cm in diameter are cured by local resection. Radiation is an alternative but not generally used as first-line therapy for small lesions. Large tumors are usually treated with a combination of resection, neck dissection, and external beam radiation. Reconstruction, if required, is done at the time of resection and can involve

▲ **Figure 8-4.** Oral hairy leukoplakia on the side of the tongue in AIDS. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger, J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

the use of myocutaneous flaps or vascularized free flaps with or without bone.

A number of clinical trials have suggested a role for beta-carotene, cyclooxygenase (COX)-2 inhibitors, vitamin E, and retinoids in producing regression of leukoplakia and reducing the incidence of recurrent SCCs. Retinoids suppress head and neck and lung carcinogenesis in animal models and inhibit carcinogenesis in individuals with pre-malignant lesions. They also seem to reduce the incidence of second primary cancers in head and neck and lung cancer patients previously treated for a primary.

ORAL CANDIDIASIS

ESSENTIALS OF DIAGNOSIS

- ▶ Fluctuating throat or mouth discomfort.
- ▶ Systemic or local immunosuppression, such as recent corticosteroid, chemotherapy, or antibiotic use.
- ▶ Erythema of the oral cavity or oropharynx with fluffy, white patches.
- ▶ Rapid resolution of symptoms with appropriate treatment.

▶ Clinical Findings

A. Symptoms and Signs

Oral candidiasis (thrush) is usually painful and looks like creamy-white curd-like patches overlying erythematous mucosa (see Figure 6–24). Because these white areas are easily rubbed off (eg, by a tongue depressor)—unlike leukoplakia or lichen planus—only the underlying irregular erythema may be seen. Oral candidiasis is commonly encountered among the following adult patients: (1) those who wear dentures, (2) those who are debilitated and have poor oral hygiene, (3) those with diabetes, (4) those with anemia, (5) those undergoing chemotherapy or local irradiation, and (6) those receiving corticosteroids (oral or systemic) or broad-spectrum antibiotics. Angular cheilitis is another manifestation of candidiasis, although it is also seen in nutritional deficiencies (Figure 8–6).

B. Diagnostic Studies

The diagnosis is made clinically. A wet preparation using potassium hydroxide will reveal spores and may show non-septate mycelia. Biopsy will show intraepithelial pseudomycelia of *Candida albicans*.

Candidiasis is often the first manifestation of HIV infection, and HIV testing should be considered in patients with no known predisposing cause for *Candida* overgrowth (see also Chapter 31). The US Department of Health Services Clinical Practice Guideline for Evaluation and Management of Early HIV Infection recommends

▲ **Figure 8-6.** Severe angular cheilitis in HIV-positive man with oral thrush. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger, J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

examination of the oral mucosa with each clinician visit as well as at a dental examination every 6 months.

► Treatment

Effective antifungal therapy may be achieved with any of the following: fluconazole (100 mg orally daily for 7 days), ketoconazole (200–400 mg with breakfast [requires acidic gastric environment for absorption] for 7–14 days), clotrimazole troches (10 mg dissolved orally five times daily), or nystatin vaginal troches (100,000 units dissolved orally five times daily) or mouth rinses (500,000 units [5 mL of 100,000 units/mL] held in the mouth before swallowing three times daily). In patients with HIV infection, however, longer courses of therapy with fluconazole may be needed, and oral itraconazole (200 mg/d) may be indicated in fluconazole-refractory cases. Many of the *Candida* species in these patients are resistant to first-line azoles and may require newer drugs, such as voriconazole. In addition, 0.12% chlorhexidine or half-strength hydrogen peroxide mouth rinses may provide local relief. Nystatin powder (100,000 units/g) applied to dentures three or four times daily for several weeks may help denture wearers.

GLOSSITIS, GLOSSODYNIA, DYSGEUSIA, & BURNING MOUTH SYNDROME

Inflammation of the tongue with loss of filiform papillae leads to a red, smooth-surfaced tongue (glossitis). Rarely painful, it may be secondary to nutritional deficiencies (eg,

niacin, riboflavin, iron, or vitamin E), drug reactions, dehydration, irritants, foods and liquids, and possibly autoimmune reactions or psoriasis. If the primary cause cannot be identified and corrected, empiric nutritional replacement therapy may be of value.

Glossodynia is burning and pain of the tongue, which may occur with or without glossitis. In the absence of any clinical findings, it has been termed “burning mouth syndrome.” Glossodynia with glossitis has been associated with diabetes mellitus, drugs (eg, diuretics), tobacco, xerostomia, and candidiasis as well as the listed causes of glossitis. Periodontal disease is not apt to be a factor. The burning mouth syndrome typically has no identifiable associated risk factors and seems to be most common in postmenopausal women. Treating possible underlying causes, changing long-term medications to alternative ones, and smoking cessation may resolve symptoms of glossitis. Both glossodynia and the burning mouth syndrome are benign, and reassurance that there is no infection or tumor is likely to be appreciated. Effective treatments for the burning mouth syndrome include alpha-lipoic acid and clonazepam. Clonazepam is most effective as a rapid dissolving tablet placed on the tongue in doses from 0.25 mg to 0.5 mg every 8–12 hours. Behavioral therapy has also been shown to be effective. Unilateral symptoms, symptoms that cannot be related to a specific medication, and symptoms and signs involving regions supplied by other cranial nerves all may suggest neuropathology, and imaging of the brain, brainstem, and skull base with MRI should be considered.

INTRAORAL ULCERATIVE LESIONS

1. Necrotizing Ulcerative Gingivitis (Trench Mouth, Vincent Angina)

Necrotizing ulcerative gingivitis, often caused by an infection of both spirochetes and fusiform bacilli, is common in young adults under stress (classically at examination time). Underlying systemic diseases may also predispose to this disorder. Clinically, there is painful acute gingival inflammation and necrosis, often with bleeding, halitosis, fever, and cervical lymphadenopathy. Warm half-strength peroxide rinses and oral penicillin (250 mg three times daily for 10 days) may help. Dental gingival curettage may prove necessary.

Feller L et al. Necrotizing periodontal diseases in HIV-seropositive subjects: pathogenic mechanisms. *J Int Acad Periodontol*. 2008 Jan;10(1):10–5. [PMID: 18333595]

2. Aphthous Ulcer (Canker Sore, Ulcerative Stomatitis)

Aphthous ulcers are very common and easy to recognize. Their cause remains uncertain, although an association with human herpesvirus 6 has been suggested. Found on freely moving, nonkeratinized mucosa (eg, buccal and labial mucosa and not attached gingiva or palate), they may be single or multiple, are usually recurrent, and appear as painful small round ulcerations with yellow-gray fibrinoid centers surrounded by red halos (Figure 8–7). Minor aphthous ulcers are < 1 cm and generally heal in 10–14 days. Major aphthous ulcers are > 1 cm and can be disabling due to the degree of associated oral pain.

Treatment is nonspecific. Topical corticosteroids (triamcinolone acetonide, 0.1%, or fluocinonide ointment, 0.05%) in an adhesive base (Orabase Plain) do appear to provide symptomatic relief. Other topical therapies shown to be effective in controlled studies include diclofenac 3% in hyaluronan 2.5%, doxymycine-cyanoacrylate, mouthwashes containing the enzymes amyloglucosidase and glucose oxidase, and amlexanox 5% oral paste. A 1-week tapering course of prednisone (40–60 mg/d) has also been used successfully. Cimetidine maintenance therapy may be useful in patients with recurrent aphthous ulcers. Thalidomide has been used selectively in recurrent aphthous ulcerations in HIV-positive patients.

Large or persistent areas of ulcerative stomatitis may be secondary to erythema multiforme or drug allergies, acute herpes simplex, pemphigus, pemphigoid, epidermolysis bullosa acquisita, bullous lichen planus, Behçet disease, or inflammatory bowel disease. SCC may occasionally present

▲ **Figure 8–7.** Aphthous stomatitis. (Courtesy of Ellen Eisenberg, MD and Dr. Joanna Douglas; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger, J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

in this fashion. When the diagnosis is not clear, incisional biopsy is indicated.

Chattopadhyay A et al. Recurrent aphthous stomatitis. *Otolaryngol Clin North Am.* 2011 Feb;44(1):79–88. [PMID: 21093624]
Scully C et al. Oral mucosal disease: recurrent aphthous stomatitis. *Br J Oral Maxillofac Surg.* 2008 Apr;46(3):198–206. [PMID: 17850936]

3. Herpetic Stomatitis

Herpetic gingivostomatitis is common, mild, and short-lived and requires no intervention in most adults. In immunocompromised persons, however, reactivation of herpes simplex virus infection is frequent and may be severe. Clinically, there is initial burning, followed by typical small vesicles that rupture and form scabs. Lesions are most commonly found on the attached gingiva and mucocutaneous junction of the lip, but lesions can also form on the tongue, buccal mucosa, and soft palate. Acyclovir (200–800 mg orally five times daily for 7–14 days) may shorten the course and reduce postherpetic pain. Differential diagnosis includes aphthous stomatitis (see above), erythema multiforme, syphilitic chancre, and carcinoma. Coxsackievirus-caused lesions (grayish white tonsillar plaques and palatal ulcers of herpangina or buccal and lip ulcers in hand-foot-and-mouth disease) are seen more commonly in children under age 6.

PHARYNGITIS & TONSILLITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Sore throat.
- ▶ Fever.
- ▶ Anterior cervical adenopathy.
- ▶ Tonsillar exudate.
- ▶ Focus is to treat group A β -hemolytic streptococcus infection to prevent rheumatic sequelae.

▶ General Considerations

Pharyngitis and tonsillitis account for over 10% of all office visits to primary care clinicians and 50% of outpatient antibiotic use. The most appropriate management continues to be debated because some of the issues are deceptively complex, but consensus has increased in recent years.

The main concern is determining who is likely to have a group A β -hemolytic streptococcal infection (GABHS), as this can lead to subsequent complications such as rheumatic fever and glomerulonephritis. A second public health policy concern is reducing the extraordinary cost (both in dollars and in the development of antibiotic-resistant *S pneumoniae*) in the United States associated with unnecessary antibiotic use. Questions now being asked: Is there still a role for culturing a sore throat, or have the rapid antigen tests supplanted this procedure under most circumstances? Are clinical criteria alone a sufficient basis for decisions about which patients should be given antibiotics? Should any patient receive any antibiotic other than penicillin (or erythromycin if penicillin-allergic)? For how long should treatment be continued? Numerous well-done studies in the past few years as well as increasing experience with rapid laboratory tests for detection of streptococci (eliminating the delay caused by culturing) appear to make a consensus approach more possible.

► Clinical Findings

A. Symptoms and Signs

The clinical features most suggestive of GABHS pharyngitis include fever over 38°C, tender anterior cervical adenopathy, lack of a cough, and a pharyngotonsillar exudate (Figures 8–8 and 8–9). These four features (the Centor criteria), when present, strongly suggest GABHS, and some would treat regardless of laboratory results. When three of the four are present, laboratory sensitivity of rapid antigen testing for GABHS exceeds 90%. When only one criterion is present, GABHS is unlikely. Sore throat may be severe, with odynophagia, tender adenopathy, and a scarlatiniform rash. An elevated white count and left shift are also possible. Hoarseness, cough, and coryza are not suggestive of this disease.

▲ **Figure 8-9.** Pharyngeal inflammation and petechiae of the soft palate caused by group A streptococcus. (Courtesy of Dr. Heinz F. Eichenwald, Public Health Image Library, CDC.)

Marked lymphadenopathy and a shaggy white-purple tonsillar exudate, often extending into the nasopharynx, suggest mononucleosis, especially if present in a young adult. With about 90% sensitivity, lymphocyte to white blood cell ratios of > 35% suggest EBV infection and not tonsillitis. Hepatosplenomegaly and a positive heterophil agglutination test or elevated anti-EBV titer are corroborative. However, about one-third of patients with infectious mononucleosis have secondary streptococcal tonsillitis, requiring treatment. Ampicillin should routinely be avoided if mononucleosis is suspected because it induces a rash that might be misinterpreted by the patient as a penicillin allergy. Diphtheria (extremely rare but described in the alcoholic population) presents with low-grade fever and an ill patient with a gray tonsillar pseudomembrane.

The most common pathogens other than GABHS in the differential diagnosis of “sore throat” are viruses, *Neisseria gonorrhoeae*, *Mycoplasma*, and *Chlamydia trachomatis*. Rhinorrhea and lack of exudate would suggest a virus, but in practice it is not possible to confidently distinguish viral upper respiratory infection from GABHS on clinical grounds alone. Infections with *Corynebacterium diphtheriae*, anaerobic streptococci, and *Corynebacterium haemolyticum* (which responds better to erythromycin than penicillin) may also mimic pharyngitis due to GABHS.

B. Laboratory Findings

A single-swab throat culture is 90–95% sensitive and the rapid antigen detection testing (RADT) is 90–99% sensitive for GABHS. Results from the RADT are available much sooner than from the throat culture.

► Treatment

Given the availability of many well-documented studies in recent years, one would think that a consensus might develop as to the most appropriate way to treat a sore throat. The Infectious Diseases Society of America recommends laboratory confirmation of the clinical diagnosis by means of either throat culture or RADT of the throat swab.

The American College of Physicians–American Society of Internal Medicine (ACP-ASIM), in collaboration with the Centers for Disease Control and Prevention, advocates use of a clinical algorithm alone—in lieu of microbiologic testing—for confirmation of the diagnosis in adults for whom the suspicion of streptococcal infection is high. Others examine the assumptions of the ACP-ASIM guideline for using a clinical algorithm alone and question whether those recommendations will achieve the stated objective of dramatically decreasing excess antibiotic use. A reasonable strategy to follow is that patients with zero or one Centor criteria are at very low risk for GABHS and therefore, do not need throat cultures or RADT of the throat swap and should not receive antibiotics. Patients with two or three Centor criteria need throat cultures or RADT of the throat swap, since positive results would warrant antibiotic treatment. Patients who have four Centor criteria are likely to have GABHS and can receive empiric therapy without throat culture or RADT.

Convincing clinical trials as well as clinician reminders and patient-based interventions may be needed before clinicians are likely to abandon long-held teachings (even though different clinicians appear to have been taught different strategies) regarding diagnosis and management of group A streptococcal pharyngitis. A Cochrane review concluded that multifaceted interventions where educational interventions occur on many levels were the only interventions whose effects were of sufficient magnitude to potentially reduce the incidence of antibiotic-resistant bacteria.

Thirty years ago, a single intramuscular injection of benzathine penicillin or procaine penicillin, 1.2 million units once, was the standard antibiotic treatment. This remains effective, but the injection is painful. It is now used for patients if compliance with an oral regimen is an issue. Currently, oral treatment is effective and preferred. Antibiotic choice aims to reduce the already low (10–20%) incidence of treatment failures (positive culture after treatment despite symptomatic resolution) and recurrences. Penicillin V potassium (250 mg orally three times daily or 500 mg twice daily for 10 days) or cefuroxime axetil (250 mg orally twice daily for 5–10 days) are both effective. The efficacy of a 5-day regimen of penicillin V potassium appears to be similar to that of a 10-day course, with a 94% clinical response rate and an 84% streptococcal eradication rate. Erythromycin (also active against *Mycoplasma* and *Chlamydia*) is a reasonable alternative to penicillin in allergic patients. Cephalosporins are somewhat more effective than penicillin in producing bacteriologic cures; 5-day administration has been successful for cefpodoxime and cefuroxime. The macrolide antibiotics have also been reported to be successful in shorter-duration regimens. Azithromycin (500 mg once daily), because of its long half-life, need be taken for only 3 days.

Adequate antibiotic treatment usually avoids the streptococcal complications of scarlet fever, glomerulonephritis, rheumatic myocarditis, and local abscess formation.

Antibiotics for treatment failures are also somewhat controversial. Surprisingly, penicillin-tolerant strains are not isolated more frequently in those who fail treatment than in those treated successfully with penicillin. The reasons for failure appear to be complex, and a second course of

treatment with the same drug is not unreasonable. Alternatives to penicillin include cefuroxime and other cephalosporins, dicloxacillin (which is β -lactamase-resistant), and amoxicillin with clavulanate. When there is a history of penicillin allergy, alternatives should be used, such as erythromycin. Erythromycin resistance—with failure rates of about 25%—is an increasing problem in many areas. In cases of severe penicillin allergy, cephalosporins should be avoided as the cross-reaction is common (8% or more).

Ancillary treatment of pharyngitis includes analgesics and anti-inflammatory agents, such as aspirin or acetaminophen. Some patients find that salt water gargling is soothing. In severe cases, anesthetic gargles and lozenges (eg, benzocaine) may provide additional symptomatic relief. Occasionally, odynophagia is so intense that hospitalization for intravenous hydration and antibiotics is necessary. (See Chapter 33.)

Patients who have had rheumatic fever should be treated with a continuous course of antimicrobial prophylaxis (erythromycin, 250 mg twice daily orally, or penicillin G, 500 mg once daily orally) for at least 5 years.

PERITONSILLAR ABSCESS & CELLULITIS

When infection penetrates the tonsillar capsule and involves the surrounding tissues, peritonsillar cellulitis results. Peritonsillar abscess (**quinsy**) and cellulitis present with severe sore throat, odynophagia, trismus, medial deviation of the soft palate and peritonsillar fold, and an abnormal muffled (“hot potato”) voice. Following therapy, peritonsillar cellulitis usually either resolves over several days or evolves into peritonsillar abscess, also known as quinsy. The existence of an abscess may be confirmed by aspirating pus from the peritonsillar fold just superior and medial to the upper pole of the tonsil. A 19-gauge or 21-gauge needle should be passed medial to the molar and no deeper than 1 cm, because the internal carotid artery may lie more medially than its usual location and pass posterior and deep to the tonsillar fossa. Most commonly, patients with peritonsillar abscess present to the emergency department and receive a dose of parenteral amoxicillin (1 g), amoxicillin-sulbactam (3 g), or clindamycin (600–900 mg). Less severe cases and patients who are able to tolerate oral intake may be treated for 7–10 days with oral antibiotics, including amoxicillin, 500 mg three times a day; amoxicillin-clavulanate, 875 mg twice a day; or clindamycin, 300 mg four times daily. Although antibiotic treatment is generally undisputed, there is controversy regarding the surgical management of peritonsillar abscess. Methods include needle aspiration, incision and drainage, and tonsillectomy. Some clinicians incise and drain the area and continue with parenteral antibiotics, whereas others aspirate only and monitor as an outpatient. To drain the abscess and avoid recurrence, it may be appropriate to consider immediate tonsillectomy

(quinsy tonsillectomy). About 10% of patients with peritonsillar abscess exhibit relative indications for tonsillectomy. All three approaches are effective and have support in the literature. Regardless of the method used, one must be sure the abscess is adequately treated, since complications such as extension to the retropharyngeal, deep neck, and posterior mediastinal spaces are possible. Bacteria may also be aspirated into the lungs, resulting in pneumonia. While there is controversy about whether a single abscess is sufficient indication for tonsillectomy, most would agree that patients with recurrent abscesses should have a tonsillectomy.

TONSILLECTOMY

Despite the frequency with which tonsillectomy is performed, the indications for the procedure remain controversial. Most clinicians would agree that airway obstruction causing sleep apnea or cor pulmonale is an absolute indication for tonsillectomy. Similarly, persistent marked tonsillar asymmetry should prompt an excisional biopsy to rule out lymphoma. Relative indications include recurrent streptococcal tonsillitis, causing considerable loss of time from school or work, recurrent peritonsillar abscess, and chronic tonsillitis.

Tonsillectomy is not an entirely benign procedure. The pros and cons of tonsillectomy need to be discussed with each prospective patient. Postoperative bleeding occurs in 2–4% of cases and on rare occasions can lead to laryngospasm and airway obstruction. Pain may be considerable, especially in the adult. Protracted emesis or fever may also occasionally occur. Secondary bleeding 5–8 days postoperatively is far more common than bleeding in the first 24 hours. There is increasing economic pressure for these procedures to be done as outpatient surgery. At present, it seems clear that outpatient tonsillectomy is usually safe when followed by a 6-hour period of uneventful observation, but individual circumstances may mandate hospitalization.

Although reports in the 1970s suggested an association of tonsillectomy with Hodgkin disease, careful review of this literature reveals no conclusively causative association.

DEEP NECK INFECTIONS

ESSENTIALS OF DIAGNOSIS

- ▶ Marked acute neck pain and swelling.
- ▶ Abscesses are emergencies because rapid airway compromise may occur.
- ▶ May spread to the mediastinum or cause sepsis.

▶ General Considerations

Ludwig angina is the most commonly encountered neck space infection. It is a cellulitis of the sublingual and submaxillary spaces, often arising from infection of the mandibular dentition. **Deep neck abscesses** most commonly originate from odontogenic infections. Other causes include suppurative lymphadenitis, direct spread of pharyngeal infection, penetrating trauma, pharyngoesophageal foreign bodies, cervical osteomyelitis, and intravenous injection of the internal jugular vein, especially in drug abusers. Recurrent deep neck infection may suggest an underlying congenital lesion such as a branchial cleft cyst. Suppurative lymphadenopathy in middle-age persons who smoke and drink alcohol regularly should be considered a manifestation of malignancy (typically metastatic SCC) until proven otherwise.

▶ Clinical Findings

Patients with **Ludwig angina** have edema and erythema of the upper neck under the chin and often of the floor of the mouth. The tongue may be displaced upward and backward by the posterior spread of cellulitis and coalescence of pus is often present in the floor of mouth. This may lead to occlusion of the airway. Microbiologic isolates include streptococci, staphylococci, *Bacteroides*, and *Fusobacterium*.

Patients with **deep neck abscesses** usually present with marked neck pain and swelling. Fever is common but not always present. *Deep neck abscesses are emergencies because they may rapidly compromise the airway.* Untreated or inadequately treated, they may spread to the mediastinum or cause sepsis.

Contrast-enhanced CT usually augments the clinical examination in defining the extent of the infection. It often will distinguish inflammation and phlegmon (requiring antibiotics) from abscess (requiring drainage), and define for the surgeon the extent of an abscess. CT with MRI may also identify thrombophlebitis of the internal jugular vein secondary to oropharyngeal inflammation. This condition, known as **Lemierre syndrome**, is rare and usually associated with severe headache. The presence of pulmonary infiltrates consistent with septic emboli in the setting of a neck abscess should lead one to suspect Lemierre syndrome.

▶ Treatment

Usual doses of penicillin plus metronidazole, ampicillin-sulbactam, clindamycin, or selective cephalosporins are good initial choices for treatment of **Ludwig angina**.

Culture and sensitivity data are then used to refine the choice. Dental consultation is advisable to address the offending tooth or teeth. External drainage via bilateral submental incisions is required if the airway is threatened or when medical therapy has not reversed the process.

Treatment of **deep neck abscesses** includes securing the airway, intravenous antibiotics, and incision and drainage. When the infection involves the floor of mouth, base of tongue, supraglottic or paraglottic space, the airway may be secured either by intubation or tracheotomy. Tracheotomy is preferable in the patients with substantial pharyngeal edema, since attempts at intubation may precipitate acute airway obstruction. Bleeding in association with a deep neck abscess is very rare but suggests carotid artery or internal jugular vein involvement and requires prompt neck exploration both for drainage of pus and for vascular control.

Patients with **Lemierre syndrome** require prompt institution of antibiotics appropriate for *Fusobacterium necrophorum* as well as the more usual upper airway pathogens. The use of anticoagulation in treatment is debated and of no proven benefit.

SNORING

ESSENTIALS OF DIAGNOSIS

- ▶ Noise produced on inspiration during sleep.
- ▶ Snoring is associated with obstructive sleep apnea (OSA) but has no disruption of sleep by clinical sleep evaluation.

▶ General Considerations

Ventilation disorders during sleep are extremely common. While OSA occurs in 5–10% of Americans, clinically relevant snoring may occur in as many as 59%. In general, sleep-disordered breathing problems are attributed to narrowing of the upper aerodigestive tract during sleep due to changes in position, muscle tone, and soft tissue hypertrophy or laxity. The most common sites of obstruction are the oropharynx and the base of the tongue. The spectrum of the problem ranges from simple snoring without cessation of airflow to OSA with long periods of apnea and life-threatening physiologic sequelae. OSA is discussed in Chapter 9. In contrast to OSA, snoring is almost exclusively a social problem, and despite its prevalence and association with OSA, there is comparatively little known about the management of this problem.

▶ Clinical Findings

A. Symptoms and Signs

All patients who complain of snoring should be evaluated for OSA as discussed in Chapter 9. Symptoms of OSA (including snoring, excessive daytime somnolence, daytime headaches, and weight gain) may be present in as many as 30% of patients without demonstrable apnea or hypopnea on formal testing. Clinical examination should include examination of the nasal cavity, nasopharynx, oropharynx, and larynx to help exclude other causes of dynamic airway obstruction. In many cases of isolated snoring, the palate and uvula appear enlarged and elongated with excessive mucosa hanging below the muscular portion of the soft palate.

B. Imaging and Diagnostic Testing

Sleep examination with polysomnography is strongly advised in the evaluation of a patient with complaints of snoring. Radiographic imaging of the head or neck is generally not necessary for management of primary snoring.

▶ Treatment

Expedient and inexpensive management solutions of snoring are sought, often with little or no benefit. Diet modification and a regimen of physical exercise can lead to improvement in snoring through weight loss and improvement in pharyngeal tone that accompanies overall physical conditioning. Position change during sleep can be effective, and time-honored treatments such as taping or sewing a tennis ball to the back of a shirt worn during sleep may satisfactorily eliminate symptoms by ensuring recumbency on one side.

Anatomic management of snoring can be challenging. As with OSA, snoring can come from a number of sites in the upper aerodigestive tract. While medical or surgical correction of nasal obstruction may help alleviate snoring problems, most interventions aim to improve airflow through the nasopharynx and oropharynx. Nonsurgical options include mandibular advancement appliances designed to pull the base of tongue forward and continuous positive airway pressure via face or nasal mask. Compliance with both of these treatment options is problematic because snorers without OSA do not notice the physiologic benefits of these devices noted by patients with sleep apnea.

Surgical correction of snoring is most commonly directed at the soft palate. Historical approaches involved resection of redundant mucosa and the uvula similar to uvulopalatopharyngoplasty which is used for OSA. Regardless of how limited the procedure or what technique was used, postoperative pain, expense of general anesthesia and high recurrence rates limit the utility of these procedures. Office-based approaches have become more widely used because of these limitations. Most of these procedures aim to stiffen the palate to prevent vibration rather than remove it. A series of procedures, including injection snoreplasty, radiofrequency thermal fibrosis, and implantable palatal device have been used with variable

success and patient tolerance. The techniques can be technically challenging. Persistent symptoms may occur following initial treatment necessitating costly (and sometimes painful) repeat procedures. The durability of these procedures in alleviating symptoms is also poorly understood and late failures can lead to patient and clinician frustration.

DISEASES OF THE SALIVARY GLAND

ACUTE INFLAMMATORY SALIVARY GLAND DISORDERS

1. Sialadenitis

Acute bacterial sialadenitis in the adult most commonly affects either the parotid or submandibular gland. It typically presents with acute swelling of the gland, increased pain and swelling with meals, and tenderness and erythema of the duct opening. Pus often can be massaged from the duct. Sialadenitis often occurs in the setting of dehydration or in association with chronic illness. Underlying Sjögren syndrome may contribute. Ductal obstruction, often by an inspissated mucous plug, is followed by salivary stasis and secondary infection. The most common organism recovered from purulent draining saliva is *S aureus*. Treatment consists of intravenous antibiotics such as nafcillin (1 g intravenously every 4–6 hours) and measures to increase salivary flow, including hydration, warm compresses, sialagogues (eg, lemon drops), and massage of the gland. Treatment can usually then be switched to an oral agent based on clinical and microbiologic improvement to complete a 10-day treatment course. Less severe cases can often be treated with oral antibiotics with similar spectrum. Complete resolution of parotid swelling and pain can take 2–3 weeks. Failure of the process to improve and ultimately resolve on this regimen suggests abscess formation, ductal stricture, stone, or tumor causing obstruction. Ultrasound or CT scan may be helpful in establishing the diagnosis. In the setting of acute illness, a severe and potentially life-threatening form of sialadenitis, sometimes called **suppurative sialadenitis**, may develop. The causative organism is usually *S aureus*, but often no pus will drain from Stensen papilla. These patients often do not respond to rehydration and intravenous antibiotics

and thus may require operative incision and drainage to resolve the infection.

2. Sialolithiasis

Calculus formation is more common in Wharton duct (draining the submandibular glands) than in Stensen duct (draining the parotid glands). Clinically, a patient may note postprandial pain and local swelling, often with a history of recurrent acute sialadenitis. Stones in Wharton duct are usually large and radiopaque, whereas those in Stensen duct are usually radiolucent and smaller. Those very close to the orifice of Wharton duct may be palpated manually in the anterior floor of the mouth and removed intraorally by dilating or incising the distal duct. The duct proximal to the stone must be temporarily clamped (using, for instance, a single throw of a suture) to keep manipulation of the stone from pushing it back toward the submandibular gland. Those more than 1.5–2 cm from the duct are too close to the lingual nerve to be removed safely in this manner. Similarly, dilation of Stensen duct, located on the buccal surface opposite the second maxillary molar, may relieve distal stricture or allow a small stone to pass. Extracorporeal shock-wave lithotripsy and fluoroscopically guided basket retrieval have been used successfully, but are being replaced by sialoendoscopy for the management of chronic sialolithiasis. Repeated episodes of sialadenitis are usually associated with stricture and chronic infection. If the obstruction cannot be safely removed or dilated, excision of the gland may be necessary to relieve recurrent symptoms.

Harrison JD. Causes, natural history, and incidence of salivary stones and obstructions. *Otolaryngol Clin North Am*. 2009 Dec;42(6):927–47. [PMID: 19962002]

CHRONIC INFLAMMATORY & INFILTRATIVE DISORDERS OF THE SALIVARY GLANDS

Numerous infiltrative disorders may cause unilateral or bilateral parotid gland enlargement. Sjögren syndrome and sarcoidosis are examples of lymphoepithelial and granulomatous diseases that may affect the salivary glands. Metabolic disorders, including alcoholism, diabetes mellitus, and vitamin deficiencies, may also cause diffuse enlargement. Several drugs have been associated with parotid enlargement, including thioureas, iodine, and drugs with cholinergic effects (eg, phenothiazines), which stimulate salivary flow and cause more viscous saliva.

Salomonsson S et al. Minor salivary gland immunohistology in the diagnosis of primary Sjögren's syndrome. *J Oral Pathol Med*. 2009 Mar;38(2):282–8. [PMID: 18793250]

SALIVARY GLAND TUMORS

Approximately 80% of salivary gland tumors occur in the parotid gland. In adults, about 80% of these are

benign. In the submandibular triangle, it is sometimes difficult to distinguish a primary submandibular gland tumor from a metastatic submandibular space node. Only 50–60% of primary submandibular tumors are benign. Tumors of the minor salivary glands are most likely to be malignant, with adenoid cystic carcinoma predominating, and may be found throughout the oral cavity or oropharynx.

Most parotid tumors present as an asymptomatic mass in the superficial part of the gland. Their presence may have been noted by the patient for months or years. Facial nerve involvement correlates strongly with malignancy. Tumors may extend deep to the plane of the facial nerve or may originate in the parapharyngeal space. In such cases, medial deviation of the soft palate is visible on intraoral examination. MRI and CT scans have largely replaced sialography in defining the extent of tumor.

When the clinician encounters a patient with an otherwise asymptomatic salivary gland mass where tumor is the most likely diagnosis, the choice is whether to simply excise the mass via a parotidectomy with facial nerve dissection or submandibular gland excision or to first obtain an FNA biopsy. Although the accuracy of FNA biopsy for malignancy has been reported to be quite high, results vary among institutions. If a negative FNA biopsy would lead to a decision not to proceed to surgery, then it should be considered. Poor overall health of the patient and the possibility of inflammatory disease as the cause of the mass are situations where FNA biopsy might be helpful. In otherwise straightforward nonrecurrent cases, excision is indicated. In benign and small low-grade malignant tumors, no additional treatment is needed. Postoperative irradiation is indicated for larger and high-grade cancers.

DISEASES OF THE LARYNX

DYSPHONIA, HOARSENESS, & STRIDOR

The primary symptoms of laryngeal disease are hoarseness and stridor. Hoarseness is caused by an abnormal vibration of the vocal folds. The voice is breathy when too much air passes incompletely apposed vocal folds, as in unilateral vocal fold paralysis or vocal fold mass. The voice is harsh when the vocal folds are stiff and vibrate irregularly, as is the case in laryngitis or malignancy. Heavy, edematous vocal folds produce a rough, low-pitched vocal quality. Stridor (a high-pitched, typically inspiratory,

sound) is the result of turbulent airflow from a narrowed upper airway. Airway narrowing at or above the vocal folds produces inspiratory stridor. Airway narrowing below the vocal fold level produces either expiratory or biphasic stridor. The timing and rapidity of onset of stridor are critically important in determining the seriousness of the airway problem. *All cases of stridor should be evaluated by a specialist and rapid-onset stridor should be evaluated emergently.*

Evaluation of an abnormal voice begins with obtaining a history of the circumstances preceding its onset and an examination of the airway.

Any patient with hoarseness that has persisted beyond 2 weeks should be evaluated by an otolaryngologist with laryngoscopy. Especially when the patient has a history of tobacco use, laryngeal cancer or lung cancer (leading to paralysis of a recurrent laryngeal nerve) must be strongly considered. In addition to structural causes of dysphonia, laryngoscopy can help identify functional problems with the voice including vocal fold paralysis, muscle tension dysphonia, and spasmodic dysphonia.

COMMON LARYNGEAL DISORDERS

1. Acute Laryngitis

Acute laryngitis is probably the most common cause of hoarseness, which may persist for a week or so after other symptoms of an upper respiratory infection have cleared. The patient should be warned to avoid vigorous use of the voice (singing, shouting) until their voice returns to normal, since persistent use may lead to the formation of traumatic vocal fold hemorrhage, polyps, and cysts. Although thought to be usually viral in origin, both *M catarrhalis* and *H influenzae* may be isolated from the nasopharynx at higher than expected frequencies. Erythromycin, cefuroxime, or amoxicillin-clavulanate may reduce the severity of hoarseness and cough. Oral or intramuscular corticosteroids may be used in highly selected cases of professional vocalists to speed recovery and allow scheduled performances. Examination of the vocal folds and assessment of vocal technique are mandatory prior to corticosteroid initiation, since inflamed vocal folds are at greater risk for hemorrhage and the subsequent development of traumatic vocal fold pathology.

2. Laryngopharyngeal Reflux

ESSENTIALS OF DIAGNOSIS

- ▶ Commonly associated with hoarseness, throat irritation, and chronic cough.
- ▶ Symptoms typically occur when upright and half of patients do not experience heartburn.
- ▶ Laryngoscopy is critical to exclude other causes of hoarseness.
- ▶ Diagnosis is made based on response to proton pump inhibitor therapy, as no gold-standard for the condition exists.
- ▶ Treatment failure with proton pump inhibitors is common and may suggest other etiologies.

Gastroesophageal reflux into the larynx (laryngopharyngeal reflux) is considered a cause of chronic hoarseness when other causes of abnormal vocal fold vibration (such as tumor or nodules) have been excluded by laryngoscopy. Gastroesophageal reflux disease (GERD) has also been suggested as a contributing factor to other symptoms such as throat clearing, throat discomfort, chronic cough, a sensation of postnasal drip, esophageal spasm, and some cases of asthma. Since less than half of patients with laryngeal acid exposure have typical symptoms of heartburn and regurgitation, the lack of such symptoms should not be construed as eliminating this cause. Indeed, most patients with symptomatic laryngopharyngeal reflux, as it is now called, do not meet criteria for GERD by pH probe testing and these entities must be considered separately. The prevalence of this condition is hotly debated in the literature and laryngopharyngeal reflux may not be as common as once thought.

Evaluation should initially exclude other causes of dysphonia through laryngoscopy; consultation with an otolaryngologist is advisable. Many clinicians opt for an empiric trial of a proton pump inhibitor. Such an empiric trial should not precede visualization of the vocal folds to exclude other causes of hoarseness. When used, the American Academy of Otolaryngology Head and Neck Surgery recommends twice daily therapy with full strength proton pump inhibitor (eg, omeprazole 40 mg orally twice daily, or equivalent) for a minimum of 3 months. Patients may note improvement in symptoms after 3 months, but the changes in the larynx often take 6 months to resolve. If symptoms improve and cessation of therapy leads to symptoms again, then a proton pump inhibitor is resumed at the lowest dose effective for remission, usually daily but at times on a demand basis. Although H₂-receptor antagonists are an alternative to proton pump inhibitors, they are generally both less clinically effective and less cost-effective. Nonresponders should undergo pH testing and manometry. Twenty-four-hour pH monitoring of the pharynx should best document laryngopharyngeal reflux and is advocated by some as the initial management step but it is costly, more difficult, and less available than

lower esophageal monitoring alone. Double pH probe (proximal and distal esophageal probes) testing is the best option for evaluation, since lower esophageal pH monitoring alone does not correlate well with laryngopharyngeal reflux symptoms. Oropharyngeal pH probe testing is available, but its ability to predict response to reflux treatment in patients with laryngopharyngeal reflux is not known.

3. Recurrent Respiratory Papillomatosis

Papillomas are common lesions of the larynx and other sites where ciliated and squamous epithelia meet. Unlike oral papillomas, recurrent respiratory papillomatosis typically becomes symptomatic, with hoarseness that occasionally progresses over weeks to months. These papillomas are almost always due to HPV types 6 and 11. The disease is more common in children where it causes hoarseness and stridor. Repeated laser vaporizations or cold knife resections via operative laryngoscopy are the mainstay of treatment. Severe cases can cause airway compromise even in adults and require treatment as often as every 6 weeks to maintain airway patency. Extension can occur into the trachea and lungs. Tracheotomy should be avoided, if possible, since it introduces an additional squamociliary junction for which papillomas appear to have an affinity. Interferon treatment has been under investigation for many years but is only indicated in severe cases with pulmonary involvement. Rarely, cases of malignant transformation have been reported (often in smokers), but recurrent respiratory papillomatosis should generally be thought of as a benign condition. Cidofovir (a cytosine nucleotide analog in use to treat cytomegalovirus retinitis) is also being investigated as intralesional therapy for recurrent respiratory papillomatosis and has had reported success in both adults and children. Because cidofovir causes adenocarcinomas in laboratory animals, its potential for carcinogenesis is being monitored. While the quadrivalent recombinant human HPV vaccine (Gardasil) is not useful as a treatment option for patients with recurrent respiratory papillomatosis, this vaccine offers hope for the eventual eradication of this benign, but terribly morbid, disease.

4. Epiglottitis

Epiglottitis (or, more correctly, supraglottitis) in adults should be suspected when a patient presents with a rapidly developing sore throat or when odynophagia (pain on swallowing) is out of proportion to apparently minimal oropharyngeal findings on examination. It is more common in diabetic patients and may be viral or bacterial in origin. Rarely in the era of *H influenzae* type b vaccine is this bacterium isolated in adults. Unlike in children, indirect laryngoscopy is generally safe and may demonstrate a swollen, erythematous epiglottitis. Lateral plain radiographs may demonstrate an enlarged epiglottis (the epiglottis “thumb sign”). Initial treatment is hospitalization for intravenous antibiotics—eg, cefixoxime, 1–2 g intravenously every 8–12 hours; or cefuroxime, 750–1500 mg intravenously every 8 hours; and dexamethasone, usually 4–10 mg as initial bolus, then 4 mg intravenously every 6 hours—and observation of the airway. Corticosteroids may be tapered as symptoms and signs resolve. Similarly, substitution of oral antibiotics may be appropriate to complete a 10-day course. Less than 10% of adults require intubation. Indications for intubation are dyspnea, rapid pace of sore throat (where progression to airway compromise may occur before the effects of corticosteroids and antibiotics), and endolaryngeal abscess noted on CT imaging. If the patient is not intubated, prudence suggests monitoring oxygen saturation with continuous pulse oximetry and initial admission to a monitored unit.

MASSES OF THE LARYNX

1. Traumatic Lesions of the Vocal Folds

Vocal fold nodules are smooth, paired lesions that form at the junction of the anterior one-third and posterior two-thirds of the vocal folds. They are a common cause of

hoarseness resulting from vocal abuse. In adults, they are referred to as “singer’s nodules” and in children, as “screamer’s nodules.” Treatment requires modification of voice habits, and referral to a speech therapist is indicated. While nearly all true nodules will resolve with behavior modification, recalcitrant nodules may require surgical excision. Often, additional pathology, such as a polyp or cyst, may be encountered.

Vocal fold polyps are unilateral masses that form within the superficial lamina propria of the vocal fold. They are related to vocal trauma and seem to follow resolution of vocal fold hemorrhage. Small, sessile polyps may resolve with conservative measures, such as voice rest and corticosteroids, but larger polyps are often irreversible and require operative removal to restore normal voice.

Vocal fold cysts are also considered traumatic lesions of the vocal folds and are either true cysts with an epithelial lining or pseudocysts. They typically form from mucus-secreting glands on the inferior aspect of the vocal folds. Cysts may fluctuate in size from week to week and cause a variable degree of hoarseness. They rarely, if ever, resolve completely and may leave behind a sulcus, or vocal fold scar, if they decompress or are marsupialized. Such scarring can be a frustrating cause of permanent dysphonia.

Polypoid corditis is different from vocal fold polyps and may form from loss of elastin fibers and loosening of the intracellular junctions within the lamina propria. This loss allows swelling of the gelatinous matrix of the superficial lamina propria (called **Reinke edema**). These changes in the vocal folds are strongly associated with smoking, but also with vocal abuse, chemical industrial irritants, and hypothyroidism. While this problem is common in both male and female smokers, women seem more troubled by the characteristic decline in modal pitch caused by the increased mass of the vocal folds. If the patient stops smoking or the lesions cause stridor and airway obstruction, surgical resection of the hyperplastic vocal fold mucosa may be indicated to improve the voice or airway, or both.

A common but often unrecognized cause of hoarseness and odynophonia are **contact ulcers** or their close relatives, **granulomas**. Both lesions form on the vocal processes of the arytenoid cartilages, and patients often can correctly inform the clinician which side is affected. The cause of these ulcers and granulomas is disputed, but they are clearly related to trauma and may be related to exposure of the underlying perichondrium. They are common following intubation and generally resolve quite quickly. Chronic ulceration or granuloma formation has been associated with gastroesophageal reflux but is also common in patients with muscle tension dysphonia. Treatment is often multimodal and an inhaled corticosteroid (eg, fluticasone 440 mcg twice daily) may be the most effective pharmacologic therapy. Adjunct treatment measures include proton pump inhibitor therapy (omeprazole 40 mg orally twice daily, or equivalent) and voice therapy with special attention to vocal hygiene. Rare cases can be quite stubborn and persistent without adequate therapy. Surgical removal is rarely, if ever, required for nonobstructive lesions.

2. Laryngeal Leukoplakia

Leukoplakia of the vocal folds is commonly found in association with hoarseness in smokers. Direct laryngoscopy with biopsy is advised in almost all cases. Histologic examination usually demonstrates mild, moderate, or severe dysplasia. In some cases, invasive SCC is present in the initial biopsy specimen. Cessation of smoking may reverse or stabilize mild or moderate dysplasia. A certain percentage of patients—estimated to be < 5% of those with mild dysplasia and about 35–60% of those with severe dysplasia—will subsequently develop SCC. Treatment options include close follow-up with laryngovideostroboscopy, serial resection, and external beam radiation therapy. Despite their cost and the lack of any evidence for their use in the treatment of leukoplakia, proton pump inhibitors have become the mainstay of treatment for these lesions.

3. Squamous Cell Carcinoma of the Larynx

ESSENTIALS OF DIAGNOSIS

- ▶ New and persistent (more than 2 weeks duration) hoarseness in a smoker.
- ▶ Persistent throat or ear pain, especially with swallowing.
- ▶ Neck mass.
- ▶ Hemoptysis.
- ▶ Stridor or other symptoms of a compromised airway.

▶ General Considerations

SCC of the larynx, the most common malignancy of the larynx, occurs almost exclusively in patients with a history of significant tobacco use. SCC is usually seen in men age 50–70 years; about 13,000 new cases are seen in United States each year. There may be an association between laryngeal cancer and HPV type 16 or 18 infection, but this association is much less strong than that between HPV 16 or 18 and oropharyngeal cancer. In both cancer types, the association with HPV seems to be strongest in nonsmokers. Laryngeal cancer is very treatable and early detection is the key to maximizing posttreatment voice, swallowing, and breathing function.

▶ Clinical Findings

A. Symptoms and Signs

A change in voice quality is most often the presenting complaint, although throat or ear pain, hemoptysis, dysphagia, weight loss, and airway compromise may occur. Because of their early impact on vocal quality, glottic cancers are among the smallest detectable human malignancies and treatment success is very high with early lesions. Neck metastases are not common in early glottic (true vocal fold) cancer in which the vocal folds are mobile, but a third of patients in whom there is impaired fold mobility will also have involved lymph nodes at neck dissection. Supraglottic carcinoma (false vocal folds, aryepiglottic folds, epiglottis), on the other hand, often metastasizes to both sides of the neck early in the disease. Complete head and neck examination, including laryngoscopy, by an experienced clinician is mandated for any person with the concerning symptoms listed under Essentials of Diagnosis.

B. Imaging and Laboratory Studies

Radiologic evaluation by CT or MRI is helpful in assessing tumor extent. Imaging evaluates neck nodes, tumor volume, and cartilage sclerosis or destruction. A chest CT scan is indicated if there are level VI enlarged nodes (around the trachea and the thyroid gland) or IV enlarged nodes (inferior to the cricoid cartilage along the internal jugular vein) or if a chest film is concerning for a second primary lesion or metastases. Laboratory evaluation includes complete blood count and liver function tests. Formal cardiopulmonary evaluation may be indicated, especially if partial laryngeal surgery is being considered. All partial laryngectomy candidates should have good to excellent lung function and exercise tolerance because chronic microaspiration may be expected following the procedure. A positron emission tomography (PET) scan or CT-PET scan may be indicated to assess for distant metastases when there appears to be advanced local or regional disease.

C. Biopsy

Diagnosis is made by biopsy at the time of laryngoscopy. At that time, true fold mobility and arytenoid fixation, as well as surface tumor extent, can be evaluated. Most otolaryngologists recommend esophagoscopy and bronchoscopy at the same time to exclude synchronous primary tumor. Although an FNA biopsy of an enlarged neck node may have already been done, it is generally acceptable to assume radiographically enlarged neck nodes (> 1–1.5 cm) or nodes with necrotic centers are neck metastases. Open biopsies of nodal metastases should be discouraged because they may lead to higher rates of tumor treatment failure.

D. Tumor Staging

The American Joint Committee on Cancer (AJCC) staging of laryngeal cancers uses the TNM system to describe tumor extent and can be used for prognosis. Early laryngeal cancers, T1 and T2 (stage I and II) lesions, involve

1–2 laryngeal subsites locally and have no nodal metastases or profound functional abnormalities. T3 and T4 lesions may involve multiple laryngeal subsites with limitation of laryngeal mobility. These locally advanced lesions are stage III or IV cancers and any size tumor with regional nodal metastases is at least a stage III tumor. Stage I and II lesions are generally treated with single modality therapy (surgery or radiation) while multimodality therapy, usually including chemotherapy with radiation therapy, is reserved for more advanced stage III and IV lesions.

► Treatment

Treatment of laryngeal carcinoma has four goals: cure, preservation of safe effective swallowing, preservation of useful voice, and avoidance of a permanent tracheostoma. For early glottic and supraglottic cancers, radiation therapy is the standard of care since cure rates are > 95% and 80%, respectively. That said, radiation therapy carries substantial morbidity and many early tumors (T1 and T2 lesions, without involved nodes) and selected advanced tumors (T3 and T4) may be treated with partial laryngectomy if at least one cricoarytenoid unit can be preserved. Five-year locoregional cure rates exceed 80–90% with surgery, and patient-reported satisfaction is excellent. In supraglottic tumors, even when clinically N0, elective limited neck dissection is indicated following surgical resection because of the high risk of neck node involvement.

For advanced stage III and IV tumors, multimodality therapy—typically including chemotherapy—is warranted. Twenty-five years ago, total laryngectomy was often recommended for such patients. However, the 1994 VA study (with induction cisplatin and 5-fluorouracil followed by irradiation alone in responders) demonstrated that two-thirds of patients could preserve their larynx. Since that study, cisplatin-based chemotherapy concomitant with radiation therapy has been shown to be superior to either irradiation alone or induction chemotherapy followed by radiation. The same benefits have been demonstrated with the epidermal growth factor receptor blocker cetuximab with lower overall systemic toxicity and better patient tolerance. However, chemoradiation of either form is associated with prolonged gastrostomy-dependent dysphagia. This high rate of chemoradiation-associated dysphagia has prompted a reevaluation of the role of extended, but less-than-total, laryngeal surgery for selected advanced laryngeal carcinoma in which at least one cricoarytenoid unit is intact. In addition, overall success in the treatment of larynx cancer has declined in parallel with the increase in organ preservation chemoradiation therapy. Some experts have proposed that this decline is the direct result of the shift in management of advanced laryngeal cancer away from surgery. Organ preservation surgery should be considered and discussed as an alternative to chemoradiation. Patient comorbidities and patient choice, after thorough discussion, play an important role in the choice between surgery and chemoradiation. The patient and treating clinicians must carefully consider *different* side effects and complications associated with different treatment modalities.

The presence of malignant adenopathy in the neck affects the prognosis greatly. Supraglottic tumors metastasize

early and bilaterally to the neck, and this must be included in the treatment plans even when the neck is apparently uninvolved. Glottic tumors in which the true vocal folds are mobile (T1 or T2) have less than a 5% rate of nodal involvement; when a fold is immobile, the rate of ipsilateral nodal involvement climbs to about 30%. An involved neck is treated by surgery or chemoradiation, or both. This decision will depend on the treatment chosen for the larynx and the extent of neck involvement.

Total laryngectomy is largely reserved for patients with advanced resectable tumors with extralaryngeal spread or cartilage involvement, for those with persistent tumor following chemoradiation, and for patients with recurrent or second primary tumor following previous radiation therapy. Voice rehabilitation via a primary (or at times secondary) tracheoesophageal puncture produces intelligible and serviceable speech in about 75–85% of patients. Indwelling prostheses that are changed every 3–6 months are a common alternative to patient-inserted prostheses, which need changing more frequently.

Long-term follow-up is critical in head and neck cancer patients. In addition to the 3–4% annual rate of second tumors and monitoring for recurrence, psychosocial aspects of treatment are common. Dysphagia, impaired communication, and altered appearance, may result in patient difficulties adapting to the workplace and to social interactions. In addition, smoking cessation and alcohol abatement are common challenges. Nevertheless, about 65% of patients with larynx cancer are cured, most have useful speech, and many resume their prior livelihoods with adaptations.

VOCAL FOLD PARALYSIS

Vocal fold paralysis can result from a lesion or damage to either the vagus or recurrent laryngeal nerve and usually results in breathy dysphonia and effortful voicing. Common causes of **unilateral recurrent laryngeal nerve** involvement include thyroid surgery (and occasionally thyroid cancer), other neck surgery (anterior discectomy and carotid endarterectomy), and mediastinal or apical involvement by lung

cancer. Skull base tumors often involve or abut upon lower cranial nerves and may affect the vagus nerve directly, or the vagus nerve may be damaged during surgical management of the lesion. While iatrogenic injury is the most common cause of unilateral vocal fold paralysis, the second most common cause is idiopathic. However, before deciding whether the paralysis is due to iatrogenic injury or is idiopathic, the clinician must exclude other causes, such as malignancy. In the absence of other cranial neuropathies, a CT scan with contrast from the skull base to the aorto-pulmonary window (the span of the recurrent laryngeal nerve) should be performed. If other cranial nerve deficits or high vagal weakness with palate paralysis is noted, a MRI scan of the brain and brainstem is warranted.

Unlike unilateral fold paralysis, **bilateral fold paralysis** usually causes inspiratory stridor with deep inspiration. If the onset of bilateral fold paralysis is insidious, it may be asymptomatic at rest and the patient may have a normal voice. However, the acute onset of bilateral vocal fold paralysis with inspiratory stridor at rest should be managed by a specialist immediately in a critical care environment. Causes of bilateral fold paralysis include thyroid surgery, esophageal cancer, and ventricular shunt malfunction. Unilateral or bilateral fold immobility may also be seen in cricoarytenoid arthritis secondary to advanced rheumatoid arthritis, intubation injuries, glottic and subglottic stenosis and, of course, laryngeal cancer. The goal of intervention is the creation of a safe airway with minimal reduction in voice quality and airway protection from aspiration. A number of fold lateralization procedures for bilateral paralysis have been advocated as a means of removing the tracheotomy tube.

Unilateral vocal fold paralysis is occasionally temporary and may take over a year to resolve spontaneously. Surgical management of persistent or irrecoverable symptomatic unilateral vocal fold paralysis has evolved over the last several decades. The primary goal is medialization of the paralyzed fold in order to create a stable platform for vocal fold vibration. Additional goals include improving pulmonary toilet by facilitating of cough and advancing diet. Success has been reported for years with injection laryngoplasty using Teflon, Gelfoam, fat and collagen. Teflon is the only permanent injectable material, but its use is discouraged because of granuloma formation within the vocal folds of some patients. Temporary injectable materials, such as collagen or fat, provide excellent temporary restoration of voice and can be placed under local or general anesthesia. Once the paralysis is determined to be permanent, formal medialization thyroplasty may be performed by creating a small window in the thyroid cartilage and placing an implant between the thyroarytenoid muscle and inner table of the thyroid cartilage. This procedure moves the vocal fold medially and creates a stable platform for bilateral, symmetric mucosal vibration.

TRACHEOSTOMY & CRICOTHYROTOMY

There are two primary indications for tracheotomy: airway obstruction at or above the level of the larynx and respiratory failure requiring prolonged mechanical ventilation. In an acute emergency, cricothyrotomy secures an airway more rapidly than tracheotomy, with fewer potential immediate complications such as pneumothorax and hemorrhage. Percutaneous dilatational tracheotomy as an elective bedside (or intensive care unit) procedure has undergone scrutiny in recent years as an alternative to tracheotomy. In experienced hands, the various methods of percutaneous tracheotomy have been documented to be safe in carefully selected patients. Simultaneous videobronchoscopy can reduce the incidence of major complications. The major cost reduction comes from avoiding the operating room. Bedside tracheotomy (in the intensive care unit) achieves similar cost reduction and is advocated by some experts as slightly less costly than the percutaneous procedures.

The most common indication for elective tracheotomy is the need for prolonged mechanical ventilation. There is no firm rule about how many days a patient must be intubated before conversion to tracheotomy should be advised. The incidence of serious complications such as subglottic stenosis increases with extended endotracheal intubation. As soon as it is apparent that the patient will require protracted ventilatory support, tracheotomy should replace the endotracheal tube. Less frequent indications for tracheostomy are life-threatening aspiration pneumonia, the need to improve pulmonary toilet to correct problems related to insufficient clearing of tracheobronchial secretions, and sleep apnea.

Posttracheotomy care requires humidified air to prevent secretions from crusting and occluding the inner cannula of the tracheotomy tube. The tracheotomy tube should be cleaned several times daily. The most frequent early complication of tracheotomy is dislodgment of the tracheotomy tube. Surgical creation of an inferiorly based tracheal flap sutured to the inferior neck skin may make reinsertion of a dislodged tube easier. It should be recalled that the act of swallowing requires elevation of the larynx, which is limited by tracheotomy. Therefore, frequent tracheal and bronchial suctioning is often required to clear the aspirated saliva as well as the increased tracheobronchial secretions. Care of the skin around the stoma is important to prevent maceration and secondary infection.

FOREIGN BODIES IN THE UPPER AERODIGESTIVE TRACT

FOREIGN BODIES OF THE TRACHEA & BRONCHI

Aspiration of foreign bodies occurs much less frequently in adults than in children. The elderly and denture wearers

appear to be at greatest risk. Wider familiarity with the Heimlich maneuver has reduced deaths. If the maneuver is unsuccessful, cricothyrotomy may be necessary. Plain chest radiographs may reveal a radiopaque foreign body. Detection of radiolucent foreign bodies may be aided by inspiration-expiration films that demonstrate air trapping distal to the obstructed segment. Atelectasis and pneumonia may occur later.

Tracheal and bronchial foreign bodies should be removed under general anesthesia with rigid bronchoscopy by a skilled endoscopist working with an experienced anesthesiologist.

Digoy GP. Diagnosis and management of upper aerodigestive tract foreign bodies. *Otolaryngol Clin North Am.* 2008 Jun;41(3):485–96. [PMID: 18435994]

ESOPHAGEAL FOREIGN BODIES

Foreign bodies in the esophagus create urgent but not life-threatening situations as long as the airway is not compromised. There is probably time to consult an experienced clinician for management. It is a useful diagnostic sign of complete obstruction if the patient is drooling or cannot handle secretions. Patients may often point to the exact level of the obstruction. Indirect laryngoscopy often shows pooling of saliva at the esophageal inlet. Plain films may detect radiopaque foreign bodies such as chicken bones. Coins tend to align in the coronal plane in the esophagus and sagittally in the trachea. If a foreign body is suspected, a barium swallow may help make the diagnosis.

The treatment of an esophageal foreign body depends very much on identification of its nature. In children, swallowed nonfood objects are common. In adults, however, food foreign bodies are more common, and there is the greater possibility of underlying esophageal pathology. Endoscopic removal and examination is usually best via flexible esophagoscopy or rigid laryngoscopy and esophagoscopy. If there is nothing sharp such as a bone, some clinicians advocate a hospitalized 24-hour observation period prior to esophagoscopy, noting that spontaneous passage of the foreign body will occur in 50% of adult patients. In the management of meat obstruction, the use of papain (meat tenderizer) should be discouraged because it can damage the esophageal mucosa and lead to stenosis or perforation.

Weissberg D et al. Foreign bodies in the esophagus. *Ann Thorac Surg.* 2007 Dec;84(6):1854–7. [PMID: 18036898]

DISEASES PRESENTING AS NECK MASSES

The differential diagnosis of neck masses is heavily dependent on the location in the neck, the age of the patient, and the presence of associated disease processes. Rapid growth and tenderness suggest an inflammatory process, while firm, painless, and slowly enlarging masses are often neoplastic. In young adults, most neck masses are benign (branchial cleft cyst, thyroglossal duct cyst, reactive lymphadenitis), although malignancy should always be

considered (lymphoma, metastatic thyroid carcinoma). Lymphadenopathy is common in HIV-positive persons, but a growing or dominant mass may well represent lymphoma. In adults over age 40, cancer is the most common cause of persistent neck mass. A metastasis from SCC arising within the mouth, pharynx, larynx, or upper esophagus should be suspected, especially if there is a history of tobacco or significant alcohol use. Especially among patients younger than 30 or older than 70, lymphoma should be considered. In any case, a comprehensive otolaryngologic examination is needed. Cytologic evaluation of the neck mass via FNA biopsy is likely to be the next step if an obvious primary tumor is not obvious on physical examination.

CONGENITAL LESIONS PRESENTING AS NECK MASSES IN ADULTS

1. Branchial Cleft Cysts

Branchial cleft cysts usually present as a soft cystic mass along the anterior border of the sternocleidomastoid muscle. These lesions are usually recognized in the second or third decades of life, often when they suddenly swell or become infected. To prevent recurrent infection and possible carcinoma, they should be completely excised, along with their fistulous tracts.

First branchial cleft cysts present high in the neck, sometimes just below the ear. A fistulous connection with the floor of the external auditory canal may be present. Second branchial cleft cysts, which are far more common, may communicate with the tonsillar fossa. Third branchial cleft cysts, which may communicate with the piriform sinus, are rare and present low in the neck.

Acierio SP et al. Congenital cervical cysts, sinuses and fistulae. *Otolaryngol Clin North Am.* 2007 Feb;40(1):161–76. [PMID: 17346566]

Papadogeorgakis N et al. Branchial cleft cysts in adults. Diagnostic procedures and treatment in a series of 18 cases. *Oral Maxillofac Surg.* 2009 Jun;13(2):79–85. [PMID: 19308468]

2. Thyroglossal Duct Cysts

Thyroglossal duct cysts occur along the embryologic course of the thyroid's descent from the tuberculum impar of the tongue base to its usual position in the low neck. Although they may occur at any age, they are most common before age 20. They present as a midline neck mass, often just below the hyoid bone, which moves with swallowing. Surgical excision is recommended to prevent recurrent infection. This requires removal of the entire fistulous tract along with the middle portion of the hyoid bone through which many of the fistulas pass. Preoperative evaluation should include a thyroid ultrasound to confirm anatomic position of the thyroid.

Lin ST et al. Thyroglossal duct cyst: a comparison between children and adults. *Am J Otolaryngol.* 2008 Mar–Apr;29(2):83–7. [PMID: 18314017]

INFECTIOUS & INFLAMMATORY NECK MASSES

1. Reactive Cervical Lymphadenopathy

Normal lymph nodes in the neck are usually < 1 cm in length. Infections involving the pharynx, salivary glands, and scalp often cause tender enlargement of neck nodes. Enlarged nodes are common in HIV-infected persons. Except for the occasional node that suppurates and requires incision and drainage, treatment is directed against the underlying infection. An enlarged node (> 1.5 cm) or node with a necrotic center that is not associated with an obvious infection should be further evaluated, especially if the patient has a history of smoking, alcohol use, or prior cancer. Other common indications for FNA biopsy of a node include its persistence or continued enlargement. Common causes of cervical adenopathy include tumor (SCC, lymphoma, occasional metastases from non-head and neck sites) and infection (eg, reactive nodes, mycobacteria [discussed below], and cat scratch disease). Rare causes of adenopathy include Kikuchi disease (histiocytic necrotizing lymphadenitis) and autoimmune adenopathy.

Leung AK et al. Cervical lymphadenitis: etiology, diagnosis, and management. *Curr Infect Dis Rep.* 2009 May;11(3):183–9. [PMID: 19366560]

2. Tuberculous & Nontuberculous Mycobacterial Lymphadenitis

Granulomatous neck masses are not uncommon. The differential diagnosis includes mycobacterial adenitis, sarcoidosis, and cat-scratch disease due to *Bartonella henselae*. Mycobacterial lymphadenitis is on the rise both in immunocompromised and immunocompetent individuals. The usual presentation of granulomatous disease in the neck is simply single or matted nodes. Although mycobacterial adenitis can extend to the skin and drain externally (as described for atypical mycobacteria and referred to as scrofula), this late presentation is no longer common.

FNA biopsy is usually the best initial diagnostic approach: cytology, smear for acid-fast bacilli, culture, and sensitivity test can all be done. Excisional biopsy of a node may be needed.

PCR from FNA (or from excised tissue) is the single most sensitive test and is particularly useful when conventional methods have not been diagnostic but clinical impression remains consistent for tuberculous infection.

Short-course therapy (6 months) consisting of an initial 4 months of streptomycin, isoniazid, rifampin, and pyrazinamide followed by 2 months of rifampin is the current recommended treatment for tuberculous lymphadenopathy (see Table 9–18). For atypical (nontuberculous) lymphadenopathy, treatment depends on sensitivity results of culture, but antibiotics likely to be useful include 6 months of isoniazid and rifampin and, for at least the first 2 months, ethambutol—all in standard dosages. Some would totally excise the involved nodes prior to chemotherapy, depending on location and other factors, but this can lead to chronic draining fistulas.

Polesky A et al. Peripheral tuberculous lymphadenitis: epidemiology, diagnosis, treatment, and outcome. *Medicine (Baltimore).* 2005 Nov;84(6):350–62. [PMID: 16267410]

3. Lyme Disease

Lyme disease, caused by the spirochete *Borrelia burgdorferi* and transmitted by ticks of the *Ixodes* genus, may have protean manifestation, but over 75% of patients have symptoms involving the head and neck. Facial paralysis, dysesthesias, dysgeusia, or other cranial neuropathies are most common. Headache, pain, and cervical lymphadenopathy may occur. See Chapter 34 for a more detailed discussion.

DePietropaolo DL et al. Diagnosis of Lyme disease. *Am Fam Physician.* 2005 Jul 15;72(2):297–304. [PMID: 16050454]
Hagemann G et al. Bilateral facial palsy in neuroborreliosis. *Arch Neurol.* 2009 Apr;66(4):534–5. [PMID: 19364942]

TUMOR METASTASES

In older adults, 80% of firm, persistent, and enlarging neck masses are metastatic in origin. The great majority of these arise from SCC of the upper aerodigestive tract. A complete head and neck examination may reveal the tumor of origin, but examination under anesthesia with direct laryngoscopy, esophagoscopy, and bronchoscopy is usually required to fully evaluate the tumor and exclude second primaries.

It is often helpful to obtain a cytologic diagnosis if initial head and neck examination fails to reveal the primary tumor. An open biopsy should be done only when neither physical examination by an experienced clinician specializing in head and neck cancer nor FNA biopsy performed by an experienced cytopathologist yields a diagnosis. In such a setting, one should strongly consider obtaining an MRI or PET scan prior to open biopsy, as these methods may yield valuable information about a possible presumed primary site or another site for FNA.

With the exception of papillary thyroid carcinoma, non-squamous cell metastases to the neck are infrequent. While tumors that are not primary in the head or neck seldom metastasize to the cervical lymph nodes, the supraclavicular lymph nodes are quite often involved by lung, gastroesophageal, and breast tumors. Infradiaphragmatic tumors, with the exception of renal cell carcinoma and testicular cancer, rarely metastasize to the neck.

Barzilai G et al. Pattern of regional metastases from cutaneous squamous cell carcinoma of the head and neck. *Otolaryngol Head Neck Surg.* 2005 Jun;132(6):852–6. [PMID: 15944554]

LYMPHOMA

About 10% of lymphomas present in the head and neck. Multiple rubbery nodes, especially in the young adult or in

patients who have AIDS, are suggestive of this disease. A thorough physical examination may demonstrate other sites of nodal or organ involvement. FNA biopsy may be diagnostic, but open biopsy is often required to determine architecture and an appropriate treatment course.

Howlett DC et al. Diagnostic adequacy and accuracy of fine needle aspiration cytology in neck lump assessment: results from a regional cancer network over a one year period. *J Laryngol Otol.* 2007 Jun;121(6):571-9. [PMID: 17134537]

Pulmonary Disorders

Mark S. Chesnutt, MD
 Thomas J. Prendergast, MD
 Emmanuel T. Tavan, MD

DISORDERS OF THE AIRWAYS

Airway disorders have diverse causes but share certain common pathophysiologic and clinical features. Airflow limitation is characteristic and frequently causes dyspnea and cough. Other symptoms are common and typically disease-specific. Disorders of the airways can be classified as those that involve the upper airways—loosely defined as those above and including the vocal folds—and those that involve the lower airways.

DISORDERS OF THE UPPER AIRWAYS

Acute upper airway obstruction can be immediately life-threatening and must be relieved promptly to avoid asphyxia. Causes of acute upper airway obstruction include trauma to the larynx or pharynx, foreign body aspiration, laryngospasm, laryngeal edema from thermal injury or angioedema, infections (acute epiglottitis, Ludwig angina, pharyngeal or retropharyngeal abscess), and acute allergic laryngitis.

Chronic obstruction of the upper airway may be caused by carcinoma of the pharynx or larynx, laryngeal or subglottic stenosis, laryngeal granulomas or webs, or bilateral vocal fold paralysis. Laryngeal or subglottic stenosis may become evident weeks or months following a period of translaryngeal endotracheal intubation. Inspiratory stridor, intercostal retractions on inspiration, a palpable inspiratory thrill over the larynx, and wheezing localized to the neck or trachea on auscultation are characteristic findings. Flow-volume loops may show flow limitations characteristic of obstruction. Soft tissue radiographs of the neck may show supraglottic or infraglottic narrowing. CT and MRI scans can reveal exact sites of obstruction. Flexible endoscopy may be diagnostic, but caution is necessary to avoid exacerbating upper airway edema and precipitating critical airway narrowing.

Vocal fold dysfunction syndrome is a condition characterized by paradoxical vocal fold adduction, resulting in both acute and chronic upper airway obstruction. It can cause dyspnea and wheezing that may present as asthma or exercise-induced asthma but may be distinguished from asthma by the lack of response to bronchodilator therapy,

normal spirometry immediately after an attack, spirometric evidence of upper airway obstruction, a negative bronchial provocation test, or direct visualization of adduction of the vocal folds on both inspiration and expiration. The condition appears to be psychogenic in nature. Bronchodilators are of no therapeutic benefit. Treatment consists of speech therapy, which uses breathing, voice, and neck relaxation exercises to abort the symptoms.

Gaissert HA et al. The compromised airway: tumors, strictures, and tracheomalacia. *Surg Clin North Am.* 2010 Oct;90(5):1065–89. [PMID: 20955884]
 Morris MJ et al. Diagnostic criteria for the classification of vocal cord dysfunction. *Chest.* 2010 Nov;138(5):1213–23. [PMID: 21051397]

DISORDERS OF THE LOWER AIRWAYS

Tracheal obstruction may be intrathoracic (below the suprasternal notch) or extrathoracic. Fixed tracheal obstruction may be caused by acquired or congenital tracheal stenosis, primary or secondary tracheal neoplasms, extrinsic compression (tumors of the lung, thymus, or thyroid; lymphadenopathy; congenital vascular rings; aneurysms, etc), foreign body aspiration, tracheal granulomas and papillomas, and tracheal trauma. Tracheomalacia, foreign body aspiration, and retained secretions may cause variable tracheal obstruction.

Acquired **tracheal stenosis** is usually secondary to previous tracheotomy or endotracheal intubation. Dyspnea, cough, and inability to clear pulmonary secretions occur weeks to months after tracheal decannulation or extubation. Physical findings may be absent until tracheal diameter is reduced 50% or more, when wheezing, a palpable tracheal thrill, and harsh breath sounds may be detected. The diagnosis is usually confirmed by plain films or CT of the trachea. Complications include recurring pulmonary infection and life-threatening respiratory failure. Management is directed toward ensuring adequate ventilation and oxygenation and avoiding manipulative procedures that may increase edema of the tracheal mucosa. Surgical reconstruction, endotracheal stent placement, or laser photoresection may be required.

Bronchial obstruction may be caused by retained pulmonary secretions, aspiration, foreign bodies, bronchomalacia, bronchogenic carcinoma, compression by extrinsic masses, and tumors metastatic to the airway. Clinical and radiographic findings vary depending on the location of the obstruction and the degree of airway narrowing. Symptoms include dyspnea, cough, wheezing, and, if infection is present, fever and chills. A history of recurrent pneumonia in the same lobe or segment or slow resolution (> 3 months) of pneumonia on successive radiographs suggests the possibility of bronchial obstruction and the need for bronchoscopy.

Roentgenographic findings include **atelectasis** (local parenchymal collapse), postobstructive infiltrates, and air trapping caused by unidirectional expiratory obstruction. CT scanning may demonstrate the nature and the exact location of obstruction of the central bronchi. MRI may be superior to CT for delineating the extent of underlying disease in the hilum, but it is usually reserved for cases in which CT findings are equivocal. Bronchoscopy is the definitive diagnostic study, particularly if tumor or foreign body aspiration is suspected. The finding of bronchial breath sounds on physical examination or an air bronchogram on chest radiograph in an area of atelectasis rules out complete airway obstruction. Bronchoscopy is unlikely to be of therapeutic benefit in this situation.

ASTHMA

ESSENTIALS OF DIAGNOSIS

- ▶ Episodic or chronic symptoms of airflow obstruction.
- ▶ Reversibility of airflow obstruction, either spontaneously or following bronchodilator therapy.
- ▶ Symptoms frequently worse at night or in the early morning.
- ▶ Prolonged expiration and diffuse wheezes on physical examination.
- ▶ Limitation of airflow on pulmonary function testing or positive bronchoprovocation challenge.

▶ General Considerations

Asthma is a common disease, affecting approximately 7–10% of the population. It is slightly more common in male children (< 14 years old) and in female adults. A genetic predisposition to asthma is recognized. Prevalence, hospitalizations, and fatal asthma have all increased in the United States over the past 20 years. Each year, approximately 500,000 hospital

admissions and 4500 deaths in the United States are attributed to asthma. Hospitalization rates have been highest among blacks and children, and death rates for asthma are consistently highest among blacks aged 15–24 years.

▶ Definition & Pathogenesis

Asthma is a chronic inflammatory disorder of the airways. No single histopathologic feature is pathognomonic but common findings include inflammatory cell infiltration with eosinophils, neutrophils, and lymphocytes (especially T lymphocytes); goblet cell hyperplasia, sometimes with plugging of small airways with thick mucus; collagen deposition beneath the basement membrane; hypertrophy of bronchial smooth muscle; airway edema; mast cell activation; and denudation of airway epithelium. This airway inflammation underlies disease chronicity and contributes to airway hyper-responsiveness and airflow limitation.

The strongest identifiable predisposing factor for the development of asthma is atopy, but obesity is increasingly recognized as a risk factor. Exposure of sensitive patients to inhaled allergens increases airway inflammation, airway hyper-responsiveness, and symptoms. Symptoms may develop immediately (immediate asthmatic response) or 4–6 hours after allergen exposure (late asthmatic response). Common allergens include house dust mites (often found in pillows, mattresses, upholstered furniture, carpets, and drapes), cockroaches, cat dander, and seasonal pollens. Substantially reducing exposure reduces pathologic findings and clinical symptoms.

Nonspecific precipitants of asthma include exercise, upper respiratory tract infections, rhinitis, sinusitis, postnasal drip, aspiration, gastroesophageal reflux, changes in the weather, and stress. Exposure to environmental tobacco smoke increases asthma symptoms and the need for medications and reduces lung function. Increased air levels of respirable particles, ozone, SO₂, and NO₂ precipitate asthma symptoms and increase emergency department visits and hospitalizations. Selected individuals may experience asthma symptoms after exposure to aspirin, nonsteroidal anti-inflammatory drugs, or tartrazine dyes. Certain other medications may also precipitate asthma symptoms (see Table 9–27). **Occupational asthma** is triggered by various agents in the workplace and may occur weeks to years after initial exposure and sensitization. Women may experience catamenial asthma at predictable times during the menstrual cycle. **Exercise-induced bronchoconstriction** begins during exercise or within 3 minutes after its end, peaks within 10–15 minutes, and then resolves by 60 minutes. This phenomenon is thought to be a consequence of the airways' attempt to warm and humidify an increased volume of expired air during exercise. **“Cardiac asthma”** is wheezing precipitated by decompensated congestive heart failure.

▶ Clinical Findings

Symptoms and signs vary widely from patient to patient as well as individually over time. General clinical findings in stable asthma patients are listed in Figure 9–1 and Table 9–1; findings seen during asthma exacerbations are listed in Tables 9–2 and 9–3.

Components of Severity		Classification of Asthma Severity ≥ 12 years of age			
		Intermittent	Persistent		
			Mild	Moderate	Severe
Impairment Normal FEV₁/FVC: 8–19 yr 85% 20–39 yr 80% 40–59 yr 75% 60–80 yr 70%	Symptoms	≤ 2 days/week	> 2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤ 2x/month	3–4x/month	> 1x/week but not nightly	Often 7x/week
	Short-acting β ₂ -agonist use for symptom control (not prevention of EIB)	≤ 2 days/week	> 2 days/week but not daily, and not more than 1x on any day	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	<ul style="list-style-type: none"> Normal FEV₁ between exacerbations FEV₁ > 80% predicted FEV₁/FVC normal 	<ul style="list-style-type: none"> FEV₁ > 80% predicted FEV₁/FVC normal 	<ul style="list-style-type: none"> FEV₁ > 60% but < 80% predicted FEV₁/FVC reduced 5% 	<ul style="list-style-type: none"> FEV₁ < 60% predicted FEV₁/FVC reduced > 5%
Risk	Exacerbations requiring oral systemic corticosteroids	0–1/year (see note)	≥ 2/year (see note) →		
		← Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time for patients in any severity category. → Relative annual risk of exacerbations may be related to FEV ₁ .			
Recommended Step for Initiating Treatment		Step 1	Step 2	Step 3	Step 4 or 5
(See Figure 9–2 for treatment steps.)		In 2–6 weeks, evaluate level of asthma control that is achieved and adjust therapy accordingly.			
		and consider short course of oral systemic corticosteroids			

EIB, exercise-induced bronchospasm; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; ICU, intensive care unit.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.
- Level of severity is determined by assessment of both impairment and risk. Assess impairment domain by patient's/caregiver's recall of previous 2–4 weeks and spirometry. Assign severity to the most severe category in which any feature occurs.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. In general, more frequent and intense exacerbations (eg, requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate greater underlying disease severity. For treatment purposes, patients who had ≥ 2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

▲ **Figure 9–1.** Classifying asthma severity and initiating treatment. (Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007. <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>.)

A. Symptoms and Signs

Asthma is characterized by episodic wheezing, difficulty in breathing, chest tightness, and cough. Excess sputum production is common. The frequency of asthma symptoms is

highly variable. Some patients have infrequent, brief attacks of asthma while others may suffer nearly continuous symptoms. Asthma symptoms may occur spontaneously or may be precipitated or exacerbated by many different triggers as discussed above. Asthma symptoms are frequently

Table 9-1. Assessing asthma control.

Components of Control		Classification of Asthma Control (≥ 12 years of age)		
		Well Controlled	Not Well Controlled	Very Poorly Controlled
Impairment	Symptoms	≤ 2 days/week	> 2 days/week	Throughout the day
	Nighttime awakenings	≤ 2×/month	1-3×/week	≥ 4×/week
	Interference with normal activity	None	Some limitation	Extremely limited
	Short-acting β ₂ -agonist use for symptom control (not prevention of EIB)	≤ 2 days/week	> 2 days/week	Several times/day
	FEV ₁ or peak flow	> 80% predicted/personal best	60-80% predicted/personal best	< 60% predicted/personal best
	Validated questionnaires			
	ATAQ ACQ ACT	0 ≤ 0.75 ¹ ≥ 20	1-2 ≥ 1.5 16-19	3-4 N/A ≤ 15
Risk	Exacerbations requiring oral system corticosteroids	0-1/year	≥ 2/year (see note)	
		Consider severity and interval since last exacerbation		
	Progressive loss of lung function	Evaluation requires long-term follow-up care		
	Treatment-related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.		
Recommended Action for Treatment (see Figure 9-2 for steps)		<ul style="list-style-type: none"> Maintain current step Regular follow-ups every 1-6 months to maintain control. Consider step down if well controlled for at least 3 months. 	<ul style="list-style-type: none"> Step up 1 step and Reevaluate in 2-6 weeks. For side effects, consider alternative treatment options. 	<ul style="list-style-type: none"> Consider short course of oral systemic corticosteroids, Step up 1-2 steps, and Reevaluate in 2 weeks. For side effects, consider alternative treatment options.

¹ACQ values of 0.76-1.4 are indeterminate regarding well-controlled asthma.

EIB, exercise-induced bronchospasm; ICU, intensive care unit.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.
- The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient's recall of previous 2-4 weeks and by spirometry or peak flow measures. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether the patient's asthma is better or worse since the last visit.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (eg, requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate poorer disease control. For treatment purposes, patients who had ≥ 2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.
- Validated Questionnaires for the impairment domain (the questionnaire did not assess lung function or the risk domain).
ATAQ = Asthma Therapy Assessment Questionnaire©
ACQ = Asthma Control Questionnaire© (user package may be obtained at www.qoltech.co.uk or juniper@qoltech.co.uk)
ACT = Asthma Control Test™
Minimal Importance Difference: 1.0 for the ATAQ; 0.5 for the ACQ; not determined for the ACT.
- Before step up in therapy:
 - Review adherence to medication, inhaler.
 - If an alternative treatment option was used in a step, discontinue and use the preferred treatment for that step.

Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007. <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>

Table 9-2. Classifying severity of asthma exacerbations.

Patients are instructed to use quick-relief medications if symptoms occur or if PEF drops below 80% predicted or personal best. If PEF is 50–79%, the patient should monitor response to quick relief medications carefully and consider contacting a clinician. If PEF is below 50%, immediate medical care is usually required. In the urgent or emergency care setting, the following parameters describe the severity and likely clinical course of an exacerbation

Severity	Symptoms and Signs	Initial PEF (or FEV ₁)	Clinical Course
Mild	Dyspnea only with activity	PEF \geq 70% predicted or personal best	<ul style="list-style-type: none"> • Usually cared for at home • Prompt relief with inhaled SABA • Possible short course of oral systemic corticosteroids
Moderate	Dyspnea interferes with or limits usual activity	PEF 40–69% predicted or personal best	<ul style="list-style-type: none"> • Usually requires office or ED visit • Relief from frequent inhaled SABA • Oral systemic corticosteroids; some symptoms last for 1–2 days after treatment is begun
Severe	Dyspnea at rest; interferes with conversation	PEF $<$ 40% predicted or personal best	<ul style="list-style-type: none"> • Usually requires ED visit and likely hospitalization • Partial relief from frequent inhaled SABA • Oral systemic corticosteroids; some symptoms last for $>$ 3 days after treatment is begun • Adjunctive therapies are helpful
<i>Subset:</i> Life-threatening	Too dyspneic to speak; perspiring	PEF $<$ 25% predicted or personal best	<ul style="list-style-type: none"> • Requires ED/hospitalization; possible ICU • Minimal or no relief from frequent inhaled SABA • Intravenous corticosteroids • Adjunctive therapies are helpful

ED, emergency department; FEV₁, forced expiratory volume in 1 second; ICU, intensive care unit; PEF, peak expiratory flow; SABA, short-acting β_2 -agonist.

Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007. <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>

worse at night; circadian variations in bronchomotor tone and bronchial reactivity reach their nadir between 3 AM and 4 AM, increasing symptoms of bronchoconstriction.

Some physical examination findings increase the probability of asthma. Nasal mucosal swelling, increased nasal secretions, and nasal polyps are often seen in patients with allergic asthma. Eczema, atopic dermatitis, or other manifestations of allergic skin disorders may also be present. Wheezing during normal breathing or a prolonged forced expiratory phase correlates well with the presence of airflow obstruction. Wheezing during forced expiration does not. Chest examination may be normal between exacerbations in patients with mild asthma. During severe asthma exacerbations, airflow may be too limited to produce wheezing, and the only diagnostic clue on auscultation may be globally reduced breath sounds with prolonged expiration. Hunched shoulders and use of accessory muscles of respiration suggest an increased work of breathing.

B. Laboratory Findings

Arterial blood gas measurements may be normal during a mild asthma exacerbation, but respiratory alkalosis and an increase in the alveolar-arterial oxygen difference ($A-a-DO_2$) are common. During severe exacerbations, hypoxemia develops and the $PaCO_2$ returns to normal. The combination of an increased $PaCO_2$ and respiratory acidosis may indicate impending respiratory failure and the need for mechanical ventilation.

C. Pulmonary Function Testing

Clinicians are able to identify airflow obstruction on examination, but they have limited ability to assess severity or to predict whether it is reversible. The evaluation for asthma should therefore include spirometry (forced expiratory volume in 1 second [FEV₁], forced vital capacity [FVC], FEV₁/FVC) before and after the administration of a short-acting bronchodilator. These measurements help determine the presence and extent of airflow obstruction and whether it is immediately reversible. Airflow obstruction is indicated by a reduced FEV₁/FVC ratio. Significant reversibility of airflow obstruction is defined by an increase of \geq 12% and 200 mL in FEV₁ or \geq 15% and 200 mL in FVC after inhaling a short-acting bronchodilator. A positive bronchodilator response strongly confirms the diagnosis of asthma but a lack of responsiveness in the pulmonary function laboratory does not preclude success in a clinical trial of bronchodilator therapy. Severe airflow obstruction results in significant air trapping, with an increase in residual volume and consequent reduction in FVC, resulting in a pattern that may mimic a restrictive ventilatory defect.

Bronchial provocation testing with inhaled histamine or methacholine may be useful when asthma is suspected but spirometry is nondiagnostic. Bronchial provocation is not recommended if the FEV₁ is less than 65% of predicted. A positive methacholine test is defined as a \geq 20% fall in the FEV₁ at exposure to a concentration of 8 mg/mL or

Table 9-3. Evaluation of asthma exacerbation severity.

	Mild	Moderate	Severe	Subset: Respiratory Arrest Imminent
Symptoms				
Breathlessness	While walking Can lie down	While at rest Prefers sitting	While at rest Sits upright	
Talks in	Sentences	Phrases	Words	
Alertness	May be agitated	Usually agitated	Usually agitated	Drowsy or confused
Signs				
Respiratory rate	Increased	Increased	Often > 30/minute	
Use of accessory muscles; suprasternal retractions	Usually not	Commonly	Usually	Paradoxical thoracoabdominal movement
Wheeze	Moderate, often only end expiratory	Loud; throughout exhalation	Usually loud; throughout inhalation and exhalation	Absence of wheeze
Pulse/minute	< 100	100-120	> 120	Bradycardia
Pulsus paradoxus	Absent < 10 mm Hg	May be present 10-25 mm Hg	Often present > 25 mm Hg	Absence suggests respiratory muscle fatigue
Functional Assessment				
PEF Percent predicted or percent personal best	≥ 70%	Approx. 40-69% or response lasts < 2 hours	< 40%	< 25% Note: PEF testing may not be needed in very severe attacks
Pao ₂ (on air)	Normal (test not usually necessary)	≥ 60 mm Hg (test not usually necessary)	< 60 mm Hg: possible cyanosis	
and/or Pco ₂	< 42 mm Hg (test not usually necessary)	< 42 mm Hg (test not usually necessary)	≥ 42 mm Hg: possible respiratory failure	
Sao ₂ percent (on air) at sea level	> 95% (test not usually necessary)	90-95% (test not usually necessary)	< 90%	
	Hypercapnia (hypoventilation) develops more readily in young children than in adults and adolescents			

PEF, peak expiratory flow; Sao₂, oxygen saturation.

Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007. <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>

less. A negative test has a negative predictive value for asthma of 95%. Exercise challenge testing may be useful in patients with symptoms of exercise-induced bronchospasm.

Peak expiratory flow (PEF) meters are handheld devices designed as personal monitoring tools. PEF monitoring can establish peak flow variability, quantify asthma severity, and provide both the patient and the clinician with objective measurements on which to base treatment decisions. There are conflicting data about whether measuring PEF improves asthma outcomes, but doing so is recommended to help confirm the diagnosis of asthma, to improve asthma control in patients with poor perception

of airflow obstruction, and to identify environmental and occupational causes of symptoms. Predicted values for PEF vary with age, height, and gender but are poorly standardized. Comparison with reference values is less helpful than comparison with the patient's own baseline. PEF shows diurnal variation. It is generally lowest on first awakening and highest several hours before the midpoint of the waking day. PEF should be measured in the morning before the administration of a bronchodilator and in the afternoon after taking a bronchodilator. A 20% change in PEF values from morning to afternoon or from day to day suggests inadequately controlled asthma. PEF values less than 200 L/min indicate severe airflow obstruction.

D. Additional Testing

Routine chest radiographs in patients with asthma are usually normal or show only hyperinflation. Other findings may include bronchial wall thickening and diminished peripheral lung vascular shadows. Chest imaging is indicated when pneumonia, another disorder mimicking asthma, or a complication of asthma such as pneumothorax is suspected.

Skin testing or in vitro testing to assess sensitivity to environmental allergens can identify atopy in patients with persistent asthma who may benefit from therapies directed at their allergic diathesis. Evaluations for paranasal sinus disease or gastroesophageal reflux should be considered in asthma patients with pertinent symptoms and in those with severe or refractory asthma symptoms.

Noninvasive assessment of underlying airway inflammation through measurement of eosinophilia in induced sputum, or fractional nitric oxide concentration in exhaled breath condensates (FeNO), offers the promise of improved diagnosis and treatment strategies. Adjusting corticosteroid dose to minimize sputum eosinophilia appears to reduce the frequency of exacerbations compared with conventional clinical management, but the data are conflicting regarding the impact of FeNO on asthma outcomes.

► Complications

Complications of asthma include exhaustion, dehydration, airway infection, and tussive syncope. Pneumothorax occurs but is rare. Acute hypercapnic and hypoxemic respiratory failure occurs in severe disease.

► Differential Diagnosis

It is prudent to consider conditions that mimic asthma in patients who have atypical symptoms or poor response to therapy. These disorders typically fall into one of four categories: upper airway disorders, lower airway disorders, systemic vasculitides, and psychiatric disorders. **Upper airway disorders** that mimic asthma include vocal fold paralysis, vocal fold dysfunction syndrome, foreign body aspiration, laryngotracheal masses, tracheal narrowing, tracheomalacia, and airway edema as in the setting of angioedema or inhalation injury. **Lower airway disorders** include nonasthmatic COPD (chronic bronchitis or emphysema), bronchiectasis, allergic bronchopulmonary mycosis, cystic fibrosis, eosinophilic pneumonia, and bronchiolitis obliterans. **Systemic vasculitides** with pulmonary involvement may have an asthmatic component, such as Churg-Strauss syndrome. **Psychiatric causes** include conversion disorders, which have been variably referred to as functional asthma, emotional laryngeal wheezing, vocal fold dysfunction, or episodic laryngeal dyskinesia. Münchausen syndrome or malingering may rarely explain a patient's complaints.

► NAEPP 3 Diagnosis & Management Guidelines

In 2007, the National Asthma Education and Prevention Program (NAEPP), in conjunction with the Global Initiative

for Asthma (GINA), a collaboration between the National Institutes of Health (NIH)/National Heart, Lung, and Blood Institute (NHLBI) and the World Health Organization (WHO), released its third Expert Panel Report providing guidelines for diagnosis and management of asthma (NAEPP 3). This report identifies four components of chronic asthma diagnosis and management: (1) assessing and monitoring asthma severity and asthma control, (2) patient education designed to foster a partnership for care, (3) control of environmental factors and comorbid conditions that affect asthma, and (4) pharmacologic agents for asthma.

1. Assessing and monitoring asthma severity and asthma control

Severity is the intrinsic intensity of the disease process. Control is the degree to which symptoms and limitations on activity are minimized by therapy. **Responsiveness** is the ease with which control is achieved with therapy. NAEPP 3 guidelines emphasize control over classifications of severity, since the latter is variable over time and in response to therapy. A measure of severity on initial presentation (see Figure 9–1) is helpful, however, in guiding the initiation of therapy. Control of asthma is assessed in terms of **impairment** (frequency and intensity of symptoms and functional limitations) and **risk** (the likelihood of acute exacerbations or chronic decline in lung function). A key insight is that these two domains of control may respond differently to treatment: some patients may have minimal impairment yet remain at risk for severe exacerbations, for example, in the setting of an upper respiratory tract infection. Table 9–1 is used to assess the adequacy of asthma control and is used in conjunction with Figure 9–2 to guide adjustments in therapy based on the level of control.

2. Patient education designed to foster a partnership for care

Active self-management reduces urgent care visits and hospitalizations and improves perceived control of asthma. Therefore, an outpatient preventive approach that includes self-management education is an integral part of effective asthma care.

All patients, but particularly those with poorly controlled symptoms or a history of severe exacerbations, should have a written asthma action plan that includes instructions for daily management and measures to take in response to specific changes in status. Patients should be taught to recognize symptoms—especially patterns indicating inadequate asthma control or predicting the need for additional therapy.

3. Control of environmental factors and comorbid conditions that affect asthma

Significant reduction in exposure to nonspecific airway irritants or to inhaled allergens in atopic patients may reduce symptoms as well as medication needs. Comorbid conditions that impair asthma management, such as rhinosinusitis, gastroesophageal reflux, obesity, and obstructive sleep apnea, should be identified and treated. This search for complicating conditions is particularly crucial in the initial evaluation of a new diagnosis, and in patients whose asthma is difficult to control or subject to frequent exacerbations.

4. Pharmacologic agents for asthma—Asthma medications can be divided into two categories: quick-relief

Key: Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy. EIB, exercise-induced bronchospasm; ICS, inhaled corticosteroid; LABA, inhaled long-acting β_2 -agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting β_2 -agonist

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Zileuton is a less desirable alternative as adjunctive therapy due to limited studies and the need to monitor liver function. Theophylline requires monitoring of serum concentration levels.
- In step 6, before oral systemic corticosteroids are introduced, a trial of high-dose ICS + LABA + either LTRA, theophylline, or zileuton may be considered, although this approach has not been studied in clinical trials.
- Step 1, 2, and 3 preferred therapies are based on Evidence A; step 3 alternative therapy is based on Evidence A for LTRA, Evidence B for theophylline, and Evidence D for zileuton. Step 4 preferred therapy is based on Evidence B, and alternative therapy is based on Evidence B for LTRA and theophylline and Evidence D for zileuton. Step 5 preferred therapy is based on Evidence B. Step 6 preferred therapy is based on (EPR 2 1997) and Evidence B for omalizumab.
- Immunotherapy for steps 2–4 is based on Evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults.
- Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur.

▲ **Figure 9–2.** Stepwise approach to managing asthma. (Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007. <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>.)

(**reliever**) medications that act principally by direct relaxation of bronchial smooth muscle, thereby promoting prompt reversal of acute airflow obstruction to relieve accompanying symptoms, and long-term control (**controller**) medications that act primarily to attenuate airway inflammation and are taken daily independent of symptoms to achieve and maintain control of persistent asthma.

Most asthma medications are administered orally or by inhalation. Inhalation of an appropriate agent results in a more rapid onset of pulmonary effects as well as fewer systemic effects compared with oral administration of the same dose. Metered-dose inhalers (MDIs) propelled by chlorofluorocarbons (CFCs) have been the most widely used delivery system, but non-CFC propellant systems such as hydrofluoroalkane (HFA), and dry powder inhalers (DPIs) are increasingly available. Proper inhaler technique and the use of an inhalation chamber with MDIs improve drug delivery to the lung and decrease oropharyngeal deposition. Nebulizer therapy is reserved for acutely ill patients and those who cannot use inhalers because of difficulties with coordination or cooperation.

► Treatment

The goals of asthma therapy are to minimize chronic symptoms that interfere with normal activity (including exercise), to prevent recurrent exacerbations, to reduce or eliminate the need for emergency department visits or hospitalizations, and to maintain normal or near-normal pulmonary function. These goals should be met while providing pharmacotherapy with the fewest adverse effects and while meeting patients' and families' expectations of satisfaction with asthma care. NAEP 3 recommendations emphasize daily anti-inflammatory therapy with inhaled corticosteroids as the cornerstone of treatment of persistent asthma.

A. Long-Term Control Medications

Anti-inflammatory agents, long-acting bronchodilators, and leukotriene modifiers comprise the important long-term control medications (Tables 9-4 and 9-5). Other classes of agents are mentioned briefly below.

1. Anti-inflammatory agents—Corticosteroids are the most potent and consistently effective anti-inflammatory agents currently available. They reduce both acute and chronic inflammation, resulting in fewer asthma symptoms, improvement in airflow, decreased airway hyper-responsiveness, and fewer asthma exacerbations. These agents may also potentiate the action of β -adrenergic agonists.

Inhaled corticosteroids are preferred, first-line agents for all patients with persistent asthma. Patients with persistent symptoms or asthma exacerbations who are not taking inhaled corticosteroids should be started on an inhaled corticosteroid. The most important determinants of agent selection and appropriate dosing are the patient's status and response to treatment. Dosages for inhaled corticosteroids vary depending on the specific agent and delivery device. For most patients, twice-daily dosing provides adequate control of asthma. Once-daily dosing may be

sufficient in selected patients. Maximum responses from inhaled corticosteroids may not be observed for months. The use of an inhalation chamber coupled with mouth washing after MDI use decreases local side effects (cough, dysphonia, oropharyngeal candidiasis) and systemic absorption. DPIs are not used with an inhalation chamber. Systemic effects (adrenal suppression, osteoporosis, skin thinning, easy bruising, and cataracts) may occur with high-dose inhaled corticosteroid therapy.

Systemic corticosteroids (oral or parenteral) are most effective in achieving prompt control of asthma during exacerbations or when initiating long-term asthma therapy in patients with severe symptoms. In patients with refractory, poorly controlled asthma, systemic corticosteroids may be required for the long-term suppression of symptoms. Repeated efforts should be made to reduce the dose to the minimum needed to control symptoms. Alternate-day treatment is preferred to daily treatment. Concurrent treatment with calcium supplements and vitamin D should be initiated to prevent corticosteroid-induced bone mineral loss in long-term administration. Bisphosphonates may offer additional protection to these patients. Rapid discontinuation of systemic corticosteroids after long-term use may precipitate adrenal insufficiency.

2. Long-acting bronchodilators

A. MEDIATOR INHIBITORS—Cromolyn sodium and nedocromil are long-term control medications that prevent asthma symptoms and improve airway function in patients with mild persistent asthma or exercise-induced symptoms. These agents modulate mast cell mediator release and eosinophil recruitment and inhibit both early and late asthmatic responses to allergen challenge and exercise-induced bronchospasm. They can be effective when taken before an exposure or exercise but do not relieve asthmatic symptoms once present. The clinical response to these agents is less predictable than the response to inhaled corticosteroids. Nedocromil may help reduce the dose requirements for inhaled corticosteroids. Both agents have excellent safety profiles.

B. β -ADRENERGIC AGONISTS—Long-acting β_2 -agonists provide bronchodilation for up to 12 hours after a single dose. Salmeterol and formoterol are the two long-acting β_2 -agonists available in the United States. They are administered via dry powder delivery devices. They are indicated for long-term prevention of asthma symptoms, nocturnal symptoms, and for prevention of exercise-induced bronchospasm. When added to low and medium daily doses of inhaled corticosteroids (Table 9-5), long-acting β_2 -agonists provide control equivalent to what is achieved by doubling the inhaled corticosteroid dose. Side effects are minimal at standard doses. Long-acting β_2 -agonists should not be used as monotherapy since they have no anti-inflammatory effect and since monotherapy with long-acting β_2 -agonists has been associated in two large studies with a small but statistically significant increased risk of severe or fatal asthma attacks. This increased risk may relate to genetic variation in the β -adrenergic receptor, but it has not been fully explained and remains an area of controversy. The efficacy of combined inhaled corticosteroid and long-acting

Table 9-4. Long-term control medications for asthma.

Medication	Dosage Form	Adult Dose	Comments
Inhaled Corticosteroids			(See Table 9-5)
Systemic Corticosteroids			(Applies to all three corticosteroids)
Methylprednisolone	2, 4, 6, 8, 16, 32 mg tablets	7.5-60 mg daily in a single dose in AM or every other day as needed for control	<ul style="list-style-type: none"> Administer single dose in AM either daily or on alternate days (alternate-day therapy may produce less adrenal suppression). Short courses or "bursts" are effective for establishing control when initiating therapy or during a period of gradual deterioration. There is no evidence that tapering the dose following improvement in symptom control and pulmonary function prevents relapse.
Prednisolone	5 mg tablets, 5 mg/5 mL, 15 mg/5 mL	Short-course "burst": to achieve control, 40-60 mg per day as single or 2 divided doses for 3-10 days	
Prednisone	1, 2.5, 5, 10, 20, 50 mg tablets; 5 mg/mL, 5 mg/mL		
Inhaled Long-Acting β_2-Agonists			Should not be used for symptom relief or exacerbations. Use with inhaled corticosteroids.
Salmeterol	DPI 50 mcg/blister	1 blister every 12 hours	<ul style="list-style-type: none"> Decreased duration of protection against EIB may occur with regular use.
Formoterol	DPI 12 mcg/single-use capsule	1 capsule every 12 hours	<ul style="list-style-type: none"> Decreased duration of protection against EIB may occur with regular use. Each capsule is for single use only; additional doses should not be administered for at least 12 hours. Capsules should be used only with the Aerolizer™ inhaler and should not be taken orally.
Combined Medication			
Fluticasone/Salmeterol	DPI 100 mcg/50 mcg, 250 mcg/50 mcg, or 500 mcg/50 mcg	1 inhalation twice daily; dose depends on severity of asthma	<ul style="list-style-type: none"> 100/50 DPI or 45/21 HFA for patient not controlled on low- to medium-dose inhaled corticosteroids 250/50 DPI or 115/21 HFA for patients not controlled on medium- to high-dose inhaled corticosteroids
	HFA 45 mcg/21 mcg 115 mcg/21 mcg 230 mcg/21 mcg		
Budesonide/ Formoterol	HFA MDI 80 mcg/4.5 mcg 160 mcg/4.5 mcg	2 inhalations twice daily; dose depends on severity of asthma	<ul style="list-style-type: none"> 80/4.5 for asthma not controlled on low- to medium-dose inhaled corticosteroids 160/4.5 for asthma not controlled on medium- to high-dose inhaled corticosteroids
Cromolyn and Nedocromil			
Cromolyn	MDI 0.8 mg/puff	2 puffs four times daily	<ul style="list-style-type: none"> 4-6 week trial may be needed to determine maximum benefit.
	Nebulizer 20 mg/ampule	1 ampule four times daily	<ul style="list-style-type: none"> Dose by MDI may be inadequate to affect hyperresponsiveness.
Nedocromil	MDI 1.75 mg/puff	2 puffs four times daily	<ul style="list-style-type: none"> One dose before exercise or allergen exposure provides effective prophylaxis for 1-2 hours. Not as effective for EIB as SABA. Once control is achieved, the frequency of dosing may be reduced.

(continued)

Table 9-4. Long-term control medications for asthma. (Continued)

Medication	Dosage Form	Adult Dose	Comments
Inhaled Long-Acting Anticholinergic			Should not be used for symptom relief or exacerbations. Use with inhaled corticosteroids.
Tiotropium	DPI 18 mcg/blister	1 blister daily	
Leukotriene Modifiers			
Leukotriene Receptor Antagonists			
Montelukast	4 mg or 5 mg chewable tablet 10 mg tablet	10 mg each night at bedtime	• Exhibits a flat dose-response curve. Doses > 10 mg will not produce a greater response in adults.
Zafirlukast	10 or 20 mg tablet	40 mg daily (20 mg tablet twice daily)	• Administration with meals decreases bioavailability; take at least 1 hour before or 2 hours after meals. • Monitor for symptoms and signs of hepatic dysfunction.
5-Lipoxygenase Inhibitor			
Zileuton	600 mg tablet	2400 mg daily (600 mg four times daily)	• Monitor hepatic enzymes (ALT).
Methylxanthines			
Theophylline	Liquids, sustained-release tablets, and capsules	Starting dose 10 mg/kg/d up to 300 mg maximum; usual maximum dose 800 mg/d	• Adjust dosage to achieve serum concentration of 5-15 mcg/mL at steady-state (at least 48 hours on same dosage). • Due to wide interpatient variability in theophylline metabolic clearance, routine serum theophylline level monitoring is important.
Immunomodulators			
Omalizumab	Subcutaneous injection, 150 mg/1.2 mL following reconstitution with 1.4 mL sterile water for injection	150-375 mg subcutaneously every 2-4 weeks, depending on body weight and pretreatment serum IgE level	• Do not administer more than 150 mg per injection site. • Monitor for anaphylaxis for 2 hours following at least the first 3 injections.

β_2 -agonist therapy has led to marketing of combination medications that deliver both agents simultaneously (see Table 9-4). Combination inhalers containing formoterol and budesonide have shown efficacy in both maintenance and rescue, given formoterol's short time to onset.

C. ANTICHOLINERGICS—The long-acting anticholinergic tiotropium has been studied as add-on therapy for patients who have either a bronchodilator response or a positive methacholine challenge that is not adequately controlled with low-dose inhaled corticosteroid. After 14 weeks of treatment, the addition of tiotropium resulted in improvements in PEF, FEV1, and symptom control; the improvements were greater than those achieved by doubling the dose of the inhaled corticosteroid for the same period of time. The addition of tiotropium was not inferior to the addition of salmeterol. The short treatment period does not permit a determination of whether long-acting β_2 -agonists are comparable to tiotropium in reducing asthma exacerbations and whether it is an effective and safe alternative to long-acting β_2 -agonists for the long-term management of asthma.

D. PHOSPHODIESTERASE INHIBITORS—Theophylline provides mild bronchodilation in asthmatic patients. Theophylline also has anti-inflammatory and immunomodulatory properties, enhances mucociliary clearance, and strengthens diaphragmatic contractility. Sustained-release theophylline preparations are effective in controlling nocturnal symptoms and as added therapy in patients with moderate or severe persistent asthma whose symptoms are inadequately controlled by inhaled corticosteroids. When added to inhaled corticosteroids, theophylline may allow equivalent control at lower corticosteroid doses.

Theophylline serum concentrations need to be monitored closely owing to the drug's narrow toxic-therapeutic range, individual differences in metabolism, and the effects of many factors on drug absorption and metabolism. Potential adverse effects at therapeutic doses include insomnia, aggravation of dyspepsia and gastroesophageal reflux symptoms, and urination difficulties in elderly men with prostatism. Dose-related toxicities include nausea, vomiting, tachyarrhythmias, headache, seizures, hyperglycemia, and hypokalemia. Newer agents that selectively inhibit phosphodiesterase-4 are in clinical trials.

Table 9-5. Estimated comparative daily dosages for inhaled corticosteroids for asthma.

Drug	Low Daily Dose Adult	Medium Daily Dose Adult	High Daily Dose Adult
Beclomethasone HFA 40 or 80 mcg/puff	80-240 mcg	> 240-480 mcg	> 480 mcg
Budesonide DPI 90, 180, or 200 mcg/inhalation	180-600 mcg	> 600-1200 mcg	> 1200 mcg
Flunisolide 250 mcg/puff	500-1000 mcg	> 1000-2000 mcg	> 2000 mcg
Flunisolide HFA 80 mcg/puff	320 mcg	> 320-640 mcg	> 640 mcg
Fluticasone HFA/MDI: 44, 110, or 220 mcg/puff DPI: 50, 100, or 250 mcg/inhalation	88-264 mcg	> 264-440 mcg	> 440 mcg
	100-300 mcg	> 300-500 mcg	> 500 mcg
Mometasone DPI 200 mcg/puff	200 mcg	400 mcg	> 400 mcg
Triamcinolone acetonide 75 mcg/puff	300-750 mcg	> 750-1500 mcg	> 1500 mcg

DPI, dry power inhaler; HFA, hydrofluoroalkaline; MDI, metered-dose inhaler.

Notes:

- The most important determinant of appropriate dosing is the clinician's judgment of the patient's response to therapy.
- Potential drug interactions

A number of the inhaled corticosteroids, including fluticasone, budesonide, and mometasone, are metabolized in the gastrointestinal tract and liver by CYP 3A4 isoenzymes. Potent inhibitors of CYP 3A4, such as ritonavir and ketoconazole, have the potential for increasing systemic concentrations of these inhaled corticosteroids by increasing oral availability and decreasing systemic clearance. Some cases of clinically significant Cushing syndrome and secondary adrenal insufficiency have been reported.

Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007. <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>

3. Leukotriene modifiers—Leukotrienes are potent biochemical mediators that contribute to airway obstruction and asthma symptoms by contracting airway smooth muscle, increasing vascular permeability and mucus secretion, and attracting and activating airway inflammatory cells. Zileuton is a 5-lipoxygenase inhibitor that decreases leukotriene production, and zafirlukast and montelukast are cysteinyl leukotriene receptor antagonists. In randomized controlled trials, these agents cause modest improvements in lung function and reductions in asthma symptoms and lessen the need for β_2 -agonist rescue therapy. These agents are alternatives to low-dose inhaled corticosteroids in patients with mild persistent asthma, although, as monotherapy, their effect is generally less than inhaled corticosteroids. In pragmatic, real-life community trials, leukotriene receptor antagonists were equivalent in efficacy to an inhaled corticosteroid as first-line long-term controller medication or to a long-acting β_2 -agonist as add-on therapy. Zileuton can cause reversible elevations in plasma aminotransferase levels, and Churg-Strauss syndrome has been diagnosed in a small number of patients who have taken montelukast or zafirlukast, although this is suspected to be an effect of corticosteroid withdrawal as opposed to a direct drug effect.

4. Desensitization—Immunotherapy for specific allergens may be considered in selected asthma patients who have exacerbations of asthma symptoms when exposed to allergens to which they are sensitive and who do not respond to

environmental control measures or other forms of conventional therapy. Studies show a reduction in asthma symptoms in patients treated with single-allergen immunotherapy. Because of the risk of immunotherapy-induced bronchoconstriction, it should be administered only in a setting where such complications can be immediately treated.

5. Omalizumab—Omalizumab is a recombinant antibody that binds IgE without activating mast cells. In clinical trials in patients with moderate to severe asthma and elevated IgE levels, omalizumab reduced the need for corticosteroids.

6. Vaccination—Patients with asthma should receive pneumococcal vaccination (Pneumovax) and annual influenza vaccinations, including influenza (seasonal and epidemic influenza A [H1N1]). Inactive vaccines (Pneumovax) are associated with few side effects but use of the live attenuated influenza vaccine intranasally may be associated with an increase in asthma exacerbations in young children.

7. Miscellaneous agents—Oral sustained-release β_2 -agonists are reserved for patients with bothersome nocturnal asthma symptoms or moderate to severe persistent asthma who do not respond to other therapies.

B. Quick-Relief Medications

Short-acting bronchodilators and systemic corticosteroids comprise the important medications in this group of agents (Table 9-6).

Table 9-6. Quick-relief medications for asthma.

Medication	Dosage Form	Adult Dose	Comments
Inhaled Short-Acting β_2-Agonists			
<i>MDI</i>			
Albuterol CFC	90 mcg/puff, 200 puffs/ canister	2 puffs 5 minutes before exercise	<ul style="list-style-type: none"> An increasing use or lack of expected effect indicates diminished control of asthma. Not recommended for long-term daily treatment. Regular use exceeding 2 days/week for symptom control (not prevention of EIB) indicates the need to step up therapy. Differences in potency exist, but all products are essentially comparable on a per puff basis. May double usual dose for mild exacerbations. Should prime the inhaler by releasing four actuations prior to use. Periodically clean HFA activator, as drug may block/plug orifice. Nonselective agents (ie, epinephrine, isoproterenol, metaproterenol) are not recommended due to their potential for excessive cardiac stimulation, especially in high doses.
Albuterol HFA	90 mcg/puff, 200 puffs/ canister	2 puffs every 4-6 hours as needed	
Pirbuterol CFC	200 mcg/puff, 400 puffs/ canister		
Levalbuterol HFA	45 mcg/puff, 200 puffs/ canister		
<i>Nebulizer solution</i>			
Albuterol	0.63 mg/3 mL 1.25 mg/3 mL 2.5 mg/3 mL 5 mg/mL (0.5%)	1.25-5 mg in 3 mL of saline every 4-8 hours as needed	<ul style="list-style-type: none"> May mix with budesonide inhalant suspension, cromolyn or ipratropium nebulizer solutions. May double dose for severe exacerbations.
Levalbuterol (R-albuterol)	0.31 mg/3 mL 0.63 mg/3 mL 1.25 mg/0.5 mL 1.25 mg/3 mL	0.63 mg-1.25 mg every 8 hours as needed	<ul style="list-style-type: none"> Compatible with budesonide inhalant suspension. The product is a sterile-filled, preservative-free, unit dose vial.
Anticholinergics			
<i>MDI</i>			
Ipratropium HFA	17 mcg/puff, 200 puffs/ canister	2-3 puffs every 6 hours	<ul style="list-style-type: none"> Evidence is lacking for anticholinergics producing added benefit to β_2-agonists in long-term control asthma therapy.
<i>Nebulizer solution</i>			
	0.25 mg/mL (0.025%)	0.25 mg every 6 hours	
<i>MDI</i>			
Ipratropium with albuterol	18 mcg/puff of ipratropium bromide and 90 mcg/puff of albuterol 200 puffs/canister	2-3 puffs every 6 hours	
<i>Nebulizer solution</i>			
	0.5 mg/3 mL ipratropium bromide and 2.5 mg/ 3 mL albuterol	3 mL every 4-6 hours	<ul style="list-style-type: none"> Contains EDTA to prevent discolorations of the solution. This additive does not induce bronchospasm.
Systemic Corticosteroids			
Methylprednisolone	2, 4, 6, 8, 16, 32 mg tablets	Short course "burst": 40-60 mg/d as single or 2 divided doses for 3-10 days	<ul style="list-style-type: none"> Short courses or "bursts" are effective for establishing control when initiating therapy or during a period of gradual deterioration. The burst should be continued until symptoms resolve and the PEF is at least 80% of personal best. This usually requires 3-10 days but may require longer. There is no evidence that tapering the dose following improvements prevents relapse.
Prednisolone	5 mg tablets, 5 mg/5 mL, 15 mg/5 mL		
Prednisone	1, 2.5, 5, 10, 20, 50 mg tablets; 5 mg/mL, 5 mg/5mL		

(continued)

Table 9-6. Quick-relief medications for asthma. (Continued)

Medication	Dosage Form	Adult Dose	Comments
	<i>Repository injection</i>		
(Methylprednisolone acetate)	40 mg/mL 80 mg/mL	240 mg intramuscularly once	May be used in place of a short burst of oral corticosteroids in patients who are vomiting or if adherence is a problem.

CFC, chlorofluorocarbon; EIB, exercise-induced bronchospasm; HFA, hydrofluoroalkane; MDI, metered-dose inhaler; PEF, peak expiratory flow.

Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007. <http://www.nhlbi.gov/guidelines/asthma/asthgdln.htm>

1. β -Adrenergic agonists—Short-acting inhaled β_2 -agonists, including albuterol, levalbuterol, bitolterol, pirbuterol, and terbutaline, are the most effective bronchodilators during exacerbations. All patients with acute symptoms should take one of these agents. There is no convincing evidence to support the use of one agent over another. β_2 -Agonists relax airway smooth muscle and cause a prompt increase in airflow and reduction of symptoms. Administration before exercise effectively prevents exercise-induced bronchoconstriction. β_2 -Selective agents may produce less cardiac stimulation than those with mixed β_1 and β_2 activities, although clinical trials have not consistently demonstrated this finding.

Inhaled β -adrenergic therapy is as effective as oral or parenteral therapy in relaxing airway smooth muscle and improving acute asthma and offers the advantages of rapid onset of action (< 5 minutes) with fewer systemic side effects. Repetitive administration produces incremental bronchodilation. One or two inhalations of a short-acting inhaled β_2 -agonist from an MDI are usually sufficient for mild to moderate symptoms. Severe exacerbations frequently require higher doses: 6–12 puffs every 30–60 minutes of albuterol by MDI with an inhalation chamber or 2.5 mg by nebulizer provide equivalent bronchodilation. Administration by nebulization does not offer more effective delivery than MDIs but does provide higher doses. With most β_2 -agonists, the recommended dose by nebulizer for acute asthma (albuterol, 2.5 mg) is 25–30 times that delivered by a single activation of the MDI (albuterol, 0.09 mg). This difference suggests that standard dosing of inhalations from an MDI will often be insufficient in the setting of an acute exacerbation. Independent of dose, nebulizer therapy may be more effective in patients who are unable to coordinate inhalation of medication from an MDI because of age, agitation, or severity of the exacerbation.

Scheduled daily use of short-acting β_2 -agonists is not recommended. Increased use (more than one canister a month) or lack of expected effect indicates diminished asthma control and dictates the need for additional long-term control therapy.

2. Anticholinergics—Anticholinergic agents reverse vagally mediated bronchospasm but not allergen- or exercise-induced bronchospasm. They may decrease mucus gland hypersecretion seen in asthma. Ipratropium bromide, a

quaternary derivative of atropine free of atropine's side effects, is less effective than β_2 -agonists for relief of acute bronchospasm, but it is the inhaled drug of choice for patients with intolerance to β_2 -agonists and with bronchospasm due to β -blocker medications. Ipratropium bromide reduces the rate of hospital admissions when added to inhaled short-acting β_2 -agonists in patients with moderate to severe asthma exacerbations.

3. Phosphodiesterase inhibitors—Methylxanthines are not recommended for therapy of asthma exacerbations. Aminophylline has clearly been shown to be less effective than β_2 -agonists when used as single-drug therapy for acute asthma and adds little except toxicity to the acute bronchodilator effects achieved by nebulized metaproterenol alone. Patients with exacerbations who are currently taking a theophylline-containing preparation should have their serum theophylline concentration measured to exclude theophylline toxicity.

4. Corticosteroids—Systemic corticosteroids are effective primary treatment for patients with moderate to severe asthma exacerbations and for patients with exacerbations who do not respond promptly and completely to inhaled β_2 -agonist therapy. These medications speed the resolution of airflow obstruction and reduce the rate of relapse. Delays in administering corticosteroids may result in delayed benefits from these important agents. Therefore, oral corticosteroids should be available for early administration at home in many patients with moderate to severe asthma. The minimal effective dose of systemic corticosteroids for asthma patients has not been identified. Outpatient prednisone “burst” therapy is 0.5–1 mg/kg/d (typically 40–60 mg) as a single or in two divided doses for 3–10 days. Severe exacerbations requiring hospitalization typically require 1 mg/kg of prednisone or methylprednisolone every 6–12 hours for 48 hours or until the FEV₁ (or PEF rate) returns to 50% of predicted (or 50% of baseline). The dose is then decreased to 60–80 mg/d until the PEF reaches 70% of predicted or personal best. No clear advantage has been found for higher doses of corticosteroids in severe exacerbations. It may be prudent to administer corticosteroids to critically ill patients via the intravenous route in order to avoid concerns about altered gastrointestinal absorption.

5. Antimicrobials—Multiple studies suggest that infections with viruses (rhinovirus) and bacteria (*Mycoplasma pneumoniae*, *Chlamydomphila pneumoniae*) predispose to acute exacerbations of asthma and may underlie chronic, severe asthma. The use of empiric antibiotics is, however, not recommended in routine asthma exacerbations because there is no consistent evidence to support improved clinical outcomes. Antibiotics should be considered when there is a high likelihood of acute bacterial respiratory tract infection, such as for patients with fever or purulent sputum and evidence of pneumonia or bacterial sinusitis.

► Treatment of Asthma Exacerbations

NAEPP 3 asthma treatment algorithms begin with an assessment of the severity of a patient's baseline asthma. Adjustments to that algorithm follow a stepwise approach based on a careful assessment of asthma control. Most instances of uncontrolled asthma are mild and can be managed successfully by patients at home with the telephone assistance of a clinician (Figure 9–3).

More severe exacerbations require evaluation and management in an urgent care or emergency department setting (Figure 9–4).

A. Mild Exacerbations

Mild asthma exacerbations are characterized by only minor changes in airway function ($PEF > 80\%$) and minimal symptoms and signs of airway dysfunction (see Tables 9–2 and 9–3). The majority of such exacerbations can be managed at home with the telephone assistance of a clinician. Many patients respond quickly and fully to an inhaled short-acting β_2 -agonist alone. However, an inhaled short-acting β_2 -agonist may need to be continued at increased doses, eg, every 3–4 hours for 24–48 hours. In patients not taking an inhaled corticosteroid, initiation of this agent should be considered during the mild exacerbation. In patients already taking an inhaled corticosteroid, a 7-day course of oral corticosteroids (0.5–1.0 mg/kg/d) may be necessary. Doubling the dose of inhaled corticosteroid is not effective in the acute setting and is not recommended in the NAEPP 3 guidelines.

B. Moderate Exacerbations

The principal goals of treatment of moderate asthma exacerbations are correction of hypoxemia, reversal of airflow obstruction, and reduction of the likelihood of recurrence of obstruction. Early intervention may lessen the severity and shorten the duration of an exacerbation. Of paramount importance is correction of hypoxemia through the use of supplemental oxygen. Airflow obstruction is treated with continuous administration of an inhaled short-acting β_2 -agonist and the early administration of systemic corticosteroids. Serial measurements of lung function to quantify the severity of airflow obstruction and its response to treatment are useful. The improvement in FEV_1 after 30 minutes of treatment correlates significantly with a broad range of indices of the severity of asthma exacerbations. Serial measurement of airflow in the emergency

department is an important factor in disposition and may reduce the rate of hospital admissions for asthma exacerbations. The post-exacerbation care plan is an important aspect of management. Regardless of the severity, all patients should be provided with necessary medications and education in how to use them, instruction in self-assessment, a follow-up appointment, and instruction in an action plan for managing recurrence.

C. Severe Exacerbations

Owing to the life-threatening nature of severe exacerbations of asthma, treatment should be started immediately once the exacerbation is recognized. All patients with a severe exacerbation should immediately receive oxygen, high doses of an inhaled short-acting β_2 -agonist, and systemic corticosteroids. A brief history pertinent to the exacerbation can be completed while treatment is being initiated. More detailed assessments, including laboratory studies, usually add little in the early phase of evaluation and management and should be postponed until after therapy is instituted.

Oxygen therapy is very important because asphyxia is a common cause of fatal asthma.

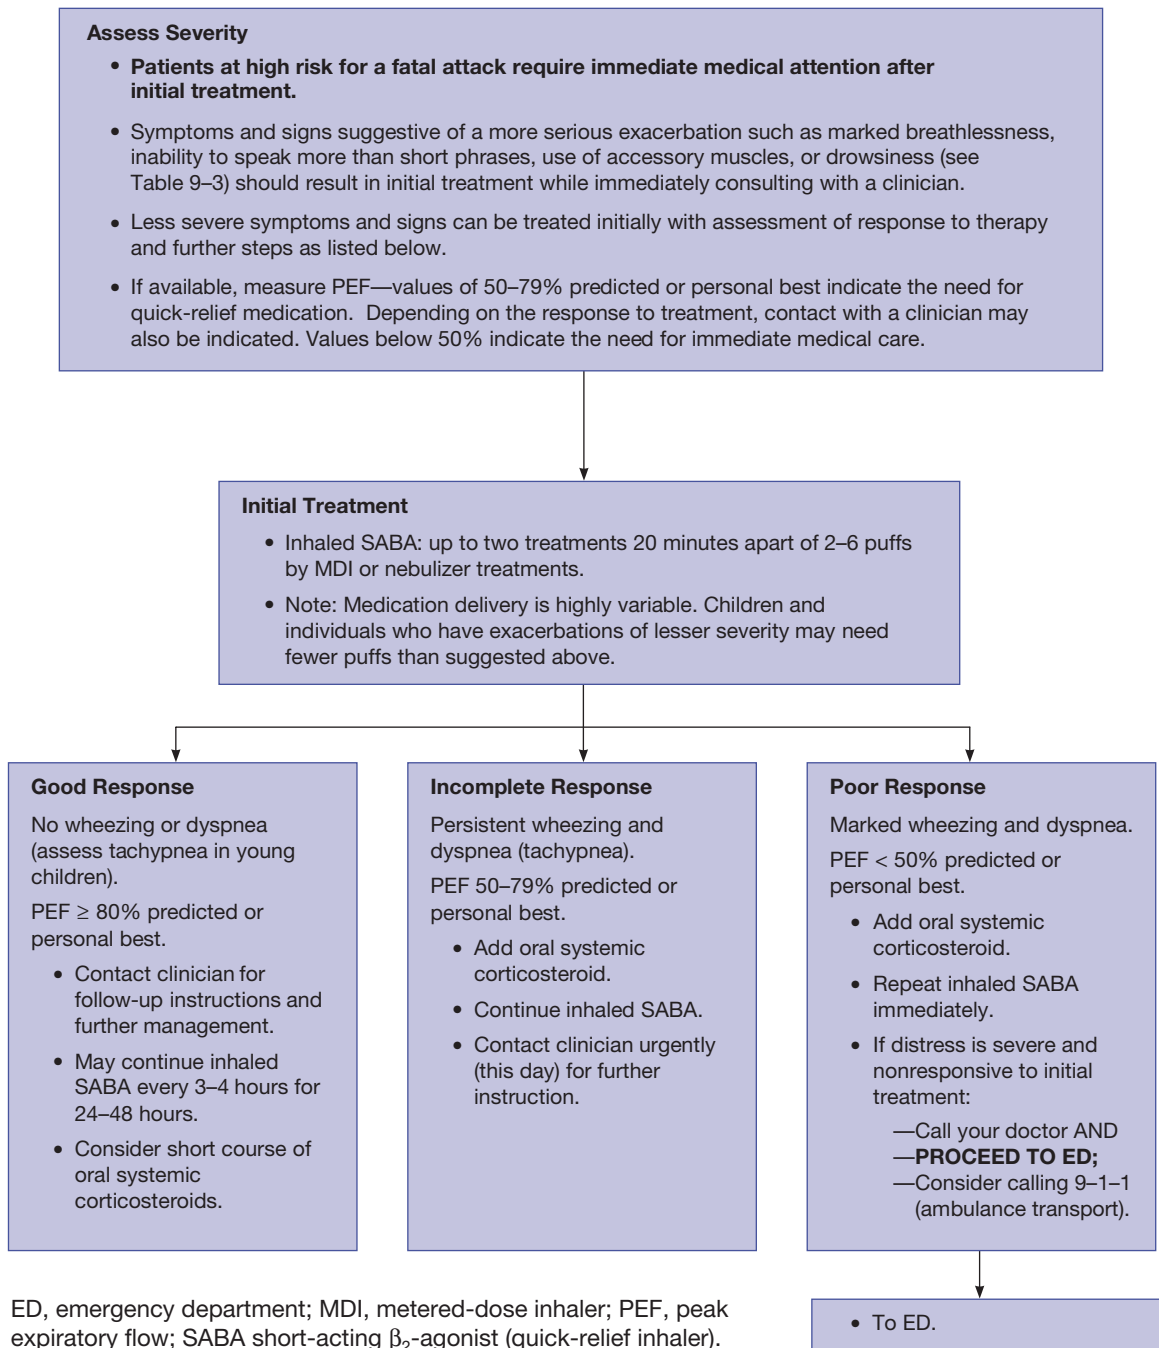

Supplemental oxygen should be given to maintain an $SaO_2 > 90\%$ or a $PaO_2 > 60$ mm Hg. Oxygen-induced hypoventilation is extremely rare, and concern for hypercapnia should never delay correction of hypoxemia.

Frequent high-dose delivery of an **inhaled short-acting β_2 -agonist** is indicated and is usually well tolerated in the setting of severe airway obstruction. Some studies suggest that continuous therapy is more effective than intermittent administration of these agents, but there is no clear consensus as long as similar doses are administered. At least three MDI or nebulizer treatments should be given in the first hour of therapy. Thereafter, the frequency of administration varies according to the improvement in airflow and associated symptoms and the occurrence of side effects. Ipratropium bromide reduces the rate of hospital admissions when added to inhaled short-acting β_2 -agonists in patients with moderate to severe asthma exacerbations.

Systemic corticosteroids are administered as detailed above. Mucolytic agents (eg, acetylcysteine, potassium iodide) may worsen cough or airflow obstruction. Anxiolytic and hypnotic drugs are generally contraindicated in severe asthma exacerbations because of their respiratory depressant effects.

Intravenous magnesium sulfate (2 g intravenously over 20 minutes) produces a detectable improvement in airflow and may reduce hospitalization rates in acute severe asthma ($FEV_1 < 25\%$ of predicted on presentation, or failure to respond to initial treatment).

Repeat assessment of patients with severe exacerbations should be made after the initial dose of inhaled bronchodilator and after three doses of inhaled bronchodilators (60–90 minutes after initiating treatment). The response to initial treatment is a better predictor of the need for hospitalization than is the severity of an exacerbation on presentation. The decision to hospitalize a patient should be based on the duration and severity of symptoms, severity

▲ **Figure 9–3.** Management of asthma exacerbations: home treatment. (Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007. <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>.)

of airflow obstruction, course and severity of prior exacerbations, medication use at the time of the exacerbation, access to medical care and medications, adequacy of social support and home conditions, and presence of psychiatric illness. In general, discharge to home is appropriate if the PEF or FEV₁ has returned to \geq 60% of predicted or personal

best and symptoms are minimal or absent. Patients with a rapid response to treatment should be observed for 30 minutes after the most recent dose of bronchodilator to ensure stability of response before discharge to home.

In the **intensive care setting**, a small subset of patients will not respond to treatment and will progress to impending

FEV₁, forced expiratory volume in 1 second; ICS, inhaled corticosteroid; MDI, metered-dose inhaler; PEF, peak expiratory flow; SABA, short-acting β_2 -agonist; SaO₂, oxygen saturation.

▲ **Figure 9-4.** Management of asthma exacerbations: emergency department and hospital-based treatment. (Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. respiratory failure due to a combination of worsening airflow obstruction and respiratory muscle fatigue (see Table 9–3). Such patients can deteriorate rapidly and thus should be monitored in a critical care setting. Intubation of an acutely ill asthma patient is technically difficult and is best done semi-electively, before the crisis of a respiratory arrest. At the time of intubation, close attention should be given to maintaining intravascular volume because hypotension commonly accompanies the administration of sedation and the initiation of positive-pressure ventilation in patients dehydrated due to poor recent oral intake and high insensible losses.

The main goals of mechanical ventilation are to ensure adequate oxygen and to avoid barotrauma. Controlled hypoventilation with permissive hypercapnia is often required to limit airway pressures. Frequent high-dose delivery of inhaled short-acting β_2 -agonists should be continued along with anti-inflammatory agents as discussed above. Many questions remain regarding the optimal delivery of inhaled β_2 -agonists to intubated, mechanically ventilated patients. Further studies are needed to determine the comparative efficacy of MDIs and nebulizers, optimal ventilator settings to use during drug delivery, ideal site along the ventilator circuit for introduction of the delivery system, and maximal acceptable drug doses. Unconventional therapies such as helium-oxygen mixtures and inhalational anesthetic agents are of unclear benefit but may be appropriate in selected patients.

▶ When to Refer

- Atypical presentation or uncertain diagnosis, particularly if additional diagnostic testing is required (bronchoprovocation challenge, skin testing for allergies, rhinoscopy, consideration of occupational exposure).
- Complicating comorbid problems, such as rhinosinusitis, tobacco use, multiple environmental allergies, suspected allergic bronchopulmonary aspergillosis.
- Suboptimal response to therapy.
- Patient is not meeting goals of asthma therapy after 3–6 months of treatment.
- Requires high-dose inhaled corticosteroids for control.
- More than two courses of oral prednisone therapy in the past 12 months.
- Any life-threatening asthma exacerbation or exacerbation requiring hospitalization in the past 12 months.
- Presence of social or psychological issues interfering with asthma management.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ History of cigarette smoking.
- ▶ Chronic cough, dyspnea, and sputum production.
- ▶ Rhonchi, decreased intensity of breath sounds, and prolonged expiration on physical examination.
- ▶ Airflow limitation on pulmonary function testing that is not fully reversible and most often progressive.

▶ General Considerations

The American Thoracic Society defines COPD as a disease state characterized by the presence of airflow obstruction due to chronic bronchitis or emphysema; the airflow obstruction is generally progressive, may be accompanied by airway hyperreactivity, and may be partially reversible. The NHLBI estimates that 14 million Americans have been diagnosed with COPD; an equal number are thought to be afflicted but remain undiagnosed. Grouped together, COPD and asthma now represent the fourth leading cause of death in the United States, with over 120,000 deaths reported annually. The death rate from COPD is increasing rapidly, especially among elderly men.

Most patients with COPD have features of both emphysema and chronic bronchitis. **Chronic bronchitis** is a clinical diagnosis defined by excessive secretion of bronchial mucus and is manifested by daily productive cough for 3 months or more in at least 2 consecutive years. **Emphysema** is a pathologic diagnosis that denotes abnormal permanent enlargement of air spaces distal to the terminal bronchiole, with destruction of their walls and without obvious fibrosis.

Cigarette smoking is clearly the most important cause of COPD in North America and Western Europe. Nearly all smokers suffer an accelerated decline in lung function that is dose- and duration-dependent. Fifteen percent develop progressively disabling symptoms in their 40s and 50s. It is estimated that 80% of patients seen for COPD have significant exposure to tobacco smoke. The remaining 20% frequently have a combination of exposures to environmental tobacco smoke, occupational dusts and chemicals, and indoor air pollution from biomass fuel used for cooking and heating in poorly ventilated buildings. Outdoor air pollution, airway infection, familial factors, and allergy

have also been implicated in chronic bronchitis, and hereditary factors (deficiency of α_1 -antitrypsin [α_1 -antitrypsin]) have been implicated in COPD. The pathogenesis of emphysema may involve excessive lysis of elastin and other structural proteins in the lung matrix by elastase and other proteases derived from lung neutrophils, macrophages, and mononuclear cells. Atopy and the tendency for bronchoconstriction to develop in response to nonspecific airway stimuli may be important risks for COPD.

► Clinical Findings

A. Symptoms and Signs

Patients with COPD characteristically present in the fifth or sixth decade of life complaining of excessive cough, sputum production, and shortness of breath. Symptoms have often been present for 10 years or more. Dyspnea is noted initially only on heavy exertion, but as the condition progresses it occurs with mild activity. In severe disease, dyspnea occurs at rest. As the disease progresses, two symptom patterns tend to emerge, historically referred to as “pink puffers” and “blue bloaters” (Table 9–7). Most COPD patients have pathologic evidence of both disorders, and

their clinical course may reflect other factors such as central control of ventilation and concomitant sleep-disordered breathing.

Pneumonia, pulmonary hypertension, cor pulmonale, and chronic respiratory failure characterize the late stage of COPD. A hallmark of COPD is the exacerbation of symptoms beyond normal day-to-day variation, often including increased dyspnea, an increased frequency or severity of cough, increased sputum volume or change in sputum character. These exacerbations are commonly precipitated by infection (more often viral than bacterial) or environmental factors. Exacerbations of COPD vary widely in severity but typically require a change in regular therapy.

B. Laboratory Findings

Spirometry provides objective information about pulmonary function and assesses the results of therapy. Pulmonary function tests early in the course of COPD reveal only evidence of abnormal closing volume and reduced midexpiratory flow rate. Reductions in FEV₁ and in the ratio of forced expiratory volume to vital capacity (FEV₁% or FEV₁/FVC ratio) (Table 9–7) occur later. In severe disease, the FVC is markedly reduced. Lung volume measurements

Table 9–7. Patterns of disease in advanced COPD.

	Type A: Pink Puffer (Emphysema Predominant)	Type B: Blue Bloater (Bronchitis Predominant)
History and physical examination	Major complaint is dyspnea, often severe, usually presenting after age 50. Cough is rare, with scant clear, mucoid sputum. Patients are thin, with recent weight loss common. They appear uncomfortable, with evident use of accessory muscles of respiration. Chest is very quiet without adventitious sounds. No peripheral edema.	Major complaint is chronic cough, productive of mucopurulent sputum, with frequent exacerbations due to chest infections. Often presents in late 30s and 40s. Dyspnea usually mild, though patients may note limitations to exercise. Patients frequently overweight and cyanotic but seem comfortable at rest. Peripheral edema is common. Chest is noisy, with rhonchi invariably present; wheezes are common.
Laboratory studies	Hemoglobin usually normal (12–15 g/dL). Pao ₂ normal to slightly reduced (65–75 mm Hg) but Sao ₂ normal at rest. Paco ₂ normal to slightly reduced (35–40 mm Hg). Chest radiograph shows hyperinflation with flattened diaphragms. Vascular markings are diminished, particularly at the apices.	Hemoglobin usually elevated (15–18 g/dL). Pao ₂ reduced (45–60 mm Hg) and Paco ₂ slightly to markedly elevated (50–60 mm Hg). Chest radiograph shows increased interstitial markings (“dirty lungs”), especially at bases. Diaphragms are not flattened.
Pulmonary function tests	Airflow obstruction ubiquitous. Total lung capacity increased, sometimes markedly so. D _{LCO} reduced. Static lung compliance increased.	Airflow obstruction ubiquitous. Total lung capacity generally normal but may be slightly increased. D _{LCO} normal. Static lung compliance normal.
Special evaluations		
\dot{V}/\dot{Q} matching	Increased ventilation to high \dot{V}/\dot{Q} areas, ie, high dead space ventilation.	Increased perfusion to low \dot{V}/\dot{Q} areas.
Hemodynamics	Cardiac output normal to slightly low. Pulmonary artery pressures mildly elevated and increase with exercise.	Cardiac output normal. Pulmonary artery pressures elevated, sometimes markedly so, and worsen with exercise.
Nocturnal ventilation	Mild to moderate degree of oxygen desaturation not usually associated with obstructive sleep apnea.	Severe oxygen desaturation, frequently associated with obstructive sleep apnea.
Exercise ventilation	Increased minute ventilation for level of oxygen consumption. Pao ₂ tends to fall, Paco ₂ rises slightly.	Decreased minute ventilation for level of oxygen consumption. Pao ₂ may rise; Paco ₂ may rise significantly.

D_{LCO}, single-breath diffusing capacity for carbon monoxide; \dot{V}/\dot{Q} , ventilation-perfusion.

reveal a marked increase in residual volume (RV), an increase in total lung capacity (TLC), and an elevation of the RV/TLC ratio, indicative of air trapping, particularly in emphysema.

Arterial blood gas measurements characteristically show no abnormalities early in COPD other than an increased $A-a-DO_2$. Indeed, they are unnecessary unless (1) hypoxemia or hypercapnia is suspected, (2) the FEV_1 is $< 40\%$ of predicted, or (3) there are clinical signs of right heart failure. Hypoxemia occurs in advanced disease, particularly when chronic bronchitis predominates. Compensated respiratory acidosis occurs in patients with chronic respiratory failure, particularly in chronic bronchitis, with worsening of acidemia during acute exacerbations.

Examination of the sputum may reveal *Streptococcus pneumoniae*, *H influenzae*, or *Moraxella catarrhalis*. Positive sputum cultures are poorly correlated with acute exacerbations, and research techniques demonstrate evidence of preceding viral infection in a majority of patients with exacerbations. The ECG may show sinus tachycardia and, in advanced disease, chronic pulmonary hypertension may produce electrocardiographic abnormalities typical of cor pulmonale. Supraventricular arrhythmias (multifocal atrial tachycardia, atrial flutter, and atrial fibrillation) and ventricular irritability also occur.

C. Imaging

Radiographs of patients with chronic bronchitis typically show only nonspecific peribronchial and perivascular markings. Plain radiographs are insensitive for the diagnosis of emphysema; they show hyperinflation with flattening of the diaphragm or peripheral arterial deficiency in about half of cases. CT of the chest, particularly using a high-resolution reconstruction algorithm, is more sensitive and specific than plain radiographs for the diagnosis of emphysema. Pulmonary hypertension may be suggested by enlargement of central pulmonary arteries in advanced disease. Doppler echocardiography provides a noninvasive estimate of pulmonary artery pressure if pulmonary hypertension is suspected.

► Differential Diagnosis

Clinical, imaging, and laboratory findings should enable the clinician to distinguish COPD from other obstructive pulmonary disorders such as bronchial asthma, bronchiectasis, cystic fibrosis, bronchopulmonary mycosis, and central airflow obstruction. Simple asthma is characterized by complete or near-complete reversibility of airflow obstruction. Bronchiectasis is distinguished from COPD by features such as recurrent pneumonia and hemoptysis, digital clubbing, and characteristic imaging abnormalities. Patients with severe α_1 -antitrypsin (α_1 -antitrypsin) deficiency are recognized by family history and the appearance of panacinar bibasilar emphysema early in life, usually in the third or fourth decade; hepatic cirrhosis and hepatocellular carcinoma may occur. Cystic fibrosis occurs in children and younger adults. Rarely, mechanical obstruction of the central airways simulates COPD. Flow-volume loops may help separate patients with central airway obstruction

from those with diffuse intrathoracic airway obstruction characteristic of COPD.

► Complications

Acute bronchitis, pneumonia, pulmonary thromboembolism, atrial dysrhythmias (such as atrial fibrillation, atrial flutter, and multifocal atrial tachycardia), and concomitant left ventricular failure may worsen otherwise stable COPD. Pulmonary hypertension, cor pulmonale, and chronic respiratory failure are common in advanced COPD. Spontaneous pneumothorax occurs in a small fraction of patients with emphysema. Hemoptysis may result from chronic bronchitis or may signal bronchogenic carcinoma.

► Prevention

COPD is largely preventable through elimination of long-term exposure to tobacco smoke. Smokers with early evidence of airflow limitation can significantly alter their disease by smoking cessation. Smoking cessation slows the decline in FEV_1 in middle-aged smokers with mild airways obstruction. Vaccination against seasonal influenza, epidemic influenza A (H1N1), and pneumococcal infection may also be of benefit.

► Treatment

The treatment of COPD is guided by the severity of symptoms or the presence of an exacerbation or stable symptoms. Standards for the management of patients with stable COPD and COPD exacerbations by the American Thoracic Society and the Global Initiative for Obstructive Lung Disease (GOLD), a joint expert committee of the NHLBI and the WHO, are incorporated in the recommendations below. See Chapter 37 for a discussion of air travel in patients with lung disease.

A. Ambulatory Patients

1. Smoking cessation—The single most important intervention in smokers with COPD is to encourage smoking cessation. Simply telling a patient to quit succeeds 5% of the time. Behavioral approaches, ranging from clinician advice to intensive group programs, may improve cessation rates. Pharmacologic therapy includes nicotine replacement (transdermal patch, gum, lozenge, inhaler, or nasal spray), bupropion, and varenicline (a partial agonist of nicotine acetylcholine receptors) (see Chapter 1). Combined pharmacotherapies (two forms of nicotine replacement, or nicotine replacement and bupropion), with or without behavioral approaches have also been recommended. The Lung Health Study reported 22% sustained abstinence at 5 years in their intervention group (behavior modification plus nicotine gum). Varenicline has proved effective but wider use has revealed significant CNS side effects, including some reports of an increase in suicide.

2. Oxygen therapy—Supplemental oxygen is the only drug therapy for which there is evidence showing improvement in the natural history of COPD in those patients with resting hypoxemia. Proved benefits of home oxygen therapy in hypoxemic patients include longer survival, reduced

hospitalization needs, and better quality of life. Survival in hypoxemic patients with COPD treated with supplemental oxygen therapy is directly proportionate to the number of hours per day oxygen is administered: in hypoxemic patients treated with continuous oxygen, the survival after 36 months is about 65%—significantly better than the survival rate of about 45% in those who are treated with only nocturnal oxygen. Oxygen by nasal prongs must be given at least 15 hours a day unless therapy is intended only for exercise or sleep. Several studies of supplemental oxygen therapy in COPD patients with low-normal resting oxygen levels (PaO₂ between 56 and 69 mm Hg) showed no survival benefit. Patients with normal or low-normal resting oxygen levels who desaturate with exertion improve their exercise tolerance and shorten recovery from dyspnea when supplemental oxygen therapy is used during activity, but there is no evidence of a mortality benefit. Requirements for Medicare coverage for a patient's home use of oxygen and oxygen equipment are listed in Table 9–8. Arterial blood gas analysis is preferred over oximetry to guide initial oxygen therapy. Hypoxemic patients with pulmonary hypertension, chronic cor pulmonale, erythrocytosis, impaired cognitive function, exercise intolerance, nocturnal restlessness, or morning headache are particularly likely to benefit from home oxygen therapy.

Home oxygen may be supplied by liquid oxygen systems, compressed gas cylinders, or oxygen concentrators. Most patients benefit from having both stationary and

portable systems. For most patients, a flow rate of 1–3 L/min achieves a PaO₂ greater than 55 mm Hg. The monthly cost of home oxygen therapy ranges from \$300.00 to \$500.00 or more, higher for liquid oxygen systems. Medicare covers approximately 80% of home oxygen expenses. **Transtracheal oxygen** is an alternative method of delivery and may be useful for patients who require higher flows of oxygen than can be delivered via the nose or who are experiencing troublesome side effects from nasal delivery such as nasal drying or epistaxis. Reservoir nasal cannulas or “pendants” and demand (pulse) oxygen delivery systems are also available to conserve oxygen.

3. Inhaled bronchodilators—Bronchodilators do not alter the inexorable decline in lung function that is a hallmark of COPD, but they offer many patients improvement in symptoms, exercise tolerance, and overall health status. Aggressiveness of bronchodilator therapy should be matched to the severity of the patient's disease. In patients who experience no symptomatic improvement, bronchodilators should be discontinued.

The most commonly prescribed short-acting bronchodilators are the anticholinergic ipratropium bromide and β_2 -agonists (eg, albuterol, metaproterenol), delivered by MDI or as an inhalation solution by nebulizer. Ipratropium bromide is generally preferred to the short-acting β_2 -agonists as a first-line agent because of its longer duration of action and absence of sympathomimetic side effects. Some studies have suggested that ipratropium achieves superior bronchodilation in COPD patients. Typical doses are two to four puffs (36–72 mcg) every 6 hours. Short-acting β_2 -agonists are less expensive and have a more rapid onset of action, commonly leading to greater patient satisfaction. At maximal doses, β_2 -agonists have bronchodilator action equivalent to that of ipratropium but may cause tachycardia, tremor, or hypokalemia. There does not appear to be any advantage of scheduled use of short-acting β_2 -agonists compared with as-needed administration. Use of both short-acting β_2 -agonists and anticholinergics at submaximal doses leads to improved bronchodilation compared with either agent alone but does not improve dyspnea.

Long-acting β_2 -agonists (eg, formoterol, salmeterol) and anticholinergics (tiotropium) appear to achieve bronchodilation that is equivalent or superior to what is experienced with ipratropium, in addition to similar improvements on health status. Although they are more expensive than short-acting agents, long-acting bronchodilators may have superior clinical efficacy in persons with advanced disease. A 2008 randomized controlled trial (RCT) of long-term administration of tiotropium added to standard therapy reported fewer exacerbations or hospitalizations, and improved dyspnea scores, in the tiotropium group. Tiotropium had no effect on long-term decline in lung function, however. Another RCT comparing the effects of tiotropium with those of salmeterol-fluticasone in COPD over 2 years reported no difference in the risk of exacerbation. The incidence of pneumonia was higher in the salmeterol-fluticasone group, yet dyspnea scores were lower and there was a mortality benefit compared with tiotropium. This last finding awaits confirmation in further studies.

Table 9–8. Home oxygen therapy: Requirements for Medicare coverage.¹

Group I (any of the following):

1. PaO₂ ≤ 55 mm Hg or Sao₂ ≤ 88% taken while awake, at rest, breathing room air.
2. During sleep (prescription for nocturnal oxygen use only):
 - a. PaO₂ ≤ 55 mm Hg or Sao₂ ≤ 88% for a patient whose awake, resting, room air PaO₂ is ≥ 56 mm Hg or Sao₂ ≥ 89%,
or
 - b. Decrease in PaO₂ > 10 mm Hg or decrease in Sao₂ > 5% associated with symptoms or signs reasonably attributed to hypoxemia (eg, impaired cognitive processes, nocturnal restlessness, insomnia).
3. During exercise (prescription for oxygen use only during exercise):
 - a. PaO₂ ≤ 55 mm Hg or Sao₂ ≤ 88% taken during exercise for a patient whose awake, resting, room air PaO₂ is ≥ 56 mm Hg or Sao₂ ≥ 89%,
and
 - b. There is evidence that the use of supplemental oxygen during exercise improves the hypoxemia that was demonstrated during exercise while breathing room air.

Group II²:

- PaO₂ = 56–59 mm Hg or Sao₂ = 89% if there is evidence of any of the following:
1. Dependent edema suggesting congestive heart failure.
 2. P pulmonale on ECG (P wave > 3 mm in standard leads II, III, or aVF).
 3. Hematocrit > 56%.

¹Centers for Medicare & Medicaid Services, 2003.

²Patients in this group must have a second oxygen test 3 months after the initial oxygen set-up.

The symptomatic benefits of long-acting bronchodilators are firmly established. Whether there is a mortality benefit associated with salmeterol-fluticasone therapy remains controversial, especially since serious concerns have been raised about the safety of both long-acting β_2 -agonists and anticholinergics. Two large RCTs in asthmatic patients reported an increase in exacerbations and mortality in patients treated with salmeterol. These findings have not been observed in COPD patients, however, and several studies report a trend toward lower mortality in patients treated with salmeterol alone, compared with placebo. Several small studies and a 2008 meta-analysis reported an increase in cardiovascular events among patients treated with long- and short-acting anticholinergics. In contrast, the 4-year tiotropium trial reported fewer cardiovascular events in the intervention group. Subsequent meta-analyses that include the 4-year tiotropium trial do not support an increase in cardiovascular events in these patients. This is an area of ongoing study but most practitioners believe that the documented benefits of anticholinergic therapy outweigh potential risks.

4. Corticosteroids—Multiple large clinical trials have reported a reduction in the frequency of COPD exacerbations and an increase in self-reported functional status in COPD patients treated with inhaled corticosteroids. These same trials demonstrate no effect of inhaled corticosteroids on mortality or the characteristic decline in lung function experienced by COPD patients. At this time, inhaled corticosteroids alone should not be considered first-line therapy in stable COPD patients, who benefit more from bronchodilators, smoking cessation, and pulmonary rehabilitation.

Combination therapy with an inhaled corticosteroid and a long-acting β_2 -agonist reduces the frequency of COPD exacerbations and improves self-reported functional status in COPD patients, compared with placebo or sole use of inhaled corticosteroids, long-acting β_2 -agonists, or anticholinergics. Addition of an inhaled corticosteroid/long-acting β_2 -agonist to tiotropium therapy in COPD patients does not reduce the frequency of COPD exacerbations but did improve hospitalization rates as well as self-reported functional status in one RCT.

Apart from acute exacerbations, COPD is not generally responsive to oral corticosteroid therapy. Only 10–20% of stable outpatients with COPD given oral corticosteroids will have a > 20% increase in FEV₁ compared with patients receiving placebo. There may be a subset of steroid-responsive COPD patients more likely to benefit from long-term oral or inhaled corticosteroids. Since there are no clinical predictors to identify such responders, empiric trials of oral corticosteroids are common. Current research provides little guidance to interpret clinically relevant benefit and clinically significant changes in spirometry, however. If empiric trials of oral corticosteroids are conducted, the baseline FEV₁ should be stable, ie, not measured during an exacerbation, and documented on maximal bronchodilator therapy. The postbronchodilator FEV₁ value is considered the appropriate baseline. After a 3–4 week trial of 0.25–0.5 mg/kg oral prednisone, the drug should be discontinued unless there is a 20% or greater increase in FEV₁.

Responders to oral agents are usually switched to inhaled corticosteroids, but there are few data to guide this practice. The use of oral or systemic corticosteroids has well-recognized adverse effects, and it is prudent to minimize cumulative oral corticosteroid exposure. Some patients may be truly “corticosteroid-dependent,” but clinical experience suggests that this is rare when all other available therapies are optimized.

5. Theophylline—Oral theophylline is a fourth-line agent for treating patients with COPD who do not achieve adequate symptom control with anticholinergics, β_2 -agonists, and inhaled corticosteroid therapy. Sustained-release theophylline improves hemoglobin saturation during sleep in COPD patients and is a first-line agent for those with sleep-related breathing disorders. Theophylline improves dyspnea ratings, exercise performance, and pulmonary function in many patients with stable COPD. Its benefits result from bronchodilation; anti-inflammatory properties; and extrapulmonary effects on diaphragm strength, myocardial contractility, and kidney function. Theophylline toxicity is a significant concern due to the drug’s narrow therapeutic window, and long-term administration requires careful monitoring of serum levels. Despite the potential adverse effects, theophylline continues to have a beneficial role in carefully selected patients.

6. Antibiotics—Antibiotics are commonly prescribed to outpatients with COPD for the following indications: (1) to treat an acute exacerbation, (2) to treat acute bronchitis, and (3) to prevent acute exacerbations of chronic bronchitis (prophylactic antibiotics). Antibiotics appear to improve outcomes slightly in the first two situations, but there is no convincing evidence to support the use of prophylactic antibiotics in patients with COPD. Patients with a COPD exacerbation associated with increased sputum purulence accompanied by dyspnea or an increase in the quantity of sputum are thought to benefit the most from antibiotic therapy. An optimal antibiotic regimen has not been identified. The choice of antibiotic depends on local bacterial resistance patterns and individual risk of *Pseudomonas aeruginosa* infection (history of *Pseudomonas* isolation, FEV₁ < 50% of predicted, recent hospitalization (2 or more days in the past 3 months), more than three courses of antibiotics within the past year, use of systemic corticosteroids). Oral antibiotic options include doxycycline (100 mg every 12 hours), trimethoprim-sulfamethoxazole (160/800 mg every 12 hours), a cephalosporin (eg, cefpodoxime 200 mg every 12 hours or cefprozil 500 mg every 12 hours), a macrolide (eg, azithromycin 500 mg followed by 250 mg daily for 5 days), a fluoroquinolone (eg, ciprofloxacin 500 mg every 12 hours), and amoxicillin-clavulanate (875/125 mg every 12 hours). Suggested duration of therapy is 3–7 days and depends on response to therapy; some studies suggest that 5 days is as effective as 7 days but with fewer adverse effects. There are few controlled trials of antibiotics in severe COPD exacerbations, but prompt administration of antibiotics is appropriate, particularly in persons with risk factors for poor outcomes (age > 65 years, FEV₁ < 50% predicted, three or more exacerbations in the past year, antibiotic

therapy within the past 3 months, comorbid conditions such as cardiac disease).

7. Pulmonary rehabilitation—Graded aerobic physical exercise programs (eg, walking 20 minutes three times weekly or bicycling) are helpful to prevent deterioration of physical condition and to improve patients' ability to carry out daily activities. Training of inspiratory muscles by inspiring against progressively larger resistive loads reduces dyspnea and improves exercise tolerance, health status, and respiratory muscle strength in some but not all patients. Pursed-lip breathing to slow the rate of breathing and abdominal breathing exercises to relieve fatigue of accessory muscles of respiration may reduce dyspnea in some patients. Many patients undergo these exercise and educational interventions in a structured rehabilitation program. In a number of studies, pulmonary rehabilitation has been shown to improve exercise capacity, decrease hospitalizations, and enhance quality of life. Referral to a comprehensive rehabilitation program is recommended in patients who have severe dyspnea, reduced quality of life, or frequent hospitalizations despite optimal medical therapy.

8. Other measures—In patients with chronic bronchitis, increased mobilization of secretions may be accomplished through the use of adequate systemic hydration, effective cough training methods, or use of a hand-held flutter device and postural drainage, sometimes with chest percussion or vibration. Postural drainage and chest percussion should be used only in selected patients with excessive amounts of retained secretions that cannot be cleared by coughing and other methods; these measures are of no benefit in pure emphysema. Expectorant-mucolytic therapy has generally been regarded as unhelpful in patients with chronic bronchitis. Cough suppressants and sedatives should be avoided as routine measures.

Human α_1 -antitrypsin is available for replacement therapy in emphysema due to congenital deficiency (PiZZ or null genotype) of α_1 -antiprotease (α_1 -antitrypsin). Patients over 18 years of age with airflow obstruction by spirometry and serum levels less than 11 $\mu\text{mol/L}$ (~ 50 mg/dL) are potential candidates for replacement therapy. α_1 -Antitrypsin is administered intravenously in a dose of 60 mg/kg body weight once weekly. There is no evidence that replacement therapy is beneficial to heterozygotes (eg, PiMZ) with low-normal serum levels, although such patients may be at slightly increased risk for emphysema, especially in the setting of tobacco smoke exposure. Severe dyspnea in spite of optimal medical management may warrant a clinical trial of an opioid (eg, morphine 5–10 mg orally every 3–4 hours, oxycodone 5–10 mg orally every 4–6 hours). Sedative-hypnotic drugs (eg, diazepam, 5 mg three times daily) marginally improve intractable dyspnea but cause significant drowsiness; they may benefit very anxious patients. Transnasal positive-pressure ventilation at home to rest the respiratory muscles is an approach to improve respiratory muscle function and reduce dyspnea in patients with severe COPD. A bilevel transnasal ventilation system has been reported to reduce dyspnea in ambulatory patients with severe COPD, but the long-term

benefits of this approach and compliance with it have not been defined.

B. Hospitalized Patients

Management of the hospitalized patient with an acute exacerbation of COPD includes supplemental oxygen (titrated to maintain Sao_2 between 90% and 94% or Pao_2 between 60 mm Hg and 70 mm Hg), inhaled ipratropium bromide (500 μg by nebulizer, or 36 μg by MDI with spacer, every 4 hours as needed) plus β_2 -agonists (eg, albuterol 2.5 mg diluted with saline to a total of 3 mL by nebulizer, or MDI, 90 μg per puff, four to eight puffs via spacer, every 1–4 hours as needed), and broad-spectrum antibiotics.

For patients without risk factors for *Pseudomonas*, management options include a fluoroquinolone (eg, levofloxacin 750 mg orally or intravenously per day, or moxifloxacin 400 mg orally or intravenously every 24 hours) or a third-generation cephalosporin (eg, ceftriaxone 1 g intravenously per day, or cefotaxime 1 g intravenously every 8 hours).

For patients with risk factors for *Pseudomonas*, therapeutic options include piperacillin-tazobactam (4.5 g intravenously every 6 hours), ceftazidime (1 g intravenously every 8 hours), cefepime (1 g intravenously every 12 hours), levofloxacin (750 mg orally or intravenously per day for 3–7 days), or corticosteroids (prednisone 30–40 mg orally per day for 7–10 days is usually sufficient) and, in selected cases, chest physiotherapy.

Theophylline should not be initiated in the acute setting, but patients taking theophylline prior to acute hospitalization should have their theophylline serum levels measured and maintained in the therapeutic range. Oxygen therapy should not be withheld for fear of worsening respiratory acidemia; hypoxemia is more detrimental than hypercapnia. Cor pulmonale usually responds to measures that reduce pulmonary artery pressure, such as supplemental oxygen and correction of acidemia; bed rest, salt restriction, and diuretics may add some benefit. Cardiac dysrhythmias, particularly multifocal atrial tachycardia, usually respond to aggressive treatment of COPD itself. Atrial flutter may require DC cardioversion after initiation of the above therapy. If progressive respiratory failure ensues, tracheal intubation and mechanical ventilation are necessary. In clinical trials of COPD patients with hypercapnic acute respiratory failure, noninvasive positive-pressure ventilation (NPPV) delivered via face mask reduced the need for intubation and shortened lengths of stay in the intensive care unit (ICU). Other studies have suggested a lower risk of nosocomial infections and less use of antibiotics in COPD patients treated with NPPV. These benefits do not appear to extend to hypoxemic respiratory failure or to patients with acute lung injury or acute respiratory distress syndrome (ARDS).

C. Surgery for COPD

1. Lung transplantation—Experience with both single and bilateral sequential lung transplantation for severe COPD is extensive. Requirements for lung transplantation are severe lung disease, limited activities of daily living, exhaustion of medical therapy, ambulatory status, potential for pulmonary rehabilitation, limited life expectancy

without transplantation, adequate function of other organ systems, and a good social support system. Average total charges for lung transplantation through the end of the first postoperative year exceed \$250,000. The 2-year survival rate after lung transplantation for COPD is 75%. Complications include acute rejection, opportunistic infection, and obliterative bronchiolitis. Substantial improvements in pulmonary function and exercise performance have been noted after transplantation.

2. Lung volume reduction surgery—Lung volume reduction surgery (LVRS), or reduction pneumoplasty, is a surgical approach to relieve dyspnea and improve exercise tolerance in patients with advanced diffuse emphysema and lung hyperinflation. Bilateral resection of 20–30% of lung volume in selected patients results in modest improvements in pulmonary function, exercise performance, and dyspnea. The duration of any improvement as well as any mortality benefit remains uncertain. Prolonged air leaks occur in up to 50% of patients postoperatively. Mortality rates in centers with the largest experience with LVRS range from 4% to 10%.

The National Emphysema Treatment Trial compared LVRS with medical treatment in a randomized, multicenter clinical trial of 1218 patients with severe emphysema. Overall, surgery improved exercise capacity but not mortality when compared with medical therapy. The persistence of this benefit remains to be defined. Subgroup analysis suggested that patients with upper lobe predominant emphysema and low exercise capacity might have improved survival, while other groups suffered excess mortality when randomized to surgery.

3. Bullectomy—Bullectomy is an older surgical procedure for palliation of dyspnea in patients with severe bullous emphysema. Bullectomy is most commonly pursued when a single bulla occupies at least 30–50% of the hemithorax. In this procedure, the surgeon removes a large emphysematous bulla that demonstrates no ventilation or perfusion on lung scanning and compresses adjacent lung with preserved function. Bullectomy can be performed with a CO₂ laser via thoracoscopy.

► Prognosis

The outlook for patients with clinically significant COPD is poor. The degree of pulmonary dysfunction at the time the patient is first seen is an important predictor of survival: median survival of patients with FEV₁ ≤ 1 L is about 4 years. A multidimensional index (the BODE index), which includes body mass index (BMI), airway obstruction (FEV₁), dyspnea (Medical Research Council dyspnea score), and exercise capacity is a tool that predicts death and hospitalization better than FEV₁ alone. Comprehensive care programs, cessation of smoking, and supplemental oxygen may reduce the rate of decline of pulmonary function, but therapy with bronchodilators and other approaches probably has little, if any, impact on the natural course of COPD.

Dyspnea at the end of life can be extremely uncomfortable and distressing to the patient and family. As patients near the end of life, meticulous attention to palliative care is essential to effectively manage dyspnea (see Chapter 5).

► When to Refer

- COPD onset occurs before the age of 40.
- Frequent exacerbations (two or more a year) despite optimal treatment.
- Severe or rapidly progressive COPD.
- Symptoms disproportionate to the severity of airflow obstruction.
- Need for long-term oxygen therapy.
- Onset of comorbid illnesses (such as bronchiectasis, heart failure, or lung cancer).

► When to Admit

- Severe symptoms or acute worsening that fails to respond to outpatient management.
- Acute or worsening hypoxemia, hypercapnia, peripheral edema, or change in mental status.
- Inadequate home care, or inability to sleep or maintain nutrition/hydration due to symptoms.
- The presence of high-risk comorbid conditions.

BRONCHIECTASIS

ESSENTIALS OF DIAGNOSIS

- Chronic productive cough with dyspnea and wheezing.
- Radiographic findings of dilated, thickened airways and scattered, irregular opacities.

► General Considerations

Bronchiectasis is a congenital or acquired disorder of the large bronchi characterized by permanent, abnormal dilation and destruction of bronchial walls. It may be caused by recurrent inflammation or infection of the airways and may be localized or diffuse. Cystic fibrosis causes about half of all cases of bronchiectasis. Other causes include lung infection (tuberculosis, fungal infections, lung abscess, pneumonia), abnormal lung defense mechanisms (humoral immunodeficiency, α_1 -antiprotease [α_1 -antitrypsin] deficiency with cigarette smoking, mucociliary clearance disorders, rheumatic diseases), and localized airway obstruction (foreign body, tumor, mucoid impaction). Immunodeficiency states that may lead to bronchiectasis include congenital or acquired panhypogammaglobulinemia; common variable immunodeficiency; selective IgA, IgM, and IgG subclass deficiencies; and acquired immunodeficiency from cytotoxic therapy, AIDS, lymphoma, multiple myeloma, leukemia, and chronic kidney and liver diseases. Most patients with bronchiectasis have panhypergammaglobulinemia, however, presumably reflecting an immune system response to chronic airway infection. Acquired primary bronchiectasis is now uncommon in the United States because of improved control of bronchopulmonary infections.

► Clinical Findings

A. Symptoms and Signs

Symptoms of bronchiectasis include chronic cough with production of copious amounts of purulent sputum, hemoptysis, and pleuritic chest pain. Dyspnea and wheezing occur in 75% of patients. Weight loss, anemia, and other systemic manifestations are common. Physical findings are nonspecific, but persistent crackles at the lung bases are common. Clubbing is infrequent in mild cases but is common in severe disease (see Figure 6–41). Copious, foul-smelling, purulent sputum is characteristic. Obstructive pulmonary dysfunction with hypoxemia is seen in moderate or severe disease.

B. Imaging

Radiographic abnormalities include dilated and thickened bronchi that may appear as “tram-tracks” or as ring-like markings on chest radiograph. Scattered irregular opacities, atelectasis, and focal consolidation may be present. High-resolution CT is the diagnostic study of choice.

C. Microbiology

Haemophilus influenzae is the most common organism recovered from non-cystic fibrosis patients with bronchiectasis. *P aeruginosa*, *S pneumoniae*, and *Staphylococcus aureus* are commonly identified. Nontuberculous mycobacteria are seen less commonly. Patients with *Pseudomonas* infection experience an accelerated course, with more frequent exacerbations and more rapid decline in lung function.

► Treatment

Treatment of acute exacerbations consists of antibiotics, daily chest physiotherapy with postural drainage and chest

percussion, and inhaled bronchodilators. Hand-held flutter valve devices may be as effective as chest physiotherapy in clearing secretions. Antibiotic therapy should be guided by sputum smears and cultures. If a specific bacterial pathogen cannot be isolated, then empiric oral antibiotic therapy for 10–14 days is appropriate. Common regimens include amoxicillin or amoxicillin-clavulanate (500 mg every 8 hours), ampicillin or tetracycline (250–500 mg four times daily), trimethoprim-sulfamethoxazole (160/800 mg every 12 hours), or ciprofloxacin (500–750 mg twice daily). It is important to screen patients for infection with nontuberculous mycobacteria because these organisms may underlie a lack of treatment response. Preventive or suppressive treatment is sometimes given to stable outpatients with bronchiectasis who have copious purulent sputum. Clinical trial data to guide this practice are scant. Common regimens include macrolides (azithromycin, 500 mg three times a week; erythromycin, 500 mg twice daily), high-dose (3 g/d) amoxicillin or alternating cycles of the antibiotics listed above given orally for 2–4 weeks. In patients with underlying cystic fibrosis, inhaled aerosolized aminoglycosides reduce colonization by *Pseudomonas* species, improve FEV₁ and reduce hospitalizations; in non-cystic fibrosis bronchiectasis, adding inhaled tobramycin to oral ciprofloxacin for acute exacerbations due to *Pseudomonas* decreases microbial sputum burden but without apparent clinical benefit. Complications of bronchiectasis include hemoptysis, cor pulmonale, amyloidosis, and secondary visceral abscesses at distant sites (eg, brain). Bronchoscopy is sometimes necessary to evaluate hemoptysis, remove retained secretions, and rule out obstructing airway lesions. Massive hemoptysis may require embolization of bronchial arteries or surgical resection. Surgical resection is otherwise reserved for the few patients with localized bronchiectasis and adequate pulmonary function in whom conservative management fails.

ALLERGIC BRONCHOPULMONARY MYCOSIS

Allergic bronchopulmonary mycosis is a pulmonary hypersensitivity disorder caused by allergy to fungal antigens that colonize the tracheobronchial tree. It usually occurs in atopic asthmatic individuals who are 20–40 years of age, in response to antigens of *Aspergillus* species. For this reason, the disorder is commonly referred to as allergic bronchopulmonary aspergillosis (ABPA). Primary criteria for the diagnosis of ABPA include (1) a clinical history of asthma, (2) peripheral eosinophilia, (3) immediate skin reactivity to *Aspergillus* antigen, (4) precipitating antibodies to *Aspergillus* antigen, (5) elevated serum IgE levels, (6) pulmonary infiltrates (transient or fixed), and (7) central bronchiectasis. If the first six of these seven primary criteria

are present, the diagnosis is almost certain. Secondary diagnostic criteria include identification of *Aspergillus* in sputum, a history of brown-flecked sputum, and late skin reactivity to *Aspergillus* antigen. High-dose prednisone (0.5–1 mg/kg orally per day) for at least 2 months is the treatment of choice, and the response in early disease is usually excellent. Depending on the overall clinical situation, prednisone can then be cautiously tapered. Relapses are frequent, and protracted or repeated treatment with corticosteroids is not uncommon. Patients with corticosteroid-dependent disease may benefit from itraconazole (200 mg orally three times a day with food for 3 days followed by twice daily for at least 16 weeks) without added toxicity. Bronchodilators (Table 9–6) are also helpful. Complications include hemoptysis, severe bronchiectasis, and pulmonary fibrosis.

CYSTIC FIBROSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Chronic or recurrent productive cough, dyspnea, and wheezing.
- ▶ Recurrent airway infections or chronic colonization of the airways with *H influenzae*, *P aeruginosa*, *S aureus*, or *Burkholderia cepacia*. Bronchiectasis and scarring on chest radiographs.
- ▶ Airflow obstruction on spirometry.
- ▶ Pancreatic insufficiency, recurrent pancreatitis, distal intestinal obstruction syndrome, chronic hepatic disease, nutritional deficiencies, or male urogenital abnormalities.
- ▶ Sweat chloride concentration > 60 mEq/L on two occasions or gene mutation known to cause cystic fibrosis.

▶ General Considerations

Cystic fibrosis is the most common cause of severe chronic lung disease in young adults and the most common fatal hereditary disorder of whites in the United States. It is an autosomal recessive disorder affecting about 1 in 3200 whites; 1 in 25 is a carrier. Cystic fibrosis is caused by abnormalities in a membrane chloride channel (the cystic fibrosis transmembrane conductance regulator [CFTR] protein) that results in altered chloride transport and water flux across the apical surface of epithelial cells. Almost all exocrine glands produce an abnormal mucus that obstructs glands and ducts and leads to tissue damage. In the respiratory tract, inadequate hydration of the tracheobronchial epithelium impairs mucociliary function. High concentration of DNA in airway secretions (due to chronic airway inflammation and autolysis of neutrophils) increases

sputum viscosity. Over 1000 mutations in the gene that encodes CFTR have been described, and at least 230 mutations are known to be associated with clinical abnormalities. The mutation referred to as $\Delta F508$ accounts for about 60% of cases of cystic fibrosis.

Over one-third of the nearly 30,000 cystic fibrosis patients in the United States are adults. Because of the wide range of alterations seen in the CFTR protein structure and function, cystic fibrosis in adults may present with a variety of pulmonary and nonpulmonary manifestations. Patients with cystic fibrosis have an increased risk of malignancies of the gastrointestinal tract, osteopenia, and arthropathies.

▶ Clinical Findings

A. Symptoms and Signs

Cystic fibrosis should be suspected in a young adult with a history of chronic lung disease (especially bronchiectasis), pancreatitis, or infertility. Cough, sputum production, decreased exercise tolerance, and recurrent hemoptysis are typical complaints. Patients also often complain of chronic rhinosinusitis symptoms, steatorrhea, diarrhea, and abdominal pain. Patients with cystic fibrosis are often malnourished with low body mass index. Digital clubbing, increased anteroposterior chest diameter, hyperresonance on percussion, and apical crackles are noted on physical examination. Sinus tenderness, purulent nasal secretions, and nasal polyps may also be seen. Nearly all men with cystic fibrosis have congenital bilateral absence of the vas deferens with azoospermia. Biliary cirrhosis and gallstones may occur.

B. Laboratory Findings

Arterial blood gas studies often reveal hypoxemia and, in advanced disease, a chronic, compensated respiratory acidosis. Pulmonary function studies show a mixed obstructive and restrictive pattern. There is a reduction in FVC, airflow rates, and TLC. Air trapping (high ratio of RV to TLC) and reduction in pulmonary diffusing capacity are common.

C. Imaging

Hyperinflation is seen early in the disease process. Peribronchial cuffing, mucus plugging, bronchiectasis (ring shadows and cysts), increased interstitial markings, small rounded peripheral opacities, and focal atelectasis are common findings. Pneumothorax can also be seen. Thin-section CT scanning often confirms the presence of bronchiectasis.

D. Diagnosis

The quantitative pilocarpine iontophoresis sweat test reveals elevated sodium and chloride levels (> 60 mEq/L) in the sweat of patients with cystic fibrosis. Two tests on different days performed in experienced laboratories are required for accurate diagnosis. A normal sweat chloride test does not exclude the diagnosis in which case genotyping or other alternative diagnostic studies (such as measurement of nasal membrane potential difference, semen analysis, or

assessment of pancreatic function) should be pursued, especially if there is a high clinical suspicion of cystic fibrosis. Standard genotyping is a limited diagnostic tool because it screens for only a fraction of the known cystic fibrosis mutations, although complete genetic testing is available.

► Treatment

Early recognition and comprehensive multidisciplinary therapy improve symptom control and the chances of survival. Referral to a regional cystic fibrosis center is strongly recommended. Conventional treatment programs focus on the following areas: clearance and reduction of lower airway secretions, reversal of bronchoconstriction, treatment of respiratory tract infections and airway bacterial burden, pancreatic enzyme replacement, and nutritional and psychosocial support (including genetic and occupational counseling). The Pulmonary Therapies Committee, established by the Cystic Fibrosis Foundation, has issued evidenced-based recommendations regarding long-term use of medications for maintenance of lung function and reduction of exacerbations in patients with cystic fibrosis.

Clearance of lower airway secretions can be promoted by postural drainage, chest percussion or vibration techniques, positive expiratory pressure (PEP) or flutter valve breathing devices, directed cough, and other breathing techniques; these approaches require detailed patient instruction by experienced personnel. Sputum viscosity is increased by the large quantities of extracellular DNA that result from chronic airway inflammation and autolysis of neutrophils. Inhaled recombinant human deoxyribonuclease (rhDNase, dornase alpha) cleaves extracellular DNA in sputum; when administered long-term at a daily nebulized dose of 2.5 mg, this therapy leads to improved FEV₁ and reduces the risk of cystic fibrosis-related respiratory exacerbations and the need for intravenous antibiotics. Inhalation of hypertonic saline twice daily has been associated with small improvements in pulmonary function and fewer pulmonary exacerbations. The beneficial effects of hypertonic saline may derive from improved airway mucous clearance.

Short-term antibiotics are used to treat active airway infections based on results of culture and susceptibility testing of sputum. *S aureus* (including methicillin-resistant strains) and a mucoid variant of *P aeruginosa* are commonly present. *H influenzae*, *Stenotrophomonas maltophilia*, and *B cepacia* (a highly drug-resistant organism) are occasionally isolated. **Long-term administration of antibiotics** is helpful in slowing disease progression and reducing exacerbations in patients with sputum cultures positive for *P aeruginosa*. These antibiotics include azithromycin 500 mg orally three times a week, which has immunomodulatory properties, and various inhaled antibiotics (eg, tobramycin, aztreonam, colistin, and levofloxacin) taken two to three times a day. The length of therapy depends on the persistent presence of *P aeruginosa* in the sputum. The incidence of atypical mycobacterial colonization is higher in cystic fibrosis patients and directed antibiotic treatment is recommended for frequent exacerbations, progressive decline in lung function, or failure to thrive. Yearly screening with sputum acid-fast bacilli cultures is advised, especially in patients taking long-term macrolide therapy.

Inhaled bronchodilators (eg, albuterol, two puffs every 4 hours as needed) should be considered in patients who demonstrate an increase of at least 12% in FEV₁ after an inhaled bronchodilator. Vaccination against pneumococcal infection and annual influenza vaccination are advised. Screening of family members and genetic counseling are suggested. An inhaled corticosteroid should be added to the treatment regimen for patients who have cystic fibrosis with persistent asthma or allergic bronchopulmonary aspergillosis.

Ivacaftor is a new oral drug, available for the 5% of cystic fibrosis patients with a G551D mutation. Ivacaftor is a potentiator of the CFTR channel that works by increasing the time the channel remains open after being activated; it has been found to improve lung function by 10% within 2 weeks of treatment, decrease pulmonary exacerbations by 55%, and decrease sweat chloride into the indeterminate range. CFTR corrector therapy for the most common mutation ($\Delta F508$) is currently under trial.

Lung transplantation is currently the only definitive treatment for advanced cystic fibrosis. Double-lung or heart-lung transplantation is required. A few transplant centers offer living lobar lung transplantation to selected patients. The 3-year survival rate following transplantation for cystic fibrosis is about 55%.

Vaccination against pneumococcal infection and annual influenza vaccination are advised. Screening of family members and genetic counseling are suggested.

► Prognosis

The longevity of patients with cystic fibrosis is increasing, and the median survival age is over 35 years. Death occurs from pulmonary complications (eg, pneumonia, pneumothorax, or hemoptysis) or as a result of terminal chronic respiratory failure and cor pulmonale.

BRONCHIOLITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Insidious onset of cough and dyspnea.
- ▶ Irreversible airflow obstruction on pulmonary function testing.
- ▶ Minimal findings on chest radiograph.
- ▶ Relevant exposure or risk factor: toxic fumes, viral infections, organ transplantation, connective tissue disease.

▶ General Considerations

Bronchiolitis is a generic term applied to varied inflammatory processes that affect the bronchioles, which are small conducting airways < 2 mm in diameter. In infants and children, bronchiolitis is common and usually caused by respiratory syncytial virus or adenovirus infection. In adults, bronchiolitis is less common but is encountered in multiple clinical settings. Disorders associated with bronchiolitis include organ transplantation, connective tissue diseases, and hypersensitivity pneumonitis. Inhalational injuries as well as postinfectious and drug-induced causes are identified by association with a known exposure or illness prior to the onset of symptoms. Idiopathic cases are characterized by the insidious onset of dyspnea or cough and include cryptogenic organizing pneumonitis (COP).

The clinical approach to bronchiolitis divides patients into groups based on etiology, but different clinical syndromes may have identical histopathological findings. As a result, no single classification scheme has been widely accepted, and there is an overlapping array of terms to describe these disorders from the viewpoints of the clinician, the pathologist, and the radiologist.

Histopathologic Findings

Acute bronchiolitis has a neutrophilic and mononuclear infiltration in the absence of fibroblast proliferation or collagen deposition. **Constrictive bronchiolitis** (also referred to as obliterative bronchiolitis, or bronchiolitis obliterans) is characterized by patchy chronic inflammation, concentric submucosal and peribronchiolar fibrosis, and smooth muscle hypertrophy causing luminal obstruction (obliteration).

In contrast to the minimally cellular pattern of constrictive bronchiolitis, **proliferative bronchiolitis** occurs when there is an organizing intraluminal exudate, consisting of fibroblasts, lipid laden (“foamy”) macrophages, and other cells that obstruct the bronchiolar lumen. These findings are more common than the constrictive pattern. When the organizing intraluminal exudate extends through the bronchiole into the alveolar space, with prominent intraluminal buds of fibroblasts embedded in immature collagen, the proliferative pattern is referred to as **cryptogenic organizing pneumonitis (COP)** formally referred to as **bronchiolitis obliterans with organizing pneumonia**

(BOOP) (see Table 9–20). **Follicular bronchiolitis** is characterized by chronic peribronchiolar inflammation and hyperplastic lymphoid follicles with reactive germinal centers arising from bronchus-associated lymphoid tissue (BALT). **Respiratory bronchiolitis** is a disorder of small airways in cigarette smokers characterized by accumulation of pigmented alveolar macrophages within respiratory bronchioles, associated with mild interstitial fibrosis and chronic inflammation. In some patients, however, respiratory bronchiolitis causes diffuse parenchymal infiltrates, a syndrome referred to as respiratory bronchiolitis-associated interstitial lung disease (RB-ILD) and considered with desquamative interstitial pneumonia (DIP) to represent part of the spectrum of the smoking-related interstitial lung diseases.

Diffuse panbronchiolitis is an idiopathic disorder of respiratory bronchioles, characterized by a peribronchiolar mixed inflammatory cell infiltrate and accumulation of lipid laden (“foamy”) macrophages within the interstitium and alveolar spaces.

▶ Clinical Findings

Acute bronchiolitis is most commonly seen following viral infection in children.

Constrictive bronchiolitis is relatively infrequent although it is the most common finding following inhalation injury. It may also be seen in rheumatoid arthritis; drug reactions; and chronic rejection following heart-lung, lung, or bone marrow transplant. Patients with constrictive bronchiolitis have airflow obstruction on spirometry; minimal radiographic abnormalities; and a progressive, deteriorating clinical course.

Proliferative bronchiolitis is associated with diverse pulmonary disorders including infection, aspiration, ARDS, hypersensitivity pneumonitis, connective tissue diseases, and organ transplantation. Compared with constrictive bronchiolitis, proliferative bronchiolitis is more likely to have an abnormal chest radiograph.

Cryptogenic organizing pneumonitis affects men and women between the ages of 50 and 70 years, typically with a dry cough, dyspnea, and constitutional symptoms that may be present for weeks to months prior to seeking medical attention. A history of a preceding viral illness is present in half of cases. Pulmonary function testing typically reveals a restrictive ventilatory defect and impaired oxygenation. The chest radiograph frequently shows bilateral patchy, ground-glass or alveolar infiltrates, although other patterns have been described (see Table 9–20).

Follicular bronchiolitis is most commonly associated with connective tissue disease, especially rheumatoid arthritis, and with immunodeficiency states.

Respiratory bronchiolitis usually occurs without symptoms or physiologic evidence of lung impairment.

Diffuse panbronchiolitis is most frequently diagnosed in Japan. Men are affected about twice as often as women, two-thirds are nonsmokers, and most patients have a history of chronic pansinusitis. Patients complain of dyspnea, cough, and sputum production, and chest examination shows crackles and rhonchi. Pulmonary function tests reveal obstructive abnormalities, and the chest radiograph

shows a distinct pattern of diffuse, small, nodular shadows with hyperinflation.

▶ Treatment

Constrictive bronchiolitis is relatively unresponsive to corticosteroids and is frequently progressive. Corticosteroids are effective in two-thirds of patients with **proliferative bronchiolitis**, and improvement can be prompt. Therapy is initiated with prednisone at 1 mg/kg/d orally for 1–3 months. The dose is then tapered slowly to 20–40 mg/d, depending on the response, and weaned over the subsequent 3–6 months as tolerated. Relapses are common if corticosteroids are stopped prematurely or tapered too quickly. Most patients with COP recover following corticosteroid treatment.

PULMONARY INFECTIONS

PNEUMONIA

1. Community-Acquired Pneumonia

ESSENTIALS OF DIAGNOSIS

- ▶ Fever or hypothermia, tachypnea, cough with or without sputum, dyspnea, chest discomfort, sweats or rigors (or both).
- ▶ Bronchial breath sounds or inspiratory crackles on chest auscultation.
- ▶ Parenchymal opacity on chest radiograph.
- ▶ Occurs outside of the hospital or within 48 hours of hospital admission in a patient not residing in a long-term care facility.

▶ General Considerations

Community-acquired pneumonia (CAP) is a common disorder, with approximately 4–5 million cases diagnosed each year in the United States, 25% of which require hospitalization. It is the most deadly infectious disease in the United States and the eighth leading cause of death. Mortality in milder cases treated as outpatients is < 1%. Among patients hospitalized for CAP, in-hospital mortality is approximately

Table 9–9. ATS/IDSA criteria for severe community-acquired pneumonia.

Major criteria ¹
Septic shock with need for vasopressor support
Respiratory failure with need for mechanical ventilation
Minor criteria ¹
Respiratory rate ≥ 30 breaths/min
Hypoxemia, defined as a $P_{aO_2}/F_{iO_2} \leq 250$
Hypothermia, with core temperature $< 36.0^\circ\text{C}$
Hypotension requiring aggressive intravenous fluid resuscitation
Confusion/disorientation
Multilobar pulmonary opacities
Leukopenia, due to infection, with white blood cell count $< 4.0 \times 10^9/\text{L}$
Thrombocytopenia, with platelet count $< 100 \times 10^9/\text{L}$
Uremia, with blood urea nitrogen level ≥ 7.1 mmol/L
Metabolic acidosis or elevated lactate level

¹Patients meeting either major criterion or three or more minor criteria generally require care in the intensive care unit.

ATS/IDSA, American Thoracic Society/Infectious Diseases Society of America.

Adapted, with permission of Oxford University Press, from Mandell LA et al. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. *Clin Infect Dis*. 2007;44:S27–72. [PMID: 17278083]

10–12% and 1-year mortality (in those over age 65) is > 40%. Risk factors for the development of CAP include advanced age; alcoholism; tobacco use; comorbid medical conditions, especially asthma or COPD; and immunosuppression. Markers of more severe illness are given in Table 9–9.

The patient's history, physical examination, and imaging studies are essential to establishing a diagnosis of CAP. None of these efforts identifies a specific microbiologic cause, however. Sputum examination may be helpful in selected patients but 40% of patients cannot produce an evaluable sputum sample and Gram stain and culture lack sensitivity for the most common causes of pneumonia. Since patient outcomes improve when the initial antibiotic choice is appropriate for the infecting organism, the American Thoracic Society and Infectious Disease Society of America recommend empiric treatment based on epidemiologic data (see Table 9–11). Such treatment improves initial antibiotic coverage, reduces unnecessary hospitalization, and appears to improve 30-day survival.

Decisions regarding hospitalization and ICU care should be based on prognostic criteria (see below).

▶ Definition & Pathogenesis

CAP is diagnosed outside of the hospital in ambulatory patients who are not residents of nursing homes or other long-term care facilities. It may also be diagnosed in a previously ambulatory patient within 48 hours after admission to the hospital.

Pulmonary defense mechanisms (cough reflex, mucociliary clearance system, immune responses) normally prevent the development of lower respiratory tract infections following aspiration of oropharyngeal secretions

containing bacteria or inhalation of infected aerosols. CAP occurs when there is a defect in one or more of these normal defense mechanisms or when a large infectious inoculum or a virulent pathogen overwhelms the immune response.

Prospective studies fail to identify the cause of CAP in 40–60% of cases; two or more causes are identified in up to 5% of cases. Bacteria are more commonly identified than viruses. The most common bacterial pathogen identified in most studies of CAP is *S pneumoniae*, accounting for approximately two-thirds of bacterial isolates. Other common bacterial pathogens include *H influenzae*, *M pneumoniae*, *C pneumoniae*, *S aureus*, *Neisseria meningitidis*, *M catarrhalis*, *Klebsiella pneumoniae*, other gram-negative rods, and *Legionella* species. Common viral causes of CAP include influenza virus, respiratory syncytial virus, adenovirus, and parainfluenza virus. A detailed assessment of epidemiologic risk factors may aid in diagnosing pneumonias due to the following uncommon causes: *Chlamydia psittaci* (psittacosis), *Coxiella burnetii* (Q fever), *Francisella tularensis* (tularemia), endemic fungi (*Blastomyces*, *Coccidioides*, *Histoplasma*), and sin nombre virus (hantavirus pulmonary syndrome).

► Clinical Findings

A. Symptoms and Signs

Most patients with CAP experience an acute or subacute onset of fever, cough with or without sputum production, and dyspnea. Other common symptoms include sweats, chills, rigors, chest discomfort, pleurisy, hemoptysis, fatigue, myalgias, anorexia, headache, and abdominal pain.

Common physical findings include fever or hypothermia, tachypnea, tachycardia, and arterial oxygen desaturation. Many patients appear acutely ill. Chest examination often reveals inspiratory crackles and bronchial breath sounds. Dullness to percussion may be observed if lobar consolidation or a parapneumonic pleural effusion is present. The clinical evaluation is < 50% sensitive compared to chest imaging for the diagnosis of CAP (see Imaging section below). In most patients, therefore, a chest radiograph is essential to the evaluation of suspected CAP.

B. Diagnostic Testing

Diagnostic testing for a specific infectious cause of CAP is not generally indicated in ambulatory patients treated as outpatients because empiric antibiotic therapy is almost always effective in this population. In ambulatory outpatients whose presentation (travel history, exposure) suggests an etiology not covered by standard therapy (eg, *Coccidioides*) or public health concerns (eg, *Mycobacterium tuberculosis*, influenza), diagnostic testing is appropriate. Diagnostic testing is recommended in hospitalized CAP patients for multiple reasons: the likelihood of an infectious cause unresponsive to standard therapy is higher in more severe illness, the inpatient setting allows narrowing of antibiotic coverage as specific diagnostic information is available, and the yield of testing is improved in more acutely ill patients.

Diagnostic testing results are used to guide initial antibiotic therapy, permit adjustment of empirically chosen

therapy to a specific infectious cause or resistance pattern, and facilitate epidemiologic analysis. There are three widely available, rapid point-of-care diagnostic tests that may guide initial therapy: the sputum Gram stain, urinary antigen tests for *S pneumoniae* and *Legionella* species, and rapid antigen detection tests for influenza. Sputum Gram stain is neither sensitive nor specific for *S pneumoniae*, the most common cause of CAP. The usefulness of a sputum Gram stain lies in broadening initial coverage in patients to be hospitalized for CAP, most commonly to cover *S aureus* (including community-acquired methicillin-resistant strains, CA-MRSA) or gram-negative rods. Urinary antigen assays for *Legionella pneumophila* and *S pneumoniae* are at least as sensitive and specific as sputum Gram stain and culture. Results are available immediately and are not affected by early initiation of antibiotic therapy. Positive tests may allow narrowing of initial antibiotic coverage. Rapid influenza testing has intermediate sensitivity but high specificity. Positive tests may reduce unnecessary antibacterial use and direct isolation of hospitalized patients.

Additional microbiologic testing including pre-antibiotic sputum and blood cultures (at least two sets with needle sticks at separate sites) has been standard practice for patients with CAP who require hospitalization. The yield of blood and sputum cultures is low. However, false-positive results are common, and the impact of culture results on patient outcomes is small. As a result, targeted testing based on specific indications is recommended (Table 9–10). Culture results are not available prior to initiation of antibiotic therapy. Their role is to allow narrowing of initial empiric antibiotic coverage, adjustment of coverage based on specific antibiotic resistance patterns, to identify unsuspected pathogens not covered by initial therapy, and to provide information for epidemiologic analysis.

Apart from microbiologic testing, hospitalized patients should undergo complete blood count with differential and a chemistry panel (including serum glucose, electrolytes, urea nitrogen, creatinine, bilirubin, and liver enzymes). Hypoxemic patients should have arterial blood gases sampled. Test results help assess severity of illness and guide evaluation and management. HIV testing should be considered in all adult patients, and performed in those with risk factors.

C. Imaging

A pulmonary opacity on chest radiography or CT scan is required to establish a diagnosis of CAP. Radiographic findings range from patchy airspace opacities to lobar consolidation with air bronchograms to diffuse alveolar or interstitial opacities. Additional findings can include pleural effusions and cavitation. Chest imaging cannot identify a specific microbiologic cause of CAP, however. There is no pattern of radiographic abnormalities pathognomonic of any infectious cause.

Chest imaging may help assess severity and response to therapy over time. Progression of pulmonary opacities during antibiotic therapy or lack of radiographic improvement over time are poor prognostic signs and also raise concerns about secondary or alternative pulmonary

Table 9–10. Clinical indications for more extensive diagnostic testing of patients with CAP.

Indication	Blood Culture	Sputum Culture	Legionella Urinary Antigen	Pneumococcal Urinary Antigen	Other

processes. Clearing of pulmonary opacities in patients with CAP can take 6 weeks or longer. Clearance is usually quickest in younger patients, nonsmokers, and those with only single lobe involvement.

D. Special Examinations

Patients with CAP who have significant pleural fluid collections may require diagnostic thoracentesis (glucose, lactate dehydrogenase [LD], and total protein levels; leukocyte count with differential; pH determination) with pleural fluid Gram stain and culture. Positive pleural cultures indicate the need for tube thoracostomy drainage.

Sputum induction and fiberoptic bronchoscopy to obtain samples of lower respiratory secretions are indicated in patients who cannot provide expectorated sputum samples or who may have *Pneumocystis jiroveci* or *M tuberculosis* pneumonia.

Procalcitonin is a calcitonin precursor released in response to bacterial toxins and inhibited by viral infections. This divergent response to bacterial and viral infections offers laboratory support for a clinical judgment of a viral process in patients with lower respiratory symptoms. Multiple clinical trials have shown that procalcitonin measurement allows clinicians to reduce both initial administration of antibiotics and the duration of antibiotic therapy in CAP without compromising patient outcomes.

Serologic assays, polymerase chain reaction tests, specialized culture tests, and other diagnostic tests for organisms such as viruses, *Legionella*, *M pneumoniae*, and *C pneumoniae* may be performed when these diagnoses are suspected.

► Differential Diagnosis

The differential diagnosis of symptoms and signs of lower respiratory tract infection is extensive and includes upper respiratory tract infections, reactive airway diseases, congestive heart failure, cryptogenic organizing pneumonitis, lung cancer, pulmonary vasculitis, pulmonary thromboembolic disease, and atelectasis.

► Treatment

Two general principles guide antibiotic therapy once the diagnosis of CAP is established: **prompt** initiation of a drug to which the etiologic pathogen is **susceptible**.

In patients who require specific diagnostic evaluation, sputum and culture specimens should be obtained prior to initiation of antibiotics. Since early administration of antibiotics to acutely ill patients is associated with improved outcomes, obtaining diagnostic specimens or test results should not delay the initial dose of antibiotics by more than 6 hours from presentation.

Optimal antibiotic therapy would be pathogen directed, but a definitive microbiologic diagnosis is rarely available on or within 6 hours of presentation. A syndromic approach to therapy, based on clinical presentation and chest imaging, does not reliably predict the microbiology of CAP. Therefore, initial antibiotic choices are typically empiric, based on acuity (treatment as an outpatient, inpatient, or ICU), patient risk factors for specific pathogens, and local antibiotic resistance patterns (Table 9–11).

Since *S pneumoniae* remains a common cause of CAP in all patient groups, local prevalence of drug-resistant

S pneumoniae significantly affects initial antibiotic choice. Prior treatment with one antibiotic in a pharmacologic class (eg, β -lactam, macrolide, fluoroquinolone) predisposes the emergence of drug-resistant *S pneumoniae*, with resistance developing against that class of antibiotics to which the pathogen was previously exposed. Definitions of resistance have shifted based on observations of continued clinical efficacy at achievable serum levels. In CAP, for parenteral penicillin G or oral amoxicillin, susceptible strains have a minimum inhibitory concentration (MIC) ≤ 2 mcg/mL; intermediate resistance is defined as an MIC between 2 mcg/mL and 4 mcg/mL because treatment failures are uncommon with MIC ≤ 4 mcg/mL. Macrolide resistance has increased; approximately one-third of *S pneumoniae* isolates now show in vitro resistance to macrolides. Treatment failures have been reported but remain rare compared to the number of patients treated; current in vivo efficacy appears to justify maintaining macrolides as first-line therapy except in areas where there is a high prevalence of resistant strains. *S pneumoniae* resistant to fluoroquinolones is rare in the United States (1% to levofloxacin, 2% to ciprofloxacin) but is increasing.

Community-acquired methicillin-resistant *S aureus* (CA-MRSA) is genetically and phenotypically different from

hospital-acquired MRSA strains. Most produce Panton-Valentine leukocidin, a cytotoxin associated with tissue necrosis. CA-MRSA is a rare cause of necrotizing pneumonia, empyema, respiratory failure, and shock; it appears to be associated with prior influenza infection. Linezolid may be preferred to vancomycin in treatment of CA-MRSA pulmonary infection because linezolid may also act to reduce Panton-Valentine leukocidin toxin production. For expanded discussions of specific antibiotics, see Chapter 30.

A. Treatment of Outpatients

See Table 9–11 for specific drug dosages. The most common etiologies of CAP in outpatients who do not require hospitalization are *S pneumoniae*; *M pneumoniae*; *C pneumoniae*; and respiratory viruses, including influenza. For previously healthy patients with no recent (90 days) use of antibiotics, the recommended treatment is a macrolide (clarithromycin or azithromycin) or doxycycline.

In patients at risk for drug resistance (antibiotic therapy within the past 90 days, age > 65 years, comorbid illness, immunosuppression, exposure to a child in daycare), the recommended treatment is a respiratory fluoroquinolone

Table 9–11. Recommended empiric antibiotics for community-acquired pneumonia.

Outpatient management

- For previously healthy patients who have not taken antibiotics within the past 3 months:
 - A macrolide (clarithromycin, 500 mg orally twice a day; or azithromycin, 500 mg orally as a first dose and then 250 mg orally daily for 4 days, or 500 mg orally daily for 3 days), *or*
 - Doxycycline, 100 mg orally twice a day.
- For patients with such comorbid medical conditions as chronic heart, lung, liver, or renal disease; diabetes mellitus; alcoholism; malignancy; asplenia; immunosuppressant conditions or use of immunosuppressive drugs; or use of antibiotics within the previous 3 months (in which case, an alternative from a different antibiotic class should be selected):
 - A respiratory fluoroquinolone (moxifloxacin, 400 mg orally daily; gemifloxacin, 320 mg orally daily; levofloxacin, 750 mg orally daily) *or*
 - A macrolide (as above) *plus* a β -lactam (amoxicillin, 1 g orally three times a day; amoxicillin-clavulanate, 2 g orally twice a day are preferred to cefpodoxime, 200 mg orally twice a day; cefuroxime, 500 mg orally twice a day).
- In regions with a high rate (> 25%) of infection with high level (MIC ≥ 16 mcg/mL) macrolide-resistant *Streptococcus pneumoniae*, consider use of alternative agents listed above in (2) for patients with comorbidities.

Inpatient management not requiring intensive care

- A respiratory fluoroquinolone
 - See above for oral therapy.
 - For intravenous therapy, moxifloxacin, 400 mg daily; levofloxacin, 750 mg daily; ciprofloxacin, 400 mg every 8–12 hours *or*
- A macrolide *plus* a β -lactam
 - See above for oral therapy.
 - For intravenous therapy, ampicillin, 1–2 g every 4–6 hours; cefotaxime, 1–2 g every 4–12 hours; ceftriaxone, 1–2 g every 12–24 hours.

Inpatient intravenous management requiring intensive care

- Azithromycin (500 mg orally as a first dose and then 250 mg orally daily for 4 days, or 500 mg orally daily for 3 days) or a respiratory fluoroquinolone *plus* an antipneumococcal β -lactam (cefotaxime, ceftriaxone, or ampicillin-sulbactam, 1.5–3 g every 6 hours).
- For patients allergic to β -lactam antibiotics, a respiratory fluoroquinolone *plus* aztreonam (1–2 g every 6–12 hours).
- For patients at risk for *Pseudomonas* infection
 - An antipneumococcal, antipseudomonal β -lactam (piperacillin-tazobactam, 3.375–4.5 g every 6 hours; ceftazidime, 1–2 g twice a day; imipenem, 0.5–1 g every 6–8 hours; meropenem, 1 g every 8 hours) *plus* ciprofloxacin (400 mg every 8–12 hours) or levofloxacin, *or*
 - The above β -lactam *plus* an aminoglycoside (gentamicin, tobramycin, amikacin, all weight-based dosing administered daily adjusted to appropriate trough levels) *plus* azithromycin or a respiratory fluoroquinolone.
- For patients at risk for methicillin-resistant *Staphylococcus aureus* infection, add vancomycin (interval dosing based on renal function to achieve serum trough concentration 15–20 mcg/mL) *or* linezolid (600 mg twice a day).

MIC, minimum inhibitory concentration.

Adapted, with permission of Oxford University Press, from Mandell LA et al. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. Clin Infect Dis. 2007;44:S27–72. [PMID: 17278083]

(moxifloxacin, gemifloxacin, or levofloxacin) or a macrolide plus a β -lactam (high-dose amoxicillin and amoxicillin-clavulanate are preferred to cefpodoxime and cefuroxime).

In regions where there is a high incidence of macrolide-resistant *S pneumoniae*, patients with no comorbidities may have a β -lactam added to a macrolide or use a respiratory fluoroquinolone as initial therapy.

There are limited data to guide recommendations for duration of treatment. The decision should be influenced by the severity of illness, the etiologic pathogen, response to therapy, other medical problems, and complications. Most expert recommendations suggest a minimum of 5 days of therapy and to continue antibiotics until the patient is afebrile for 48–72 hours. There appears to be no advantage to routinely extending antibiotic therapy beyond 3 days following clinical improvement with defervescence.

B. Treatment of Hospitalized Patients

The most common etiologies of CAP in patients who require hospitalization but not intensive care are *S pneumoniae*, *M pneumoniae*, *C pneumoniae*, *H influenzae*, *Legionella* species, and respiratory viruses. Some patients have aspiration as an immediate precipitant to the CAP without a specific bacterial etiology. First-line therapy in hospitalized patients is a respiratory fluoroquinolone (eg, moxifloxacin, gemifloxacin, or levofloxacin) or the combination of a macrolide (clarithromycin or azithromycin) plus a β -lactam (cefotaxime, ceftriaxone, or ampicillin) (see Table 9–11).

Almost all patients who are admitted to a hospital for treatment of CAP receive intravenous antibiotics. However, no studies demonstrated superior outcomes in hospitalized patients who received intravenous antibiotics compared with those who received oral antibiotics, as long as patients were able to tolerate the oral therapy and the drug was well absorbed. Duration of antibiotic treatment is the same as for outpatients with CAP.

The most common etiologies of CAP in patients who require admission to intensive care are *S pneumoniae*, *Legionella* species, *H influenzae*, *Enterobacteriaceae* species, *S aureus* and *Pseudomonas* species. First-line therapy in ICU patients with CAP is azithromycin or a respiratory fluoroquinolone (moxifloxacin, gemifloxacin, or levofloxacin) plus an antipneumococcal β -lactam (cefotaxime, ceftriaxone, or ampicillin-sulbactam). In patients at risk for *Pseudomonas* infection, use an antipneumococcal, antipseudomonal β -lactam (piperacillin-tazobactam, cefepime, imipenem, meropenem) plus ciprofloxacin or levofloxacin; the above antipneumococcal β -lactam plus an aminoglycoside (gentamicin, tobramycin, amikacin) plus azithromycin or a respiratory fluoroquinolone (moxifloxacin, gemifloxacin, or levofloxacin).

► Prevention

Polyvalent pneumococcal vaccine (containing capsular polysaccharide antigens of 23 common strains of *S pneumoniae*) has the potential to prevent or lessen the severity of the majority of pneumococcal infections in immunocompetent patients. Indications for pneumococcal vaccination include age ≥ 65 years or any chronic illness that increases the risk of CAP (see Chapter 30). Immunocompromised

patients and those at highest risk for fatal pneumococcal infections should receive a single revaccination 6 years after the first vaccination. Immunocompetent persons 65 years of age or older should receive a second dose of vaccine if the patient first received the vaccine 6 or more years previously and was under 65 years old at the time of vaccination.

The seasonal influenza vaccine is effective in preventing severe disease due to influenza virus with a resulting positive impact on both primary influenza pneumonia and secondary bacterial pneumonias. The seasonal influenza vaccine is administered annually to persons at risk for complications of influenza infection (age ≥ 65 years, residents of long-term care facilities, patients with pulmonary or cardiovascular disorders, patients recently hospitalized with chronic metabolic disorders) as well as health care workers and others who are able to transmit influenza to high-risk patients.

Hospitalized patients who would benefit from pneumococcal and influenza vaccines should be vaccinated during hospitalization. The vaccines can be given simultaneously, and there are no contraindications to use immediately after an episode of pneumonia.

► When to Admit

Once a diagnosis of CAP is made, the first management decision is to determine the site of care: Is it safe to treat the patient at home or does he or she require hospital or intensive care admission? There are two widely used clinical prediction rules available to guide admission and triage decisions, the Pneumonia Severity Index (PSI) and the CURB-65.

A. Hospital Admission Decision

The PSI is a validated prediction model that uses 20 items from demographics, medical history, physical examination, laboratory and imaging to stratify patients into five risk groups. The PSI is weighted toward discrimination at low predicted mortality. In conjunction with clinical judgment, it facilitates safe decisions to treat CAP in the outpatient setting. An on-line PSI risk calculator is available at <http://pda.ahrq.gov/clinic/psi/psicalc.asp>. The CURB-65 assesses five simple, independent predictors of increased mortality (confusion, uremia, respiratory rate, blood pressure and age > 65) to calculate a 30-day predicted mortality. Compared with the PSI, the simpler CURB-65 is less discriminating at low mortality but excellent at identifying patients with high mortality who may benefit from ICU level care. A modified version (CRB-65) dispenses with serum blood urea nitrogen and eliminates the need for laboratory testing. Both have the advantage of simplicity: Patients with zero CRB-65 predictors have a low predicted mortality ($< 1\%$) and usually do not need hospitalization; hospitalization should be considered for those with one or two predictors, since they have an increased risk of death, and urgent hospitalization is required for those with three or four predictors.

B. Intensive Care Unit Admission Decision

Expert opinion has defined major and minor criteria to identify patients at high risk for death (see Table 9–9). Either major criterion or three or more minor criteria of illness severity generally require ICU level care (see Table 9–9).

In addition to pneumonia-specific issues, good clinical practice always makes an admission decision in light of the whole patient. Additional factors that suggest the need for inpatient hospitalization include the following:

- Exacerbations of underlying disease that would benefit from hospitalization.
- Other medical or psychosocial needs (such as cognitive dysfunction, psychiatric disease, homelessness, drug abuse, lack of outpatient resources, or poor overall functional status).
- Failure of outpatient therapy, including inability to maintain oral intake and medications.

2. Nosocomial Pneumonia (Hospital-Acquired, Ventilator-Associated, and Health Care–Associated)

ESSENTIALS OF DIAGNOSIS

- ▶ **Hospital-acquired pneumonia (HAP)** occurs > 48 hours after admission to the hospital or other health care facility and excludes any infection present at the time of admission.
- ▶ **Health care–associated pneumonia (HCAP)** occurs in community members whose extensive contact with healthcare has changed their risk for virulent and drug resistant organisms.
- ▶ At least two of the following: fever, leukocytosis, purulent sputum.
- ▶ New or progressive parenchymal opacity on chest radiograph.
- ▶ Especially common in patients requiring intensive care or mechanical ventilation.

▶ General Considerations

Hospitalized patients carry different flora with different resistance patterns than healthy patients in the community,

and their health status may place them at higher risk for more severe infection. The diagnostic approach and antibiotic treatment of patients with hospital-acquired pneumonia (HAP) is, therefore, different from patients with CAP. Similarly, management of patients in whom pneumonia develops following endotracheal intubation and mechanical ventilation (ventilator-associated pneumonia or VAP) should address issues specific to this group of patients. Some community members have extensive contact with the healthcare system and carry flora that more closely resemble hospitalized patients than healthy community residents. When pneumonia develops in these persons, the infection is referred to as health care–associated pneumonia (HCAP). Initial management and antibiotic therapy should be targeted to the common flora and specific risk factors for severe disease.

Considered together, these nosocomial pneumonias (HAP/VAP/HCAP) represent an important cause of morbidity and mortality despite widespread use of preventive measures, advances in diagnostic testing, and potent new antimicrobial agents. HAP is the second most common cause of infection among hospital inpatients and is the leading cause of death due to infection with mortality rates ranging from 20% to 50%. While a minority of cases occurs in ICU patients, the highest-risk patients are those in ICUs or who are being mechanically ventilated; these patients also experience higher morbidity and mortality from HAP. As management of more chronic illnesses shifts to the outpatient setting, more cases of HCAP are caused by unusual organisms, and there is a high frequency of drug resistance. Definitive identification of the infectious cause of a lower respiratory infection is rarely available on presentation, thus, rather than pathogen-directed antibiotic treatment, the choice of empiric therapy is informed by epidemiologic and patient data.

▶ Definition & Pathogenesis

HAP develops more than 48 hours after admission to the hospital and VAP develops in a mechanically ventilated patient more than 48 hours after endotracheal intubation. HCAP is defined as pneumonia that occurs in a nonhospitalized patient with extensive healthcare contact, and the risk factors for HCAP are outlined in Table 9–12.

Three factors distinguish nosocomial pneumonia from CAP: (1) different infectious causes; (2) different antibiotic susceptibility patterns, specifically, a higher incidence of drug resistance; and (3) the patients' underlying health status that puts them at risk for more severe infections. Since access to the lower respiratory tract occurs primarily through microaspiration, nosocomial pneumonia starts with a change in upper respiratory tract flora. Colonization of the pharynx and possibly the stomach with bacteria is the most important step in the pathogenesis of nosocomial pneumonia. Pharyngeal colonization is promoted by exogenous factors (eg, instrumentation of the upper airway with nasogastric and endotracheal tubes; contamination by dirty hands, equipment, and contaminated aerosols; and treatment with broad-spectrum antibiotics that promote the emergence of drug-resistant organisms) and patient factors (eg, malnutrition, advanced age, altered

Table 9–12. Risk factors for health care–associated pneumonia.

- Antibiotic therapy in the preceding 90 days.
- Acute care hospitalization for at least 2 days in the preceding 90 days.
- Residence in a nursing home or extended care facility.
- Home infusion therapy, including chemotherapy, within the past 30 days.
- Long-term dialysis within the past 30 days.
- Home wound care.
- Family member with an infection involving a multiple drug-resistant pathogen.
- Immunosuppressive disease or immunosuppressive therapy.

consciousness, swallowing disorders, and underlying pulmonary and systemic diseases). Within 48 hours of admission, 75% of seriously ill hospitalized patients have their upper airway colonized with organisms from the hospital environment.

Impaired cellular and mechanical defense mechanisms in the lungs of hospitalized patients raise the risk of infection after aspiration has occurred. Tracheal intubation increases the risk of lower respiratory infection by mechanical obstruction of the trachea, impairment of mucociliary clearance, trauma to the mucociliary escalator system, and interference with coughing. Tight adherence of bacteria such as *Pseudomonas* to the tracheal epithelium and the biofilm that lines the endotracheal tube makes clearance of these organisms from the lower airway difficult.

The role of the stomach in the pathogenesis of HCAP remains controversial. Observational studies have suggested that elevation of gastric pH due to antacids, H₂-receptor antagonists, proton pump inhibitors (PPIs), or

Table 9–13. Organisms prevalent in nosocomial pneumonias.¹

- *Streptococcus pneumoniae*, often drug resistant, in HCAP
- *Staphylococcus aureus*, methicillin-sensitive (MSSA)
- *S aureus*, methicillin-resistant (MRSA)
- Gram-negative rods, non-ESBL
- ESBL-producing gram-negative rods including *Klebsiella pneumoniae*, *Escherichia coli* and *Enterobacter* species

¹Nosocomial pneumonias include hospital-associated pneumonia (HAP), ventilator-associated pneumonia (VAP), and health care-associated pneumonia (HCAP).

enteral feeding is associated with gastric microbial overgrowth, tracheobronchial colonization, and HAP/VAP. Sucralfate, a cytoprotective agent that does not alter gastric pH, is associated with a trend toward a lower incidence of VAP. The Infectious Disease Society of America recommends that acid suppressive medications (H₂-receptor antagonists and PPIs) only be given to patients at high risk for stress gastritis.

The microbiology of the nosocomial pneumonias differs from CAP but is substantially the same among HAP, VAP, and HCAP (Table 9–13). The most common organisms responsible for HAP include *S aureus* (both methicillin-sensitive *S aureus* and MRSA), *P aeruginosa*, gram-negative rods including non-extended spectrum β-lactamase (ESBL) producing and ESBL-producing (*Enterobacter* species, *K pneumoniae*, and *Escherichia coli*). VAP patients may be infected with *Acinetobacter* species and *Stenotrophomonas maltophilia*. HCAP patients may have common organisms (*S pneumoniae*, *H influenzae*) that are more likely to be drug resistant, or flora that resembles HAP. Anaerobic organisms (bacteroides, anaerobic streptococci, fusobacterium) may also cause pneumonia in the hospitalized patient; when isolated, they are commonly part of a polymicrobial flora. Mycobacteria, fungi, chlamydiae, viruses, rickettsiae, and protozoal organisms are uncommon causes of nosocomial pneumonias.

► Clinical Findings

A. Symptoms and Signs

The symptoms and signs associated with nosocomial pneumonias are nonspecific; however, two or more clinical findings (fever, leukocytosis, purulent sputum) in the setting of a new or progressive pulmonary opacity on chest radiograph are approximately 70% sensitive and 75% specific for the diagnosis of VAP in one study. Other findings include those listed above for CAP.

The differential diagnosis of new lower respiratory tract symptoms and signs in hospitalized patients includes congestive heart failure, atelectasis, aspiration, ARDS, pulmonary thromboembolism, pulmonary hemorrhage, and drug reactions.

B. Laboratory Findings

Diagnostic evaluation for suspected nosocomial pneumonia includes blood cultures from two different sites. Blood cultures can identify the pathogen in up to 20% of all patients with nosocomial pneumonias; positivity is associated with increased risk of complications and other sites of infection. Blood counts and clinical chemistry tests do not establish a specific diagnosis of HCAP; however, they help define the severity of illness and identify complications. The assessment of oxygenation by an arterial blood gas or pulse oximetry determination helps define the severity of illness and determines the need assisted ventilation. Thoracentesis for pleural fluid analysis should be considered in patients with pleural effusions.

Examination of sputum is attended by the same disadvantages as in CAP. Gram stains and cultures of sputum are

neither sensitive nor specific in the diagnosis of nosocomial pneumonias. The identification of a bacterial organism by culture of sputum does not prove that the organism is a lower respiratory tract pathogen. However, it can be used to help identify bacterial antibiotic sensitivity patterns and as a guide to adjusting empiric therapy.

C. Imaging

Radiographic findings in HAP/VAP are nonspecific and often confounded by other processes that led initially to hospitalization or ICU admission. (See also CAP section above.)

D. Special Examinations

Endotracheal aspiration using a sterile suction catheter and fiberoptic bronchoscopy with bronchoalveolar lavage or a protected specimen brush can be used to obtain lower respiratory tract secretions for analysis, most commonly in patients with VAP. Endotracheal aspiration cultures have significant negative predictive value but limited positive predictive value in the diagnosis of specific infectious causes of HAP/VAP. An invasive diagnostic approach using quantitative culture of bronchoalveolar lavage samples or protected specimen brush samples in patients in whom VAP is suspected leads to

significantly less antibiotic use, earlier attenuation of organ dysfunction, and fewer deaths at 14 days. Measurement of procalcitonin levels holds promise as a noninvasive strategy to distinguish bacterial pneumonia from noninfectious causes of fever with pulmonary infiltrates in hospitalized patients.

► Treatment

Treatment of the nosocomial pneumonias, like treatment of CAP, is usually empiric (Table 9–14). Because of the high mortality rate, therapy should be started as soon as pneumonia is suspected. There is no consensus on the best regimens because this patient population is heterogeneous and local flora and resistance patterns must be taken into account.

After results of sputum, blood, and pleural fluid cultures are available, it may be possible to de-escalate initially broad therapy. Duration of antibiotic therapy should be individualized based on the pathogen, severity of illness, response to therapy, and comorbid conditions. Data from a large trial assessing treatment outcomes in VAP suggest that 8 days of antibiotics is as effective as 15 days, except in cases caused by *P aeruginosa*.

For expanded discussions of specific antibiotics, see Chapter 30.

Table 9–14. Recommended empirical antibiotics for nosocomial pneumonias.¹

<p>When there is low risk for multiple drug-resistant pathogens, use one of the following:</p> <ul style="list-style-type: none"> Ceftriaxone, 1–2 g intravenously every 12–24 hours Gemifloxacin, 320 mg orally daily Moxifloxacin, 400 mg orally or intravenously daily Levofloxacin, 750 mg orally or intravenously daily Ciprofloxacin, 400 mg intravenously every 8–12 hours Ampicillin-sulbactam, 1.5–3 g intravenously every 6 hours Piperacillin-tazobactam 3.375–4.5 g intravenously every 6 hours Ertapenem, 1 g intravenously daily

3. Anaerobic Pneumonia & Lung Abscess

ESSENTIALS OF DIAGNOSIS

- ▶ History of or predisposition to aspiration.
- ▶ Indolent symptoms, including fever, weight loss, malaise.
- ▶ Poor dentition.
- ▶ Foul-smelling purulent sputum (in many patients).
- ▶ Infiltrate in dependent lung zone, with single or multiple areas of cavitation or pleural effusion.

▶ General Considerations

Aspiration of small amounts of oropharyngeal secretions occurs during sleep in normal individuals but rarely causes disease. Sequelae of aspiration of larger amounts of material include nocturnal asthma, chemical pneumonitis, mechanical obstruction of airways by particulate matter, bronchiectasis, and pleuropulmonary infection. Individuals predisposed to disease induced by aspiration include those with depressed levels of consciousness due to drug or alcohol use, seizures, general anesthesia, or central nervous system disease; those with impaired deglutition due to esophageal disease or neurologic disorders; and those with tracheal or nasogastric tubes, which disrupt the mechanical defenses of the airways.

Periodontal disease and poor dental hygiene, which increase the number of anaerobic bacteria in aspirated

material, are associated with a greater likelihood of anaerobic pleuropulmonary infection. Aspiration of infected oropharyngeal contents initially leads to pneumonia in dependent lung zones, such as the posterior segments of the upper lobes and superior and basilar segments of the lower lobes. Body position at the time of aspiration determines which lung zones are dependent. The onset of symptoms is insidious. By the time the patient seeks medical attention, necrotizing pneumonia, lung abscess, or empyema may be apparent.

Most aspiration patients with necrotizing pneumonia, lung abscess, and empyema are found to be infected with multiple species of anaerobic bacteria. Most of the remainder are infected with both anaerobic and aerobic bacteria. *Prevotella melaninogenica*, *Peptostreptococcus*, *Fusobacterium nucleatum*, and *Bacteroides* species are commonly isolated anaerobic bacteria.

▶ Clinical Findings

A. Symptoms and Signs

Patients with anaerobic pleuropulmonary infection usually present with constitutional symptoms such as fever, weight loss, and malaise. Cough with expectoration of foul-smelling purulent sputum suggests anaerobic infection, though the absence of productive cough does not rule out such an infection. Dentition is often poor. Patients are rarely edentulous; if so, an obstructing bronchial lesion is usually present.

B. Laboratory Findings

Expectorated sputum is inappropriate for culture of anaerobic organisms because of contaminating mouth flora. Representative material for culture can be obtained only by transthoracic aspiration, thoracentesis, or bronchoscopy with a protected brush. Transthoracic aspiration is rarely indicated, because drainage occurs via the bronchus and anaerobic pleuropulmonary infections usually respond well to empiric therapy.

C. Imaging

The different types of anaerobic pleuropulmonary infection are distinguished on the basis of their radiographic appearance. **Lung abscess** appears as a thick-walled solitary cavity surrounded by consolidation. An air-fluid level is usually present. Other causes of cavitary lung disease (tuberculosis, mycosis, cancer, infarction, granulomatosis with polyangiitis [formerly Wegener granulomatosis]) should be excluded. **Necrotizing pneumonia** is distinguished by multiple areas of cavitation within an area of consolidation. **Empyema** is characterized by the presence of purulent pleural fluid and may accompany either of the other two radiographic findings. Ultrasonography is of value in locating fluid and may also reveal pleural loculations.

▶ Treatment

Drugs of choice are clindamycin (600 mg intravenously every 8 hours until improvement, then 300 mg orally every

6 hours) or amoxicillin-clavulanate (875 mg orally every 12 hours). Penicillin (amoxicillin, 500 mg every 8 hours, or penicillin G, 1–2 million units intravenously every 4–6 hours) plus metronidazole (500 mg orally or intravenously every 8–12 hours) is another option. Penicillin alone is inadequate treatment for anaerobic pleuropulmonary infections because an increasing number of anaerobic organisms produce β -lactamases, and up to 20% of patients do not respond to penicillins. Antibiotic therapy for anaerobic pneumonia should be continued until the chest radiograph improves, a process that may take a month or more; patients with lung abscesses should be treated until radiographic resolution of the abscess cavity is demonstrated. Anaerobic pleuropulmonary disease requires adequate drainage with tube thoracostomy for the treatment of empyema. Open pleural drainage is sometimes necessary because of the propensity of these infections to produce loculations in the pleural space.

PULMONARY INFILTRATES IN THE IMMUNOCOMPROMISED HOST

Pulmonary infiltrates in immunocompromised patients (patients with HIV disease, absolute neutrophil counts < 1000/mcL, current or recent exposure to myelosuppressive or immunosuppressive drugs, or those currently taking > 5 mg/d prednisone) may arise from infectious or noninfectious causes. Infection may be due to bacterial, mycobacterial, fungal, protozoal, helminthic, or viral pathogens. Noninfectious processes such as pulmonary edema, alveolar hemorrhage, drug reactions, pulmonary thromboembolic disease, malignancy, and radiation pneumonitis may mimic infection.

Although almost any pathogen can cause pneumonia in a compromised host, two clinical tools help the clinician narrow the differential diagnosis. The first is knowledge of the underlying immunologic defect. Specific immunologic defects are associated with particular infections. Defects in humoral immunity predispose to bacterial infections; defects in cellular immunity lead to infections with viruses, fungi, mycobacteria, and protozoa. Neutropenia and impaired granulocyte function predispose to infections from *S aureus*, *Aspergillus*, gram-negative bacilli, and *Candida*. Second, the time course of infection also provides clues to the etiology of pneumonia in immunocompromised patients. A fulminant pneumonia is often caused by bacterial infection, whereas an insidious pneumonia is more apt to be caused by viral, fungal, protozoal, or mycobacterial infection. Pneumonia occurring within 2–4 weeks after organ transplantation is usually bacterial, whereas several months or more after transplantation *P jiroveci*, viruses (eg, cytomegalovirus), and fungi (eg, *Aspergillus*) are encountered more often.

Clinical Findings

Chest radiography is rarely helpful in narrowing the differential diagnosis. Examination of expectorated sputum for bacteria, fungi, mycobacteria, *Legionella*, and *P jiroveci* is important and may preclude the need for expensive, invasive diagnostic procedures. Sputum induction is often necessary for diagnosis. The sensitivity of induced sputum for detection of *P jiroveci* depends on institutional expertise, number of specimens analyzed, and detection methods.

Routine evaluation frequently fails to identify a causative organism. The clinician may begin empiric antimicrobial therapy before proceeding to invasive procedures such as bronchoscopy, transthoracic needle aspiration, or open lung biopsy. The approach to management must be based on the severity of the pulmonary infection, the underlying disease, the risks of empiric therapy, and local expertise and experience with diagnostic procedures. Bronchoalveolar lavage using the flexible bronchoscope is a safe and effective method for obtaining representative pulmonary secretions for microbiologic studies. It involves less risk of bleeding and other complications than bronchial brushing and transbronchial biopsy. Bronchoalveolar lavage is especially suitable for the diagnosis of *P jiroveci* pneumonia in patients with AIDS when induced sputum analysis is negative. Surgical lung biopsy, now often performed by video-assisted thoracoscopy, provides the definitive option for diagnosis of pulmonary infiltrates in the immunocompromised host. However, a specific diagnosis is obtained in only about two-thirds of cases, and the information obtained rarely affects the outcome.

PULMONARY TUBERCULOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Fatigue, weight loss, fever, night sweats, and productive cough.
- ▶ Risk factors for acquisition of infection: household exposure, incarceration, drug use, travel to an endemic area.
- ▶ Chest radiograph: pulmonary opacities, most often apical.
- ▶ Acid-fast bacilli on smear of sputum or sputum culture positive for *M tuberculosis*.

► General Considerations

Tuberculosis is one of the world's most widespread and deadly illnesses. *M tuberculosis*, the organism that causes tuberculosis infection and disease, infects one-third of the world's population. In 2009, there were 9.4 million new cases of tuberculosis worldwide with 1.7 million people dying of the disease. In the United States, an estimated 11 million people are infected with *M tuberculosis*. Tuberculosis occurs disproportionately among disadvantaged populations such as the malnourished, homeless, and those living in overcrowded and substandard housing. There is an increased occurrence of tuberculosis among HIV-positive individuals.

Infection with *M tuberculosis* begins when a susceptible person inhales airborne droplet nuclei containing viable organisms. Tubercle bacilli that reach the alveoli are ingested by alveolar macrophages. Infection follows if the inoculum escapes alveolar macrophage microbicidal activity. Once infection is established, lymphatic and hematogenous dissemination of tuberculosis typically occurs before the development of an effective immune response. This stage of infection, **primary tuberculosis**, is usually clinically and radiographically silent. In most persons with intact cell-mediated immunity, T cells and macrophages surround the organisms in granulomas that limit their multiplication and spread. The infection is contained but not eradicated, since viable organisms may lie dormant within granulomas for years to decades.

Individuals with **latent tuberculosis infection** do not have active disease and cannot transmit the organism to others. However, reactivation of disease may occur if the host's immune defenses are impaired. Active tuberculosis will develop in approximately 6% of individuals with latent tuberculosis infection who are not given preventive therapy; half of these cases occur in the 2 years following primary infection. Diverse conditions such as gastrectomy, silicosis, diabetes mellitus, and an impaired immune response (eg, HIV infection; therapy with corticosteroids, tumor necrosis factor inhibitors or other immunosuppressive drugs) are associated with an increased risk of reactivation.

In approximately 5% of cases, the immune response is inadequate to contain the primary infection and **progressive primary tuberculosis** develops, accompanied by both pulmonary and constitutional symptoms as described below. The clinical presentation does not definitively distinguish primary disease from reactivation of latent tuberculosis infection. Standard teaching has held that 90% of tuberculosis in adults represents activation of latent disease. However, DNA fingerprinting of the bacillus suggests that as many as one-third of new cases of tuberculosis in urban populations are primary infections resulting from person-to-person transmission.

The prevalence of drug-resistant strains is increasing worldwide; however, in the United States, the rate of drug-resistant isolates has fallen to < 1%. Risk factors for drug resistance include immigration from countries with a high prevalence of drug-resistant tuberculosis, close and prolonged contact with individuals with drug-resistant tuberculosis, unsuccessful previous therapy, and nonadherence

to treatment. Drug resistance may be single or multiple. **Drug-resistant tuberculosis** is resistant to one first-line antituberculous drug, either isoniazid or rifampin. **Multidrug-resistant tuberculosis** is resistant to isoniazid and rifampin, and possibly additional agents. **Extensively drug-resistant tuberculosis** is resistant to isoniazid, rifampin, fluoroquinolones, and either aminoglycosides or capreomycin or both. Outcomes of drug-resistant tuberculosis treatment are worse than when the isolate is drug-sensitive, but outcomes appear to vary with HIV status. One retrospective study conducted in the United States showed that 97% of HIV-negative patients were cured of multidrug-resistant tuberculosis, while all 11 HIV-positive patients died. In a review of extensively drug-resistant tuberculosis cases in the United States, mortality was 10% and 68% in HIV-negative and HIV-positive patients, respectively. In one South African study, 52 of 53 HIV-positive patients with extensively drug-resistant tuberculosis died (median survival was 16 days from time of diagnosis).

► Clinical Findings

A. Symptoms and Signs

The patient with pulmonary tuberculosis typically presents with slowly progressive constitutional symptoms of malaise, anorexia, weight loss, fever, and night sweats. Chronic cough is the most common pulmonary symptom. It may be dry at first but typically becomes productive of purulent sputum as the disease progresses. Blood-streaked sputum is common, but significant hemoptysis is rarely a presenting symptom; life-threatening hemoptysis may occur in advanced disease. Dyspnea is unusual unless there is extensive disease. Rarely, the patient is asymptomatic. On physical examination, the patient appears chronically ill and malnourished. On chest examination, there are no physical findings specific for tuberculosis infection. The examination may be normal or may reveal classic findings such as posttussive apical rales.

B. Laboratory Findings

Definitive diagnosis depends on recovery of *M tuberculosis* from cultures or identification of the organism by DNA or RNA amplification techniques. Three consecutive morning sputum specimens are advised. Fluorochrome staining with rhodamine-auramine of concentrated, digested sputum specimens is performed initially as a screening method, with confirmation by the Kinyoun or Ziehl-Neelsen stains. Demonstration of acid-fast bacilli on sputum smear does not establish a diagnosis of *M tuberculosis*, since nontuberculous mycobacteria may colonize the airways and are increasingly recognized to cause clinical illness in patients with underlying structural lung disease.

In patients thought to have tuberculosis who cannot produce satisfactory specimens or when the smear of the spontaneously expectorated sputum is negative for acid-fast bacilli, sputum induction with 3% hypertonic saline should be performed. Flexible bronchoscopy with bronchial washings has similar diagnostic yield to induced sputum;

transbronchial lung biopsies do not significantly increase the diagnostic yield but may lead to earlier diagnosis by identifying tissue granulomas. Post-bronchoscopy expectorated sputum specimens should be collected. Early morning aspiration of gastric contents after an overnight fast is suitable only for culture and not for stained smear because nontuberculous mycobacteria may be present in the stomach in the absence of tuberculous infection. Positive blood cultures for *M tuberculosis* are uncommon in patients with normal CD4 cell counts but the organism may be cultured from blood in up to 50% of HIV-seropositive patients with tuberculosis whose CD4 cell counts are < 100/mcL.

Traditional light-microscopic examination of stained sputum for acid-fast bacilli and culture of sputum specimens remain the mainstay of tuberculosis diagnosis. The slow rate of mycobacterial growth, the urgency to provide early, appropriate treatment to patients to improve their outcomes and limit community spread, and concerns about potential drug toxicities in patients treated empirically who do not have tuberculosis infection, have fostered interest in rapid diagnostic techniques (see Table 9–15). Molecular diagnostics offer multiple options and many

advantages at significant increased expense. Nucleic acid amplification testing not only detects *M tuberculosis* (NAAT-TB) but it also identifies resistance markers (NAAT-R). NAAT-TB can identify *M tuberculosis* within hours of sputum processing, allowing early isolation and treatment, but the negative predictive value is low in smear-negative patients. NAAT-R allows rapid identification of primary drug resistance and is indicated in the following patients: (1) those treated previously for tuberculosis, (2) those born (or who lived for > 1 year) in a country with moderate tuberculosis incidence or a high incidence of multiple drug-resistant isolates, (3) contacts of patients with multidrug-resistant tuberculosis, or (4) those who are HIV seropositive. Clinical suspicion remains the critical factor in interpreting all these studies. Standard drug susceptibility testing of culture isolates is considered routine for the first isolate of *M tuberculosis*, when a treatment regimen is failing, and when sputum cultures remain positive after 2 months of therapy.

Needle biopsy of the pleura reveals granulomatous inflammation in approximately 60% of patients with pleural effusions caused by *M tuberculosis*. Pleural fluid cultures

Table 9-15. Essential laboratory tests for the detection of *Mycobacterium tuberculosis*.¹

Test	Time to Result	Test Characteristics
Acid-fast bacilli light microscopy	1 day	Three morning specimens recommended. Combined sensitivity of 70% (54% for the first specimen, 11% for the second specimen, and 5% for the third specimen). First morning specimen increased yield by 12% compared to spot specimen.
Nucleic acid amplification test, detection (NAAT-TB)	1 day	Sensitivity/specificity high for smear-positive specimens, 85–97% for both, but sensitivity falls in smear-negative specimens to ~66%. Therefore, a positive NAAT in smear-negative patients with intermediate to high (> 30%) pretest probability of <i>M tuberculosis</i> infection is helpful while a negative NAAT is not. Should not be ordered in patients with low pretest probability of <i>M tuberculosis</i> infection.
Nucleic acid amplification test, resistance markers (NAAT-R)	1–2 days	Multiple assays for rifampin and isoniazid are available. Specificity uniformly high, > 98%. Sensitivity varies from about 84% to 96% increases with multiple specimens. See text for indications for testing.
Mycobacterial growth detection Liquid (broth based) medium Solid (agar or egg based) medium	Up to 6–8 weeks Avg 10–14 days Avg 3–4 weeks	Liquid culture methods are more sensitive (~90% and 76%, respectively) with shorter time to detection but higher contamination with bacterial growth than solid culture methods. Specificity exceeds 99% for all methods.
Identification of <i>M tuberculosis</i> complex by DNA probe or high performance liquid chromatography	1 day ¹	May be useful in areas of low <i>M tuberculosis</i> incidence where nontuberculous mycobacteria are commonly isolated.
First-line drug susceptibility testing (liquid medium)	1–2 weeks ¹	Gold standard. Should be performed routinely on the initial isolate.
Second-line and novel compound drug susceptibility testing Liquid (broth based) medium Solid (agar or egg based) medium	1–2 weeks ¹ 3–4 weeks ¹	

¹Following detection of mycobacterial growth.

This official statement of the American Thoracic Society and the Centers for Disease Control and Prevention was adopted by the ATS Board of Directors, July 1999. This statement was endorsed by the Council of the Infectious Disease Society of America, September 1999. *Am J Respir Crit Care Med.* 2000 Apr;161(4 Pt 1):1376-95.

for *M tuberculosis* are positive in less than 23–58% of cases of pleural tuberculosis. Culture of three pleural biopsy specimens combined with microscopic examination of a pleural biopsy yields a diagnosis in up to 90% of patients with pleural tuberculosis. Tests for pleural fluid adenosine deaminase (approximately 90% sensitivity and specificity for pleural tuberculosis at levels > 70 units/L) and interferon-gamma (89% sensitivity, 97% specificity in a recent meta-analysis) can be extremely helpful diagnostic aids, particularly in making decisions to pursue invasive testing in complex cases.

C. Imaging

Contrary to traditional teaching, molecular analysis demonstrates that radiographic abnormalities in pulmonary tuberculosis do not distinguish primary disease from reactivation of latent tuberculosis. The only independent predictor of an atypical pattern on chest radiograph—that is, not associated with upper lobe or cavitory disease—is an impaired host immune response.

The chest imaging pattern traditionally associated with primary disease includes small unilateral infiltrates, hilar and paratracheal lymph node enlargement, and segmental atelectasis. Pleural effusion is present in 30–40% of patients, sometimes as the sole radiographic abnormality. Reactivation tuberculosis traditionally has been associated with fibrocavitary apical disease (Figure 9–5), discrete nodules, and pneumonic infiltrates, usually in the apical or posterior segments of the upper lobes or in the superior segments of the lower lobes. Radiographic evidence of disease in other locations may be present in up to 30% of patients. This is especially true in elderly patients, in whom lower lobe infiltrates with or without pleural effusion are frequently encountered. Lower lung tuberculosis may masquerade as pneumonia or lung cancer. A “miliary” pattern (diffuse small nodular densities) can be seen with

▲ **Figure 9–5.** Advanced bilateral pulmonary tuberculosis. (Public Health Image Library, CDC.)

hematologic or lymphatic dissemination of the organism. Immunocompromised patients—particularly those with late-stage HIV infection—often display lower lung zone, diffuse, or miliary infiltrates; pleural effusions; and involvement of hilar and, in particular, mediastinal lymph nodes.

Resolution of active tuberculosis leaves characteristic radiographic findings. Dense nodules in the pulmonary hila, with or without obvious calcification, upper lobe fibronodular scarring, and bronchiectasis with volume loss are common findings. Ghon (calcified primary focus) and Ranke (calcified primary focus and calcified hilar lymph node) complexes are seen in a minority of patients.

D. Special Examinations

Testing for latent tuberculosis infection is used to evaluate an asymptomatic person in whom *M tuberculosis* infection is suspected (eg, following contact exposure) or to establish the prevalence of tuberculosis infection in a population. Testing may be used in a person with symptoms of active tuberculosis, but a positive test does not distinguish between active and latent infection. Routine testing of individuals at low risk for tuberculosis is not recommended.

The traditional approach to latent tuberculosis infection is the **tuberculin skin test**. The Mantoux test is the preferred method: 0.1 mL of purified protein derivative (PPD) containing 5 tuberculin units is injected intradermally on the volar surface of the forearm using a 27-gauge needle on a tuberculin syringe. The transverse width in millimeters of induration at the skin test site is measured after 48–72 hours. To optimize test performance, criteria for determining a positive reaction vary depending on the likelihood of infection. Table 9–16 summarizes the criteria established by the Centers for Disease Control and Prevention for interpretation of the Mantoux tuberculin skin test. Sensitivity and specificity of the tuberculin skin test are high: 77% and 97%, respectively. Specificity falls to 59% in populations previously vaccinated with bacillus Calmette-Guérin (BCG, an extract of *Mycobacterium bovis*). False-negative tuberculin skin test reactions may result from improper testing technique; concurrent infections, including fulminant tuberculosis; malnutrition; advanced age; immunologic disorders; malignancy; corticosteroid therapy; chronic kidney disease; and HIV infection. Some individuals with latent tuberculosis infection may have a negative tuberculin skin test when tested many years after exposure. Anergy testing is not recommended for routine use to distinguish a true-negative result from anergy. Poor anergy test standardization and lack of outcome data limit the evaluation of its effectiveness. Interpretation of the tuberculin skin test in persons who have previously received BCG vaccination is the same as in those who have not had BCG.

Interferon gamma release assays are in vitro assays of CD4+ T-cell-mediated interferon gamma release in response to stimulation by specific *M tuberculosis* antigens. The antigens are absent from all BCG strains and most nontuberculous mycobacteria; therefore, in whole blood, the specificity of interferon gamma release assays is

Table 9–16. Classification of positive tuberculin skin test reactions.¹

Induration Size	Group
≥ 5 mm	<ol style="list-style-type: none"> 1. HIV-positive persons. 2. Recent contacts of individuals with active tuberculosis. 3. Persons with fibrotic changes on chest x-rays suggestive of prior tuberculosis. 4. Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of > 15 mg/d of prednisone for 1 month or more).
≥ 10 mm	<ol style="list-style-type: none"> 1. Recent immigrants (< 5 years) from countries with a high prevalence of tuberculosis (eg, Asia, Africa, Latin America). 2. HIV-negative injection drug users. 3. Mycobacteriology laboratory personnel. 4. Residents of and employees² in the following high-risk congregate settings: correctional institutions; nursing homes and other long-term facilities for the elderly; hospitals and other health care facilities; residential facilities for AIDS patients; and homeless shelters. 5. Persons with the following medical conditions that increase the risk of tuberculosis: gastrectomy, ≥ 10% below ideal body weight, jejunioileal bypass, diabetes mellitus, silicosis, advanced chronic kidney disease, some hematologic disorders, (eg, leukemias, lymphomas), and other specific malignancies (eg, carcinoma of the head or neck and lung). 6. Children < 4 years of age or infants, children, and adolescents exposed to adults at high risk.
≥ 15 mm	<ol style="list-style-type: none"> 1. Persons with no risk factors for tuberculosis.

¹A tuberculin skin test reaction is considered positive if the transverse diameter of the *indurated* area reaches the size required for the specific group. All other reactions are considered negative.

²For persons who are otherwise at low risk and are tested at entry into employment, a reaction of > 15 mm induration is considered positive.

Data from Screening for tuberculosis and tuberculosis infection in high-risk populations: recommendations of the Advisory Council for the Elimination of Tuberculosis. *MMWR Morb Mortal Wkly Rep* 1995 Sep 8;44(RR-11):19–34. [PMID: 7565540]

superior to the tuberculin skin test in BCG-vaccinated individuals. Sensitivity is comparable to the tuberculin skin test: 60–90% depending on the specific assay and study population. Sensitivity is reduced by HIV infection, particularly in patients with low CD4 counts. Specificity is high, > 95%. Potential advantages of interferon gamma release assay testing include fewer false-positive results from prior BCG vaccination, better discrimination of positive responses due to nontuberculous mycobacteria, and the requirement for only one patient contact (ie, no need for the patient to return to have the tuberculin skin test read 48–72 hours later). Disadvantages include the need for specialized laboratory equipment and personnel, and the substantially increased cost compared to the tuberculin skin test.

In endemic areas, interferon gamma release assays are no more sensitive than the tuberculin skin test in active tuberculosis (20–40% false-negative rate) and cannot distinguish active from latent disease. Interferon gamma release assays should not be used to exclude active tuberculosis.

Guidelines established by the US Centers for Disease Control and Prevention allow interferon gamma release assays to be used interchangeably with the tuberculin skin testing in the diagnosis of latent tuberculosis infection. Interferon gamma release assays are preferred in patients with prior BCG vaccination; the tuberculin skin test is preferred in children under 5 years old. Routine use of both tests is not recommended. In individuals with a positive tuberculin skin test but a low prior probability of latent tuberculosis infection and low risk for progression to active disease, the interferon gamma release assay may be helpful

as a confirmatory test to exclude a false-positive tuberculin skin test.

► Treatment

A. General Measures

The goals of therapy are to eliminate all tubercle bacilli from an infected individual while avoiding the emergence of clinically significant drug resistance. The basic principles of antituberculous treatment are (1) to administer multiple drugs to which the organisms are susceptible; (2) to add at least two new antituberculous agents to a regimen when treatment failure is suspected; (3) to provide the safest, most effective therapy in the shortest period of time; and (4) to ensure adherence to therapy.

All suspected and confirmed cases of tuberculosis should be reported promptly to local and state public health authorities. Public health departments will perform case investigations on sources and patient contacts to determine if other individuals with untreated, infectious tuberculosis are present in the community. They can identify infected contacts eligible for treatment of latent tuberculous infection, and ensure that a plan for monitoring adherence to therapy is established for each patient with tuberculosis. Patients with tuberculosis should be treated by clinicians who are skilled in the management of this infection. Clinical expertise is especially important in cases of drug-resistant tuberculosis.

Nonadherence to antituberculous treatment is a major cause of treatment failure, continued transmission of tuberculosis, and the development of drug resistance. Adherence to treatment can be improved by providing

detailed patient education about tuberculosis and its treatment in addition to a case manager who oversees all aspects of an individual patient's care. **Directly observed therapy (DOT)**, which requires that a health care worker physically observe the patient ingest antituberculous medications in the home, clinic, hospital, or elsewhere, also improves adherence to treatment. The importance of direct observation of therapy cannot be overemphasized. The CDC recommends DOT for all patients with drug-resistant tuberculosis and for those receiving intermittent (twice- or thrice-weekly) therapy.

Hospitalization for initial therapy of tuberculosis is not necessary for most patients. It should be considered if a patient is incapable of self-care or is likely to expose new, susceptible individuals to tuberculosis. Hospitalized patients with active disease require a private room with negative-pressure ventilation until tubercle bacilli are no longer found in their sputum ("smear-negative") on three consecutive smears taken on separate days.

Characteristics of antituberculous drugs are provided in Table 9–17. Additional treatment considerations can be

found in Chapter 33. More complete information can be obtained from the CDC's Division of Tuberculosis Elimination Web site at <http://www.cdc.gov/tb/>.

B. Treatment of Tuberculosis in HIV-Negative Persons

Most patients with previously untreated pulmonary tuberculosis can be effectively treated with either a 6-month or a 9-month regimen, though the 6-month regimen is preferred. The initial phase of a 6-month regimen consists of 2 months of daily isoniazid, rifampin, pyrazinamide, and ethambutol. Once the isolate is determined to be isoniazid-sensitive, ethambutol may be discontinued. If the *M tuberculosis* isolate is susceptible to isoniazid and rifampin, the second phase of therapy consists of isoniazid and rifampin for a minimum of 4 additional months, with treatment to extend at least 3 months beyond documentation of conversion of sputum cultures to negative for *M tuberculosis*. If DOT is used, medications may be given intermittently using one of three regimens: (1) Daily isoniazid, rifampin,

Table 9–17. Characteristics of antituberculous drugs.

Drug	Most Common Side Effects	Tests for Side Effects	Drug Interactions	Remarks
Isoniazid	Peripheral neuropathy, hepatitis, rash, mild CNS effects.	AST and ALT; neurologic examination.	Phenytoin (synergistic); disulfiram.	Bactericidal to both extracellular and intracellular organisms. Pyridoxine, 10 mg orally daily as prophylaxis for neuritis; 50–100 mg orally daily as treatment.
Rifampin	Hepatitis, fever, rash, flu-like illness, gastrointestinal upset, bleeding problems, kidney failure.	CBC, platelets, AST and ALT.	Rifampin inhibits the effect of oral contraceptives, quinidine, corticosteroids, warfarin, methadone, digoxin, oral hypoglycemics; aminosalicylic acid may interfere with absorption of rifampin. Significant interactions with protease inhibitors and nonnucleoside reverse transcriptase inhibitors.	Bactericidal to all populations of organisms. Colors urine and other body secretions orange. Discoloring of contact lenses.
Pyrazinamide	Hyperuricemia, hepatotoxicity, rash, gastrointestinal upset, joint aches.	Uric acid, AST, ALT.	Rare.	Bactericidal to intracellular organisms.
Ethambutol	Optic neuritis (reversible with discontinuance of drug; rare at 15 mg/kg); rash.	Red-green color discrimination and visual acuity.	Rare.	Bacteriostatic to both intracellular and extracellular organisms. Mainly used to inhibit development of resistant mutants. Use with caution in kidney disease or when ophthalmologic testing is not feasible.
Streptomycin	Eighth nerve damage, nephrotoxicity.	Vestibular function (audiograms); BUN and creatinine.	Neuromuscular blocking agents may be potentiated and cause prolonged paralysis.	Bactericidal to extracellular organisms. Use with caution in older patients or those with kidney disease.

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CBC, complete blood count.

pyrazinamide, and ethambutol for 2 months, followed by isoniazid and rifampin two or three times each week for 4 months if susceptibility to isoniazid and rifampin is demonstrated. (2) Daily isoniazid, rifampin, pyrazinamide, and ethambutol for 2 weeks, then administration of the same agents twice a week for 6 weeks followed by administration of isoniazid and rifampin twice each week for 4 months if susceptibility to isoniazid and rifampin is demonstrated. (3) Isoniazid, rifampin, pyrazinamide, and ethambutol three times a week for 6 months.

Patients who cannot or should not (eg, pregnant women) take pyrazinamide should receive daily isoniazid and rifampin along with ethambutol for 4–8 weeks. If susceptibility to isoniazid and rifampin is demonstrated or drug resistance is unlikely, ethambutol can be discontinued and isoniazid and rifampin may be given twice a week for a total of 9 months of therapy. If drug resistance is a concern, patients should receive isoniazid, rifampin, and ethambutol for 9 months. Patients with smear- and culture-negative disease (eg, pulmonary tuberculosis diagnosed on clinical grounds) and patients for whom drug susceptibility testing is not available can be treated with 6 months of isoniazid and rifampin combined with pyrazinamide for the first 2 months. This regimen assumes low prevalence of drug resistance. Previous guidelines have used streptomycin interchangeably with ethambutol. Increasing worldwide streptomycin resistance has made this drug less useful as empiric therapy.

When a twice-weekly or thrice-weekly regimen is used instead of a daily regimen, the dosages of isoniazid, pyrazinamide, and ethambutol or streptomycin must be increased. Recommended dosages for the initial treatment of tuberculosis are listed in Table 9–18. Fixed-dose combinations of isoniazid and rifampin (Rifamate) and of isoniazid, rifampin, and pyrazinamide (Rifater) are available to simplify treatment. Single tablets improve compliance but are more expensive than the individual drugs purchased separately.

C. Treatment of Tuberculosis in HIV-Positive Persons

Management of tuberculosis is complex in patients with concomitant HIV disease. Experts in the management of both tuberculosis and HIV disease should be involved in the care of such patients. The CDC has published detailed recommendations for the treatment of tuberculosis in HIV-positive patients. These documents can be obtained by accessing the CDC Division of Tuberculosis Elimination Web site at <http://www.cdc.gov/tb/>.

The basic approach to HIV-positive patients with tuberculosis is similar to that detailed above for patients without HIV disease. Additional considerations in HIV-positive patients include: (1) longer duration of therapy and (2) drug interactions between rifamycin derivatives such as rifampin and rifabutin, used to treat tuberculosis, and some of the protease inhibitors and nonnucleoside reverse transcriptase inhibitors (NNRTIs), used to treat HIV (see above Web site). DOT should be used for all HIV-positive tuberculosis patients. Pyridoxine (vitamin B₆), 25–50 mg orally each day, should be administered to all

HIV-positive patients being treated with isoniazid to reduce central and peripheral nervous system side effects.

D. Treatment of Drug-Resistant Tuberculosis

Patients with drug-resistant *M tuberculosis* infection require careful supervision and management. Clinicians who are unfamiliar with the treatment of drug-resistant tuberculosis should seek expert advice. Tuberculosis resistant only to isoniazid can be successfully treated with a 6-month regimen of rifampin, pyrazinamide, and ethambutol or streptomycin or a 12-month regimen of rifampin and ethambutol. When isoniazid resistance is documented during a 9-month regimen without pyrazinamide, isoniazid should be discontinued. If ethambutol was part of the initial regimen, rifampin and ethambutol should be continued for a minimum of 12 months. If ethambutol was not part of the initial regimen, susceptibility tests should be repeated and two other drugs to which the organism is susceptible should be added. Treatment of *M tuberculosis* isolates resistant to agents other than isoniazid and treatment of drug resistance in HIV-infected patients require expert consultation.

Multidrug-resistant tuberculosis and extensively drug-resistant tuberculosis call for an individualized daily DOT plan under the supervision of a clinician experienced in the management of these entities. Treatment regimens are based on the patient's overall status and the results of susceptibility studies. Most drug-resistant isolates are resistant to at least isoniazid and rifampin and require a minimum of three drugs to which the organism is susceptible. These regimens are continued until culture conversion is documented, and then a two-drug regimen is continued for at least another 12 months. Some experts recommend at least 18–24 months of a three-drug regimen.

E. Treatment of Extrapulmonary Tuberculosis

In most cases, regimens that are effective for treating pulmonary tuberculosis are also effective for treating extrapulmonary disease. However, many experts recommend 9 months of therapy when miliary, meningial, or bone and joint disease is present. Treatment of skeletal tuberculosis is enhanced by early surgical drainage and debridement of necrotic bone. Corticosteroid therapy has been shown to help prevent cardiac constriction from tuberculous pericarditis and to reduce neurologic complications from tuberculous meningitis (see Chapter 33).

F. Treatment of Pregnant or Lactating Women

Tuberculosis in pregnancy is usually treated with isoniazid, rifampin, and ethambutol for 2 months, followed by isoniazid and rifampin for an additional 7 months. Ethambutol can be stopped after the first month if isoniazid and rifampin susceptibility is confirmed. Since the risk of teratogenicity with pyrazinamide has not been clearly defined, pyrazinamide should be used only if resistance to other drugs is documented and susceptibility to pyrazinamide is likely. Streptomycin is contraindicated in pregnancy because it may cause congenital deafness. Pregnant women taking isoniazid should receive pyridoxine

(vitamin B₆), 10–25 mg orally once a day, to prevent peripheral neuropathy.

Small concentrations of antituberculous drugs are present in breast milk. First-line therapy is not known to be harmful to nursing newborns at these concentrations. Therefore, breastfeeding is not contraindicated while receiving first-line antituberculous therapy. Lactating women receiving other agents should consult a tuberculosis expert.

G. Treatment Monitoring

Adults should have measurements of serum bilirubin, hepatic enzymes, urea nitrogen, creatinine, and a complete blood count (including platelets) before starting chemotherapy for tuberculosis. Visual acuity and red-green color vision tests are recommended before initiation of ethambutol and serum uric acid before starting pyrazinamide. Audiometry should be performed if streptomycin therapy is initiated.

Routine monitoring of laboratory tests for evidence of drug toxicity during therapy is not recommended, unless baseline results are abnormal or liver disease is suspected. Monthly questioning for symptoms of drug toxicity is advised. Patients should be educated about common side effects of antituberculous medications and instructed to seek medical attention should these symptoms occur. Monthly follow-up of outpatients is recommended, including sputum smear and culture for *M tuberculosis* until cultures convert to negative. Patients with negative sputum cultures after 2 months of treatment should have at least one additional sputum smear and culture performed at the end of therapy. Patients with drug-resistant isolates should have sputum cultures performed monthly during the entire course of treatment. A chest radiograph at the end of therapy provides a useful baseline for any future films.

Patients whose cultures do not become negative or whose symptoms do not resolve despite 3 months of therapy should be evaluated for drug-resistant organisms and for nonadherence to the treatment regimen. DOT is required for the remainder of the treatment regimen, and the addition of at least two drugs not previously given should be considered pending repeat drug susceptibility testing. The clinician should seek expert assistance if drug resistance is newly found, if the patient remains symptomatic, or if smears or cultures remain positive.

Patients with only a clinical diagnosis of pulmonary tuberculosis (smears and cultures negative for *M tuberculosis*) whose symptoms and radiographic abnormalities are unchanged after 3 months of treatment usually either have another process or have had tuberculosis in the past.

H. Treatment of Latent Tuberculosis

Treatment of latent tuberculous infection is essential to controlling and eliminating tuberculosis in the United States. Treatment of latent tuberculous infection substantially reduces the risk that infection will progress to active disease. Targeted testing with the tuberculin skin test or interferon gamma release assays is used to identify persons who are at high risk for tuberculosis and who stand to benefit from treatment of latent infection. Table 9–16 gives

the tuberculin skin test criteria for treatment of latent tuberculous infection. In general, patients with a positive tuberculin skin test or interferon gamma release assay who are at increased risk for exposure or disease are treated. It is essential that each person who meets the criteria for treatment of latent tuberculous infection undergo a careful assessment to exclude active disease. A history of past treatment for tuberculosis and contraindications to treatment should be sought. All patients at risk for HIV infection should be tested for HIV. Patients suspected of having tuberculosis should receive one of the recommended multidrug regimens for active disease until the diagnosis is confirmed or excluded.

Some close contacts of persons with active tuberculosis should be evaluated for treatment of latent tuberculous infection despite a negative tuberculin skin test reaction (< 5 mm induration). These include immunosuppressed persons and those who may develop disease quickly after tuberculous infection. Close contacts who have a negative tuberculin skin test reaction on initial testing should be retested 10–12 weeks later.

Several treatment regimens for both HIV-negative and HIV-positive persons are available for the treatment of latent tuberculous infection: (1) **Isoniazid:** A 9-month oral regimen (minimum of 270 doses administered within 12 months) is considered optimal. Dosing options include a daily dose of 300 mg or twice-weekly doses of 15 mg/kg. Persons at risk for developing isoniazid-associated peripheral neuropathy (diabetes mellitus, uremia, malnutrition, alcoholism, HIV infection, pregnancy, seizure disorder) may be given supplemental pyridoxine (vitamin B₆), 10–50 mg/d. (2) **Rifampin and pyrazinamide:** A 2-month oral regimen (60 doses administered within 3 months) of daily rifampin (10 mg/kg up to a maximum dose of 600 mg) and pyrazinamide (15–20 mg/kg up to a maximum dose of 2 g) is recommended. This regimen has been associated with significant hepatotoxicity, so careful laboratory monitoring is required. (3) **Rifampin:** Patients who cannot tolerate isoniazid or pyrazinamide can be considered for a 4-month regimen (minimum of 120 doses administered within 6 months) of rifampin. HIV-positive patients receiving protease inhibitors or NNRTIs who are given rifampin require management by experts in both tuberculosis and HIV disease (see Treatment of Tuberculosis in HIV-Positive Persons, above).

Contacts of persons with isoniazid-resistant, rifampin-sensitive tuberculosis should receive a 2-month regimen of rifampin and pyrazinamide or a 4-month regimen of daily rifampin alone. Contacts of persons with drug-resistant tuberculosis should receive two drugs to which the infecting organism has demonstrated susceptibility. Contacts in whom the tuberculin skin test or interferon gamma release assay is negative and contacts who are HIV seronegative may be observed without treatment or treated for 6 months. HIV-positive contacts should be treated for 12 months. All contacts of persons with multidrug-resistant tuberculosis or extensively drug-resistant tuberculosis should have 2 years of follow-up regardless of treatment.

Persons with a positive tuberculin skin test (≥ 5 mm of induration) and fibrotic lesions suggestive of old tubercu-

losis on chest radiographs who have no evidence of active disease and no history of treatment for tuberculosis should receive 9 months of isoniazid, or 2 months of rifampin and pyrazinamide, or 4 months of rifampin (with or without isoniazid). Pregnant or breastfeeding women with latent tuberculosis should receive either daily or twice-weekly isoniazid with pyridoxine (vitamin B₆).

Baseline laboratory testing is indicated for patients at risk for liver disease, patients with HIV infection, women who are pregnant or within 3 months of delivery, and persons who use alcohol regularly. Patients receiving treatment for latent tuberculous infection should be evaluated once a month to assess for symptoms and signs of active tuberculosis and hepatitis and for adherence to their treatment regimen. Routine laboratory testing during treatment is indicated for those with abnormal baseline laboratory tests and for those at risk for developing liver disease.

Vaccine BCG is an antimycobacterial vaccine developed from an attenuated strain of *M bovis*. Millions of individuals worldwide have been vaccinated with BCG. However, it is not generally recommended in the United States because of the low prevalence of tuberculous infection, the vaccine's interference with the ability to determine latent tuberculous infection using tuberculin skin test reactivity, and its variable effectiveness against pulmonary tuberculosis. BCG vaccination in the United States should only be undertaken after consultation with local health officials and experts in the management of tuberculosis. Vaccination of health care workers should be considered on an individual basis in settings in which a high percentage of tuberculosis patients are infected with strains resistant to both isoniazid and rifampin, in which transmission of such drug-resistant *M tuberculosis* and subsequent infection are likely, and in which comprehensive tuberculous infection-control precautions have been implemented but have not been successful. The BCG vaccine is contraindicated in persons with impaired immune responses due to disease or medications.

► Prognosis

Almost all properly treated immunocompetent patients with tuberculosis can be cured. Relapse rates are less than 5% with current regimens. The main cause of treatment failure is nonadherence to therapy.

PULMONARY DISEASE CAUSED BY NONTUBERCULOUS MYCOBACTERIA

ESSENTIALS OF DIAGNOSIS

- Chronic cough, sputum production, and fatigue; less commonly: malaise, dyspnea, fever, hemoptysis, and weight loss.
- Parenchymal opacities on chest radiograph, often with thin-walled cavities, that spread contiguously and often involve overlying pleura.
- Isolation of nontuberculous mycobacteria in a sputum culture.

► General Considerations

Mycobacteria other than *M tuberculosis*—nontuberculous mycobacteria (NTM), sometimes referred to as “atypical” mycobacteria—are ubiquitous in water and soil and have been isolated from tap water. There appears to be a continuing increase in the number and prevalence of NTM species. Marked geographic variability exists, both in the NTM species responsible for disease and in the prevalence of disease. These organisms are not considered communicable from person to person, have distinct laboratory characteristics, and are often resistant to most antituberculous drugs. See Chapter 33 for further information.

► Definition & Pathogenesis

The diagnosis of lung disease caused by NTM is based on a combination of clinical, radiographic, and bacteriologic criteria and the exclusion of other diseases that can resemble the condition. Specific diagnostic criteria are discussed below. Complementary data are important for diagnosis because NTM organisms can reside in or colonize the airways without causing clinical disease.

Mycobacterium avium complex (MAC) is the most frequent cause of NTM pulmonary disease in humans in the United States. *Mycobacterium kansasii* is the next most frequent pulmonary pathogen. Other NTM causes of

pulmonary disease include *Mycobacterium abscessus*, *Mycobacterium xenopi*, and *Mycobacterium mageritense*; the list of more unusual etiologic NTM species is long. Most NTM cause a chronic pulmonary infection that resembles tuberculosis but tends to progress more slowly. Disseminated disease is rare in immunocompetent hosts; however, disseminated MAC disease is common in patients with AIDS.

► Clinical Findings

A. Symptoms and Signs

NTM infection among immunocompetent hosts frequently presents in one of three prototypical patterns: cavitary, upper lobe lesions in older male smokers that may mimic *M tuberculosis*; nodular bronchiectasis affecting the mid lung zones in middle-aged women with chronic cough; and hypersensitivity pneumonitis following environmental exposure. Most patients with NTM infection experience a chronic cough, sputum production, and fatigue. Less common symptoms include malaise, dyspnea, fever, hemoptysis, and weight loss. Symptoms from coexisting lung disease (COPD, bronchiectasis, previous mycobacterial disease, cystic fibrosis, and pneumoconiosis) may confound the evaluation. In patients with bronchiectasis, coinfection with NTM and *Aspergillus* is a negative prognostic factor. New or worsening infiltrates as well as adenopathy or pleural effusion (or both) are described in HIV-positive patients with NTM infection as part of the immune reconstitution inflammatory syndrome following institution of highly active antiretroviral therapy.

B. Laboratory Findings

The diagnosis of NTM infection rests on recovery of the pathogen from cultures. Sputum cultures positive for atypical mycobacteria do not prove infection because NTM may exist as saprophytes colonizing the airways or may be environmental contaminants. Bronchial washings are considered to be more sensitive than expectorated sputum samples; however, their specificity for clinical disease is not known.

Bacteriologic criteria have been proposed based on studies of patients with cavitary disease with MAC or *M kansasii*. Diagnostic criteria in immunocompetent persons include the following: positive culture results from at least two separate expectorated sputum samples; or positive culture from at least one bronchial wash; or a positive culture from pleural fluid or any other normally sterile site. The diagnosis can also be established by demonstrating NTM cultured from a lung biopsy, bronchial wash, or sputum plus histopathologic changes such as granulomatous inflammation in a lung biopsy. Rapid species identification of some NTM is possible using DNA probes or high-pressure liquid chromatography.

Diagnostic criteria are less stringent for patients with severe immune suppression. HIV-infected patients may show significant MAC growth on culture of bronchial washings without clinical infection; therefore, HIV patients being evaluated for MAC infection must be considered individually.

Drug susceptibility testing on cultures of NTM is recommended for the following NTM: (1) *Mycobacterium*

avium intracellulare to macrolides only (clarithromycin and azithromycin); (2) *M kansasii* to rifampin; and (3) rapid growers (such as *Mycobacterium fortuitum*, *Mycobacterium chelonae*, *M abscessus*) to amikacin, doxycycline, imipenem, fluoroquinolones, clarithromycin, cefoxitin, and sulfonamides.

C. Imaging

Chest radiographic findings include infiltrates that are progressive or persist for at least 2 months, cavitary lesions, and multiple nodular densities. The cavities are often thin-walled and have less surrounding parenchymal infiltrate than is commonly seen with MTB infections. Evidence of contiguous spread and pleural involvement is often present. High-resolution CT of the chest may show multiple small nodules with or without multifocal bronchiectasis. Progression of pulmonary infiltrates during therapy or lack of radiographic improvement over time are poor prognostic signs and also raise concerns about secondary or alternative pulmonary processes. Clearing of pulmonary infiltrates due to NTM is slow.

► Treatment

Establishing NTM infection does not mandate treatment in all cases, for two reasons. First, clinical disease may never develop in some patients, particularly asymptomatic patients with few organisms isolated from single specimens. Second, the spectrum of clinical disease severity is very wide; in patients with mild or slowly progressive symptoms, traditional chemotherapeutic regimens using a combination of agents may lead to drug-induced side effects worse than the disease itself.

Specific treatment regimens and responses to therapy vary with the species of NTM. HIV-seronegative patients with MAC pulmonary disease usually receive a combination of daily clarithromycin or azithromycin, rifampin or rifabutin, and ethambutol (Table 9–18). For patients with severe fibrocavitary disease, streptomycin or amikacin is added for the first 2 months. The optimal duration of treatment is unknown, but therapy should be continued for 12 months after sputum conversion. Medical treatment is initially successful in about two-thirds of cases, but relapses after treatment are common; long-term benefit is demonstrated in about half of all patients. Those who do not respond favorably generally have active but stable disease. Surgical resection is an alternative for the patient with progressive disease that responds poorly to chemotherapy; the success rate with surgical therapy is good. Disease caused by *M kansasii* responds well to drug therapy. A daily regimen of rifampin, isoniazid, and ethambutol for at least 18 months with a minimum of 12 months of negative cultures is usually successful. Rapidly growing mycobacteria (*M abscessus*, *M fortuitum*, *M chelonae*) are generally resistant to standard antituberculous therapy.

► When to Refer

Patients with rapidly growing mycobacteria infection should be referred for expert management.

Table 9–18. Recommended dosages for the initial treatment of tuberculosis.

Drugs	Daily	Cost ¹	Twice a Week ²	Cost ¹ /wk	Three Times a Week ²	Cost ¹ /wk
Isoniazid	5 mg/kg Max: 300 mg/dose	\$0.13/300 mg	15 mg/kg Max: 900 mg/dose	\$0.78	15 mg/kg Max: 900 mg/dose	\$1.17
Rifampin	10 mg/kg Max: 600 mg/dose	\$5.15/600 mg	10 mg/kg Max: 600 mg/dose	\$10.30	10 mg/kg Max: 600 mg/dose	\$15.45

PULMONARY NEOPLASMS

See Chapter 39 for discussions of Lung Cancer, Secondary Lung Cancer, and Mesothelioma.

SCREENING FOR LUNG CANCER

Two large, randomized controlled trials reported findings in 2011 that clarify the utility of lung cancer screening. The Prostate, Lung, Colorectal and Ovarian Randomized Trial (PLCO) randomized 154,901 adults (52% current or former smokers) between the ages of 55 and 74 years to receive either no screening or annual posterior-anterior chest radiographs for 4 consecutive years. The investigators monitored the participants after screening for an average of 12 years. Results showed no mortality benefit from four annual chest radiographs either in the whole cohort or in a subset of heavy smokers who met the entry criteria for the other major trial, the National Lung Screening Trial (NLST). The NLST enrolled 53,454 current or former smokers (minimum 30-pack year exposure history) between the ages of 55 and 74 years who were randomly assigned to one of two screening modalities: three annual posterior-anterior chest radiographs or three annual low-dose chest CT scans. They were monitored for an additional 6.5 years after screening. Compared with chest

radiography, low-dose chest CT detected more early-stage lung cancers and fewer advanced-stage lung cancers, indicating that CT screening systematically shifted the time of diagnosis to earlier stages, thereby providing more persons the opportunity for effective treatment. Furthermore, compared with chest radiographs, the cohort that received three annual CT scans had a statistically significant mortality benefit, with reductions in both lung cancer deaths (20.0%) and all-cause mortality (6.7%). This is the first time that evidence from a randomized, controlled trial demonstrated that lung cancer screening reduces all-cause mortality.

Additional information from PLCO, the NLST, and multiple other ongoing randomized trials are expected over the next few years. Salient issues that temper enthusiasm for widespread screening at this time include the following: (1) **Generalizability to community practice:** NLST-participating institutions demonstrated a high level of expertise in imaging interpretation and diagnostic evaluation. Ninety-six percent of findings on CT were false positives but the vast majority of patients were monitored with serial imaging. Invasive diagnostic evaluations were uncommon and were associated with a low complication rate (1.4%). (2) **Duration of screening:** The rate of detection of new lung cancers did not fall with each subsequent annual screening over 3 years. Since each year lung cancers first become detectable during that screening interval, the optimal number of annual CT scans is unknown as is the optimal screening interval. (3) **Overdiagnosis:** After 6.5 years of post-screening observation, there were more lung cancers in the NLST CT cohort than the chest radiography cohort (1060 and 941, respectively). Since the groups were randomized and well matched, lung cancer incidence should have been identical. Therefore, 11% of the lung cancers detected by CT remained clinically silent and invisible on chest radiograph for 6.5 years. Many, perhaps most, of these lung cancers will never cause clinical disease and represent overdiagnosis. (4) **Cost effectiveness:**

The number needed to screen with three annual chest CT scans to prevent one death from lung cancer was 320.

Clear evidence exists showing the benefit of screening with low-dose chest CT in high-risk individuals, and there is no evidence of benefit in a mixed population screened with chest radiography. The role of lung cancer screening will be an area of intense research interest for the coming several years.

SOLITARY PULMONARY NODULE

A solitary pulmonary nodule, sometimes referred to as a “coin lesion,” is a < 3 cm isolated, rounded opacity on chest imaging outlined by normal lung and not associated with infiltrate, atelectasis, or adenopathy. Most are asymptomatic and represent an unexpected finding on chest radiography or CT scanning. The finding is important because it carries a significant risk of malignancy. The frequency of malignancy in surgical series ranges from 10% to 68% depending on patient population. Most benign nodules are infectious granulomas. **Benign neoplasms** such as hamartomas account for less than 5% of solitary nodules.

The goals of evaluation are to identify and resect malignant tumors in patients who will benefit from resection while avoiding invasive procedures in benign disease. The task is to identify nodules with a sufficiently high probability of malignancy to warrant biopsy or resection or a sufficiently low probability of malignancy to justify observation.

Symptoms alone rarely establish the cause, but clinical and imaging data can be used to assess the probability of malignancy. Malignant nodules are rare in persons under age 30. Above age 30, the likelihood of malignancy increases with age. Smokers are at increased risk, and the likelihood of malignancy increases with the number of cigarettes smoked daily. Patients with a prior malignancy have a higher likelihood of having a malignant solitary nodule.

The first and most important step in the imaging evaluation is to review old imaging studies. Comparison with prior studies allows estimation of doubling time, which is an important marker for malignancy. Rapid progression (doubling time less than 30 days) suggests infection while long-term stability (doubling time greater than 465 days) suggests benignity. Certain radiographic features help in estimating the probability of malignancy. Size is correlated with malignancy. A study of solitary nodules identified by CT scan showed a 1% malignancy rate in those measuring 2–5 mm, 24% in 6–10 mm, 33% in 11–20 mm, and 80% in 21–45 mm. The appearance of a smooth, well-defined edge is characteristic of a benign process. Ill-defined margins or a lobular appearance suggest malignancy. A high-resolution CT finding of spiculated margins and a peripheral

halo are both highly associated with malignancy. Calcification and its pattern are also helpful clues. Benign lesions tend to have dense calcification in a central or laminated pattern. Malignant lesions are associated with sparser calcification that is typically stippled or eccentric. Cavitory lesions with thick (> 16 mm) walls are much more likely to be malignant. High-resolution CT offers better resolution of these characteristics than chest radiography and is more likely to detect lymphadenopathy or the presence of multiple lesions. Chest CT is indicated in any suspicious solitary pulmonary nodule.

Treatment

Based on clinical and radiologic data, the clinician should assign a specific probability of malignancy to the lesion. The decision whether to recommend a biopsy or surgical excision depends on the interpretation of this probability in light of the patient’s unique clinical situation. The probabilities in parentheses below represent guidelines only and should not be interpreted as prescriptive.

In the case of solitary pulmonary nodules, a continuous probability function may be grouped into three categories. In patients with a **low probability (< 5%) of malignancy** (eg, age under 30, lesions stable for more than 2 years, characteristic pattern of benign calcification), watchful waiting is appropriate. Management consists of serial imaging studies (CT scans or chest radiographs) at intervals that identify growth suggestive of malignancy. Three-dimensional reconstruction of high-resolution CT images provides a more sensitive test for growth.

Patients with a **high probability (> 60%) of malignancy** should proceed directly to resection following staging, provided the surgical risk is acceptable. Biopsies rarely yield a specific benign diagnosis and are not indicated.

Optimal management of patients with an **intermediate probability of malignancy (5–60%)** remains controversial. The traditional approach is to obtain a diagnostic biopsy either through transthoracic needle aspiration (TTNA) or bronchoscopy. Bronchoscopy yields a diagnosis in 10–80% of procedures depending on the size of the nodule and its location. In general, the bronchoscopic yield for nodules that are < 2 cm and peripheral is low, although complications are generally rare. Newer bronchoscopic modalities such as electromagnetic navigation and ultrathin bronchoscopy are being studied, although their impact upon diagnostic yield remains uncertain. TTNA has a higher diagnostic yield, reported to be between 50% and 97%. The yield is strongly operator-dependent, however, and is affected by the location and size of the lesion. Complications are higher than bronchoscopy, with pneumothorax occurring in up to 30% of patients, with up to one-third of these patients requiring placement of a chest tube.

Disappointing diagnostic yields and a high false-negative rate (up to 20–30% in TTNA) have prompted alternative approaches. **Positron emission tomography (PET)** detects increased glucose metabolism within malignant lesions with high sensitivity (85–97%) and specificity (70–85%). Many diagnostic algorithms have incorporated PET into the assessment of patients with inconclusive

high-resolution CT findings. A positive PET increases the likelihood of malignancy, and a negative PET correctly excludes cancer in most cases. False-negative PET scans can occur with tumors with low metabolic activity (well-differentiated adenocarcinomas, carcinoids, and bronchioalveolar tumors), and follow-up CT imaging is typically performed at discrete intervals to ensure absence of growth. PET has several drawbacks, however: resolution below 1 cm is poor, the test is expensive, and availability remains limited.

Sputum cytology is highly specific but lacks sensitivity. It is used in central lesions and in patients who are poor candidates for invasive diagnostic procedures. Researchers have attempted to improve the sensitivity of sputum cytology through the use of monoclonal antibodies to proteins that are up-regulated in pulmonary malignancies. Such tests offer promise but remain research tools at this time.

Some centers recommend **video-assisted thoracoscopic surgery (VATS)** resection of all solitary pulmonary nodules with intermediate probability of malignancy. In some cases, the surgeon will remove the nodule and evaluate it in the operating room with frozen section. If the nodule is malignant, he or she will proceed to lobectomy and lymph node sampling, either thoracoscopically or through conversion to standard thoracotomy. This approach is less common when PET scanning is available.

All patients should be provided with an estimate of the likelihood of malignancy, and their preferences should be used to help guide diagnostic and therapeutic decisions. A strategy that recommends observation may not be preferred by a patient who desires a definitive diagnosis. Similarly, a surgical approach may not be agreeable to all patients unless the presence of cancer is definitive. Patient preferences should be elicited, and patients should be well informed regarding the specific risks and benefits associated with the recommended approach as well as the alternative strategies.

RIGHT MIDDLE LOBE SYNDROME

Right middle lobe syndrome is recurrent or persistent atelectasis of the right middle lobe. This collapse is related to the relatively long length and narrow diameter of the right middle lobe bronchus and the oval (“fish mouth”) opening to the lobe, in the setting of impaired collateral ventilation. Fiberoptic bronchoscopy or CT scan is often necessary to rule out obstructing tumor. Foreign body or other benign causes are common.

BRONCHIAL CARCINOID TUMORS

Carcinoid and bronchial gland tumors are sometimes termed “bronchial adenomas.” This term should be avoided because it implies that the lesions are benign when, in fact, carcinoid tumors and bronchial gland carcinomas are low-grade malignant neoplasms.

Carcinoid tumors are about six times more common than bronchial gland carcinomas, and most of them occur as pedunculated or sessile growths in central bronchi. Men and women are equally affected. Most patients are under 60 years of age. Common symptoms of bronchial carcinoid tumors are hemoptysis, cough, focal wheezing, and recurrent pneumonia. Peripherally located bronchial carcinoid tumors are rare and present as asymptomatic solitary pulmonary nodules. **Carcinoid syndrome** (flushing, diarrhea, wheezing, hypotension) is rare. Fiberoptic bronchoscopy may reveal a pink or purple tumor in a central airway. These lesions have a well-vascularized stroma, and biopsy may be complicated by significant bleeding. CT scanning is helpful to localize the lesion and to follow its growth over time. Octreotide scintigraphy is also available for localization of these tumors.

Bronchial carcinoid tumors grow slowly and rarely metastasize. Complications involve bleeding and airway obstruction rather than invasion by tumor and metastases. Surgical excision of clinically symptomatic lesions is often necessary, and the prognosis is generally favorable. Most bronchial carcinoid tumors are resistant to radiation and chemotherapy (see Chapter 39).

MEDIASTINAL MASSES

Various developmental, neoplastic, infectious, traumatic, and cardiovascular disorders may cause masses that appear in the mediastinum on chest radiograph. A useful convention arbitrarily divides the mediastinum into three compartments—anterior, middle, and posterior—in order to classify mediastinal masses and assist in differential diagnosis. Specific mediastinal masses have a predilection for one or more of these compartments; most are located in the anterior or middle compartment. The differential diagnosis of an **anterior mediastinal mass** includes thymoma, teratoma, thyroid lesions, lymphoma, and mesenchymal tumors (lipoma, fibroma). The differential diagnosis of a **middle mediastinal mass** includes lymphadenopathy,

pulmonary artery enlargement, aneurysm of the aorta or innominate artery, developmental cyst (bronchogenic, enteric, pleuropericardial), dilated azygous or hemiazygous vein, and foramen of Morgagni hernia. The differential diagnosis of a **posterior mediastinal mass** includes hiatal hernia, neurogenic tumor, meningocele, esophageal tumor, foramen of Bochdalek hernia, thoracic spine disease, and extramedullary hematopoiesis. The neurogenic tumor group includes neurilemmoma, neurofibroma, neurosarcoma, ganglioneuroma, and pheochromocytoma.

Symptoms and signs of mediastinal masses are nonspecific and are usually caused by the effects of the mass on surrounding structures. Insidious onset of retrosternal chest pain, dysphagia, or dyspnea is often an important clue to the presence of a mediastinal mass. In about half of cases, symptoms are absent, and the mass is detected on routine chest radiograph. Physical findings vary depending on the nature and location of the mass.

CT scanning is helpful in management; additional radiographic studies of benefit include barium swallow if esophageal disease is suspected, Doppler sonography or venography of brachiocephalic veins and the superior vena cava, and angiography. MRI is useful; its advantages include better delineation of hilar structures and distinction between vessels and masses. MRI also allows imaging in multiple planes, whereas CT permits only axial imaging. Tissue diagnosis is necessary if a neoplastic disorder is suspected. Treatment and prognosis depend on the underlying cause of the mediastinal mass.

INTERSTITIAL LUNG DISEASE (DIFFUSE PARENCHYMAL LUNG DISEASE)

ESSENTIALS OF DIAGNOSIS

- ▶ Insidious onset of progressive dyspnea and non-productive chronic cough; extrapulmonary findings may accompany specific diagnoses.
- ▶ Tachypnea, small lung volumes, bibasilar dry rales; digital clubbing and right heart failure with advanced disease.
- ▶ Chest radiographs with low lung volumes and patchy distribution of ground glass, reticular, nodular, reticulonodular, or cystic opacities.
- ▶ Reduced lung volumes, pulmonary diffusing capacity and 6-minute walk distance; hypoxemia with exercise.

Interstitial lung disease, or diffuse parenchymal lung disease, comprises a heterogeneous group of disorders that share common presentations (dyspnea), physical findings (late inspiratory crackles), and chest radiographs (septal thickening and reticulonodular changes).

The term “interstitial” is misleading since the pathologic process usually begins with injury to the alveolar epithelial or capillary endothelial cells (alveolitis). Persistent alveolitis may lead to obliteration of alveolar capillaries and reorganization of the lung parenchyma, accompanied by irreversible fibrosis. The process does not affect the airways proximal to the respiratory bronchioles. At least 180 disease entities may present as interstitial lung disease. Table 9–19 outlines a selected list of differential diagnoses of

Table 9–19. Differential diagnosis of interstitial lung disease.

Drug-related

Antiarrhythmic agents (amiodarone)
 Antibacterial agents (nitrofurantoin, sulfonamides)
 Antineoplastic agents (bleomycin, cyclophosphamide, methotrexate, nitrosoureas)
 Antirheumatic agents (gold salts, penicillamine)
 Phenytoin

Environmental and occupational (inhalation exposures)

Dust, inorganic (asbestos, silica, hard metals, beryllium)
 Dust, organic (thermophilic actinomycetes, avian antigens, *Aspergillus* species)
 Gases, fumes, and vapors (chlorine, isocyanates, paraquat, sulfur dioxide)
 Ionizing radiation
 Talc (injection drug users)

Infections

Fungus, disseminated (*Coccidioides immitis*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*)
 Mycobacteria, disseminated
Pneumocystis jirovecii
 Viruses

Primary pulmonary disorders

Cryptogenic organizing pneumonia (COP)
 Idiopathic interstitial pneumonia: Acute interstitial pneumonia, desquamative interstitial pneumonia, nonspecific interstitial pneumonia, usual interstitial pneumonia, respiratory bronchiolitis-associated interstitial lung disease
 Pulmonary alveolar proteinosis

Systemic disorders

Acute respiratory distress syndrome
 Amyloidosis
 Ankylosing spondylitis
 Autoimmune disease: Dermatomyositis, polymyositis, rheumatoid arthritis, systemic sclerosis (scleroderma), systemic lupus erythematosus
 Chronic eosinophilic pneumonia
 Goodpasture syndrome
 Idiopathic pulmonary hemosiderosis
 Inflammatory bowel disease
 Langerhans cell histiocytosis (eosinophilic granuloma)
 Lymphangitic spread of cancer (lymphangitic carcinomatosis)
 Lymphangioleiomyomatosis
 Pulmonary edema
 Pulmonary venous hypertension, chronic
 Sarcoidosis
 Granulomatosis polyangiitis [formerly Wegener granulomatosis]

interstitial lung disease. In most patients, no specific cause can be identified. In the remainder, drugs and a variety of organic and inorganic dusts are the principal causes. The history—particularly the occupational and medication history—may provide evidence of a specific cause.

The connective tissue diseases are a group of immunologically mediated inflammatory disorders including rheumatoid arthritis, systemic lupus erythematosus, scleroderma, polymyositis-dermatomyositis, Sjögren syndrome, and other overlap conditions. The presence of diffuse parenchymal lung disease in the setting of an established connective tissue disease is suggestive of the etiology. In some cases, lung disease precedes the more typical manifestations of the underlying connective tissue disease by months or years.

Known causes of interstitial lung disease are dealt with in their specific sections. The important idiopathic forms are discussed below.

IDIOPATHIC INTERSTITIAL PNEUMONIAS

ESSENTIALS OF DIAGNOSIS

- ▶ Important to identify specific fibrosing disorders.
- ▶ Idiopathic disease may require biopsy for diagnosis.
- ▶ Accurate diagnosis identifies patients most likely to benefit from therapy.

▶ General Considerations

The most common diagnosis among patients with interstitial lung disease is idiopathic interstitial pneumonia. Historically, this diagnosis was based on clinical and radiographic criteria with only a small number of patients undergoing surgical lung biopsy. When biopsies were obtained, the common element of fibrosis led to the grouping together of several histologic patterns under the category of idiopathic interstitial pneumonia. These distinct histopathologic features are now recognized as being associated with different natural histories and responses to therapy (see Table 9–20). Therefore, in the evaluation of patients with interstitial lung disease, clinicians should attempt to identify specific disorders.

Patients with idiopathic interstitial pneumonia may have any of the histologic patterns described in Table 9–20. The first step in evaluation is to identify patients whose disease is truly idiopathic. As indicated in Table 9–19, most identifiable causes of interstitial lung disease are infectious, drug-related, or environmental or occupational agents. Interstitial lung diseases associated with other medical conditions (pulmonary-renal syndromes, collagen-vascular disease) may be identified through a careful medical history. Apart from acute interstitial pneumonia, the clinical presentations of the idiopathic interstitial pneumonias are sufficiently similar to preclude a specific diagnosis. Chest radiographs and high-resolution CT scans are occasionally diagnostic. Ultimately, many patients with apparently idiopathic disease require surgical lung biopsy to make a

definitive diagnosis. The importance of accurate diagnosis is twofold. First, it allows the clinician to provide accurate information about the cause and natural history of the illness. Second, accurate diagnosis helps distinguish patients most likely to benefit from therapy.

▶ Clinical Findings

A. Symptoms, Signs, and Imaging

The diagnosis of usual interstitial pneumonia (UIP) can be made on clinical grounds alone in selected patients (Table 9–20). A diagnosis of UIP can be made with 90% confidence in patients over 65 years of age who have (1) idiopathic disease by history and who demonstrate inspiratory crackles on physical examination; (2) restrictive physiology on pulmonary function testing; (3) characteristic radiographic evidence of progressive fibrosis over several years; and (4) diffuse, patchy fibrosis with pleural-based honeycombing on high-resolution CT scan. Such patients do not need surgical lung biopsy.

B. Special Studies

Three diagnostic techniques are in common use: bronchoalveolar lavage, transbronchial biopsy, and surgical lung biopsy, either through an open procedure or using VATS.

Bronchoalveolar lavage may provide a specific diagnosis in cases of infection, particularly with *P jiroveci* or mycobacteria, or when cytologic examination reveals the presence of malignant cells. The findings may be suggestive and sometimes diagnostic of eosinophilic pneumonia, Langerhans cell histiocytosis, or alveolar proteinosis. Analysis of the cellular constituents of lavage fluid may suggest a specific disease, but these findings are not diagnostic.

Transbronchial biopsy through the flexible bronchoscope is easily performed in most patients. The risks of pneumothorax (5%) and hemorrhage (1–10%) are low. However, the tissue specimens recovered are small, sampling error is common, and crush artifact may complicate diagnosis. Transbronchial biopsy can make a definitive diagnosis of sarcoidosis, lymphangitic spread of carcinoma, pulmonary alveolar proteinosis, miliary tuberculosis, and Langerhans cell histiocytosis. Note that the diagnosis of UIP cannot be confirmed on transbronchial lung biopsy since the histologic diagnosis requires a pattern of changes rather than a single pathognomonic finding. Transbronchial biopsy may exclude UIP by confirming a specific alternative diagnosis. Transbronchial biopsy also cannot establish a specific diagnosis of idiopathic interstitial pneumonia. These patients generally require surgical lung biopsy.

Surgical lung biopsy is the standard for diagnosis of interstitial lung disease. Two or three biopsies taken from multiple sites in the same lung, including apparently normal tissue, may yield a specific diagnosis as well as prognostic information regarding the extent of fibrosis versus active inflammation. Patients under age 60 without a specific diagnosis generally should undergo surgical lung biopsy. In older and sicker patients, the risks and benefits must be weighed carefully for three reasons: (1) the morbidity

Table 9–20. Idiopathic interstitial pneumonias.

Name and Clinical Presentation	Histopathology	Radiographic Pattern	Response to Therapy and Prognosis
<p>Usual interstitial pneumonia (UIP) Age 55–60, slight male predominance. Insidious dry cough and dyspnea lasting months to years. Clubbing present at diagnosis in 25–50%. Diffuse fine late inspiratory crackles on lung auscultation. Restrictive ventilatory defect and reduced diffusing capacity on pulmonary function tests. ANA and RF positive in ~25% in the absence of documented collagen-vascular disease.</p>	<p>Patchy, temporally and geographically nonuniform distribution of fibrosis, honeycomb change, and normal lung. Type I pneumocytes are lost, and there is proliferation of alveolar type II cells. “Fibroblast foci” of actively proliferating fibroblasts and myofibroblasts. Inflammation is generally mild and consists of small lymphocytes. Intra-alveolar macrophage accumulation is present but is not a prominent feature.</p>	<p>Diminished lung volume. Increased linear or reticular bibasilar and subpleural opacities. Unilateral disease is rare. High-resolution CT scanning shows minimal ground-glass and variable honeycomb change. Areas of normal lung may be adjacent to areas of advanced fibrosis. Between 2% and 10% have normal chest radiographs and high-resolution CT scans on diagnosis.</p>	<p>No randomized study has demonstrated improved survival compared with untreated patients. Inexorably progressive. Response to corticosteroids and cytotoxic agents at best 15%, and these probably represent misclassification of histopathology. Median survival approximately 3 years, depending on stage at presentation. Current interest in antifibrotic agents.</p>
<p>Respiratory bronchiolitis-associated interstitial lung disease (RB-ILD)¹ Age 40–45. Presentation similar to that of UIP though in younger patients. Similar results on pulmonary function tests, but less severe abnormalities. Patients with respiratory bronchiolitis are invariably heavy smokers.</p>	<p>Increased numbers of macrophages evenly dispersed within the alveolar spaces. Rare fibroblast foci, little fibrosis, minimal honeycomb change. In RB-ILD the accumulation of macrophages is localized within the peribronchiolar air spaces; in DIP¹, it is diffuse. Alveolar architecture is preserved.</p>	<p>May be indistinguishable from UIP. More often presents with a nodular or reticulonodular pattern. Honeycombing rare. High-resolution CT more likely to reveal diffuse ground-glass opacities and upper lobe emphysema.</p>	<p>Spontaneous remission occurs in up to 20% of patients, so natural history unclear. Smoking cessation is essential. Prognosis clearly better than that of UIP: median survival greater than 10 years. Corticosteroids thought to be effective, but there are no randomized clinical trials to support this view.</p>
<p>Acute interstitial pneumonia (AIP) Clinically known as Hamman-Rich syndrome. Wide age range, many young patients. Acute onset of dyspnea followed by rapid development of respiratory failure. Half of patients report a viral syndrome preceding lung disease. Clinical course indistinguishable from that of idiopathic ARDS.</p>	<p>Pathologic changes reflect acute response to injury within days to weeks. Resembles organizing phase of diffuse alveolar damage. Fibrosis and minimal collagen deposition. May appear similar to UIP but more homogeneous and there is no honeycomb change—though this may appear if the process persists for more than a month in a patient on mechanical ventilation.</p>	<p>Diffuse bilateral airspace consolidation with areas of ground-glass attenuation on high-resolution CT scan.</p>	<p>Supportive care (mechanical ventilation) critical but effect of specific therapies unclear. High initial mortality: Fifty to 90 percent die within 2 months after diagnosis. Not progressive if patient survives. Lung function may return to normal or may be permanently impaired.</p>
<p>Nonspecific interstitial pneumonia (NSIP) Age 45–55. Slight female predominance. Similar to UIP but onset of cough and dyspnea over months, not years.</p>	<p>Nonspecific in that histopathology does not fit into better-established categories. Varying degrees of inflammation and fibrosis, patchy in distribution but uniform in time, suggesting response to single injury. Most have lymphocytic and plasma cell inflammation without fibrosis. Honeycombing present but scant. Some have advocated division into cellular and fibrotic subtypes.</p>	<p>May be indistinguishable from UIP. Most typical picture is bilateral areas of ground-glass attenuation and fibrosis on high-resolution CT. Honeycombing is rare.</p>	<p>Treatment thought to be effective, but no prospective clinical studies have been published. Prognosis overall good but depends on the extent of fibrosis at diagnosis. Median survival greater than 10 years.</p>
<p>Cryptogenic organizing pneumonia (COP, formerly bronchiolitis obliterans organizing pneumonia [BOOP]) Typically age 50–60 but wide variation. Abrupt onset, frequently weeks to a few months following a flu-like illness. Dyspnea and dry cough prominent, but constitutional symptoms are common: fatigue, fever, and weight loss. Pulmonary function tests usually show restriction, but up to 25% show concomitant obstruction.</p>	<p>Included in the idiopathic interstitial pneumonias on clinical grounds. Buds of loose connective tissue (Masson bodies) and inflammatory cells fill alveoli and distal bronchioles.</p>	<p>Lung volumes normal. Chest radiograph typically shows interstitial and parenchymal disease with discrete, peripheral alveolar and ground-glass infiltrates. Nodular opacities common. High-resolution CT shows subpleural consolidation and bronchial wall thickening and dilation.</p>	<p>Rapid response to corticosteroids in two-thirds of patients. Long-term prognosis generally good for those who respond. Relapses are common.</p>

¹Includes desquamative interstitial pneumonia (DIP).

ANA, antinuclear antibody; ARDS, acute respiratory distress syndrome; RF, rheumatoid factor; UIP, usual interstitial pneumonia.

of the procedure can be significant; (2) a definitive diagnosis may not be possible even with surgical lung biopsy; and (3) when a specific diagnosis is made, there may be no effective treatment. Empiric therapy or no treatment may be preferable to surgical lung biopsy in some patients.

► Treatment

Treatment of idiopathic interstitial pneumonia is controversial. No randomized study has demonstrated that any treatment improves survival or quality of life compared with no treatment. Clinical experience suggests that patients with RB-ILD, nonspecific interstitial pneumonia (NSIP), or COP (see Table 9–20) frequently respond to corticosteroids and should be given a trial of therapy—typically prednisone, 1–2 mg/kg/d for a minimum of 2 months. The same therapy is almost uniformly ineffective in patients with UIP. Since this therapy carries significant morbidity, experts do not recommend routine use of corticosteroids in patients with UIP. A number of antifibrotic (pirfenidone, interferon gamma 1b) and immunomodulator/immunosuppressant (cyclosporine A, azathioprine, etanercept) agents have been investigated and none of them are recommended for the treatment of UIP in monotherapy or combination therapy. While the use of imatinib mesylate, a tyrosine kinase inhibitor, did not show any benefits, other tyrosine kinase inhibitors are under clinical trial. The only definitive treatment for UIP is lung transplantation, with a 5-year survival rate estimated at 50%.

SARCOIDOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Symptoms related to the lung, skin, eyes, peripheral nerves, liver, kidney, heart, and other tissues.
- ▶ Demonstration of noncaseating granulomas in a biopsy specimen.
- ▶ Exclusion of other granulomatous disorders.

► General Considerations

Sarcoidosis is a systemic disease of unknown etiology characterized in about 90% of patients by granulomatous inflammation of the lung. The incidence is highest in North American blacks and northern European whites; among blacks, women are more frequently affected than men. Onset of disease is usually in the third or fourth decade.

► Clinical Findings

A. Symptoms and Signs

Patients may have malaise, fever, and dyspnea of insidious onset. Symptoms from skin involvement (erythema, lupus pernio [Figure 9–6]), iritis, peripheral neuropathy, arthritis (see Chapter 20), or cardiomyopathy may also cause the patient to seek care. Some individuals are asymptomatic and come to medical attention after abnormal findings (typically bilateral hilar and right paratracheal lymphadenopathy) on chest radiographs. Physical findings are atypical of interstitial lung disease in that crackles are uncommon on chest examination. Other symptoms and findings may include parotid gland enlargement, hepatosplenomegaly, and lymphadenopathy.

B. Laboratory Findings

Laboratory tests may show leukopenia, an elevated erythrocyte sedimentation rate, and hypercalcemia (about 5% of patients) or hypercalciuria (20%). Angiotensin-converting enzyme (ACE) levels are elevated in 40–80% of patients with active disease. This finding is neither sensitive nor specific enough to have diagnostic significance. Physiologic testing may reveal evidence of airflow obstruction, but restrictive changes with decreased lung volumes and diffusing capacity are more common. Skin test anergy is present in 70%. ECG may show conduction disturbances and dysrhythmias.

C. Imaging

Radiographic findings are variable and include bilateral hilar adenopathy alone (radiographic stage I), hilar adenopathy

▲ **Figure 9–6.** Skin involvement in sarcoidosis (lupus pernio), here involving the nasal rim. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine.* McGraw-Hill, 2009.)

and parenchymal involvement (radiographic stage II), or parenchymal involvement alone (radiographic stage III). Parenchymal involvement is usually manifested radiographically by diffuse reticular infiltrates, but focal infiltrates, acinar shadows, nodules and, rarely, cavitation may be seen. Pleural effusion is noted in fewer than 10% of patients.

D. Special Examinations

The diagnosis of sarcoidosis generally requires histologic demonstration of noncaseating granulomas in biopsies from a patient with other typical associated manifestations. Other granulomatous diseases (eg, berylliosis, tuberculosis, fungal infections) and lymphoma must be excluded. Biopsy of easily accessible sites (eg, palpable lymph nodes, skin lesions, or salivary glands) is likely to be positive. Transbronchial lung biopsy has a high yield (75–90%) as well, especially in patients with radiographic evidence of parenchymal involvement. Some clinicians believe that tissue biopsy is not necessary when stage I radiographic findings are detected in a clinical situation that strongly favors the diagnosis of sarcoidosis (eg, a young black woman with erythema nodosum). Biopsy is essential whenever clinical and radiographic findings suggest the possibility of an alternative diagnosis such as lymphoma. Bronchoalveolar lavage fluid in sarcoidosis is usually characterized by an increase in lymphocytes and a high CD4/CD8 cell ratio. Bronchoalveolar lavage does not establish a diagnosis but may be useful in following the activity of sarcoidosis in selected patients. All patients require a complete ophthalmologic evaluation.

► Treatment

Indications for treatment with oral corticosteroids (prednisone, 0.5–1.0 mg/kg/d) include disabling constitutional symptoms, hypercalcemia, iritis, uveitis, arthritis, central nervous system involvement, cardiac involvement, granulomatous hepatitis, cutaneous lesions other than erythema nodosum, and progressive pulmonary lesions. Long-term therapy is usually required over months to years. Serum ACE levels usually fall with clinical improvement. Immunosuppressive drugs and cyclosporine have been tried, primarily when corticosteroid therapy has been exhausted, but experience with these drugs is limited.

► Prognosis

The outlook is best for patients with hilar adenopathy alone; radiographic involvement of the lung parenchyma is associated with a worse prognosis. Erythema nodosum portends a good outcome. About 20% of patients with lung involvement suffer irreversible lung impairment, characterized by progressive fibrosis, bronchiectasis, and cavitation. Pneumothorax, hemoptysis, mycetoma formation in lung cavities, and respiratory failure often complicate this advanced stage. Myocardial sarcoidosis occurs in about 5% of patients, sometimes leading to restrictive cardiomyopathy, cardiac dysrhythmias, and conduction disturbances. Death from pulmonary insufficiency occurs in about 5% of patients.

Patients require long-term follow-up; at a minimum, yearly physical examination, pulmonary function tests, chemistry panel, ophthalmologic evaluation, chest radiograph, and ECG.

PULMONARY ALVEOLAR PROTEINOSIS

Pulmonary alveolar proteinosis is a rare disease in which phospholipids accumulate within alveolar spaces. The condition may be primary (idiopathic) or secondary (occurring in immune deficiency; hematologic malignancies; inhalation of mineral dusts; or following lung infections, including tuberculosis and viral infections). Progressive dyspnea is the usual presenting symptom, and chest radiograph shows bilateral alveolar infiltrates suggestive of pulmonary edema. The diagnosis is based on demonstration of characteristic findings on bronchoalveolar lavage (milky appearance and PAS-positive lipoproteinaceous material) in association with typical clinical and radiographic features. In some cases, transbronchial or surgical lung biopsy (revealing amorphous intra-alveolar phospholipid) is necessary.

The course of the disease varies. Some patients experience spontaneous remission; others develop progressive respiratory insufficiency. Pulmonary infection with nocardia or fungi may occur. Therapy for alveolar proteinosis consists of periodic whole lung lavage.

EOSINOPHILIC PULMONARY SYNDROMES

Eosinophilic pulmonary syndromes are a diverse group of disorders typically characterized by eosinophilic pulmonary infiltrates, dyspnea, and cough. Many patients have constitutional symptoms, including fever. Common causes include exposure to medications (nitrofurantoin, phenytoin, ampicillin, acetaminophen, ranitidine) or infection with helminths (eg, *Ascaris*, hookworms, *Strongyloides*) or filariae (eg, *Wuchereria bancrofti*, *Brugia malayi*, tropical pulmonary eosinophilia). **Löffler syndrome** refers to acute eosinophilic pulmonary infiltrates in response to transpulmonary passage of helminth larvae. Pulmonary eosinophilia can also be a feature of other illnesses, including ABPA, Churg-Strauss syndrome, systemic hypereosinophilic syndromes, eosinophilic granuloma of the lung (properly referred to as pulmonary Langerhans cell histiocytosis), neoplasms, and numerous interstitial lung diseases. If an

extrinsic cause is identified, therapy consists of removal of the offending drug or treatment of the underlying parasitic infection.

One-third of cases are idiopathic, and there are two common syndromes. **Chronic eosinophilic pneumonia** is seen predominantly in women and is characterized by fever, night sweats, weight loss, and dyspnea. Asthma is present in half of cases. Chest radiographs often show peripheral infiltrates, the “photographic negative” of pulmonary edema. Bronchoalveolar lavage typically has a marked eosinophilia; peripheral blood eosinophilia is present in greater than 80%. Therapy with oral prednisone (1 mg/kg/d for 1–2 weeks followed by a gradual taper over many months) usually results in dramatic improvement; however, most patients require at least 10–15 mg of prednisone every other day for a year or more (sometimes indefinitely) to prevent relapses. **Acute eosinophilic pneumonia** is an acute, febrile illness characterized by cough and dyspnea, sometimes rapidly progressing to respiratory failure. The chest radiograph is abnormal but nonspecific. Bronchoalveolar lavage frequently shows eosinophilia but peripheral blood eosinophilia is rare at the onset of symptoms. The response to corticosteroids is usually dramatic.

DISORDERS OF THE PULMONARY CIRCULATION

PULMONARY VENOUS THROMBOEMBOLISM

ESSENTIALS OF DIAGNOSIS

- ▶ Predisposition to venous thrombosis, usually of the lower extremities.
- ▶ One or more of the following: dyspnea, chest pain, hemoptysis, syncope.
- ▶ Tachypnea and a widened alveolar-arterial P_{O_2} difference.
- ▶ Elevated rapid D-dimer and characteristic defects on CT arteriogram of the chest, ventilation-perfusion lung scan, or pulmonary angiogram.

▶ General Considerations

Pulmonary venous thromboembolism, often referred to as pulmonary embolism (PE), is a common, serious, and potentially fatal complication of thrombus formation within the deep venous circulation. PE is the third leading cause of death among hospitalized patients. Despite this prevalence, most cases are not recognized antemortem, and less than 10% of

patients with fatal emboli have received specific treatment for the condition. Management demands a vigilant systematic approach to diagnosis and an understanding of risk factors so that appropriate preventive therapy can be given.

Many substances can embolize to the pulmonary circulation, including air (during neurosurgery, from central venous catheters), amniotic fluid (during active labor), fat (long bone fractures), foreign bodies (talc in injection drug users), parasite eggs (schistosomiasis), septic emboli (acute infectious endocarditis), and tumor cells (renal cell carcinoma). The most common embolus is thrombus, which may arise anywhere in the venous circulation or heart but most often originates in the deep veins of the lower extremities. Thrombi confined to the calf rarely embolize to the pulmonary circulation. However, about 20% of calf vein thrombi propagate proximally to the popliteal and iliofemoral veins, at which point they may break off and embolize to the pulmonary circulation. Pulmonary emboli will develop in 50–60% of patients with proximal deep venous thrombosis (DVT); half of these embolic events will be asymptomatic. Approximately 50–70% of patients who have symptomatic pulmonary emboli will have lower extremity DVT when evaluated.

PE and DVT are two manifestations of the same disease. The risk factors for PE are the risk factors for thrombus formation within the venous circulation: venous stasis, injury to the vessel wall, and hypercoagulability (Virchow triad). Venous stasis increases with immobility (bed rest—especially postoperative—obesity, stroke), hyperviscosity (polycythemia), and increased central venous pressures (low cardiac output states, pregnancy). Vessels may be damaged by prior episodes of thrombosis, orthopedic surgery, or trauma. Hypercoagulability can be caused by medications (oral contraceptives, hormonal replacement therapy) or disease (malignancy, surgery) or may be the result of inherited gene defects. The most common inherited cause in white populations is resistance to activated protein C, also known as factor V Leiden. The trait is present in approximately 3% of healthy American men and in 20–40% of patients with idiopathic venous thrombosis. Other major risks for hypercoagulability include the following: deficiencies or dysfunction of protein C, protein S, and antithrombin; prothrombin gene mutation; and the presence of antiphospholipid antibodies (lupus anticoagulant and anticardiolipin antibody).

PE has multiple physiologic effects. Physical obstruction of the vascular bed and vasoconstriction from neurohumoral reflexes both increase pulmonary vascular resistance. Massive thrombus may cause right ventricular failure. Vascular obstruction increases physiologic dead space (wasted ventilation) and leads to hypoxemia through right-to-left shunting, decreased cardiac output, and surfactant depletion causing atelectasis. Reflex bronchoconstriction promotes wheezing and increased work of breathing.

▶ Clinical Findings

A. Symptoms and Signs

The clinical diagnosis of PE is notoriously difficult for two reasons. First, the clinical findings depend on both the size of

the embolus and the patient's preexisting cardiopulmonary status. Second, common symptoms and signs of pulmonary emboli are not specific to this disorder (Table 9–21).

Indeed, no single symptom or sign or combination of clinical findings is specific to PE. Some findings are fairly sensitive: dyspnea and pain on inspiration occur in 75–85% and 65–75% of patients, respectively. Tachypnea is the only sign reliably found in more than half of patients. A common clinical strategy is to use combinations of clinical findings to identify patients' risk for PE. For example, 97% of patients in the original Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED I) study with angiographically proved pulmonary emboli had one or more of three findings: dyspnea, chest pain with breathing, or tachypnea. Wells and colleagues have published and validated a simple clinical decision rule that quantifies and dichotomizes this clinical risk assessment, allowing diversion of patients deemed unlikely to have PE to a simpler diagnostic algorithm (see Integrated Approach to Diagnosis of Pulmonary Embolism).

B. Laboratory Findings

The ECG is abnormal in 70% of patients with PE. However, the most common abnormalities are sinus tachycardia and nonspecific ST and T wave changes, each seen in approximately 40% of patients. Five percent or less of patients in the PIOPED I study had P pulmonale, right ventricular hypertrophy, right axis deviation, and right bundle branch block.

Arterial blood gases usually reveal acute respiratory alkalosis due to hyperventilation. The arterial PO₂ and the alveolar-arterial oxygen difference (A–a–DO₂) are usually abnormal in patients with PE compared with healthy, age-matched controls. However, arterial blood gases are not diagnostic: among patients who were evaluated in the PIOPED I study, neither the PO₂ nor the A–a–DO₂ differentiated between those with and those without pulmonary emboli. Profound hypoxia with a normal chest radiograph in the absence of preexisting lung disease is highly suspicious for PE.

Table 9–21. Frequency of specific symptoms and signs in patients at risk for pulmonary thromboembolism.

	UPET ¹ PE + (n = 327)	PIOPED ² PE + (n = 117)	PIOPED ² PE – (n = 248)
Symptoms			
Dyspnea	84%	73%	72%

¹Data from the Urokinase-Streptokinase Pulmonary Embolism Trial, as reported in Bell WR, et al. The clinical features of submassive and massive pulmonary emboli. *Am J Med.* 1977 Mar;62(3):355–60. [PMID: 842555]

²Data from patients enrolled in the PIOPED I study, as reported in Stein PD et al. Clinical, laboratory, roentgenographic, and electrocardiographic findings in patients with acute pulmonary embolism and no preexisting cardiac or pulmonary disease. *Chest.* 1991 Sep; 100(3):598–603. [PMID: 1909617]

³P < .05 comparing patients in the PIOPED I study.

PE+, confirmed diagnosis of pulmonary embolism; PE–, diagnosis of pulmonary embolism ruled out; nr, not reported.

Plasma levels of **D-dimer**, a degradation product of cross-linked fibrin, are elevated in the presence of thrombus. Using a D-dimer threshold between 300 and 500 ng/mL, a rapid quantitative enzyme-linked immunosorbent assay (ELISA) has shown a sensitivity for venous thromboembolism of 95–97% and a specificity of 45%. Therefore, a D-dimer < 500 ng/mL using a rapid quantitative ELISA provides strong evidence against venous thromboembolism, with a likelihood ratio of 0.11–0.13. Appropriate diagnostic thresholds have not been established for patients in whom D-dimer is elevated.

Serum troponin I, troponin T, and plasma beta-natriuretic peptide (BNP) levels are typically higher in patients with PE compared with those without embolism; the presence and magnitude of the elevation are not useful in diagnosis, but correlate with adverse outcomes, including death, mechanical ventilation and prolonged hospitalization.

C. Imaging and Special Examinations

1. Chest radiography—The chest radiograph is necessary to exclude other common lung diseases and to permit interpretation of the ventilation-perfusion (\dot{V}/\dot{Q}) scan, but it does not establish the diagnosis by itself. The chest radiograph was normal in only 12% of patients with confirmed PE in the PIOPEd I study. The most frequent findings were atelectasis, parenchymal infiltrates, and pleural effusions. However, the prevalence of these findings was the same in hospitalized patients without PE. A prominent central pulmonary artery with local oligemia (Westermarck sign) or pleural-based areas of increased opacity that represent intraparenchymal hemorrhage (Hampton hump) are uncommon. Paradoxically, the chest radiograph may be most suggestive of PE when normal in the setting of hypoxemia.

2. CT—Helical CT pulmonary angiography is used as the initial diagnostic study in North America for suspected PE. Helical CT pulmonary angiography requires administration of intravenous radiocontrast dye but is otherwise noninvasive. A high quality study is very sensitive for the detection of thrombus in the proximal pulmonary arteries but less so in more distal arteries where it may miss as many as 75% of subsegmental defects, compared with pulmonary angiography. Comparing helical CT pulmonary angiography to the \dot{V}/\dot{Q} scan as the initial test for PE, detection of thrombi is roughly comparable, although more alternative pulmonary diagnoses are made with CT scanning.

Test characteristics of helical CT pulmonary angiography vary widely by study and facility. Factors influencing results include patient size and cooperation, the type and quality of the scanner, the imaging protocol, and the experience of the interpreting radiologist. The 2006 PIOPEd II study, using multidetector (four-row) helical CT and excluding the 6% of patients whose studies were “inconclusive,” reported sensitivity of 83% and specificity of 96%.

A 15–20% false-negative rate is high for a screening test, and raises the practical question whether it is safe to withhold anticoagulation in patients with a negative helical CT. Research data provide two complementary answers. The insight of PIOPEd I, that the clinical assessment of pretest

probability improves the performance of the \dot{V}/\dot{Q} scan, was confirmed with helical CT pulmonary angiography in PIOPEd II, where positive and negative predictive values were highest in patients with concordant clinical assessments but poor with conflicting assessments. The negative predictive value of a normal helical CT in patients with a high pretest probability was only 60%. Therefore, a normal helical CT alone does not exclude PE in high-risk patients, and either empiric therapy or further testing is indicated.

A large, prospective trial, the Christopher Study, incorporated objective, validated pretest clinical assessment into diagnostic algorithms using D-dimer measurement. In this study, patients with a high pretest probability and a negative helical CT pulmonary angiogram who were not receiving anticoagulation had a low (< 2%) 3-month incidence of subsequent PE. This low rate of complications supports the contention that many false-negative studies represent clinically insignificant, small distal thrombi and provides support for monitoring most patients with a high-quality negative helical CT pulmonary angiogram off therapy (see Integrated Approach to Diagnosis of Pulmonary Embolism below). The rate of false-positive helical CT pulmonary angiograms and overtreatment of PE has not been as well studied to date.

3. Ventilation-perfusion lung scanning—A perfusion scan is performed by injecting radiolabeled microaggregated albumin into the venous system, allowing the particles to embolize to the pulmonary capillary bed. To perform a ventilation scan, the patient breathes a radioactive gas or aerosol while the distribution of radioactivity in the lungs is recorded. A defect on perfusion scanning represents diminished blood flow to that region of the lung. This finding is not specific for PE. Defects in the perfusion scan are interpreted in conjunction with the ventilation scan to give a high, low, or intermediate (indeterminate) probability that PE is the cause of the abnormalities. Criteria for the combined interpretation of ventilation and perfusion scans (commonly referred to as a single test, the \dot{V}/\dot{Q} scan) are complex, confusing, and not completely standardized. A normal perfusion scan excludes the diagnosis of clinically significant PE (negative predictive value of 91% in the PIOPEd I study). A high-probability \dot{V}/\dot{Q} scan is most often defined as having two or more segmental perfusion defects in the presence of normal ventilation and is sufficient to make the diagnosis of PE in most instances (positive predictive value of 88% among PIOPEd I patients). \dot{V}/\dot{Q} scans are most helpful when they are either normal or indicate a high probability of PE. Such readings are reliable—interobserver agreement is best for normal and high-probability scans—and they carry predictive power. The likelihood ratios associated with normal and high-probability scans are 0.10 and 18, respectively, indicating significant and frequently conclusive changes from pretest to posttest probability.

However, 75% of PIOPEd I \dot{V}/\dot{Q} scans were nondiagnostic, ie, of low or intermediate probability. At angiography, these patients had an overall incidence of PE of 14% and 30%, respectively.

One of the most important findings of PIOPEd I was that the clinical assessment of pretest probability could be

used to aid the interpretation of the \dot{V}/\dot{Q} scan. For patients with low-probability \dot{V}/\dot{Q} scans and a low (20% or less) clinical pretest probability of PE, the diagnosis was confirmed in only 4%. Such patients may reasonably be observed off therapy without angiography. All other patients with nondiagnostic \dot{V}/\dot{Q} scans require further testing to determine the presence of venous thromboembolism.

4. Venous thrombosis studies—Seventy percent of patients with PE will have DVT on evaluation, and approximately half of patients with DVT will have PE on angiography. Since the history and physical examination are neither sensitive nor specific for PE and since the results of \dot{V}/\dot{Q} scanning are frequently equivocal, documentation of DVT in a patient with suspected PE establishes the need for treatment and may preclude further testing.

Commonly available diagnostic techniques include venous ultrasonography, impedance plethysmography, and contrast venography. In most centers, **venous ultrasonography** is the test of choice to detect proximal DVT. Inability to compress the common femoral or popliteal veins in symptomatic patients is diagnostic of first-episode DVT (positive predictive value of 97%); full compressibility of both sites excludes proximal DVT (negative predictive value of 98%). The test is less accurate in distal thrombi, recurrent thrombi, or in asymptomatic patients. Impedance plethysmography relies on changes in electrical impedance between patent and obstructed veins to determine the presence of thrombus. Accuracy is comparable though not quite as high as ultrasonography. Both ultrasonography and impedance plethysmography are useful in the serial examination of patients with high clinical suspicion of venous thromboembolism but negative leg studies. In patients with suspected first-episode DVT and a negative ultrasound or impedance plethysmography examination, multiple studies have confirmed the safety of withholding anticoagulation while conducting two sequential studies on days 1–3 and 7–10. Similarly, patients with nondiagnostic \dot{V}/\dot{Q} scans and an initial negative venous ultrasound or impedance plethysmography examination may be monitored off therapy with serial leg studies over 2 weeks. When serial examinations are negative for proximal DVT, the risk of subsequent venous thromboembolism over the following 6 months is less than 2%.

Contrast venography remains the reference standard for the diagnosis of DVT. An intraluminal filling defect is diagnostic of venous thrombosis. However, venography has significant shortcomings and has been replaced by venous ultrasound as the diagnostic procedure of choice. Venography may be useful in complex situations where there is discrepancy between clinical suspicion and noninvasive testing.

5. Pulmonary angiography—Pulmonary angiography remains the reference standard for the diagnosis of PE. An intraluminal filling defect in more than one projection establishes a definitive diagnosis. Secondary findings highly suggestive of PE include abrupt arterial cutoff, asymmetry of blood flow—especially segmental oligemia—or a prolonged arterial phase with slow filling. Pulmonary angiography was performed in 755 patients in

the PIOPED I study. A definitive diagnosis was established in 97%; in 3% the studies were nondiagnostic. Four patients (0.8%) with negative angiograms subsequently had pulmonary thromboemboli at autopsy. Serial angiography has demonstrated minimal resolution of thrombus prior to day 7 following presentation. Thus, negative angiography within 7 days of presentation excludes the diagnosis.

Pulmonary angiography is a safe but invasive procedure with well-defined morbidity and mortality data. Minor complications occur in approximately 5% of patients. Most are allergic contrast reactions, transient kidney injury, or related to percutaneous catheter insertion; cardiac perforation and arrhythmias are reported but rare. Among the PIOPED I patients who underwent angiography, there were five deaths (0.7%) directly related to the procedure.

The appropriate role of pulmonary angiography in the diagnosis of PE remains a subject of ongoing debate. There is wide agreement that angiography is indicated in any patient in whom the diagnosis is in doubt when there is a high clinical pretest probability of PE or when the diagnosis of PE must be established with certainty, as when anticoagulation is contraindicated or placement of an inferior vena cava filter is contemplated.

6. MRI—MRI has sensitivity and specificity equivalent to contrast venography in the diagnosis of DVT. It has improved sensitivity when compared with venous ultrasound in the diagnosis of DVT, without loss of specificity. The test is noninvasive and avoids the use of potentially nephrotoxic radiocontrast dye. However, artifacts introduced by respiratory and cardiac motion have limited the use of MRI in the diagnosis of PE. New techniques have improved sensitivity and specificity to levels comparable with helical CT, but MRI remains primarily a research tool for PE.

▶ Integrated Approach to Diagnosis of Pulmonary Embolism

An integrated approach to diagnosis of PE uses the clinical likelihood of venous thromboembolism derived from a clinical prediction rule (Table 9–22) along with the results of diagnostic tests to come to one of three decision points: to establish venous thromboembolism (PE or DVT) as the diagnosis, to exclude venous thromboembolism with sufficient confidence to follow the patient off anticoagulation, or to refer the patient for additional testing. An ideal diagnostic algorithm would proceed in a cost-effective, stepwise fashion to come to these decision points at minimal risk to the patient. Most North American centers use a rapid D-dimer and helical CT pulmonary angiography based diagnostic algorithm (Figure 9–7). The standard \dot{V}/\dot{Q} scan based algorithm (Table 9–23) remains useful in many patients, especially those who are not able to undergo CT pulmonary angiography (eg, those with advanced chronic kidney disease). In the rigorously conducted Christopher Study, the incidence of venous thromboembolism was only 1.3% and fatal PE occurred in just 0.5% of persons monitored for 3 months off anticoagulation therapy after objective, validated tools for clinical assessment,

Table 9-22. Clinical prediction rule for pulmonary embolism (PE).

Variable	Points
Clinical symptoms and signs of deep venous thrombosis (DVT) (leg swelling and pain with palpation of deep veins)	3.0
Alternative diagnosis less likely than PE	3.0
Heart rate > 100 beats/min	1.5
Immobilization for more than 3 days or surgery in previous 4 weeks	1.5
Previous PE or DVT	1.5
Hemoptysis	1.0
Cancer (with treatment within past 6 months or palliative care)	1.0
Three-tiered clinical probability assessment	Score
High	> 6.0
Moderate	2.0 to 6.0
Low	< 2.0
Dichotomous clinical probability assessment	Score
PE likely	> 4.0
PE unlikely	< or = 4.0

Data from Wells PS et al. Derivation of a simple clinical model to categorize patients probability of pulmonary embolism: increasing the models utility with the SimpliRED D-dimer. *Thromb Haemost.* 2000 Mar;83(3):416-20. [PMID: 10744147]

quantitative rapid D-dimer assays and a negative helical CT pulmonary angiography. The incidence of PE following a negative evaluation by these three means is comparable to that seen following negative pulmonary angiography.

► **Prevention**

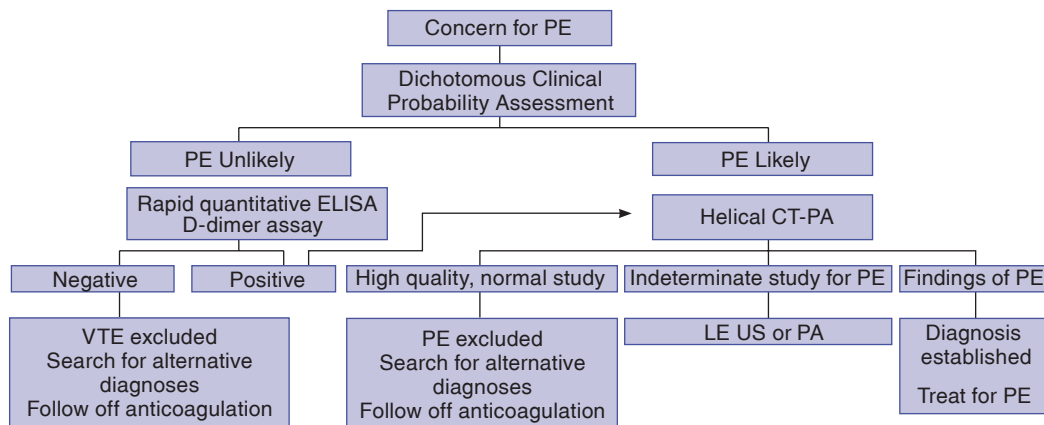

Venous thromboembolism is often clinically silent until it presents with significant morbidity or mortality. It is a prevalent disease, clearly associated with identifiable risk factors. For example, the incidence of proximal DVT, PE, and fatal PE in untreated patients undergoing hip fracture surgery is reported to be 10–20%, 4–10%, and 0.2–5%, respectively. There is unambiguous evidence of the efficacy of prophylactic therapy in this and other clinical situations, yet it remains underused. Only about 50% of surgical deaths from PE had received any form of preventive therapy. A discussion of strategies for the prevention of venous thromboembolism can be found in Chapter 14.

► **Treatment**

A. Anticoagulation

Anticoagulation is not definitive therapy but a form of secondary prevention. Heparin binds to and accelerates the ability of antithrombin to inactivate thrombin, factor Xa, and factor IXa. It thus retards additional thrombus formation, allowing endogenous fibrinolytic mechanisms to lyse existing clot. The standard regimen of heparin followed by 6 months of oral warfarin results in an 80–90% reduction in the risk of both recurrent venous thrombosis and death from PE. LMWHs are as effective as unfractionated heparin in the treatment of venous thromboembolism (see Tables 14–15, 14–19, 14–20).

The optimal duration of anticoagulation therapy for venous thromboembolism is unknown. There appears to be a protective benefit to continued anticoagulation in first-episode venous thromboembolism (twice the rate of recurrence in 6 weeks compared with 6 months of therapy) and recurrent disease (eightfold risk of recurrence in 6 months compared with 4 years of therapy). These studies do not distinguish patients with reversible risk factors,

Data from The PIOPED Investigators. Value of the ventilation/perfusion scan in acute pulmonary embolism: results of the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED). *JAMA*. 1990 May 23–30;263(20):2753–9. [PMID: 2332918] CT-PA, helical CT pulmonary angiography; LE US, lower extremity venous ultrasound for DVT; PE, pulmonary embolism.

such as surgery or transient immobility, from patients who have a nonreversible hypercoagulable state such as factor V Leiden, inhibitor deficiency, antiphospholipid syndrome, or malignancy. A randomized controlled trial of low-dose warfarin (INR 1.5–2.0) versus no therapy following 6 months of standard therapy in patients with idiopathic DVT was stopped early. The protective benefits of continued anticoagulation include fewer DVTs in addition to a trend toward lower mortality despite more hemorrhage in the warfarin group. Risk reductions were consistent across groups with and without inherited thrombophilia.

For many patients, venous thrombosis is a recurrent disease, and continued therapy results in a lower rate of recurrence at the cost of an increased risk of hemorrhage. Therefore, the appropriate duration of therapy needs to take into consideration potentially reversible risk factors, the individual's age, the likelihood and potential consequences of hemorrhage, and patient preferences for continued therapy. It is reasonable to continue therapy for 6 months after a first episode when there is a reversible risk factor, 12 months after a first-episode of idiopathic thrombosis,

and 6–12 months to indefinitely in patients with nonreversible risk factors or recurrent disease. D-dimer testing has been suggested to have a role in identifying those who may benefit from continued anticoagulation after 3 months of therapy. This is an area of active research.

The major complication of anticoagulation is hemorrhage. Risk factors for hemorrhage include the intensity of the anticoagulant effect; the duration of therapy; concomitant administration of drugs such as aspirin that interfere with platelet function; and patient characteristics, particularly increased age, previous gastrointestinal hemorrhage, and coexistent chronic kidney disease.

The reported incidence of major hemorrhage following intravenous administration of unfractionated heparin is nil to 7%; that of fatal hemorrhage is nil to 2%. The incidence with LMWHs is not statistically different. There is no information comparing hemorrhage rates at different doses of heparin. The risk of death from another pulmonary embolism during subtherapeutic heparin administration in the first 24–48 hours after diagnosis is significant; it appears to outweigh the risk of short-term supratherapeutic heparin levels. The incidence of hemorrhage during

therapy with warfarin is reported to be between 3% and 4% per patient year. The frequency varies with the target INR and is consistently higher when the INR exceeds 4.0. There is no apparent additional antithrombotic benefit in venous thromboembolism with a target INR above 2.0–3.0 (see Chapter 14).

B. Thrombolytic Therapy

Streptokinase, urokinase, and recombinant tissue plasminogen activator (rt-PA; alteplase) increase plasmin levels and thereby directly lyse intravascular thrombi. In patients with established PE, thrombolytic therapy accelerates resolution of emboli within the first 24 hours compared with standard heparin therapy. This is a consistent finding using angiography, \dot{V}/\dot{Q} scanning, echocardiography, and direct measurement of pulmonary artery pressures. However, at 1 week and 1 month after diagnosis, these agents show no difference in outcome compared with heparin and warfarin. There is no evidence that thrombolytic therapy improves mortality. Subtle improvements in pulmonary function, including improved single-breath diffusing capacity and a lower incidence of exercise-induced pulmonary hypertension, have been observed. The reliability and clinical importance of these findings is unclear. The major disadvantages of thrombolytic therapy compared with heparin are its greater cost and a significant increase in major hemorrhagic complications. The incidence of intracranial hemorrhage in patients with PE treated with alteplase is 2.1% compared with 0.2% in patients treated with heparin.

Current evidence supports thrombolytic therapy for PE in patients at high risk for death in whom the more rapid resolution of thrombus may be lifesaving. Such patients are usually hemodynamically unstable despite heparin therapy. Absolute contraindications to thrombolytic therapy include active internal bleeding and stroke within the past 2 months. Major contraindications include uncontrolled hypertension and surgery or trauma within the past 6 weeks. The role of thrombolysis in patients who are hemodynamically stable but with echocardiographic evidence of right heart strain from acute pulmonary embolism is unclear and is subject to considerable practice variation.

C. Additional Measures

Interruption of the inferior vena cava may be indicated in patients with a major contraindication to anticoagulation who have or are at high risk for development of proximal DVT or PE. Placement of an inferior vena cava filter is also recommended for recurrent thromboembolism despite adequate anticoagulation, for chronic recurrent embolism with a compromised pulmonary vascular bed (eg, in pulmonary hypertension), and with the concurrent performance of surgical pulmonary embolectomy or pulmonary thromboendarterectomy. Percutaneous transjugular placement of a mechanical filter is the preferred mode of inferior vena cava interruption. These devices reduce the short-term incidence of PE in patients presenting with

proximal lower extremity DVT. However, they are associated with a twofold increased risk of recurrent DVT in the first 2 years following placement.

In rare critically ill patients for whom thrombolytic therapy is contraindicated or unsuccessful, mechanical or surgical extraction of thrombus may be indicated. Pulmonary embolectomy is an emergency procedure of last resort with a very high mortality rate. It is performed only in a few specialized centers. Several catheter devices to fragment and extract thrombus through a transvenous approach have been reported in small numbers of patients. Comparative outcomes with surgery, thrombolytic therapy, or heparin have not been studied.

▶ Prognosis

PE is estimated to cause more than 50,000 deaths annually. In the majority of deaths, PE is not recognized antemortem or death occurs before specific treatment can be initiated. These statistics highlight the importance of preventive therapy in high-risk patients (see Chapter 14). The outlook for patients with diagnosed and appropriately treated PE is generally good. Overall prognosis depends on the underlying disease rather than the PE itself. Death from recurrent thromboemboli is uncommon, occurring in less than 3% of cases. Perfusion defects resolve in most survivors. Chronic thromboembolic pulmonary hypertension develops in approximately 1% of patients. Selected patients may benefit from pulmonary endarterectomy.

PULMONARY HYPERTENSION

ESSENTIALS OF DIAGNOSIS

- ▶ Dyspnea, fatigue, chest pain, and syncope on exertion.
- ▶ Narrow splitting of second heart sound with loud pulmonary component; findings of right ventricular hypertrophy and cardiac failure in advanced disease.
- ▶ Hypoxemia and increased wasted ventilation on pulmonary function tests.
- ▶ Electrocardiographic evidence of right ventricular strain or hypertrophy and right atrial enlargement.
- ▶ Enlarged central pulmonary arteries on chest radiograph.

▶ General Considerations

The pulmonary circulation is unique because of its high blood flow, low pressure (normally 25/8 mm Hg, mean 12), and low resistance (normally 200–250 dynes/sec/cm⁻⁵). It can accommodate large increases in blood flow during exercise with only modest increases in pressure because of its ability to recruit and distend lung blood vessels. Contraction of smooth muscle in the walls of pulmonary arteriolar resistance vessels becomes an important factor in numerous pathologic states. Pulmonary hypertension is present when pulmonary artery pressure rises to a level inappropriate for a given cardiac output. Once present, pulmonary hypertension is self-perpetuating. It introduces secondary structural abnormalities in pulmonary vessels, including smooth muscle hypertrophy and intimal proliferation, and these may eventually stimulate atheromatous changes and in situ thrombosis, leading to further narrowing of the arterial bed.

Idiopathic (formerly primary) pulmonary hypertension (see Chapter 10) is pulmonary arterial hypertension that occurs in the absence of other disease of the lungs or heart. This condition is also called **plexogenic pulmonary arteriopathy**, in reference to the characteristic histopathologic plexiform lesion found in muscular pulmonary arteries. Untreated, it is characterized by progressive dyspnea, a rapid downhill course, and an invariably fatal outcome.

Idiopathic pulmonary hypertension must be distinguished from **secondary pulmonary hypertension** that occurs with many disorders including systemic sclerosis, hepatic cirrhosis and portal hypertension, HIV infection, chronic thromboembolic disease, and the use of anorectic drugs. Selected mechanisms responsible for **secondary pulmonary hypertension** and examples of corresponding clinical conditions are set forth in Table 9–24.

Pulmonary arteriolar vasoconstriction due to chronic hypoxemia may complicate any chronic lung disease and compound the effects of loss of pulmonary blood vessels (as seen with disorders such as emphysema and pulmonary fibrosis) and obstruction of the pulmonary vascular bed

Table 9–24. Mechanisms of pulmonary hypertension and examples of corresponding clinical conditions.

Reduction in cross-sectional area of pulmonary arterial bed
Vasoconstriction
Hypoxemia from any cause (chronic lung disease, sleep-disordered breathing, etc)
Acidosis
Loss of vessels
Lung resection
Emphysema
Vasculitis
Interstitial lung disease
Collagen-vascular disease
Plexogenic narrowing of vessels
Pulmonary embolism (thromboemboli, tumor emboli, etc)
In situ thrombosis
Schistosomiasis
Sickle cell disease
Narrowing of vessels
Secondary structural changes due to pulmonary hypertension
Increased pulmonary venous pressure
Constrictive pericarditis
Left ventricular failure or reduced compliance
Mitral stenosis
Left atrial myxoma
Pulmonary veno-occlusive disease
Mediastinal diseases compressing pulmonary veins
Increased pulmonary blood flow
Congenital left-to-right intracardiac shunts
Increased blood viscosity
Polycythemia
Miscellaneous
Pulmonary hypertension occurring in association with hepatic cirrhosis and portal hypertension
HIV infection

(as seen with disorders such as chronic pulmonary thromboembolic disease). Sustained increases in pulmonary venous pressure from left ventricular failure (systolic, diastolic, or both), mitral stenosis, and pulmonary veno-occlusive disease may cause “postcapillary” pulmonary hypertension. Increased pulmonary blood flow due to intracardiac shunts and increased blood viscosity due to polycythemia can also cause pulmonary hypertension.

Pulmonary veno-occlusive disease is a rare cause of postcapillary pulmonary hypertension occurring in children and young adults. The cause is unknown, but associations with various conditions—such as viral infections, hematopoietic stem cell or bone marrow transplantation, chemotherapy (typically multiple agents administered repeatedly over many cycles), and many different autoimmune disorders—have been described. The disease is characterized by progressive fibrotic occlusion of pulmonary veins and venules, along with secondary hypertensive changes in the pulmonary arterioles and muscular pulmonary arteries. Nodular areas of pulmonary congestion, edema, hemorrhage, and hemosiderosis are found. Chest radiography reveals prominent, symmetric interstitial markings, Kerley B lines, pulmonary artery dilation, and normally sized left atrium and left ventricle. Antemortem

diagnosis is often difficult but is occasionally established by open lung biopsy. There is no effective therapy, and most patients die within 2 years as a result of progressive pulmonary hypertension.

► Clinical Findings

A. Symptoms and Signs

Pulmonary hypertension may cause or contribute to dyspnea, present initially on exertion and later at rest. Dull, retrosternal chest pain resembling angina pectoris may be present. Fatigue and syncope on exertion also occur, presumably a result of reduced cardiac output related to elevated pulmonary artery pressures or bradycardia. Secondary pulmonary hypertension is difficult to recognize clinically in the early stages, when symptoms and signs are primarily those of the underlying disease.

The signs of pulmonary hypertension include narrow splitting of the second heart sound, accentuation of the pulmonary component of the second heart sound, and a systolic ejection click. In advanced cases, tricuspid and pulmonary valve insufficiency and signs of right ventricular failure and cor pulmonale are found.

B. Laboratory Findings

Polycythemia is found in many cases of pulmonary hypertension that are associated with chronic hypoxemia. Electrocardiographic changes are those of right axis deviation, right ventricular hypertrophy, right ventricular strain, or right atrial enlargement.

C. Imaging and Special Examinations

Radiographs and high-resolution CT scans of the chest can assist in the diagnosis of pulmonary hypertension and determination of the cause. In chronic disease, dilation of the right and left main and lobar pulmonary arteries and enlargement of the pulmonary outflow tract are seen; in advanced disease, right ventricular and right atrial enlargement are seen. Peripheral “pruning” of large pulmonary arteries is characteristic of pulmonary hypertension in severe emphysema.

Echocardiography is helpful in evaluating patients thought to have mitral stenosis, left atrial myxoma, and pulmonary valvular disease and may also reveal right ventricular enlargement and paradoxical motion of the interventricular septum. Doppler ultrasonography is a reliable noninvasive means of estimating pulmonary artery systolic pressure. However, precise hemodynamic measurements can only be obtained with right heart catheterization, which is helpful when postcapillary pulmonary hypertension, intracardiac shunting, or thromboembolic disease is considered as part of the differential diagnosis.

The following studies may be useful to exclude causes of secondary pulmonary hypertension: pulmonary function tests (advanced emphysema and severe restriction are associated with elevations in pulmonary artery pressures, a reduction in the single breath diffusing capacity from diminution of the pulmonary capillary bed may suggest chronic thromboembolic disease), liver function tests, HIV

test, collagen-vascular serologic studies, sleep study, and surgical lung biopsy. CT pulmonary angiography, \dot{V}/\dot{Q} lung scanning, and pulmonary angiography are very helpful in identifying patients with pulmonary hypertension caused by recurrent pulmonary thromboemboli, a condition that is often difficult to recognize clinically.

► Treatment

Treatment of idiopathic pulmonary hypertension is discussed in Chapter 10. Treatment of secondary pulmonary hypertension consists mainly of treating the underlying disorder. Early recognition of pulmonary hypertension is crucial to interrupt the self-perpetuating cycle responsible for rapid clinical progression. Most patients who present with symptoms and signs of pulmonary hypertension, however, already have advanced disease. If hypoxemia or acidosis is detected, corrective measures should be started immediately. Supplemental oxygen administered for at least 15 hours per day has been demonstrated to slow the progression of pulmonary hypertension in patients with hypoxemic COPD.

Permanent anticoagulation is indicated in idiopathic pulmonary hypertension but should be given only to those patients with secondary pulmonary hypertension at high risk for thromboembolism. Vasodilator therapy using various pharmacologic agents (eg, calcium antagonists, hydralazine, isoproterenol, diazoxide, nitroglycerin) has shown disappointing results in secondary pulmonary hypertension. Other agents in research trials include subcutaneous (treprostinil), inhaled (iloprost), and oral (beraprost) prostacyclin analogs, endothelin receptor antagonists (bosentan), and phosphodiesterase inhibitors (sildenafil). Some of these agents have shown improvement in functional status but, so far, there is no evidence for improved outcomes. Combination therapy is an area of active research. Patients most likely to benefit from long-term pulmonary vasodilator therapy are those who respond favorably to a vasodilator challenge at right heart catheterization. It is clear that long-term oral vasodilator therapy should be used only if hemodynamic benefit is documented. Complications of pulmonary vasodilator therapy include systemic hypotension, hypoxemia, and even death.

Continuous long-term intravenous infusion (using a portable pump) of prostacyclin (PGI₂; epoprostenol), a potent pulmonary vasodilator, has been shown to confer hemodynamic and symptomatic benefits in selected patients with idiopathic pulmonary hypertension. This is the first therapy to demonstrate improved survival of patients with idiopathic pulmonary hypertension. Limitations of continuous infusion prostacyclin are difficulties in titration, technical problems with portable delivery systems, and the high cost of the drug. Patients with marked polycythemia (hematocrit > 60%) should undergo repeated phlebotomy in an attempt to reduce blood viscosity. Cor pulmonale complicating pulmonary hypertension is treated by managing the underlying pulmonary disease and by using diuretics, salt restriction and, in appropriate patients, supplemental oxygen. The use of digitalis in cor pulmonale remains controversial. Pulmonary

thromboendarterectomy may benefit selected patients with pulmonary hypertension secondary to chronic thrombotic obstruction of major pulmonary arteries.

Single or double lung transplantation may be performed on patients with end-stage idiopathic (primary) pulmonary hypertension. The 2-year survival rate is 50%.

► Prognosis

The prognosis in secondary pulmonary hypertension depends on the course of the underlying disease. The prognosis is favorable when pulmonary hypertension is detected early and the conditions leading to it are readily reversed. Patients with pulmonary hypertension due to fixed obliteration of the pulmonary vascular bed generally respond poorly to therapy; development of cor pulmonale in these cases implies a poor prognosis.

PULMONARY VASCULITIS

Granulomatosis with polyangiitis [formerly Wegener granulomatosis] is an idiopathic disease manifested by a combination of glomerulonephritis, necrotizing granulomatous vasculitis of the upper and lower respiratory tracts, and varying degrees of small vessel vasculitis. Chronic sinusitis, arthralgias, fever, skin rash, and weight loss are frequent presenting symptoms. Specific pulmonary complaints occur less often. The most common sign of lung disease is nodular pulmonary infiltrates, often with cavitation, seen on chest radiography. Tracheal stenosis and endobronchial disease are sometimes seen. The diagnosis is most often based on serologic testing and biopsy of lung, sinus tissue, or kidney with demonstration of necrotizing granulomatous vasculitis. See Chapter 20.

Allergic angiitis and granulomatosis (Churg-Strauss syndrome) is an idiopathic multisystem vasculitis of small and medium-sized arteries that occurs in patients with asthma. The skin and lungs are most often involved, but other organs, including the paranasal sinuses, the heart, gastrointestinal tract, liver, and peripheral nerves, may also be affected. Peripheral eosinophilia > 1500 cells/mcL or > 10% of peripheral WBCs is the rule. Abnormalities on chest radiographs range from transient opacities to multiple nodules. This illness may be part of a spectrum that includes polyarteritis nodosa. The diagnosis requires demonstration of histologic features including fibrinoid necrotizing epithelioid and eosinophilic granulomas.

► Treatment

Treatment of pulmonary vasculitis usually requires corticosteroids and cyclophosphamide. Oral prednisone (1 mg/kg

ideal body weight per day initially, tapering slowly to alternate-day therapy over 3–6 months) is the corticosteroid of choice; in granulomatosis with polyangiitis, some clinicians may use cyclophosphamide alone. For fulminant vasculitis, therapy may be initiated with intravenous methylprednisolone (up to 1 g intravenously per day) for several days. Cyclophosphamide (1–2 mg/kg ideal body weight orally per day initially, with dosage adjustments to avoid neutropenia) is given until complete remission is obtained and then is slowly tapered, and often replaced with methotrexate or azathioprine for maintenance therapy.

► Prognosis

Five-year survival rates in patients with these vasculitis syndromes have been improved by the combination therapy. Complete remissions can be achieved in over 90% of patients with granulomatosis with polyangiitis. The addition of trimethoprim-sulfamethoxazole (one double-strength tablet by mouth twice daily) to standard therapy may help prevent relapses.

ALVEOLAR HEMORRHAGE SYNDROMES

Diffuse alveolar hemorrhage may occur in a variety of immune and nonimmune disorders. Hemoptysis, alveolar infiltrates on chest radiograph, anemia, dyspnea, and occasionally fever are characteristic. Rapid clearing of diffuse lung infiltrates within 2 days is a clue to the diagnosis of diffuse alveolar hemorrhage. Pulmonary hemorrhage can be associated with an increased DL_{CO} .

Causes of **immune alveolar hemorrhage** have been classified as anti-basement membrane antibody disease (Goodpasture syndrome), vasculitis and collagen vascular disease (systemic lupus erythematosus, [granulomatosis with polyangiitis formerly, **Wegener granulomatosis**], systemic necrotizing vasculitis, and others), and pulmonary capillaritis associated with idiopathic rapidly progressive glomerulonephritis. **Nonimmune causes** of diffuse hemorrhage include coagulopathy, mitral stenosis, necrotizing pulmonary infection, drugs (penicillamine), toxins (trimellitic anhydride), and idiopathic pulmonary hemosiderosis.

Goodpasture syndrome is idiopathic recurrent alveolar hemorrhage and rapidly progressive glomerulonephritis. The disease is mediated by anti-glomerular basement membrane antibodies. Goodpasture syndrome occurs mainly in men who are in their 30s and 40s. Hemoptysis is the usual presenting symptom, but pulmonary hemorrhage may be occult. Dyspnea, cough, hypoxemia, and diffuse bilateral alveolar infiltrates are typical features. Iron

deficiency anemia and microscopic hematuria are usually present. The diagnosis is based on characteristic linear IgG deposits detected by immunofluorescence in glomeruli or alveoli and on the presence of anti-glomerular basement membrane antibody in serum. Combinations of immunosuppressive drugs (initially methylprednisolone, 30 mg/kg intravenously over 20 minutes every other day for three doses, followed by daily oral prednisone, 1 mg/kg/d; with cyclophosphamide, 2 mg/kg orally per day) and plasmapheresis have yielded excellent results.

Idiopathic pulmonary hemosiderosis is a disease of children or young adults characterized by recurrent pulmonary hemorrhage; in contrast to Goodpasture syndrome, renal involvement and anti-glomerular basement membrane antibodies are absent, but iron deficiency is typical. Treatment of acute episodes of hemorrhage with corticosteroids may be useful. Recurrent episodes of pulmonary hemorrhage may result in interstitial fibrosis and pulmonary failure.

Ioachimescu OC et al. Diffuse alveolar hemorrhage: diagnosing it and finding the cause. *Cleve Clin J Med.* 2008 Apr;75(4):258, 260, 264–5. [PMID: 18491433]

ENVIRONMENTAL & OCCUPATIONAL LUNG DISORDERS

SMOKE INHALATION

The inhalation of products of combustion may cause serious respiratory complications. As many as one-third of patients admitted to burn treatment units have pulmonary injury from smoke inhalation. Morbidity and mortality due to smoke inhalation may exceed those attributed to the burns themselves. The death rate of patients with both severe burns and smoke inhalation exceeds 50%.

All patients in whom significant smoke inhalation is suspected must be assessed for three consequences of smoke inhalation: impaired tissue oxygenation, thermal injury to the upper airway, and injury to the lower airways and lung parenchyma. Impaired tissue oxygenation may result from inhalation of a hypoxemia gas mixture, carbon monoxide or cyanide, or from alterations in \dot{V}/\dot{Q} matching, and is an immediate threat to life. Immediate treatment with 100% oxygen is essential. The management of patients with carbon monoxide and cyanide poisoning is discussed in Chapter 38. The clinician must recognize that patients with carbon monoxide poisoning display a normal partial pressure of oxygen in arterial blood (PaO_2) but have a low *measured* (ie, not oximetric) hemoglobin saturation (SaO_2). Treatment with 100% oxygen should be continued until the measured carboxyhemoglobin level falls to less than 10% and concomitant metabolic acidosis has resolved.

Thermal injury to the mucosal surfaces of the upper airway occurs from inhalation of super-heated gases. Complications including mucosal edema, upper airway obstruction, and impaired ability to clear oral secretions usually become evident by 18–24 hours and produce inspiratory stridor. Respiratory failure occurs in severe

cases. Early management (see also Chapter 37) includes the use of a high-humidity face mask with supplemental oxygen, gentle suctioning to evacuate oral secretions, elevation of the head 30 degrees to promote clearing of secretions, and topical epinephrine to reduce edema of the oropharyngeal mucous membrane. Helium-oxygen gas mixtures (Heliox) may reduce labored breathing due to critical upper airway narrowing. Close monitoring with arterial blood gases and later with oximetry is important. Examination of the upper airway with a fiberoptic laryngoscope or bronchoscope is superior to routine physical examination. Endotracheal intubation is often necessary to establish airway patency and is likely to be necessary in patients with deep facial burns or oropharyngeal or laryngeal edema. Tracheotomy should be avoided if possible because of an increased risk of pneumonia and death from sepsis.

Injury to the lower airways and lung parenchyma results from inhalation of toxic gases and products of combustion, including aldehydes and organic acids. The site of lung injury depends on the solubility of the gases inhaled, the duration of exposure, and the size of inhaled particles that transport noxious gases to distal lung units. Bronchorrhoea and bronchospasm are seen early after exposure along with dyspnea, tachypnea, and tachycardia. Labored breathing and cyanosis may follow. Physical examination at this stage reveals diffuse wheezing and rhonchi. Bronchiolar and alveolar edema (eg, ARDS) may develop within 1–2 days after exposure. Sloughing of the bronchiolar mucosa may occur within 2–3 days, leading to airway obstruction, atelectasis, and worsening hypoxemia. Bacterial colonization and pneumonia are common by 5–7 days after the exposure.

Treatment of smoke inhalation consists of supplemental oxygen, bronchodilators, suctioning of mucosal debris and mucopurulent secretions via an indwelling endotracheal tube, chest physical therapy to aid clearance of secretions, and adequate humidification of inspired gases. Positive end-expiratory pressure (PEEP) has been advocated to treat bronchiolar edema. Judicious fluid management and close monitoring for secondary bacterial infection with daily sputum Gram stains round out the management protocol.

The routine use of corticosteroids for lung injury from smoke inhalation has been shown to be ineffective and may even be harmful. Routine or prophylactic use of antibiotics is not recommended.

Patients who survive should be watched for the late development of bronchiolitis obliterans.

Mlcak RP et al. Respiratory management of inhalation injury. *Burns.* 2007 Feb;33(1):2–13. [PMID: 17223484]

PULMONARY ASPIRATION SYNDROMES

Aspiration of material into the tracheobronchial tree results from various disorders that impair normal deglutition, especially disturbances of consciousness and esophageal dysfunction.

1. Acute Aspiration of Gastric Contents (Mendelson Syndrome)

Acute aspiration of gastric contents may be catastrophic. The pulmonary response depends on the characteristics and amount of gastric contents aspirated. The more acidic the material, the greater the degree of chemical pneumonitis. Aspiration of pure gastric acid (pH < 2.5) causes extensive desquamation of the bronchial epithelium, bronchiolitis, hemorrhage, and pulmonary edema. Acute gastric aspiration is one of the most common causes of ARDS. The clinical picture is one of abrupt onset of respiratory distress, with cough, wheezing, fever, and tachypnea. Crackles may be audible at the bases of the lungs. Hypoxemia may be noted immediately after aspiration occurs. Radiographic abnormalities, consisting of patchy alveolar opacities in dependent lung zones, appear within a few hours. If particulate food matter has been aspirated along with gastric acid, radiographic features of bronchial obstruction may be observed. Fever and leukocytosis are common even in the absence of infection.

Treatment of acute aspiration of gastric contents consists of supplemental oxygen, measures to maintain the airway, and the usual measures for treatment of acute respiratory failure. There is no evidence to support the routine use of prophylactic antibiotics or corticosteroids after gastric aspiration. Secondary pulmonary infection, which occurs in about one-fourth of patients, typically appears 2–3 days after aspiration. Management of infection depends on the observed flora of the tracheobronchial tree. Hypotension secondary to alveolar capillary membrane injury and intravascular volume depletion is common and is managed with the judicious administration of intravenous fluids.

2. Chronic Aspiration of Gastric Contents

Chronic aspiration of gastric contents may result from primary disorders of the larynx or the esophagus, such as achalasia, esophageal stricture, systemic sclerosis (scleroderma), esophageal carcinoma, esophagitis, and gastroesophageal reflux. In the last condition, relaxation of the tone of the lower esophageal sphincter allows reflux of gastric contents into the esophagus and predisposes to chronic pulmonary aspiration, especially at night. Cigarette smoking, consumption of alcohol or caffeine, and use of theophylline are known to relax the lower esophageal sphincter. Pulmonary disorders linked to gastroesophageal reflux and chronic aspiration include asthma, chronic cough, bronchiectasis, and pulmonary fibrosis. Even in the absence of aspiration, acid in the esophagus may trigger bronchospasm or bronchial hyperreactivity through reflex mechanisms.

The diagnosis and management of gastroesophageal reflux and chronic aspiration is challenging. A discussion of strategies for the evaluation, prevention, and management of extraesophageal reflux manifestations can be found in Chapter 15.

3. “Café Coronary”

Acute obstruction of the upper airway by food is associated with difficulty swallowing, old age, dental problems that

impair chewing, and use of alcohol and sedative drugs. The Heimlich procedure is lifesaving in many cases.

4. Retention of an Aspirated Foreign Body

Retention of an aspirated foreign body in the tracheobronchial tree may produce both acute and chronic conditions, including atelectasis, postobstructive hyperinflation, both acute and recurrent pneumonia, bronchiectasis, and lung abscess. Occasionally, a misdiagnosis of asthma, COPD, or lung cancer is made in adult patients who have aspirated a foreign body. The plain chest radiograph usually suggests the site of the foreign body. In some cases, an expiratory film, demonstrating regional hyperinflation due to a check-valve effect, is helpful. Bronchoscopy is usually necessary to establish the diagnosis and attempt removal of the foreign body.

5. Aspiration of Inert Material

Aspiration of inert material may cause asphyxia if the amount aspirated is massive and if cough is impaired, in which case immediate tracheobronchial suctioning is necessary. Most patients suffer no serious sequelae from aspiration of inert material.

6. Aspiration of Toxic Material

Aspiration of toxic material into the lung usually results in clinically evident pneumonia. **Hydrocarbon pneumonitis** is caused by aspiration of ingested petroleum distillates, eg, gasoline, kerosene, furniture polish, and other household petroleum products. Lung injury results mainly from vomiting of ingested products and secondary aspiration. Therapy is supportive. The lung should be protected from repeated aspiration with a cuffed endotracheal tube if necessary. **Lipoid pneumonia** is a chronic syndrome related to the repeated aspiration of oily materials, eg, mineral oil, cod liver oil, and oily nose drops; it usually occurs in elderly patients with impaired swallowing. Patchy opacities in dependent lung zones and lipid-laden macrophages in expectorated sputum are characteristic findings.

OCCUPATIONAL PULMONARY DISEASES

Many acute and chronic pulmonary diseases are directly related to inhalation of noxious substances encountered in the workplace. Disorders that are linked to occupational exposures may be classified as follows: (1) pneumoconiosis, (2) hypersensitivity pneumonitis, (3) obstructive airway disorders, (4) pulmonary edema, (5) lung cancer, (6) pleural diseases, and (7) miscellaneous disorders.

1. Pneumoconioses

Pneumoconioses are chronic fibrotic lung diseases caused by the inhalation of inorganic dusts. Pneumoconioses due to inhalation of inert dusts may be asymptomatic disorders with diffuse nodular opacities on chest radiograph or may be severe, symptomatic, life-shortening disorders. Clinically important pneumoconioses include coal worker's pneumoconiosis, silicosis, and asbestosis (Table 9–25). Treatment for each is supportive.

A. Coal Worker's Pneumoconiosis

In coal worker's pneumoconiosis, ingestion of inhaled coal dust by alveolar macrophages leads to the formation of coal macules, usually 2–5 mm in diameter, that appear on chest radiograph as diffuse small opacities that are especially prominent in the upper lung. Simple coal worker's pneumoconiosis is usually asymptomatic; pulmonary function abnormalities are unimpressive. Cigarette smoking does not increase the prevalence of coal worker's pneumoconiosis but may have an additive detrimental effect on ventilatory function. In complicated coal worker's pneumoconiosis

(“**progressive massive fibrosis**”), conglomeration and contraction in the upper lung zones occur, with radiographic features resembling complicated silicosis. **Caplan syndrome** is a rare condition characterized by the presence of necrobiotic rheumatoid nodules (1–5 cm in diameter) in the periphery of the lung in coal workers with rheumatoid arthritis.

B. Silicosis

In silicosis, extensive or prolonged inhalation of free silica (silicon dioxide) particles in the respirable range (0.3–5 mcm) causes the formation of small rounded opacities (silicotic nodules) throughout the lung. Calcification of the periphery of hilar lymph nodes (“eggshell” calcification) is an unusual radiographic finding that strongly suggests silicosis. Simple silicosis is usually asymptomatic and has no effect on routine pulmonary function tests; in complicated silicosis, large conglomerate densities appear in the upper lung and are accompanied by dyspnea and obstructive and restrictive pulmonary dysfunction. The incidence of pulmonary tuberculosis is increased in patients with silicosis. All patients with silicosis should have a tuberculin skin test and a current chest radiograph. If old, healed pulmonary tuberculosis is suspected, multidrug treatment for tuberculosis (not single-agent preventive therapy) should be instituted.

C. Asbestosis

Asbestosis is a nodular interstitial fibrosis occurring in workers exposed to asbestos fibers (shipyard and construction workers, pipe fitters, insulators) over many years (typically 10–20 years). Patients with asbestosis usually first seek medical attention at least 15 years after exposure with the following symptoms and signs: progressive dyspnea, inspiratory crackles, and in some cases, clubbing and cyanosis. The radiographic features of asbestosis include linear streaking at the lung bases, opacities of various shapes and sizes, and honeycomb changes in advanced cases. The presence of pleural calcifications may be a clue to diagnosis. High-resolution CT scanning is the best imaging method for asbestosis because of its ability to detect parenchymal fibrosis and define the presence of coexisting pleural plaques. Cigarette smoking in asbestos workers increases the prevalence of radiographic pleural and parenchymal changes and markedly increases the incidence of lung carcinoma. It may also interfere with the clearance of short asbestos fibers from the lung. Pulmonary function studies show restrictive dysfunction and reduced diffusing capacity. The presence of a ferruginous body in tissue suggests significant asbestos exposure; however, other histologic features must be present for diagnosis. There is no specific treatment.

Table 9–25. Selected pneumoconioses.

Disease	Agent	Occupations
Metal dusts		
Siderosis	Metallic iron or iron oxide	Mining, welding, foundry work
Stannosis	Tin, tin oxide	Mining, tin-working, smelting
Baritosis	Barium salts	Glass and insecticide manufacturing
Coal dust		
Coal worker's pneumoconiosis	Coal dust	Coal mining
Inorganic dusts		
Silicosis	Free silica (silicon dioxide)	Rock mining, quarrying, stone cutting, tunneling, sandblasting, pottery, diatomaceous earth
Silicate dusts		
Asbestosis	Asbestos	Mining, insulation, construction, shipbuilding
Talcosis	Magnesium silicate	Mining, insulation, construction, shipbuilding
Kaolin pneumoconiosis	Sand, mica, aluminum silicate	Mining of china clay; pottery and cement work
Shaver disease	Aluminum powder	Manufacture of corundum

2. Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis (also called extrinsic allergic alveolitis) is a nonatopic, nonasthmatic inflammatory pulmonary disease. It is manifested mainly as an occupational disease (Table 9–26), in which exposure to inhaled organic antigens leads to an acute illness. Prompt diagnosis is essential since symptoms are usually reversible if the offending antigen is removed from the patient's environment early in the course of illness. Continued exposure may lead to progressive disease. The histopathology of acute hypersensitivity pneumonitis is characterized by interstitial infiltrates of lymphocytes and plasma cells, with noncaseating granulomas in the interstitium and air spaces.

► Clinical Findings

A. Acute Illness

The symptoms are characterized by sudden onset of malaise, chills, fever, cough, dyspnea, and nausea 4–8 hours after exposure to the offending antigen. This may occur after the patient has left work or even at night and thus may mimic paroxysmal nocturnal dyspnea. Bibasilar crackles, tachypnea, tachycardia, and (occasionally) cyanosis are noted. Small nodular densities sparing the apices and bases of the lungs are noted on chest radiograph. Laboratory

studies reveal an increase in the white blood cell count with a shift to the left, hypoxemia, and the presence of precipitating antibodies to the offending agent in serum. Hypersensitivity pneumonitis antibody panels against common offending antigens are available; positive results, while supportive, do not establish a definitive diagnosis. Pulmonary function studies reveal restrictive dysfunction and reduced diffusing capacity.

B. Subacute Illness

A subacute hypersensitivity pneumonitis syndrome (15% of cases) is characterized by the insidious onset of chronic cough and slowly progressive dyspnea, anorexia, and weight loss. Chronic exposure leads to progressive respiratory insufficiency and the appearance of pulmonary fibrosis on chest imaging. Surgical lung biopsy may be necessary for the diagnosis of subacute and chronic hypersensitivity pneumonitis. Even with surgical lung biopsy, however, chronic hypersensitivity pneumonitis may be difficult to diagnose because histopathologic patterns overlap with several idiopathic interstitial pneumonias.

► Treatment

Treatment of acute hypersensitivity pneumonitis consists of identification of the offending agent and avoidance of further exposure. In severe acute or protracted cases, oral corticosteroids (prednisone, 0.5 mg/kg daily as a single morning dose for 2 weeks, tapered to nil over 4–6 weeks) may be given. Change in occupation is often unavoidable.

Table 9–26. Selected causes of hypersensitivity pneumonitis.

Disease	Antigen	Source
Farmer's lung	<i>Micropolyspora faeni</i> , <i>Thermoactinomyces vulgaris</i>	Moldy hay
"Humidifier" lung	Thermophilic actinomycetes	Contaminated humidifiers, heating systems, or air conditioners
Bird fancier's lung ("pigeon-breeder's disease")	Avian proteins	Bird serum and excreta
Bagassosis	<i>Thermoactinomyces sacchari</i> and <i>T vulgaris</i>	Moldy sugar cane fiber (bagasse)
Sequoiosis	Graphium, <i>Aureobasidium</i> , and other fungi	Moldy redwood sawdust
Maple bark stripper's disease	<i>Cryptostroma (Coniosporium) corticale</i>	Rotting maple tree logs or bark
Mushroom picker's disease	Same as farmer's lung	Moldy compost
Suberosis	<i>Penicillium frequentans</i>	Moldy cork dust
Detergent worker's lung	<i>Bacillus subtilis</i> enzyme	Enzyme additives

 Lacasse Y et al. Myths and controversies in hypersensitivity pneumonitis. *Semin Respir Crit Care Med*. 2008 Dec;29(6):631–42. [PMID: 19221961]

3. Obstructive Airway Disorders

Occupational pulmonary diseases manifested as obstructive airway disorders include occupational asthma, industrial bronchitis, and byssinosis.

A. Occupational Asthma

It has been estimated that from 2% to 5% of all cases of asthma are related to occupation. Offending agents in the workplace are numerous; they include grain dust, wood dust, tobacco, pollens, enzymes, gum arabic, synthetic dyes, isocyanates (particularly toluene diisocyanate), rosin (soldering flux), inorganic chemicals (salts of nickel, platinum, and chromium), trimellitic anhydride, phthalic anhydride, formaldehyde, and various pharmaceutical agents. Diagnosis of occupational asthma depends on a high index of suspicion, an appropriate history, spirometric studies before and after exposure to the offending substance, and peak flow rate measurements in the workplace. Bronchial provocation testing may be helpful in some cases. Treatment consists of avoidance of further exposure to the offending agent and bronchodilators, but symptoms may persist for years after workplace exposure has been terminated.

B. Industrial Bronchitis

Industrial bronchitis is chronic bronchitis found in coal miners and others exposed to cotton, flax, or hemp dust. Chronic disability from industrial bronchitis is infrequent.

C. Byssinosis

Byssinosis is an asthma-like disorder in textile workers caused by inhalation of cotton dust. The pathogenesis is obscure. Chest tightness, cough, and dyspnea are characteristically worse on Mondays or the first day back at work, with symptoms subsiding later in the week. Repeated exposure leads to chronic bronchitis.

4. Toxic Lung Injury

Toxic lung injury from inhalation of irritant gases is discussed in the section on smoke inhalation. **Silo-filler's disease** is acute toxic high-permeability pulmonary edema caused by inhalation of nitrogen dioxide encountered in recently filled silos. Bronchiolitis obliterans is a common late complication, which may be prevented by early treatment of the acute reaction with corticosteroids. Extensive exposure to silage gas may be fatal. Inhalation of the compound diacetyl, a constituent of butter-flavoring, has been linked to the development of bronchiolitis obliterans among microwave popcorn production workers.

5. Lung Cancer

Many industrial pulmonary carcinogens have been identified, including asbestos, radon gas, arsenic, iron, chromium, nickel, coal tar fumes, petroleum oil mists, isopropyl oil, mustard gas, and printing ink. Cigarette smoking acts as a cocarcinogen with asbestos and radon gas to cause bronchogenic carcinoma. Asbestos alone causes malignant mesothelioma. Almost all histologic types of lung cancer have been associated with these carcinogens. Chloromethyl methyl ether specifically causes small cell carcinoma of the lung.

6. Pleural Diseases

Occupational diseases of the pleura may result from exposure to asbestos (see above) or talc. Inhalation of talc causes pleural plaques that are similar to those caused by asbestos. Benign asbestos pleural effusion occurs in some asbestos workers and may cause chronic blunting of the costophrenic angle on chest radiograph.

7. Other Occupational Pulmonary Diseases

Occupational agents are also responsible for other pulmonary disorders. These include exposure to beryllium, which now occurs in machining and handling of beryllium products and alloys. Beryllium miners are not at risk for berylliosis and beryllium is no longer used in fluorescent lamp production, which was a source of exposure before 1950. **Berylliosis**, an acute or chronic pulmonary disorder, occurs from absorption of beryllium through the lungs or skin and widely disseminated throughout the body. Acute berylliosis is a toxic, ulcerative tracheobronchitis and

chemical pneumonitis following intense and severe exposure to beryllium. Chronic berylliosis, a systemic disease closely resembling sarcoidosis, is more common. Chronic pulmonary beryllium disease is thought to be an alveolitis mediated by the proliferation of beryllium-specific helper-inducer T cells in the lung.

DRUG-INDUCED LUNG DISEASE

Typical patterns of pulmonary response to drugs implicated in drug-induced respiratory disease are summarized in Table 9–27. Pulmonary injury due to drugs occurs as a result of allergic reactions, idiosyncratic reactions, overdose, or undesirable side effects. In most patients, the mechanism of pulmonary injury is unknown.

Precise diagnosis of drug-induced pulmonary disease is often difficult, because results of routine laboratory studies are not helpful and radiographic findings are not specific. A high index of suspicion and a thorough medical history of drug usage are critical to establishing the diagnosis of drug-induced lung disease. The clinical response to cessation of the suspected offending agent is also helpful. Acute episodes of drug-induced pulmonary disease usually disappear 24–48 hours after the drug has been discontinued, but chronic syndromes may take longer to resolve. Challenge tests to confirm the diagnosis are risky and rarely performed.

Treatment of drug-induced lung disease consists of discontinuing the offending agent immediately and managing the pulmonary symptoms appropriately.

Inhalation of crack cocaine may cause a spectrum of acute pulmonary syndromes, including pulmonary infiltration with eosinophilia, pneumothorax and pneumomediastinum, bronchiolitis obliterans, and acute respiratory failure associated with diffuse alveolar damage and alveolar hemorrhage. Corticosteroids have been used with variable success to treat alveolar hemorrhage.

RADIATION LUNG INJURY

The lung is an exquisitely radiosensitive organ that can be damaged by external beam radiation therapy. The degree of pulmonary injury is determined by the volume of lung irradiated, the dose and rate of exposure, and potentiating factors (eg, concurrent chemotherapy, previous radiation therapy in the same area, and simultaneous withdrawal of corticosteroid therapy). Symptomatic radiation lung injury occurs in about 10% of patients treated for carcinoma of

Table 9–27. Pulmonary manifestations of selected drug toxicities.

Asthma	Pulmonary edema
β-Blockers	Noncardiogenic
Aspirin	Aspirin
Nonsteroidal anti-inflammatory drugs	Chlordiazepoxide
Histamine	Cocaine
Methacholine	Ethchlorvynol
Acetylcysteine	Heroin
Aerosolized pentamidine	Cardiogenic
Any nebulized medication	β-Blockers
Chronic cough	Pleural effusion
Angiotensin-converting enzyme inhibitors	Bromocriptine
Pulmonary infiltration	Nitrofurantoin
Without eosinophilia	Any drug inducing systemic lupus erythematosus
Amitriptyline	Methysergide
Azathioprine	Chemotherapeutic agents (eg, carmustine, cyclophosphamide, dasatinib, docetaxel, GM-CSF, methotrexate)
Amiodarone	Mediastinal widening
With eosinophilia	Phenytoin
Sulfonamides	Corticosteroids
L-Tryptophan	Methotrexate
Nitrofurantoin	Respiratory failure
Penicillin	Neuromuscular blockade
Methotrexate	Aminoglycosides
Crack cocaine	Succinylcholine
Drug-induced systemic lupus erythematosus	Gallamine
Hydralazine	Dimethyltubocurarine (metocurine)
Procainamide	Central nervous system depression
Isoniazid	Sedatives
Chlorpromazine	Hypnotics
Phenytoin	Opioids
Interstitial pneumonitis/fibrosis	Alcohol
Nitrofurantoin	Tricyclic antidepressants
Bleomycin	Oxygen
Busulfan	
Cyclophosphamide	
Methysergide	
Phenytoin	

GM-CSF, granulocyte-macrophage colony-stimulating factor.

the breast, 5–15% of patients treated for carcinoma of the lung, and 5–35% of patients treated for lymphoma. Two phases of the pulmonary response to radiation are apparent: an acute phase (radiation pneumonitis) and a chronic phase (radiation fibrosis).

1. Radiation Pneumonitis

Acute radiation pneumonitis usually occurs 2–3 months (range 1–6 months) after completion of radiotherapy and is characterized by insidious onset of dyspnea, intractable dry cough, chest fullness or pain, weakness, and fever. Late radiation pneumonitis may develop 6–12 months after completion of radiation. The pathogenesis of acute radiation pneumonitis is unknown, but there is speculation that hypersensitivity mechanisms are involved. The dominant histopathologic findings are a lymphocytic interstitial

pneumonitis progressing to an exudative alveolitis. Inspiratory crackles may be heard in the involved area. In severe disease, respiratory distress and cyanosis occur that are characteristic of ARDS. An increased white blood cell count and elevated sedimentation rate are common. Pulmonary function studies reveal reduced lung volumes, reduced lung compliance, hypoxemia, reduced diffusing capacity, and reduced maximum voluntary ventilation. Chest radiography, which correlates poorly with the presence of symptoms, usually demonstrates alveolar or nodular opacities limited to the irradiated area. Air bronchograms are often observed. Sharp borders of an opacity may help distinguish radiation pneumonitis from other conditions such as infectious pneumonia, lymphangitic spread of carcinoma, and recurrent tumor; however, the opacity may extend beyond the radiation field. No specific therapy is proved to be effective in radiation pneumonitis, but prednisone (1 mg/kg/d orally) is commonly given immediately for about 1 week. The dose is then reduced and maintained at 20–40 mg/d for several weeks, then slowly tapered. Radiation pneumonitis may improve in 2–3 weeks following onset of symptoms as the exudative phase resolves. Acute respiratory failure, if present, is treated supportively. Death from ARDS is unusual in radiation pneumonitis.

2. Pulmonary Radiation Fibrosis

Radiation fibrosis may occur with or without antecedent radiation pneumonitis. Cor pulmonale and chronic respiratory failure are rare. Radiographic findings include obliteration of normal lung markings, dense interstitial and pleural fibrosis, reduced lung volumes, tenting of the diaphragm, and sharp delineation of the irradiated area. No specific therapy is proven effective, and corticosteroids have no value. Pulmonary fibrosis may develop after an intervening period (6–12 months) of well being in patients who experience radiation pneumonitis. Pulmonary radiation fibrosis occurs in most patients who receive a full course of radiation therapy for cancer of the lung or breast. Most patients are asymptomatic, although slowly progressive dyspnea may occur.

3. Other Complications of Radiation Therapy

Other complications of radiation therapy directed to the thorax include pericardial effusion, constrictive pericarditis, tracheoesophageal fistula, esophageal candidiasis, radiation dermatitis, and rib fractures. Small pleural effusions, radiation pneumonitis outside the irradiated area, spontaneous pneumothorax, and complete obstruction of central airways are unusual occurrences.

PLEURAL DISEASES

PLEURITIS

Pain due to acute pleural inflammation is caused by irritation of the parietal pleura. Such pain is localized, sharp, and fleeting; it is made worse by coughing, sneezing, deep breathing, or movement. When the central portion of the diaphragmatic parietal pleura is irritated, pain may be referred to the ipsilateral shoulder. There are numerous causes of pleuritis. The setting in which pleuritic pain develops helps narrow the differential diagnosis. In young, otherwise healthy individuals, pleuritis is usually caused by viral respiratory infections or pneumonia. The presence of pleural effusion, pleural thickening, or air in the pleural space requires further diagnostic and therapeutic measures. Simple rib fracture may cause severe pleurisy.

Treatment of pleuritis consists of treating the underlying disease. Analgesics and anti-inflammatory drugs (eg, indomethacin, 25 mg orally two or three times daily) are often helpful for pain relief. Codeine (30–60 mg orally every 8 hours) may be used to control cough associated with pleuritic chest pain if retention of airway secretions is not a likely complication. Intercostal nerve blocks are sometimes helpful but the benefit is usually transient.

PLEURAL EFFUSION

ESSENTIALS OF DIAGNOSIS

- ▶ May be asymptomatic; chest pain frequently seen in the setting of pleuritis, trauma, or infection; dyspnea is common with large effusions.
- ▶ Dullness to percussion and decreased breath sounds over the effusion.
- ▶ Radiographic evidence of pleural effusion.
- ▶ Diagnostic findings on thoracentesis.

▶ General Considerations

There is constant movement of fluid from parietal pleural capillaries into the pleural space at a rate of 0.01 mL/kg body weight/h. Absorption of pleural fluid occurs through parietal pleural lymphatics. The resultant homeostasis leaves 5–15 mL of fluid in the normal pleural space. A pleural effusion is an abnormal accumulation of fluid in the pleural space. Pleural effusions may be classified by differential diagnosis (Table 9–28) or by underlying pathophysiology. Five pathophysiologic processes account for most pleural effusions: increased production of fluid in the setting of normal capillaries due to increased hydrostatic or decreased oncotic pressures (**transudates**); increased production of fluid due to abnormal capillary permeability (**exudates**); decreased lymphatic clearance of fluid from the pleural space (**exudates**); infection in the pleural space (**empyema**); and bleeding into the pleural space (**hemothorax**). **Parapneumonic** pleural effusions are exudates that accompany bacterial pneumonias.

Table 9–28. Causes of pleural fluid transudates and exudates.

Transudates	Exudates
Congestive heart failure (> 90% of cases)	Pneumonia (parapneumonic effusion)
Cirrhosis with ascites	Cancer
Nephrotic syndrome	Pulmonary embolism
Peritoneal dialysis	Bacterial infection
Myxedema	Tuberculosis
Atelectasis (acute)	Connective tissue disease
Constrictive pericarditis	Viral infection
Superior vena cava obstruction	Fungal infection
Pulmonary embolism	Rickettsial infection
	Parasitic infection
	Asbestos
	Meigs syndrome
	Pancreatic disease
	Uremia
	Chronic atelectasis
	Trapped lung
	Chylothorax
	Sarcoidosis
	Drug reaction
	Post-myocardial injury syndrome

Diagnostic thoracentesis should be performed whenever there is a new pleural effusion and no clinically apparent cause. Observation is appropriate in some situations (eg, symmetric bilateral pleural effusions in the setting of congestive heart failure), but an atypical presentation or failure of an effusion to resolve as expected warrants thoracentesis. Sampling allows visualization of the fluid in addition to chemical and microbiologic analyses to identify the pathophysiologic processes listed above.

▶ Clinical Findings

A. Symptoms and Signs

Patients with pleural effusions most often report dyspnea, cough, or respirophasic chest pain. Symptoms are more common in patients with existing cardiopulmonary disease. Small pleural effusions are less likely to be symptomatic than larger effusions. Physical findings are usually absent in small effusions. Larger effusions may present with dullness to percussion and diminished or absent breath sounds over the effusion. Compressive atelectasis may cause bronchial breath sounds and egophony just above the effusion. A massive effusion with increased intrapleural pressure may cause contralateral shift of the trachea and bulging of the intercostal spaces. A pleural friction rub indicates infarction or pleuritis.

B. Laboratory Findings

The gross appearance of pleural fluid helps identify several types of pleural effusion. Grossly purulent fluid signifies empyema. Milky white pleural fluid should be centrifuged. A clear supernatant above a pellet of white cells indicates empyema, whereas a persistently turbid supernatant

suggests a **chylous effusion**; analysis of this supernatant reveals chylomicrons and a high triglyceride level (> 100 mg/dL [1 mmol/L]), often from disruption of the thoracic duct. **Hemorrhagic pleural effusion** is a mixture of blood and pleural fluid. Ten thousand red cells per milliliter create blood-tinged pleural fluid; 100,000/mL create grossly bloody pleural fluid. **Hemothorax** is the presence of gross blood in the pleural space, usually following chest trauma or instrumentation. It is defined as a ratio of pleural fluid hematocrit to peripheral blood hematocrit > 0.5 .

Pleural fluid samples should be sent for measurement of protein, glucose, and LD in addition to total and differential white blood cell counts. Chemistry determinations are used to classify effusions as transudates or exudates. This classification is important because the differential diagnosis and subsequent evaluation for each entity is vastly different (Table 9–28). A **pleural exudate** is an effusion that has *one or more* of the following laboratory features: (1) ratio of pleural fluid protein to serum protein > 0.5 ; (2) ratio of pleural fluid LD to serum LD > 0.6 ; (3) pleural fluid LD greater than two-thirds the upper limit of

normal serum LD. **Pleural transudates** occur in the setting of normal capillary integrity and demonstrate none of the laboratory features of exudates. A transudate suggests the absence of local pleural disease; characteristic laboratory findings include a glucose equal to serum glucose, pH between 7.40 and 7.55, and fewer than 1.0×10^3 white blood cells/mcL ($1.0 \times 10^9/L$) with a predominance of mononuclear cells.

Congestive heart failure accounts for 90% of transudates. Bacterial pneumonia and cancer are the most common causes of exudative effusion. Other causes of exudates with characteristic laboratory findings are summarized in Table 9–29.

Pleural fluid pH is useful in the assessment of parapneumonic effusions. A pH below 7.30 suggests the need for drainage of the pleural space. An elevated amylase level in pleural fluid suggests pancreatitis, pancreatic pseudocyst, adenocarcinoma of the lung or pancreas, or esophageal rupture.

Suspected tuberculous pleural effusion should be evaluated by thoracentesis with culture along with pleural

Table 9–29. Characteristics of important exudative pleural effusions.

Etiology or Type of Effusion	Gross Appearance	White Blood Cell Count (cells/mcL)	Red Blood Cell Count (cells/mcL)	Glucose	Comments
Malignancy	Turbid to bloody; occasionally serous	1000 to $< 100,000$ M	100 to several hundred thousand	Equal to serum levels; < 60 mg/dL in 15% of cases	Eosinophilia uncommon; positive results on cytologic examination
Uncomplicated parapneumonic	Clear to turbid	5000–25,000 P	< 5000	Equal to serum levels	Tube thoracostomy unnecessary
Empyema	Turbid to purulent	25,000–100,000 P	< 5000	Less than serum levels; often very low	Drainage necessary; putrid odor suggests anaerobic infection
Tuberculosis	Serous to serosanguineous	5000–10,000 M	$< 10,000$	Equal to serum levels; occasionally < 60 mg/dL	Protein > 4.0 g/dL and may exceed 5 g/dL; eosinophils ($> 10\%$) or mesothelial cells ($> 5\%$) make diagnosis unlikely; see text for discussion of additional diagnostic tests
Rheumatoid	Turbid; greenish yellow	1000–20,000 M or P	< 1000	< 40 mg/dL	Secondary empyema common; high LD, low complement, high rheumatoid factor, cholesterol crystals are characteristic
Pulmonary infarction	Serous to grossly bloody	1000–50,000 M or P	100 to $> 100,000$	Equal to serum levels	Variable findings; no pathognomonic features
Esophageal rupture	Turbid to purulent; red-brown	< 5000 to $> 50,000$ P	1000–10,000	Usually low	High amylase level (salivary origin); pneumothorax in 25% of cases; effusion usually on left side; pH < 6.0 strongly suggests diagnosis
Pancreatitis	Turbid to serosanguineous	1000–50,000 P	1000–10,000	Equal to serum levels	Usually left-sided; high amylase level

LD, lactate dehydrogenase; M, mononuclear cell predominance; P, polymorphonuclear leukocyte predominance.

biopsy, since pleural fluid culture positivity for *M tuberculosis* is low (< 23–58% of cases). Closed pleural biopsy reveals granulomatous inflammation in approximately 60% of patients, and culture of three pleural biopsy specimens combined with histologic examination of a pleural biopsy for granulomas yields a diagnosis in up to 90% of patients. Tests for pleural fluid adenosine deaminase (approximately 90% sensitivity and specificity for pleural tuberculosis at levels >70 units/L) and interferon-gamma (89% sensitivity, 97% specificity in a meta-analysis) can be extremely helpful diagnostic aids, particularly in making decisions to pursue invasive testing in complex patients.

Between 40% and 80% of exudative pleural effusions are malignant, while over 90% of malignant pleural effusions are exudative. Almost any form of cancer may cause effusions, but the most common causes are lung cancer (one-third of cases) and breast cancer. In 5–10% of malignant pleural effusions, no primary tumor is identified. The term “**paramalignant**” pleural effusion refers to an effusion in a patient with cancer when repeated attempts to identify tumor cells in the pleura or pleural fluid are non-diagnostic but when there is a presumptive relation to the underlying malignancy. For example, superior vena cava syndrome with elevated systemic venous pressures causing a transudative effusion would be “paramalignant.”

Pleural fluid specimens should be sent for cytologic examination in all cases of exudative effusions in patients suspected of harboring an underlying malignancy. The diagnostic yield depends on the nature and extent of the underlying malignancy. Sensitivity is between 50% and 65%. A negative cytologic examination in a patient with a high prior probability of malignancy should be followed by one repeat thoracentesis. If that examination is negative, thoracoscopy is preferred to closed pleural biopsy. The sensitivity of thoracoscopy is 92–96%.

C. Imaging

The lung is less dense than water and floats on pleural fluid that accumulates in dependent regions. Subpulmonary fluid may appear as lateral displacement of the apex of the diaphragm with an abrupt slope to the costophrenic sulcus or a greater than 2 cm separation between the gastric air bubble and the lung. On a standard upright chest radiograph, approximately 75–100 mL of pleural fluid must accumulate in the posterior costophrenic sulcus to be visible on the lateral view, and 175–200 mL must be present in the lateral costophrenic sulcus to be visible on the frontal view. Chest CT scans may identify as little as 10 mL of fluid. At least 1 cm of fluid on the decubitus view is necessary to permit blind thoracentesis. Ultrasonography is useful to guide thoracentesis in the setting of smaller effusions.

Pleural fluid may become trapped (loculated) by pleural adhesions, thereby forming unusual collections along the lateral chest wall or within lung fissures. Round or oval fluid collections in fissures that resemble intraparenchymal masses are called pseudotumors. Massive pleural effusion causing opacification of an entire hemithorax is most commonly caused by cancer but may be seen in tuberculosis and other diseases.

► Treatment

A. Transudative Pleural Effusion

Transudative pleural effusions characteristically occur in the absence of pleural disease. Therefore, treatment is directed at the underlying condition. Therapeutic thoracentesis for severe dyspnea typically offers only transient benefit. Pleurodesis and tube thoracostomy are rarely indicated.

B. Malignant Pleural Effusion

Chemotherapy or radiation therapy or both offer temporary control in some malignant effusions but are generally ineffective in lung cancer in the pleural space except for small cell lung cancer. Asymptomatic malignant effusions usually do not require specific treatment. Symptomatic patients should have a therapeutic thoracentesis. If symptoms are relieved but the effusion returns, the options are serial thoracenteses, attempted pleurodesis, or placement of an indwelling drainage catheter that the patient can access at home. Choice among these options depends on the rate of reaccumulation in addition to the functional status, tolerance for discomfort, and life expectancy of the patient. Consultation with a thoracic specialist is advised. See Chapter 39.

C. Parapneumonic Pleural Effusion

Parapneumonic pleural effusions are divided into three categories: simple or uncomplicated, complicated, and empyema. **Uncomplicated parapneumonic effusions** are free-flowing sterile exudates of modest size that resolve quickly with antibiotic treatment of pneumonia. They do not need drainage. **Empyema** is gross infection of the pleural space indicated by positive Gram stain or culture. Empyema should always be drained by tube thoracostomy to facilitate clearance of infection and to reduce the probability of fibrous encasement of the lung, causing permanent pulmonary impairment.

Complicated parapneumonic effusions present the most difficult management decisions. They tend to be larger than simple parapneumonic effusions and to show more evidence of inflammatory stimuli such as low glucose level, low pH, or evidence of loculation. Inflammation probably reflects ongoing bacterial invasion of the pleural space despite rare positive bacterial cultures. The morbidity associated with complicated effusions is due to their tendency to form a fibropurulent pleural “peel,” trapping otherwise functional lung and leading to permanent impairment. Tube thoracostomy is indicated when pleural fluid glucose is < 60 mg/dL (3.3 mmol/L) or the pH is < 7.2. These thresholds have not been prospectively validated and should not be interpreted strictly. The clinician should consider drainage of a complicated effusion if the pleural fluid pH is between 7.2 and 7.3 or the LD is > 1000 units/L (20 mckat/L). Pleural fluid cell count and protein have little diagnostic value in this setting.

Tube thoracostomy drainage of empyema or parapneumonic effusions is frequently complicated by loculation that prevents adequate drainage. Intrapleural instillation of

fibrinolytic agents has not been shown in controlled trials to improve drainage. The combination of intrapleural tissue plasminogen activator and deoxyribonuclease (DNase), an enzyme that catalyses extracellular DNA and degrades biofilm formation within the pleural cavity, has been found to improve clinical outcome (increased drainage, decrease length of stay and surgical referral) compared with placebo or either agent alone.

D. Hemothorax

A small-volume hemothorax that is stable or improving on chest radiographs may be managed by close observation. In all other cases, hemothorax is treated by immediate insertion of a large-bore thoracostomy tube to: (1) drain existing blood and clot, (2) quantify the amount of bleeding, (3) reduce the risk of fibrothorax, and (4) permit apposition of the pleural surfaces in an attempt to reduce hemorrhage. Thoracotomy may be indicated to control hemorrhage, remove clot, and treat complications such as bronchopleural fistula formation.

SPONTANEOUS PNEUMOTHORAX

ESSENTIALS OF DIAGNOSIS

- ▶ Acute onset of unilateral chest pain and dyspnea.
- ▶ Minimal physical findings in mild cases; unilateral chest expansion, decreased tactile fremitus, hyperresonance, diminished breath sounds, mediastinal shift, cyanosis and hypotension in tension pneumothorax.
- ▶ Presence of pleural air on chest radiograph.

▶ General Considerations

Pneumothorax, or accumulation of air in the pleural space, is classified as spontaneous (primary or secondary) or traumatic. Primary spontaneous pneumothorax occurs in the absence of an underlying lung disease, whereas secondary spontaneous pneumothorax is a complication of pre-existing pulmonary disease. Traumatic pneumothorax results from penetrating or blunt trauma. Iatrogenic pneumothorax may follow procedures such as thoracentesis, pleural biopsy, subclavian or internal jugular vein catheter

placement, percutaneous lung biopsy, bronchoscopy with transbronchial biopsy, and positive-pressure mechanical ventilation. Tension pneumothorax usually occurs in the setting of penetrating trauma, lung infection, cardiopulmonary resuscitation, or positive-pressure mechanical ventilation. In tension pneumothorax, the pressure of air in the pleural space exceeds ambient pressure throughout the respiratory cycle. A check-valve mechanism allows air to enter the pleural space on inspiration and prevents egress of air on expiration.

Primary pneumothorax affects mainly tall, thin boys and men between the ages of 10 and 30 years. It is thought to occur from rupture of subpleural apical blebs in response to high negative intrapleural pressures. Family history and cigarette smoking may also be important factors.

Secondary pneumothorax occurs as a complication of COPD, asthma, cystic fibrosis, tuberculosis, *Pneumocystis* pneumonia, menstruation (catamenial pneumothorax), and a wide variety of interstitial lung diseases including sarcoidosis, lymphangioleiomyomatosis, Langerhans cell histiocytosis, and tuberous sclerosis. Aerosolized pentamidine and a prior history of *Pneumocystis* pneumonia are considered risk factors for the development of pneumothorax. One-half of patients with pneumothorax in the setting of recurrent (but not primary) *Pneumocystis* pneumonia will develop pneumothorax on the contralateral side. The mortality rate of pneumothorax in *Pneumocystis* pneumonia is high.

▶ Clinical Findings

A. Symptoms and Signs

Chest pain ranging from minimal to severe on the affected side and dyspnea occur in nearly all patients. Symptoms usually begin during rest and usually resolve within 24 hours even if the pneumothorax persists. Alternatively, pneumothorax may present with life-threatening respiratory failure if underlying COPD or asthma is present.

If pneumothorax is small (< 15% of a hemithorax), physical findings, other than mild tachycardia, are normal. If pneumothorax is large, diminished breath sounds, decreased tactile fremitus, and decreased movement of the chest are often noted. Tension pneumothorax should be suspected in the presence of marked tachycardia, hypotension, and mediastinal or tracheal shift.

B. Laboratory Findings

Arterial blood gas analysis is often unnecessary but reveals hypoxemia and acute respiratory alkalosis in most patients. Left-sided primary pneumothorax may produce QRS axis and precordial T wave changes on the ECG that may be misinterpreted as acute myocardial infarction.

C. Imaging

Demonstration of a visceral pleural line on chest radiograph is diagnostic and may only be seen on an expiratory film. A few patients have secondary pleural effusion that demonstrates a characteristic air-fluid level on chest radiography. In supine patients, pneumothorax on a conventional chest radiograph may appear as an abnormally radiolucent

costophrenic sulcus (the “deep sulcus” sign). In patients with tension pneumothorax, chest radiographs show a large amount of air in the affected hemithorax and contralateral shift of the mediastinum.

► Differential Diagnosis

If the patient is a young, tall, thin, cigarette-smoking man, the diagnosis of primary spontaneous pneumothorax is usually obvious and can be confirmed by chest radiograph. In secondary pneumothorax, it is sometimes difficult to distinguish loculated pneumothorax from an emphysematous bleb. Occasionally, pneumothorax may mimic myocardial infarction, pulmonary embolism, or pneumonia.

► Complications

Tension pneumothorax may be life-threatening. Pneumomediastinum and subcutaneous emphysema may occur as complications of spontaneous pneumothorax. If pneumomediastinum is detected, rupture of the esophagus or a bronchus should be considered.

► Treatment

Treatment depends on the severity of pneumothorax and the nature of the underlying disease. In a reliable patient with a small (< 15% of a hemithorax), stable spontaneous primary pneumothorax, observation alone may be appropriate. Many small pneumothoraces resolve spontaneously as air is absorbed from the pleural space; supplemental oxygen therapy may increase the rate of reabsorption. Simple aspiration drainage of pleural air with a small-bore catheter (eg, 16 gauge angiocatheter or larger drainage catheter) can be performed for spontaneous primary pneumothoraces that are large or progressive. Placement of a small-bore chest tube (7F to 14F) attached to a one-way Heimlich valve provides protection against development of tension pneumothorax and may permit observation from home. The patient should be treated symptomatically for cough and chest pain, and followed with serial chest radiographs every 24 hours.

Patients with secondary pneumothorax, large pneumothorax, tension pneumothorax, or severe symptoms or those who have a pneumothorax on mechanical ventilation should undergo chest tube placement (tube thoracostomy). The chest tube is placed under water-seal drainage, and suction is applied until the lung expands. The chest tube can be removed after the air leak subsides.

All patients who smoke should be advised to discontinue smoking and warned that the risk of recurrence is 50%. Future exposure to high altitudes, flying in unpresurized aircraft, and scuba diving should be avoided.

Indications for thoracoscopy or open thoracotomy include recurrences of spontaneous pneumothorax, any occurrence of bilateral pneumothorax, and failure of tube thoracostomy for the first episode (failure of lung to reexpand or persistent air leak). Surgery permits resection of blebs responsible for the pneumothorax and pleurodesis by mechanical abrasion and insufflation of talc.

Management of pneumothorax in patients with *Pneumocystis* pneumonia is challenging because of a tendency

toward recurrence, and there is no consensus on the best approach. Use of a small chest tube attached to a Heimlich valve has been proposed to allow the patient to leave the hospital. Some clinicians favor its insertion early in the course.

► Prognosis

An average of 30% of patients with spontaneous pneumothorax experience recurrence of the disorder after either observation or tube thoracostomy for the first episode. Recurrence after surgical therapy is less frequent. Following successful therapy, there are no long-term complications.

DISORDERS OF CONTROL OF VENTILATION

The principal influences on ventilatory control are arterial PCO_2 , pH, PO_2 , and brainstem tissue pH. These variables are monitored by peripheral and central chemoreceptors. Under normal conditions, the ventilatory control system maintains arterial pH and PCO_2 within narrow limits; arterial PO_2 is more loosely controlled.

Abnormal control of ventilation can be seen with a variety of conditions ranging from rare disorders such as Ondine curse, neuromuscular disorders, myxedema, starvation, and carotid body resection to more common disorders such as asthma, COPD, obesity, congestive heart failure, and sleep-related breathing disorders. A few of these disorders will be discussed in this section.

Ward SA. Ventilatory control in humans: constraints and limitations. *Exp Physiol.* 2007 Mar;92(2):357–66. [PMID: 17234715]

PRIMARY ALVEOLAR HYPOVENTILATION

Primary alveolar hypoventilation (“Ondine curse”) is a rare syndrome of unknown cause characterized by inadequate alveolar ventilation despite normal neurologic function and normal airways, lungs, chest wall, and ventilatory muscles. Hypoventilation is even more marked during sleep. Individuals with this disorder are usually nonobese males in their third or fourth decades who have lethargy, headache, and somnolence. Dyspnea is absent. Physical examination may reveal cyanosis and evidence of pulmonary hypertension and cor pulmonale. Hypoxemia and hypercapnia are present and improve with voluntary

hyperventilation. Erythrocytosis is common. Treatment with ventilatory stimulants is usually unrewarding. Augmentation of ventilation by mechanical methods (phrenic nerve stimulation, rocking bed, mechanical ventilators) has been helpful to some patients. Adequate oxygenation should be maintained with supplemental oxygen, but nocturnal oxygen therapy should be prescribed only if diagnostic nocturnal polysomnography has demonstrated its efficacy and safety. Primary alveolar hypoventilation resembles—but should be distinguished from—**central alveolar hypoventilation**, in which impaired ventilatory drive with chronic respiratory acidemia and hypoxemia follows an insult to the brainstem (eg, bulbar poliomyelitis, infarction, meningitis, encephalitis, trauma).

Weese-Mayer DE et al; ATS Congenital Central Hypoventilation Syndrome Subcommittee. An official ATS clinical policy statement: congenital central hypoventilation syndrome: genetic basis, diagnosis, and management. *Am J Respir Crit Care Med.* 2010 Mar 15;181(6):626–44. [PMID: 20208042]

OBSIDITY-HYOVENTILATION SYNDROME (Pickwickian Syndrome)

In obesity-hypoventilation syndrome, alveolar hypoventilation appears to result from a combination of blunted ventilatory drive and increased mechanical load imposed upon the chest by obesity. Voluntary hyperventilation returns the PCO₂ and the PO₂ toward normal values, a correction not seen in lung diseases causing chronic respiratory failure such as COPD. Most patients with obesity-hypoventilation syndrome also suffer from obstructive sleep apnea (see below), which must be treated aggressively if identified as a comorbid disorder. Therapy of obesity-hypoventilation syndrome consists mainly of weight loss, which improves hypercapnia and hypoxemia as well as the ventilatory responses to hypoxia and hypercapnia. NPPV is helpful in some patients. Respiratory stimulants may be helpful and include theophylline, acetazolamide, and medroxyprogesterone acetate, 10–20 mg every 8 hours orally. Improvement in hypoxemia, hypercapnia, erythrocytosis, and cor pulmonale are goals of therapy.

Mokhlesi B et al. Assessment and management of patients with obesity hypoventilation syndrome. *Proc Am Thorac Soc.* 2008 Feb 15;5(2):218–25. [PMID: 18250215]

HYPERVENTILATION SYNDROMES

Hyperventilation is an increase in alveolar ventilation that leads to hypocapnia. It may be caused by a variety of conditions, such as pregnancy, hypoxemia, obstructive and infiltrative lung diseases, sepsis, hepatic dysfunction, fever, and pain. The term “central neurogenic hyperventilation” denotes a monotonous, sustained pattern of rapid and deep breathing seen in comatose patients with brainstem injury of multiple causes. Functional hyperventilation may be acute or chronic. **Acute hyperventilation** presents with

hyperpnea, paresthesias, carpopedal spasm, tetany, and anxiety. **Chronic hyperventilation** may present with various nonspecific symptoms, including fatigue, dyspnea, anxiety, palpitations, and dizziness. The diagnosis of chronic hyperventilation syndrome is established if symptoms are reproduced during voluntary hyperventilation. Once organic causes of hyperventilation have been excluded, treatment of acute hyperventilation consists of rebreathing expired gas from a paper bag held over the face in order to decrease respiratory alkalemia and its associated symptoms. Anxiolytic drugs may also be useful.

Foster GT et al. Respiratory alkalosis. *Respir Care.* 2001 Apr;46(4):384–91. [PMID: 11262557]
Laffey JG et al. Hypocapnia. *N Engl J Med.* 2002 Jul 4;347(1):43–53. [PMID: 12097540]

SLEEP-RELATED BREATHING DISORDERS

Abnormal ventilation during sleep is manifested by apnea (breath cessation for at least 10 seconds) or hypopnea (decrement in airflow with drop in hemoglobin saturation of at least 4%). Episodes of apnea are **central** if ventilatory effort is absent for the duration of the apneic episode, **obstructive** if ventilatory effort persists throughout the apneic episode but no airflow occurs because of transient obstruction of the upper airway, and **mixed** if absent ventilatory effort precedes upper airway obstruction during the apneic episode. Pure central sleep apnea is uncommon; it may be an isolated finding or may occur in patients with primary alveolar hypoventilation or with lesions of the brainstem. Obstructive and mixed sleep apneas are more common and may be associated with life-threatening cardiac arrhythmias, severe hypoxemia during sleep, daytime somnolence, pulmonary hypertension, cor pulmonale, systemic hypertension, and secondary erythrocytosis.

OBSTRUCTIVE SLEEP APNEA

ESSENTIALS OF DIAGNOSIS

- ▶ Daytime somnolence or fatigue.
- ▶ A history of loud snoring with witnessed apneic events.
- ▶ Overnight polysomnography demonstrating apneic episodes with hypoxemia.

▶ General Considerations

Upper airway obstruction during sleep occurs when loss of normal pharyngeal muscle tone allows the pharynx to collapse passively during inspiration. Patients with anatomically narrowed upper airways (eg, micrognathia, macroglossia, obesity, tonsillar hypertrophy) are predisposed to the development of obstructive sleep apnea. Ingestion of alcohol or sedatives before sleeping or nasal obstruction of any type, including the common cold, may

precipitate or worsen the condition. Hypothyroidism and cigarette smoking are additional risk factors for obstructive sleep apnea. Before making the diagnosis of obstructive sleep apnea, a drug history should be obtained and a seizure disorder, narcolepsy, and depression should be excluded.

► Clinical Findings

A. Symptoms and Signs

Most patients with obstructive or mixed sleep apnea are obese, middle-aged men. Systemic hypertension is common. Patients may complain of excessive daytime somnolence, morning sluggishness and headaches, daytime fatigue, cognitive impairment, recent weight gain, and impotence. Bed partners usually report loud cyclical snoring, breath cessation, witnessed apneas, restlessness, and thrashing movements of the extremities during sleep. Personality changes, poor judgment, work-related problems, depression, and intellectual deterioration (memory impairment, inability to concentrate) may also be observed.

Physical examination may be normal or may reveal systemic and pulmonary hypertension with cor pulmonale. The patient may appear sleepy or even fall asleep during the evaluation. The oropharynx is frequently found to be narrowed by excessive soft tissue folds, large tonsils, pendulous uvula, or prominent tongue. Nasal obstruction by a deviated nasal septum, poor nasal airflow, and a nasal twang to the speech may be observed. A “bull neck” appearance is common.

B. Laboratory Findings

Erythrocytosis is common. Thyroid function tests should be obtained.

C. Other Studies

Observation of the sleeping patient may reveal loud snoring interrupted by episodes of increasingly strong ventilatory effort that fail to produce airflow. A loud snort often accompanies the first breath following an apneic episode. Definitive diagnostic evaluation for suspected sleep apnea includes otorhinolaryngologic examination and overnight **polysomnography** (the monitoring of multiple physiologic factors during sleep). Screening may be performed using home nocturnal pulse oximetry, which when normal has a high negative predictive value in ruling out significant sleep apnea. A complete **polysomnography** examination includes electroencephalography, electro-oculography, electromyography, ECG, pulse oximetry, and measurement of respiratory effort and airflow. **Polysomnography** reveals apneic episodes lasting as long as 60 seconds. Oxygen saturation falls, often to very low levels. Bradydysrhythmias, such as sinus bradycardia, sinus arrest, or atrioventricular block, may occur. Tachydysrhythmias, including paroxysmal supraventricular tachycardia, atrial fibrillation, and ventricular tachycardia, may be seen once airflow is reestablished.

► Treatment

Weight loss and strict avoidance of alcohol and hypnotic medications are the first steps in management. Weight loss

may be curative, but most patients are unable to lose the 10–20% of body weight required. **Nasal continuous positive airway pressure (nasal CPAP)** at night is curative in many patients. Polysomnography is frequently necessary to determine the level of CPAP (usually 5–15 cm H₂O) necessary to abolish obstructive apneas. Unfortunately, only about 75% of patients continue to use nasal CPAP after 1 year. Pharmacologic therapy for obstructive sleep apnea is disappointing. Supplemental oxygen may lessen the severity of nocturnal desaturation but may also lengthen apneas; it should not be routinely prescribed. Polysomnography is necessary to assess the effects of oxygen therapy. Mechanical devices inserted into the mouth at bedtime to hold the jaw forward and prevent pharyngeal occlusion have modest effectiveness in relieving apnea; however, patient compliance is not optimal.

Uvulopalatopharyngoplasty (UPPP), a procedure consisting of resection of pharyngeal soft tissue and amputation of approximately 15 mm of the free edge of the soft palate and uvula, is helpful in approximately 50% of selected patients. It is more effective in eliminating snoring than apneic episodes. UPPP may be performed on an outpatient basis with a laser. **Nasal septoplasty** is performed if gross anatomic nasal septal deformity is present. **Tracheostomy** relieves upper airway obstruction and its physiologic consequences and represents the definitive treatment for obstructive sleep apnea. However, it has numerous adverse effects, including granuloma formation, difficulty with speech, and stoma and airway infection. Furthermore, the long-term care of the tracheostomy, especially in obese patients, can be difficult. Tracheostomy and other maxillofacial surgery approaches are reserved for patients with life-threatening arrhythmias or severe disability who have not responded to conservative therapy.

Some patients with sleep apnea have nocturnal bradycardia. A pilot study in 15 patients with either central or obstructive sleep apnea showed some improvement in oxygen saturation with atrial pacing. This single study must be considered preliminary.

ACUTE RESPIRATORY FAILURE

Respiratory failure is defined as respiratory dysfunction resulting in abnormalities of oxygenation or ventilation (CO₂ elimination) severe enough to threaten the function of vital organs. Arterial blood gas criteria for respiratory failure are not absolute but may be arbitrarily established

Table 9–30. Selected causes of acute respiratory failure in adults.

Airway disorders	Neuromuscular and related disorders
Asthma	Primary neuromuscular diseases
Acute exacerbation of chronic bronchitis or emphysema	Guillain-Barré syndrome
Obstruction of pharynx, larynx, trachea, main stem bronchus, or lobar bronchus by edema, mucus, mass, or foreign body	Myasthenia gravis
Pulmonary edema	Poliomyelitis
Increased hydrostatic pressure	Polymyositis
Left ventricular dysfunction (eg, myocardial ischemia, heart failure)	Drug- or toxin-induced Botulism
Mitral regurgitation	Organophosphates
Left atrial outflow obstruction (eg, mitral stenosis)	Neuromuscular blocking agents
Volume overload states	Aminoglycosides
Increased pulmonary capillary permeability	Spinal cord injury
Acute respiratory distress syndrome	Phrenic nerve injury or dysfunction
Acute lung injury	Electrolyte disturbances: hypokalemia, hypophosphatemia
Unclear etiology	Myxedema
Neurogenic	Central nervous system disorders
Negative pressure (inspiratory airway obstruction)	Drugs: sedative, hypnotic, opioid, anesthetics
Reexpansion	Brainstem respiratory center disorders: trauma, tumor, vascular disorders, hypothyroidism
Tocolytic-associated	Intracranial hypertension
Parenchymal lung disorders	Central nervous system infections
Pneumonia	Increased CO₂ production
Interstitial lung diseases	Fever
Diffuse alveolar hemorrhage syndromes	Infection
Aspiration	Hyperalimentation with excess caloric and carbohydrate intake
Lung contusion	Hyperthyroidism
Pulmonary vascular disorders	Seizures
Thromboembolism	Rigors
Air embolism	Drugs
Amniotic fluid embolism	
Chest wall, diaphragm, and pleural disorders	
Rib fracture	
Flail chest	
Pneumothorax	
Pleural effusion	
Massive ascites	
Abdominal distention and abdominal compartment syndrome	

as a PO₂ under 60 mm Hg (7.8 kPa) or a PCO₂ over 50 mm Hg (6.5 kPa). Acute respiratory failure may occur in a variety of pulmonary and nonpulmonary disorders (Table 9–30). Only a few selected general principles of management will be reviewed here.

► Clinical Findings

Symptoms and signs of acute respiratory failure are those of the underlying disease combined with those of hypoxemia

or hypercapnia. The chief symptom of hypoxemia is dyspnea, though profound hypoxemia may exist in the absence of complaints. Signs of hypoxemia include cyanosis, restlessness, confusion, anxiety, delirium, tachypnea, bradycardia or tachycardia, hypertension, cardiac dysrhythmias, and tremor. Dyspnea and headache are the cardinal symptoms of hypercapnia. Signs of hypercapnia include peripheral and conjunctival hyperemia, hypertension, tachycardia, tachypnea, impaired consciousness, papilledema, and asterixis. The symptoms and signs of acute respiratory failure are both insensitive and nonspecific; therefore, the clinician must maintain a high index of suspicion and obtain arterial blood gas analysis if respiratory failure is suspected.

► Treatment

Treatment of the patient with acute respiratory failure consists of: (1) specific therapy directed toward the underlying disease; (2) respiratory supportive care directed toward the maintenance of adequate gas exchange; and (3) general supportive care. Only the last two aspects are discussed below.

A. Respiratory Support

Respiratory support has both nonventilatory and ventilatory aspects.

1. Nonventilatory aspects—The main therapeutic goal in acute hypoxemic respiratory failure is to ensure adequate oxygenation of vital organs. Inspired oxygen concentration should be the lowest value that results in an arterial hemoglobin saturation of $\geq 90\%$ (PO₂ ≥ 60 mm Hg [7.8 kPa]). Higher arterial oxygen tensions are of no proven benefit. Restoration of normoxia may rarely cause hypoventilation in patients with chronic hypercapnia; however, *oxygen therapy should not be withheld for fear of causing progressive respiratory acidemia*. Hypoxemia in patients with obstructive airway disease is usually easily corrected by administering low-flow oxygen by nasal cannula (1–3 L/min) or Venturi mask (24–40%). Higher concentrations of oxygen are necessary to correct hypoxemia in patients with ARDS, pneumonia, and other parenchymal lung diseases.

2. Ventilatory aspects—Ventilatory support consists of maintaining patency of the airway and ensuring adequate alveolar ventilation. Mechanical ventilation may be provided via face mask (noninvasive) or through tracheal intubation.

A. NONINVASIVE POSITIVE-PRESSURE VENTILATION—NPPV delivered via a full face mask or nasal mask is first-line therapy in COPD patients with hypercapnic respiratory failure who can protect and maintain the patency of their airway, handle their own secretions, and tolerate the mask apparatus. Several studies have demonstrated the effectiveness of this therapy in reducing intubation rates and ICU stays in patients with ventilatory failure. Patients with acute lung injury or ARDS or those who suffer from severely impaired oxygenation do not benefit and should be intubated if they require mechanical ventilation. A bilevel positive pressure ventilation mode is preferred for most patients.

B. TRACHEAL INTUBATION—Indications for tracheal intubation include: (1) hypoxemia despite supplemental oxygen, (2) upper airway obstruction, (3) impaired airway protection, (4) inability to clear secretions, (5) respiratory acidosis, (6) progressive general fatigue, tachypnea, use of accessory respiratory muscles, or mental status deterioration, and (7) apnea. In general, orotracheal intubation is preferred to nasotracheal intubation in urgent or emergency situations because it is easier, faster, and less traumatic. The position of the tip of the endotracheal tube at the level of the aortic arch should be verified by chest radiograph immediately following intubation, and auscultation should be performed to verify that both lungs are being inflated. Only tracheal tubes with high-volume, low-pressure air-filled cuffs should be used. Cuff inflation pressure should be kept below 20 mm Hg if possible to minimize tracheal mucosal injury.

C. MECHANICAL VENTILATION—Indications for mechanical ventilation include: (1) apnea, (2) acute hypercapnia that is not quickly reversed by appropriate specific therapy, (3) severe hypoxemia, and (4) progressive patient fatigue despite appropriate treatment.

Several modes of positive-pressure ventilation are available. Controlled mechanical ventilation (CMV; also known as assist-control or A-C) and synchronized intermittent mandatory ventilation (SIMV) are ventilatory modes in which the ventilator delivers a minimum number of breaths of a specified tidal volume each minute. In both CMV and SIMV, the patient may trigger the ventilator to deliver additional breaths. In CMV, the ventilator responds to breaths initiated by the patient above the set rate by delivering additional full tidal volume breaths. In SIMV, additional breaths are not supported by the ventilator unless the pressure support mode is added. Numerous alternative modes of mechanical ventilation now exist, the most popular being pressure support ventilation (PSV), pressure control ventilation (PCV), and CPAP.

PEEP is useful in improving oxygenation in patients with diffuse parenchymal lung disease such as ARDS. It should be used cautiously in patients with localized parenchymal disease, hyperinflation, or very high airway pressure requirements during mechanical ventilation.

D. COMPLICATIONS OF MECHANICAL VENTILATION—Potential complications of mechanical ventilation are numerous. Migration of the tip of the endotracheal tube into a main bronchus can cause atelectasis of the contralateral lung and overdistention of the intubated lung. Barotrauma (alternatively referred to as “volutrauma”), manifested by subcutaneous emphysema, pneumomediastinum, subpleural air cysts, pneumothorax, or systemic gas embolism, may occur in patients whose lungs are overdistended by excessive tidal volumes, especially those with hyperinflation caused by airflow obstruction. Subtle parenchymal lung injury due to overdistention of alveoli is another potential hazard. Strategies to avoid barotrauma include deliberate hypoventilation through the use of low mechanical tidal volumes and respiratory rates, resulting in “permissive hypercapnia.”

Acute respiratory alkalosis caused by overventilation is common. Hypotension induced by elevated intrathoracic pressure that results in decreased return of systemic venous blood to the heart may occur in patients treated with PEEP, those with severe airflow obstruction, and those with intravascular volume depletion. Ventilator-associated pneumonia is another serious complication of mechanical ventilation.

B. General Supportive Care

Maintenance of adequate nutrition is vital; parenteral nutrition should be used only when conventional enteral feeding methods are not possible. Overfeeding, especially with carbohydrate-rich formulas, should be avoided, because it can increase CO₂ production and may potentially worsen or induce hypercapnia in patients with limited ventilatory reserve. However, failure to provide adequate nutrition is more common. Hypokalemia and hypophosphatemia may worsen hypoventilation due to respiratory muscle weakness. Sedative-hypnotics and opioid analgesics are frequently used. They should be titrated carefully to avoid oversedation, leading to prolongation of intubation. Temporary paralysis with a nondepolarizing neuromuscular blocking agent is occasionally used to facilitate mechanical ventilation and to lower oxygen consumption. Prolonged muscle weakness due to an acute myopathy is a potential complication of these agents. Myopathy is more common in patients with kidney injury and in those given concomitant corticosteroids.

Psychological and emotional support of the patient and family, skin care to avoid decubitus ulcers, and meticulous avoidance of health care–associated infection and complications of tracheal tubes are vital aspects of comprehensive care for patients with acute respiratory failure.

Attention must also be paid to preventing complications associated with serious illness. Stress gastritis and ulcers may be avoided by administering sucralfate (1 g orally twice a day), histamine H₂-receptor antagonists, or PPIs. There is some concern that the latter two agents, which raise the gastric pH, may permit increased growth of gram-negative bacteria in the stomach, predisposing to pharyngeal colonization and ultimately HCAP; many clinicians therefore prefer sucralfate. The risk of DVT and PE may be reduced by subcutaneous administration of heparin (5000 units every 12 hours), the use of LMWH (see Table 14–13), or placement of a sequential compression device on an extremity.

► Course & Prognosis

The course and prognosis of acute respiratory failure vary and depend on the underlying disease. The prognosis of acute respiratory failure caused by uncomplicated sedative or narcotic drug overdose is excellent. Acute respiratory failure in patients with COPD who do not require intubation and mechanical ventilation has a good immediate prognosis. On the other hand, ARDS associated with sepsis has an extremely poor prognosis, with mortality rates of about 90%. Overall, adults requiring mechanical ventilation for all causes of acute respiratory failure have survival

rates of 62% to weaning, 43% to hospital discharge, and 30% to 1 year after hospital discharge.

ACUTE RESPIRATORY DISTRESS SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Acute onset of respiratory failure.
- ▶ Bilateral radiographic pulmonary opacities.
- ▶ Absence of elevated left atrial pressure (if measured, pulmonary capillary wedge pressure ≤ 18 mm Hg).
- ▶ Ratio of partial pressure of oxygen in arterial blood (P_{aO_2}) to fractional concentration of inspired oxygen (F_{iO_2}) < 200 , regardless of the level of PEEP.

General Considerations

ARDS denotes acute hypoxemic respiratory failure following a systemic or pulmonary insult without evidence of heart failure. ARDS is the most severe form of acute lung injury and is characterized by bilateral, widespread radiographic pulmonary infiltrates, normal pulmonary capillary wedge pressure (≤ 18 mm Hg) and a P_{aO_2}/F_{iO_2} ratio < 200 . ARDS may follow a wide variety of clinical events (Table 9–31). Common risk factors for ARDS include sepsis, aspiration of gastric contents, shock, infection, lung contusion, nonthoracic trauma, toxic inhalation, near-drowning, and multiple blood transfusions. About one-third of ARDS patients initially have sepsis syndrome. Pro-inflammatory cytokines released from stimulated inflammatory cells appear to be pivotal in lung injury. Although the mechanism of lung injury varies with the cause, damage to capillary endothelial cells and alveolar epithelial cells is common to ARDS regardless of cause. Damage to these cells causes increased vascular permeability and decreased production and activity of surfactant; these abnormalities lead to interstitial and alveolar pulmonary edema, alveolar collapse, and hypoxemia.

Clinical Findings

ARDS is marked by the rapid onset of profound dyspnea that usually occurs 12–48 hours after the initiating event. Labored breathing, tachypnea, intercostal retractions, and crackles are noted on physical examination. Chest radiography shows diffuse or patchy bilateral infiltrates that

Table 9–31. Selected disorders associated with ARDS.

Systemic Insults	Pulmonary Insults
Trauma	Aspiration of gastric contents
Sepsis	Embolism of thrombus, fat, air, or amniotic fluid
Pancreatitis	Miliary tuberculosis
Shock	Diffuse pneumonia (eg, SARS)
Multiple transfusions	Acute eosinophilic pneumonia
Disseminated intravascular coagulation	Cryptogenic organizing pneumonitis
Burns	Upper airway obstruction
Drugs and drug overdose	Free-base cocaine smoking
Opioids	Near-drowning
Aspirin	Toxic gas inhalation
Phenothiazines	Nitrogen dioxide
Tricyclic antidepressants	Chlorine
Amiodarone	Sulfur dioxide
Chemotherapeutic agents	Ammonia
Nitrofurantoin	Smoke
Protamine	Oxygen toxicity
Thrombotic thrombocytopenic purpura	Lung contusion
Cardiopulmonary bypass	Radiation exposure
Head injury	High-altitude exposure
Paraquat	Lung reexpansion or reperfusion

ARDS, acute respiratory distress syndrome; SARS, severe acute respiratory syndrome.

rapidly become confluent; these characteristically spare the costophrenic angles. Air bronchograms occur in about 80% of cases. Upper lung zone venous engorgement is distinctly uncommon. Heart size is normal, and pleural effusions are small or nonexistent. Marked hypoxemia occurs that is refractory to treatment with supplemental oxygen. Many patients with ARDS demonstrate multiple organ failure, particularly involving the kidneys, liver, gut, central nervous system, and cardiovascular system.

Differential Diagnosis

Since ARDS is a physiologic and radiographic syndrome rather than a specific disease, the concept of differential diagnosis does not strictly apply. Normal-permeability (“cardiogenic” or hydrostatic) pulmonary edema must be excluded, however, because specific therapy is available for that disorder. Measurement of pulmonary capillary wedge pressure by means of a flow-directed pulmonary artery catheter may be required in selected patients with suspected cardiac dysfunction. Routine use of the Swan-Ganz catheter in ARDS is discouraged.

Prevention

No measures that effectively prevent ARDS have been identified; specifically, prophylactic use of PEEP in patients at risk for ARDS has not been shown to be effective. Intravenous methylprednisolone does not prevent ARDS when given early to patients with sepsis syndrome or septic shock.

► Treatment

Treatment of ARDS must include identification and specific treatment of the underlying precipitating and secondary conditions (eg, sepsis). Meticulous supportive care must then be provided to compensate for the severe dysfunction of the respiratory system associated with ARDS and to prevent complications (see above).

Treatment of the hypoxemia seen in ARDS usually requires tracheal intubation and positive-pressure mechanical ventilation. The lowest levels of PEEP (used to recruit atelectatic alveoli) and supplemental oxygen required to maintain the PaO₂ above 55 mm Hg (7.13 kPa) or the SaO₂ above 88% should be used. Efforts should be made to decrease FiO₂ to less than 60% as soon as possible in order to avoid oxygen toxicity. PEEP can be increased as needed as long as cardiac output and oxygen delivery do not decrease and airway pressures do not increase excessively. Prone positioning may transiently improve oxygenation in selected patients by helping recruit atelectatic alveoli; however, great care must be taken during the maneuver to avoid dislodging catheters and tubes.

A variety of mechanical ventilation strategies are available. A multicenter study of 800 patients demonstrated that a protocol using volume-control ventilation with low tidal volumes (6 mL/kg of ideal body weight) resulted in a 10% absolute mortality reduction over therapy with standard tidal volumes (defined as 12 mL/kg of ideal body weight); this trial reported the lowest mortality (31%) of any intervention to date for ARDS.

Approaches to hemodynamic monitoring and fluid management in patients with acute lung injury have been carefully studied. A prospective, randomized trial comparing hemodynamic management guided either by a pulmonary artery catheter or a central venous catheter using an explicit management protocol demonstrated that a pulmonary artery catheter should not be routinely used for the management of acute lung injury. A subsequent randomized, prospective clinical study of restrictive fluid intake and diuresis as needed to maintain central venous pressure < 4 mm Hg or pulmonary artery occlusion pressure < 8 mm Hg (conservative strategy group) versus a fluid management protocol to target a central venous pressure of 10–14 mm Hg or a pulmonary artery occlusion pressure 14–18 mm Hg (liberal strategy group), showed that patients in the conservative strategy group experienced faster improvement in lung function and spent significantly fewer days on mechanical ventilation

and in the ICU without an improvement in death by 60 days or worsening nonpulmonary organ failure at 28 days. Oxygen delivery can be increased in anemic patients by ensuring that hemoglobin concentrations are at least 7 g/dL (70 g/L); patients are not likely to benefit from higher levels. Increasing oxygen delivery to supranormal levels through the use of inotropes and high hemoglobin concentrations is not clinically useful and may be harmful. Strategies to decrease oxygen consumption include the appropriate use of sedatives, analgesics, and antipyretics.

A large number of innovative therapeutic interventions to improve outcomes in ARDS patients have been or are being investigated. Unfortunately, to date, none have consistently shown benefit in clinical trials. Systemic corticosteroids have been studied extensively with variable and inconsistent results. While a few small studies suggest some specific improved outcomes when given within the first 2 weeks after the onset of ARDS, the routine use of corticosteroids is not recommended.

► Course & Prognosis

The mortality rate associated with ARDS is 30–40%. If ARDS is accompanied by sepsis, the mortality rate may reach 90%. The major causes of death are the primary illness and secondary complications such as multiple organ system failure or sepsis. Median survival is about 2 weeks. Many patients who succumb to ARDS and its complications die after withdrawal of support (see Withdrawal of Support in Chapter 5). Most survivors of ARDS are left with some pulmonary symptoms (cough, dyspnea, sputum production), which tend to improve over time. Mild abnormalities of oxygenation, diffusing capacity, and lung mechanics persist in some individuals.

 Manesh R. Patel, MD

FUNCTIONAL CLASSIFICATION OF HEART DISEASE

In the management of patients with heart disease, it is important to quantify and monitor the severity of symptoms. A commonly used classification system is that of the New York Heart Association (NYHA), shown below. However, in monitoring individual patients, it is better to document specific activities that produce symptoms, such as walking a distance; climbing stairs; or performing activities of daily living, such as using a vacuum sweeper or going grocery shopping.

Class I: No limitation of physical activity. Ordinary physical activity does not cause undue fatigue, dyspnea, or anginal pain.

Class II: Slight limitation of physical activity. Ordinary physical activity results in symptoms.

Class III: Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes symptoms.

Class IV: Unable to engage in any physical activity without discomfort. Symptoms may be present even at rest.

Other classifications have been proposed, but these are universally accepted, and clinically can be applied to both heart failure and anginal symptoms. Some experts use the category of **Class V** to describe symptoms that are atypical and can occur either at rest or with exertion.

A task force from the American College of Cardiology/American Heart Association (ACC/AHA) proposed that patients with heart failure be classified into four stages:

Stage A: Those at **high risk** for congestive heart failure (CHF) but no structural heart disease (ie, hypertension, coronary artery disease [CAD]) and no symptoms.

Stage B: Those with structural heart disease associated with CHF and **no symptoms**.

Stage C: Those with structural heart disease who have **current or prior symptoms**.

Stage D: Those with **refractory CHF** requiring some device or special intervention.

[PMID: 16168305]

CONGENITAL HEART DISEASE

Congenital lesions account for only about 2% of heart disease that presents in adulthood. As surgical and medical techniques have improved, more and more children are now reaching adulthood, and it is estimated that there are well over 1 million adults in the United States surviving with congenital heart disease. In fact, there are more adults with congenital heart disease than children. The ACC/AHA has published guidelines for the management of adults with congenital heart disease.

PULMONARY STENOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Asymptomatic unless patient has at least moderately severe lesions.
- ▶ Severe cases may present with right-sided heart failure.
- ▶ High-pitched systolic ejection murmur maximal in the second left interspace with radiation to the left shoulder.
- ▶ P₂ delayed and soft or absent. Ejection click often present and decreases with inspiration—the only right heart auscultatory event that decreases with inspiration, all others increase.
- ▶ Echocardiography/Doppler is diagnostic.
- ▶ Patients with peak pulmonic valve gradients > 60 mm Hg or mean of 40 mm Hg by echocardiography/Doppler should undergo intervention regardless of symptoms.
- ▶ A dysplastic pulmonary valve usually requires surgical treatment, while a domed pulmonary valve stenosis usually can be treated with balloon valvuloplasty.
- ▶ RV outflow tract obstruction due to conduit stenosis may be treated with a percutaneous pulmonary valve.

▶ General Considerations

Stenosis of the pulmonary valve or RV infundibulum increases the resistance to RV outflow, raises the RV pressure, and limits pulmonary blood flow. Pulmonic stenosis is often congenital, associated with other cardiac lesions. Pulmonary blood flow preferentially goes to the left lung in valvular pulmonic stenosis. Most patients with valvular pulmonic stenosis have a domed valve, though some patients have a dysplastic valve, especially those with Noonan syndrome. The phenotype of Noonan syndrome includes short stature, web neck, dental malocclusion, antimongoloid slanting of the eyes, mental retardation, and hypogonadism. Unlike those with a domed valve, patients with a dysplastic valve do not have a dilated main pulmonary artery (PA) or commissural fusion. In the absence of associated shunts, arterial saturation is normal. Infundibular stenosis may be so severe that the right ventricle (RV) is divided into a low-pressure and high-pressure chamber (double-chambered RV). Peripheral pulmonic stenosis can accompany valvular pulmonic stenosis and may be part of a variety of clinical syndromes, including the congenital rubella syndrome. Patients who have had the Ross procedure for aortic valve disease (transfer of the pulmonary valve to the aortic position with a homograft pulmonary valve placed in the pulmonary position) may experience postoperative (noncongenital) pulmonic stenosis due to an immune response in the homograft.

▶ Clinical Findings

A. Symptoms and Signs

The gradients obtained by echocardiography/Doppler, rather than cardiac catheterization data, are now used clinically. Mild pulmonic stenosis is present if the peak gradient by echocardiography/Doppler is < 30 mm Hg, moderate pulmonic stenosis is present if the peak gradient is between 30 mm Hg and 60 mm Hg, and severe pulmonic stenosis is present if the peak gradient is > 60 mm Hg or the mean gradient is > 40 mm Hg. Mild cases of pulmonic stenosis are asymptomatic; moderate to severe pulmonic stenosis may cause symptoms of dyspnea on exertion, syncope, chest pain, and eventually RV failure.

On examination, there is often a palpable parasternal lift due to right ventricular hypertrophy (RVH) and the pulmonary outflow tract may be palpable if it is enlarged. A loud, harsh systolic murmur and occasionally a prominent thrill are present in the left second and third interspaces parasternally. The murmur radiates toward the left shoulder due to the flow pattern and increases with inspiration. In mild to moderate pulmonic stenosis, a loud ejection click can be heard to precede the murmur; this sound decreases with inspiration as the increased RV filling from inspiration prematurely opens the valve during atrial systole. This is the only right-sided auscultatory event that decreases with inspiration. The reason for this is that the valve excursion in systole is less with inspiration than with expiration. This relates to premature opening of the pulmonary valve with the atrial kick into the RV. The click therefore diminishes in intensity when more volume is ejected into the RV with inspiration, raising the RV diastolic pressure. The second sound is obscured by the murmur in severe cases; the pulmonary component may be diminished, delayed, or absent. A right-sided S₄ and a prominent *a* wave in the venous pulse are present when there is RV diastolic dysfunction or a *c-v* wave if there is tricuspid regurgitation present. Right-sided S₄ gallops may be best heard in the right subclavicular area (where left-sided gallops would be distinctly uncommon). Pulmonic valve regurgitation is relatively uncommon in primary pulmonic stenosis and may be very difficult to hear, as the gradient between the reduced PA diastolic pressure and the elevated RV diastolic pressure may be quite small (low-pressure pulmonic regurgitation).

B. ECG and Chest Radiography

Right axis deviation or RVH is noted; peaked P waves provide evidence of right atrial (RA) overload. Heart size may be normal on radiographs, or there may be a prominent RV and RA or gross cardiac enlargement, depending on the severity. There is often poststenotic dilation of the main and left pulmonary arteries. The dilatation is primarily due to intrinsic abnormalities of the vessel wall, though the jet flow from the pulmonary stenosis is primarily toward the left PA, and the left PA is usually larger than the right. Pulmonary vascularity is usually normal. A careful look at the chest radiograph may reveal greater vascular perfusion of the left than the right base (Chen sign) due to the flow differential discussed earlier. Calcium may also be present in the main PA or pulmonic valve.

C. Diagnostic Studies

Echocardiography/Doppler is the diagnostic tool of choice, can provide evidence for a doming valve versus a dysplastic valve, can determine the gradient across the valve, and can provide information regarding subvalvular obstruction and the presence or absence of tricuspid or pulmonic valvular regurgitation. Catheterization is usually unnecessary for the diagnosis; it should be used only if the data are unclear or in preparation for either a percutaneous intervention or surgery. MRI and CT do not add additional information unless there is concern regarding associated cardiac lesions or peripheral pulmonary arterial lesions.

► Prognosis & Treatment

Patients with mild pulmonic stenosis have a normal life span with no intervention. Moderate stenosis may be asymptomatic in childhood and adolescence, but symptoms often appear as patients grow older. The degree of stenosis does worsen with time in many patients, so serial follow-up is important. Severe stenosis is rarely associated with sudden death but can cause right heart failure in patients as early as in their 20s and 30s. Pregnancy and exercise tends to be well tolerated except in severe stenosis.

Class I indications for intervention include all symptomatic patients and all those with a resting peak gradient over 60 mm Hg or mean > 40 mm Hg, regardless of symptoms. Percutaneous balloon valvuloplasty is highly successful in domed valve patients and is the treatment of choice. Surgical commissurotomy can also be done, or pulmonary valve replacement (with either a bioprosthetic valve or homograft) when pulmonic regurgitation is too severe or the valve is dysplastic. Pulmonary outflow tract obstruction due to RV to PA conduit obstruction or to homograft pulmonary valve stenosis can be relieved with a percutaneously implanted pulmonary valve. The applicability of this approach to primary pulmonic valve stenosis remains under investigation.

In accordance with the newest guideline recommendations, endocarditis prophylaxis is unnecessary unless there has been prior pulmonary valve endocarditis (a very rare entity).

► When to Refer

All symptomatic patients and all asymptomatic patients whose peak pulmonary valve gradient is > 60 mm Hg or mean gradient > 40 mm Hg should be referred to a cardiologist with an interest and expertise in adult congenital heart disease.

COARCTATION OF THE AORTA

ESSENTIALS OF DIAGNOSIS

- ▶ Usual presentation is systemic hypertension.
- ▶ A gradient of > 20 mm Hg by echocardiography/Doppler may be significant due to collaterals around the coarctation area reducing gradient despite severe obstruction.
- ▶ Associated bicuspid aortic valve (in 50% of patients).
- ▶ Some patients have a webbed neck (XO karyotype, Turner syndrome).
- ▶ Absent or weak femoral pulses. Delay of the palpable pulse between the femoral and brachial or radial artery.
- ▶ Systolic pressure is higher in upper extremities than in lower extremities; diastolic pressures are similar.
- ▶ ECG shows left ventricular hypertrophy; chest radiograph shows rib notching; echocardiography/Doppler is diagnostic.

► General Considerations

Coarctation of the aorta consists of localized narrowing of the aortic arch just distal to the origin of the left subclavian artery. Collateral circulation develops around the coarctation through the intercostal arteries and the branches of the subclavian arteries and can result in a lower transcoarctation gradient by enabling blood flow to bypass the obstruction. Coarctation is a cause of secondary hypertension and should be considered in young patients with elevated blood pressure (BP). The renin–angiotensin system is reset, however, and contributes to the hypertension occasionally seen even after coarctation repair. A bicuspid valve is seen in over 50% of the cases, and there is an increased incidence of cerebral berry aneurysms.

► Clinical Findings

A. Symptoms and Signs

If cardiac failure does not occur in infancy, there are usually no symptoms until the hypertension produces left ventricular (LV) failure or cerebral hemorrhage occurs. Strong arterial pulsations are seen in the neck and suprasternal notch. Hypertension is present in the arms, but the pressure is normal or low in the legs. This difference is exaggerated by exercise. Femoral pulsations are weak and are delayed in comparison with the brachial or radial pulse. Patients may have severe coarctation, but with large collateral blood vessels may have relatively small gradients because of high flow through the collaterals to the aorta distal to the coarctation. A continuous murmur heard superiorly and midline in the back or over the left anterior chest may be present when collaterals carry a lot of flow.

A significant peak gradient is > 20 mm Hg. Obtaining an angiogram is important because the gradient may not reflect the severity of the lesion. The coarctation itself may result in systolic ejection murmurs at the base, often heard posteriorly. There may be an associated aortic regurgitation or stenosis murmur due to the bicuspid aortic valve.

B. ECG and Chest Radiography

The ECG usually shows LV hypertrophy (LVH). Radiography shows scalloping of the ribs due to enlarged collateral intercostal arteries, dilation of the left subclavian artery and poststenotic aortic dilation, and LV enlargement. The coarctation region and the poststenotic dilation of the descending aorta may result in a “3” sign along aortic shadow on the PA chest radiograph (the notch in the “3” representing the area of coarctation).

C. Diagnostic Studies

Echocardiography/Doppler is usually diagnostic and may provide additional evidence for a bicuspid aortic valve. Both MRI and CT can also provide excellent images of the coarctation local anatomy. MRI and echocardiography/Doppler can also provide estimates of the gradient across the lesion. Cardiac catheterization provides definitive gradient information and is necessary if percutaneous stenting is to be considered.

► Prognosis & Treatment

Cardiac failure is common in infancy and in older untreated patients; it is uncommon in late childhood and young adulthood. Patients with a demonstrated gradient of > 20 mm Hg should be considered for intervention, especially if there is evidence of collateral blood vessels. Most untreated patients with the adult form of coarctation die before age 50 years from the complications of hypertension, rupture of the aorta, infective endarteritis, or cerebral hemorrhage. Aortic dissection also occurs with increased frequency. Coarctation of any significance may be poorly tolerated in pregnancy because of the inability to support the placental flow.

Resection of the coarctation site has a surgical mortality rate of 1–4% and includes risk of spinal cord injury. The percutaneous interventional procedure of choice is endovascular stenting when anatomically feasible. Recently, self-expanding and balloon-expandable covered stents have been shown to have a potential advantage over bare metal stents. Otherwise, surgical resection (usually with end-to-end anastomosis) should be performed. About 25% of surgically corrected patients continue to be hypertensive years after surgery because of permanent changes in the renin–angiotensin system, endothelial dysfunction, aortic stiffness, altered arch morphology, and increased ventricular stiffness.

► When to Refer

All patients with coarctation and a detectable gradient should be referred to a cardiologist with an interest in adult congenital heart disease.

ATRIAL SEPTAL DEFECT & PATENT FORAMEN OVALE

ESSENTIALS OF DIAGNOSIS

- ▶ Often asymptomatic and discovered on routine physical examination.
- ▶ RV lift; S₂ widely split and fixed.
- ▶ All atrial septal defects should be closed either by a percutaneous device or by surgery if there is any evidence of an RV volume overload regardless of symptoms.
- ▶ Echocardiography/Doppler is diagnostic.
- ▶ A patent foramen ovale is present in 25% of the population but can lead to paradoxical emboli and cerebrovascular events. Suspicion should be highest in patients who have cryptogenic stroke before age 55 years.

► General Considerations

The most common form of atrial septal defect (ASD) (80% of cases) is persistence of the ostium secundum in the mid septum. A second less common abnormality is persistence of the ostium primum (low in the septum). In many patients with an ostium primum defect, there are mitral or tricuspid valve clefts as well as a ventricular septal defect (VSD) as part of the atrioventricular (AV) septal defect. A third form of ASD is the **sinus venosus defect**, a hole usually at of the upper or lower part of the atrial septum due to failure of the embryonic superior vena cava (SVC) or the inferior vena cava (IVC) to merge with the atria properly. The IVC sinus venosus defect is uncommon. The SVC sinus venosus defect is usually associated with an anomalous connection of the right upper pulmonary vein into the SVC. The **coronary sinus ASD** is rare and basically an unroofed coronary sinus. In all cases, normally oxygenated blood from the higher-pressure LA passes into the RA, increasing RV output and pulmonary blood flow. In children, the degree of shunting across these defects may be quite large (pulmonary to systemic blood flow ratios of 3:1 or so). As the RV diastolic pressure rises from the chronic

volume overload, the RA pressure may rise and the degree of left-to-right shunting may decrease. Eventually, if the RA pressure exceeds the LA, the shunt may reverse and be primarily right-to-left and systemic cyanosis appears. The major factor in the direction of shunt flow is thus the compliance of the respective atrial chambers.

The pulmonary pressures are modestly elevated in most patients with an ASD due to the high pulmonary blood flow, but severe pulmonary hypertension with cyanosis (Eisenmenger physiology) is actually unusual, occurring in only about 15% of the patients with an ASD alone. Eventual RV failure may occur though, and most shunts should be corrected unless they are quite small ($< 1.5:1$ left-to-right shunt). In adults, a large left-to-right shunt may have begun to reverse, so the absolute left-to-right shunt measurement (Q_p/Q_s , where Q_p = pulmonary flow and Q_s = systemic flow) at the time the patient is studied may underestimate the original shunt size. In addition, in most patients the LV and LA compliance normally declines more over time than the RV and RA, and the natural history of small atrial septal shunts is to increase the left-to-right shunt as the patient ages.

ASDs predispose to atrial fibrillation due to RA enlargement, and paradoxical right-to-left emboli do occur. Interestingly, paradoxical emboli may be more common in patients with a patent foramen ovale (PFO) than a true ASD. An **aneurysm of the atrial septum** is not a true aneurysm but rather simply redundancy of the atrial septum. When present with a PFO, the back and forth swinging of the redundant atrial septum (“jump rope septum”) tends to pull open the PFO. This helps explain why more right-to-left shunting occurs in patients with an atrial septal aneurysm and PFO than in those with a PFO alone and creates the anatomic substrate for the occurrence of paradoxical emboli.

► Clinical Findings

A. Symptoms and Signs

Patients with a small or moderate ASD or with a PFO are asymptomatic unless a complication occurs. There is only trivial shunting in a PFO. With larger ASD shunts, exertional dyspnea or cardiac failure may develop, most commonly in the fourth decade of life or later. Prominent RV and PA pulsations are then readily visible and palpable. A moderately loud systolic ejection murmur can be heard in the second and third interspaces parasternally as a result of increased flow through the pulmonary valve. S_2 is widely split and does not vary with breathing due to the fact that the left-to-right shunt decreases as the RA pressure increases with inspiration and the increased RV flow is held relatively constant in inspiration and expiration (“fixed” splitting of the second sound results). In very large left-to-right shunts, a tricuspid rumble may be heard due to the high flow across the tricuspid valve.

B. ECG and Chest Radiography

Right axis deviation or RVH may be present depending on the size of the RV volume overload. Incomplete or complete right bundle branch block is present in nearly all cases of ASD, and superior axis deviation is noted in the AV septal defect, where complete heart block is often seen as well.

With sinus venosus defects, the P axis is leftward of $+15^\circ$ due to abnormal atrial activation with loss of the upper RA tissue from around the sinus node. In some patients with a secundum defect, there is notching in the inferior QRS leads (sometimes referred to as *crochetage* since the negative spike resembles a crochet needle). The chest radiograph shows large pulmonary arteries, increased pulmonary vascularity, an enlarged RA and RV, and a small aortic knob with all pre-tricuspid valve cardiac left-to-right shunts.

C. Diagnostic Studies

Echocardiography demonstrates evidence of RA and RV volume overload. The atrial defect is usually observed, although sinus venosus defects may be elusive. Many patients with a PFO also have an atrial septal aneurysm (defined as > 10 mm excursion of the septum from the static position). Echocardiography with agitated saline bubble contrast can demonstrate a right-to-left shunt, and both pulsed and color flow Doppler flow studies can demonstrate shunting in either direction. A transesophageal echocardiogram (TEE) is helpful when transthoracic echocardiography quality is not optimal because it improves the sensitivity for detection of small shunts and provides a better assessment of PFO anatomy. Radionuclide flow studies quantify left-to-right shunting by observing the bolus of contrast within the lung fields and demonstrating early recirculation, but these studies are rarely used any longer. Both CT and MRI can elucidate the atrial septal anatomy and demonstrate associated lesions, such as anomalous pulmonary venous connections. Atrial septal anatomy can be complex and MRI can both define multiple fenestrations and reveal whether there is an adequate rim around the defect to allow for safe positioning of an atrial septal device. Cardiac catheterization can define the size and location of the shunt and determine the pulmonary pressure and pulmonary vascular resistance (PVR). Cardiac catheterization is required if percutaneous closure is to be contemplated.

► Prognosis & Treatment

Patients with small atrial shunts live a normal life span with no intervention. Large shunts usually cause disability by age 40 years. Because left-to-right shunts tend to increase with age-related changes in LV compliance, most clinicians believe that closure of all left-to-right shunts over $1.5:1$ should be accomplished. This situation always results in RV volume overload. Current guidelines suggest that all ASDs should be closed if there is any evidence of RV volume overload on the echocardiogram. Increased PVR and pulmonary hypertension secondary to pulmonary vascular disease rarely occur in childhood or young adult life in secundum defects but are more common in primum defects. After age 40 years, cardiac arrhythmias (especially atrial fibrillation) and heart failure occur with increased frequency due to the chronic right heart volume overload. Paradoxical systemic arterial embolization also becomes more of a concern as RV compliance is lost and the left-to-right shunt begins to reverse.

PFOs are usually not associated with significant shunting, and therefore the patients are asymptomatic and the heart size is normal. However, PFOs are responsible for most

paradoxical emboli and are one of the most frequent causes of cryptogenic strokes in patients under age 55 years.

Occasionally, a PFO may be responsible for cyanosis, especially if the RA pressure is elevated from pulmonary or RV hypertension or from severe tricuspid regurgitation. Rarely, an enlarged aorta can torque the atrial septum and enlarge the PFO. Right-to-left shunting can usually be demonstrated by saline contrast (“bubbles”) injected during echocardiography.

Surgery involves anything from simple stitching of the foramen closed to patching of the hole with Dacron or a pericardial patch. Anomalous pulmonary venous connections are baffled to the LA through the sinus venosus defect when such anomalous veins are present. For ostium secundum ASDs, percutaneous closure by use of a variety of devices is preferred over surgery. The percutaneous closure devices often resemble double mesh umbrellas that lock the septum between the Dacron umbrellas when opened, although many designs are available, including a “coil-like” device (Hexel) with Dacron attachment where a few Dacron covered coils are placed on each side of the septum.

Patients with a PFO who have symptoms related to stroke or transient ischemic attack (especially if the age is under 55) or who have hypoxemia (especially upon standing—so called platypnea orthodeoxia) should probably have the PFO closed if no other cause for symptoms is evident. Migraine headaches with aura may be more common in patients with a PFO, suggesting some unknown substance normally metabolized in the lung is entering the systemic circulation through the PFO. However, a randomized trial of use of a PFO closure device generally did not demonstrate benefit and a case-control study did not confirm the relationship between migraine plus aura and a PFO. For patients with cryptogenic stroke or transient ischemic attack, it remains uncertain whether closure of the PFO, either by open surgical or percutaneous techniques, has any advantage over anticoagulation with either warfarin or aspirin. There are no data yet suggesting that PFO closure is better than medical therapy for cryptogenic stroke, although ongoing randomized trials will help settle this issue. The first reported trial, CLOSURE 1, did not demonstrate a clear advantage to PFO closure with a percutaneous device compared to medical therapy with aspirin. Other trials are nearing completion, and the final recommendation for how to treat this situation should soon become clearer. When cyanosis might be improved by PFO closure, it is appropriate to consider it. PFO closure is also occasionally recommended for deep sea divers to help prevent the “bends” due to nitrous oxide shunting.

▶ When to Refer

- All patients with an ASD initially discovered at echocardiography/Doppler should be evaluated by a cardiologist with expertise in adult congenital disease to ensure no other structural disease is present and to investigate whether the RV is enlarged.
- If the RA and RV sizes remain normal, serial echocardiography should be performed.
- If the RA and RV volumes increase, then referral to a cardiologist who performs percutaneous closure is warranted.

- Patients < 55 years of age with an apparent paradoxical embolus and a PFO should be referred for possible closure of the defect, although studies have yet to prove the effectiveness of percutaneous closure.
- Patients with cyanosis and a PFO with evidence for a right-to-left shunt by agitated saline bubble contrast on echocardiography.

VENTRICULAR SEPTAL DEFECT

ESSENTIALS OF DIAGNOSIS

- ▶ A restrictive VSD is small and makes a louder murmur than an unrestricted one.
- ▶ Small defects may be asymptomatic.
- ▶ Larger defects may result in pulmonary hypertension (Eisenmenger physiology) if not repaired.
- ▶ Echocardiography/Doppler is diagnostic.

▶ General Considerations

De novo VSDs are uncommon in adults. Congenital VSDs occur in various parts of the ventricular septum. Four types are often described: in **type A**, the VSD lies underneath the semilunar valves; in **type B**, the VSD is membranous with three variations; in **type C**, the inlet VSD is present below the tricuspid valve and often part of the AV canal defect; and **type D** is the muscular VSD. Membranous and muscular septal defects may spontaneously close in childhood as the septum grows and hypertrophies. A left-to-right shunt is present unless there is associated RV hypertension. The smaller the defect, the greater the gradient from the LV to the RV and the louder the murmur. The presentation in adults is dependent on the size of the shunt and whether there is associated pulmonic or subpulmonic stenosis that has protected the lung from the systemic pressure and volume. Unprotected lungs with large shunts invariably lead to pulmonary vascular disease and severe pulmonary hypertension (Eisenmenger physiology).

► Clinical Findings

A. Symptoms and Signs

The clinical features depend on the size of the defect and the presence or absence of RV outflow obstruction or increased PVR. Small shunts are associated with loud, harsh holosystolic murmurs in the left third and fourth interspaces along the sternum. A systolic thrill is common. Larger shunts may create RV volume and pressure overload. If pulmonary hypertension occurs, high-pressure pulmonary regurgitation may result. Right heart failure may gradually become evident late in the course, and the shunt will begin to balance or reverse as RV and LV systolic pressures equalize with the advent of pulmonary hypertension. Cyanosis from right-to-left shunting may then occur.

B. ECG and Chest Radiography

The ECG may be normal or may show right, left, or biventricular hypertrophy, depending on the size of the defect and the PVR. With large shunts, the RV, the LV, the LA, and the pulmonary arteries are enlarged and pulmonary vascularity is increased on chest radiographs. If an increased PVR (pulmonary hypertension) evolves, an enlarged PA with pruning of the distal pulmonary vascular bed is seen. In rare cases of a VSD high in the ventricular septum, an aortic cusp may prolapse into the VSD and reduce the VSD shunt but result in acute aortic regurgitation.

C. Diagnostic Studies

Echocardiography can demonstrate the size of the overloaded chambers and can usually define the defect anatomy. Doppler can qualitatively assess the magnitude of shunting by noting the gradient from LV to RV and, if some tricuspid regurgitation is present, the RV systolic pressure can be estimated. The septal leaflet of the tricuspid valve may be part of the VSD anatomy and the complex appears as a ventricular septal “aneurysm.” Color flow Doppler helps delineate the shunt severity and the presence of valvular regurgitation. MRI and cardiac CT can often visualize the defect and describe any other anatomic abnormalities. MRI can provide quantitative shunt data as well. Radionuclide flow studies are rarely used to quantify the relative size of the left-to-right shunt. Cardiac catheterization is usually reserved for those with at least moderate shunting to determine the PVR and the degree of pulmonary hypertension. A PVR of > 7.0 absolute units or a PVR/systemic vascular resistance (SVR) ratio of > 0.67 (two-thirds systemic) usually implies inoperability. The vasoreactivity of the pulmonary circuit may be tested at catheterization using agents such as inhaled nitric oxide.

► Prognosis & Treatment

Patients with the typical murmur as the only abnormality have a normal life expectancy except for the threat of infective endocarditis. Endocarditis is more typical of smaller shunts due to the high velocity of the jet lesion damaging the tricuspid septal leaflet or RV free wall. Antibiotic prophylaxis is still recommended in this situation. With large

shunts, CHF may develop early in life, and survival beyond age 40 years is unusual without intervention.

The newest guidelines for the management of patients with VSD include the following:

1. **Medical management (class 2b recommendation):** Pulmonary vasodilatory therapy is appropriate for adults with a VSD and severe pulmonary hypertension. The response to inhaled nitric oxide is used to guide which agent would be the best option.
2. **Surgical management (class 1 recommendation):** Closure is indicated when the left-to-right shunt ratio is > 2.0 or there is clinical LV volume overload. In addition, closure is recommended if there has been a history of infective endocarditis.
3. **Surgical management (class 2b recommendation):** Closure is reasonable if the left-to-right shunt is > 1.5 and pulmonary pressure and PVR are less than two-thirds systemic pressure and SVR. Closure is also reasonable if the shunt ratio is > 1.5 and there is evidence for heart failure.

Small shunts (pulmonary-to-systemic flow ratio < 1.5) in asymptomatic patients do not require surgery or other intervention. The presence of RV infundibular stenosis or pulmonary valve stenosis may protect the pulmonary circuit such that some patients even with a large VSD may still be operable as adults.

Surgical repair of a VSD is generally a low-risk procedure unless there is significant Eisenmenger physiology. Currently, several new percutaneous closure devices are under investigation for nonsurgical closure of VSDs. Devices for muscular VSDs are approved and those for membranous VSDs are being implanted with promising results; however, conduction disturbance is a major complication. The devices are also approved for closure of a VSD related to acute myocardial infarction, although the results in this very high-risk patient population have not been encouraging. The drugs used to treat pulmonary hypertension secondary to VSD are similar to those used to treat idiopathic (“primary”) pulmonary hypertension (see below).

► When to Refer

All patients with a VSD should be referred to a cardiologist with expertise in adult congenital disease initially to decide if long-term follow-up is warranted.

TETRALOGY OF FALLOT

ESSENTIALS OF DIAGNOSIS

- ▶ Five features are characteristic:
 - VSD.
 - RVH.
 - RV outflow obstruction from infundibular stenosis.
 - Overriding aorta in half (< 50% of the aorta over the septum).
 - A right-sided aortic arch is seen in 25%.
- ▶ Echocardiography/Doppler may underestimate significant pulmonic regurgitation. Be wary if the RV is enlarged.
- ▶ Arrhythmias are common and periodic Holter monitoring is recommended.
- ▶ If the QRS width is > 180 msec, the patient may be subject to serious arrhythmias and sudden death.

▶ General Considerations

Patients with tetralogy of Fallot have a VSD, RV infundibular stenosis, RVH, and a dilated aorta (in about 50% of patients it overrides the septum). If there is an associated ASD, the complex is referred to as pentalogy of Fallot. There may or may not be pulmonary valve stenosis as well, usually due to a bicuspid pulmonary valve. The aorta can be quite enlarged and aortic regurgitation may occur. If more than 50% of the aorta overrides into the RV outflow tract, the situation is considered as double outlet RV. Two vascular abnormalities are common: a right-sided aortic arch (in 25%) and anomalous left anterior descending coronary artery from the right cusp (7–9%). The latter is important in that surgical correction must avoid cutting this vessel when repairing the RV outflow obstruction and resulting in an anterior myocardial infarction.

Most adult patients have undergone prior surgery. If significant RV outflow obstruction is present in infancy, a Blalock-Taussig (or similar) shunt is often the initial surgical procedure to improve pulmonary blood flow. This procedure enables blood to reach the underperfused lung either by directly attaching one of the subclavian arteries to the PA (**classic Blalock shunt**) or by creating a conduit between the two (**modified Blalock shunt**). Other types of systemic to pulmonary shunts no longer in use include a window between the right PA and the aorta (**Waterston-Cooley shunt**) or a window between the left PA and the descending aorta (**Potts shunt**). In the adult, there may be a reduced upper extremity pulse on the side used for the classic Blalock procedure. **Total repair** of the tetralogy of Fallot generally includes a VSD patch and usually an enlarging RV outflow tract patch, as well as a take-down of the Blalock shunt. Often the RV outflow tract patch extends through the pulmonary valve into the PA (transannular patch), and the patient is left with varying degrees of pulmonic regurgitation. Over the years, the volume overload from severe pulmonary regurgitation becomes

the major hemodynamic problem seen in adults. Ventricular arrhythmias can also originate from the edge of the patch, and tend to increase with the size of the RV.

▶ Clinical Findings

Most adult patients in whom tetralogy of Fallot has been repaired are relatively asymptomatic unless right heart failure occurs or arrhythmias become an issue. Patients can be active and generally require no specific therapy except endocarditis prophylaxis.

A. Symptoms and Signs

Physical examination should include checking both arms for any loss of pulse from a prior shunt procedure in infancy. The jugular venous pulsations (JVP) may reveal an increased *a* wave from poor RV compliance or rarely a *c-v* wave due to tricuspid regurgitation. The right-sided arch has no consequence. The precordium may be active, often with a persistent pulmonary outflow murmur. P₂ may or may not be audible. A right-sided gallop may be heard. A residual VSD or aortic regurgitation murmur may be present. At times, the insertion site of a prior Blalock or other shunt may create a stenotic area in the PA and a continuous murmur occurs as a result.

B. ECG and Chest Radiography

The ECG reveals RVH and right axis deviation; in repaired tetralogy, there is often a right bundle branch block pattern. The chest radiograph shows a classic boot-shaped heart with prominence of the RV and a concavity in the RV outflow tract. This may be less impressive following repair. The aorta may be enlarged and right-sided. Importantly, the width of the QRS should be examined yearly. There are data that persons at greatest risk for sudden death are those with a QRS width of > 180 msec. The width of the QRS corresponds to the RV size, and in some patients, the QRS width actually decreases following relief of the pulmonary regurgitation with use of a prosthetic pulmonary valve.

C. Diagnostic Studies

Echocardiography/Doppler usually establishes the diagnosis by noting the unrestricted (large) VSD, the RV infundibular stenosis, and the enlarged aorta. In patients who have had tetralogy of Fallot repaired, echocardiography/Doppler also provides data regarding the amount of pulmonic regurgitation, RV and LV function, and the presence of aortic regurgitation.

Cardiac MRI and CT can quantitate both the pulmonary insufficiency and the RV volumes. In addition, cardiac MRI and CT can identify whether there is either a native pulmonary arterial branch stenosis or a stenosis at the distal site of a prior Blalock or other shunts such as an ASD. Cardiac catheterization is occasionally required to document the degree of pulmonic regurgitation because noninvasive studies depend on velocity gradients. Pulmonary angiography demonstrates the degree of pulmonic regurgitation, and RV angiography helps assess any postoperative outflow tract aneurysm.

► Prognosis & Treatment

A few patients with “just the right amount” of pulmonic stenosis enter adulthood without having had surgery. However, most adult patients have had surgical repair of tetralogy of Fallot, including VSD closure, resection of infundibular muscle, and insertion of an outflow tract patch. Many have a transannular patch resulting in pulmonic regurgitation. Patients should be monitored to ensure the RV volume does not increase. Low-pressure pulmonic regurgitation is difficult to diagnose except during cardiac catheterization due to the fact that the RV diastolic pressures tend to be high and the pulmonary arterial diastolic pressure is low. This means there is little gradient between the PA and the RV in diastole, so that there may be little murmur or evidence for turbulence on color flow Doppler. If the RV begins to enlarge, it must be assumed that this is due to pulmonic regurgitation until proven otherwise. Early surgical pulmonary valve replacement is increasingly being favored. A percutaneous approach may evolve for very selected patients.

If an anomalous coronary is present, then an extracardiac conduit around it from the RV to the PA may be necessary. By 20-year follow-up, reoperation is needed in about 10–15%, not only for severe pulmonic regurgitation but also for residual infundibular stenosis. Usually the pulmonary valve is replaced with a pulmonary homograft, though a porcine bioprosthetic valve is also suitable. Cryoablation of tissue giving rise to arrhythmias is sometimes performed at the time of reoperation. Branch pulmonary stenosis may be percutaneously opened by stenting. All patients require endocarditis prophylaxis. Most adults with stable hemodynamics can be quite active, and most women can carry a pregnancy adequately.

Arrhythmias are not uncommon with both atrial fibrillation and ventricular ectopy noted especially after the age of 45. Left heart disease appears to cause these arrhythmias more often than right heart disease. Biventricular dysfunction is not an uncommon consequence as the patient ages. The cause of associated LV dysfunction is often multifactorial and frequently unclear.

► When to Refer

All patients with tetralogy of Fallot should be referred to a cardiologist with expertise in adult congenital heart disease.

PATENT DUCTUS ARTERIOSUS

ESSENTIALS OF DIAGNOSIS

- ▶ Rare in adults.
- ▶ Adults with small or moderate size patent ductus arteriosus are usually asymptomatic, at least until middle age.
- ▶ Widened pulse pressure; loud S_2 .
- ▶ Continuous murmur over left pulmonary area; thrill common.
- ▶ Echocardiography/Doppler is helpful, but the lesion is best visualized by MRI, CT, or contrast angiography.

► General Considerations

The embryonic ductus arteriosus allows shunting of blood from the PA to the aorta in utero. The ductus arteriosus normally closes immediately after birth so that pulmonary blood flows only to the pulmonary arteries. Failure to close results in a persistent shunt connecting the left PA and aorta, usually near the origin of the left subclavian artery. Prior to birth, the ductus is kept patent by the effect of circulating prostaglandins; in the neonate, a patent ductus can often be closed by administration of a prostaglandin inhibitor such as indomethacin. The effect of the persistent left-to-right shunt on the pulmonary circuit is dependent on the size of the ductus. If large enough, pulmonary hypertension (Eisenmenger physiology) may occur. A small ductus may be well tolerated until adulthood.

► Clinical Findings

A. Symptoms and Signs

There are no symptoms unless LV failure or pulmonary hypertension develops. The heart is of normal size or slightly enlarged, with a hyperdynamic apical impulse. The pulse pressure is wide, and diastolic pressure is low. A continuous rough “machinery” murmur, accentuated in late systole at the time of S_2 , is heard best in the left first and second interspaces at the left sternal border. Thrills are common. If pulmonary hypertension is present (Eisenmenger physiology), the shunt may reverse and the lower body receives desaturated blood, while the upper body receives saturated blood. Thus, the hands appear normal while the toes are cyanotic and clubbed.

B. ECG and Chest Radiography

A normal tracing or LVH is found, depending on the magnitude of shunting. On chest radiographs, the heart is normal in size and contour, or there may be LV and LA enlargement. The PA, aorta, and LA are prominent because they all are in the shunt pathway.

C. Diagnostic Studies

Echocardiography/Doppler can determine LV, RV, and atrial dimensions. Color flow Doppler allows visualization of the high velocity shunt jet into the proximal left PA. Cardiac MRI and CT can demonstrate the abnormality and assess the size of the pulmonary arteries. Cardiac catheterization can establish the shunt size and direction, and define the size and anatomic features of the ductus. It can also help determine whether pulmonary hypertension has occurred. If percutaneous closure is feasible, catheterization with the use of occluder devices can be therapeutic.

► Prognosis & Treatment

Large shunts cause a high mortality rate from cardiac failure early in life. Smaller shunts are compatible with long survival, CHF being the most common complication. Infective endocarditis or endarteritis may rarely occur, and antibiotic prophylaxis for dental procedures continues to be recommended by some clinicians.

Surgical ligation of the patent ductus can be accomplished with excellent results. If the ductus has a “neck” and is of small enough size, percutaneous approaches using either coils or occluder devices are the preferred therapy. Newer duct occluder devices have a high success rate at a very low risk and are preferred. Patients with Eisenmenger physiology who have not undergone surgical ligation may benefit from vasodilator therapy. To monitor these latter patients, serial assessment of toe oxygen saturation as a marker of improvement in the right-to-left shunt is important because of the reversal in flow in the ductus.

Table 10–1 outlines the current recommendations for intervention in adult patients with a patent ductus arteriosus.

► When to Refer

All patients with patent ductus arteriosus should be referred to a cardiologist with expertise in adult congenital disease.

Laughon M et al. Patent ductus arteriosus management: what are the next steps? *J Pediatr*. 2010 Sep;157(3):355–7. [PMID: 20580017]

Warnes CA et al. ACC/AHA 2008 Guidelines for the Management of Adults With Congenital Heart Disease. A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2008 Dec 2;118(23):e714–833. [PMID: 18997169]

VALVULAR HEART DISEASE

At one time, most cases of valvular disease in the United States were due to rheumatic heart disease. While this is still true in developing countries, other causes are much more common. In the elderly, “degenerative” calcific aortic valvular disease is believed to be due to a process similar to that which produces atherosclerosis, and studies have suggested that up to 25% of adults over age 65 have some

Table 10–1. Recommendations for interventions in patients with patent ductus arteriosus.¹

Class I

- A. Closure of a patent ductus arteriosus either percutaneously or surgically is indicated for the following:
 1. Presence of left atrial or left ventricular enlargement, pulmonary artery hypertension, or net left-to-right shunting (level of evidence: C)
 2. Prior endarteritis (level of evidence: C)
- B. Consultation with adult congenital heart disease interventional cardiologists is recommended before surgical closure is selected as the method of repair for patients with a calcified patent ductus arteriosus (level of evidence: C).
- C. Surgical repair by a surgeon experienced in coronary heart disease surgery is recommended when:
 1. The patent ductus arteriosus is too large for device closure (level of evidence: C).
 2. Distorted ductal anatomy precludes device closure (eg, aneurysm or endarteritis) (level of evidence: B).

Class IIa

- A. It is reasonable to close an asymptomatic small patent ductus arteriosus by catheter device (level of evidence: C).
- B. Patent ductus arteriosus closure is reasonable for patients with pulmonary artery hypertension with a net left-to-right shunt (level of evidence: C).

Class III

Patent ductus arteriosus closure is not indicated for patients with pulmonary artery hypertension and net right-to-left shunt (level of evidence: C).

¹Class I indicates treatment is useful and effective, class IIa indicates weight of evidence is in favor of usefulness/efficacy, class IIb indicates weight of evidence is less well established, and class III indicates intervention is not useful/effective and may be harmful. Type A recommendations are based on data derived from multiple randomized clinical trials or meta-analyses. Type B recommendations are based on data derived from a single randomized clinical trials or large nonrandomized studies. Type C recommendations are based on consensus of opinion of the experts or on data derived from small studies, retrospective studies, or registries.

ACC/AHA, American College of Cardiology/American Heart Association.

thickening of their aortic valve (aortic sclerosis) while 2–3% have frank aortic stenosis. Aortic sclerosis alone is a marker for future cardiovascular events and death. There is also increasing information that genetic markers associated with aortic stenosis play a role in the expression of this disease. Calcium deposition may also occur in the mitral annulus creating enough dysfunction of the valve that either stenosis or regurgitation (or both) results. Mitral valve prolapse is still frequently seen and rarely associated with the hyperadrenergic syndrome in younger patients. AV valvular regurgitation may be due to LV dysfunction (mitral regurgitation) or RV dysfunction (tricuspid regurgitation).

The typical findings of each native lesion are described in Table 10–2. Table 10–3 outlines bedside maneuvers to distinguish among the various murmurs.

Table 10–2. Differential diagnosis of valvular heart disease.

	Mitral Stenosis	Mitral Regurgitation	Aortic Stenosis	Aortic Regurgitation	Tricuspid Stenosis	Tricuspid Regurgitation
Inspection	Malar flush, precordial bulge, and diffuse pulsation in young patients.	Usually prominent and hyperdynamic apical impulse to left of MCL.	Sustained PMI, prominent atrial filling wave.	Hyperdynamic PMI to left of MCL and downward. Visible carotid pulsations. Pulsating nailbeds (Quincke), head bob (deMusset).	Giant <i>a</i> wave in jugular pulse with sinus rhythm. Peripheral edema or ascites, or both.	Large <i>v</i> wave in jugular pulse; time with carotid pulsation. Peripheral edema or ascites, or both.
Palpation	“Tapping” sensation over area of expected PMI. Right ventricular pulsation left third to fifth ICS parasternally when pulmonary hypertension is present. P_2 may be palpable.	Forceful, brisk PMI; systolic thrill over PMI. Pulse normal, small, or slightly collapsing.	Powerful, heaving PMI to left and slightly below MCL. Systolic thrill over aortic area, sternal notch, or carotid arteries in severe disease. Small and slowly rising carotid pulse. If bicuspid AS, check for delay at femoral artery to exclude coarctation.	Apical impulse forceful and displaced significantly to left and downward. Prominent carotid pulses. Rapidly rising and collapsing pulses (Corrigan pulse).	Pulsating, enlarged liver in ventricular systole.	Right ventricular pulsation. Systolic pulsation of liver.
Heart sounds, rhythm, and blood pressure	S_1 loud if valve mobile. Opening snap following S_2 . The worse the disease, the closer the S_2 -opening snap interval.	S_1 normal or buried in early part of murmur (exception in mitral prolapse where murmur may be late). Prominent third heart sound when severe MR. Atrial fibrillation common. Blood pressure normal. Midsystolic clicks may be present and may be multiple.	A_2 normal, soft, or absent. Prominent S_4 . Blood pressure normal, or systolic pressure normal with high diastolic pressure.	S_1 normal or reduced, A_2 loud. Wide pulse pressure with diastolic pressure < 60 mm Hg. When severe, gentle compression of femoral artery with diaphragm of stethoscope may reveal diastolic flow (Duroziez) and pressure in leg on palpation > 40 mm Hg than arm (Hill).	S_1 often loud.	Atrial fibrillation may be present.
Murmurs						
Location and transmission	Localized at or near apex. Diastolic rumble best heard in left lateral position; may be accentuated by having patient do sit-ups. Rarely, short diastolic murmur along lower left sternal border (Graham Steell) in severe pulmonary hypertension.	Loudest over PMI; posteriorly directed jets (ie, anterior mitral prolapse) transmitted to left axilla, left infrascapular area; anteriorly directed jets (ie, posterior mitral prolapse) heard over anterior precordium. Murmur unchanged after premature beat.	Right second ICS parasternally or at apex, heard in carotid arteries and occasionally in upper interscapular area. May sound like MR at apex (Gallavardin phenomenon), but murmur occurs after S_1 and stops before S_2 .	Diastolic: louder along left sternal border in third to fourth interspace. Heard over aortic area and apex. May be associated with low-pitched middiastolic murmur at apex (Austin Flint) due to functional mitral stenosis. If due to an enlarged aorta, murmur may radiate to right sternal border.	Third to fifth ICS along left sternal border out to apex. Murmur increases with inspiration.	Third to fifth ICS along left sternal border. Murmur hard to hear but increases with inspiration. Sit-ups can increase cardiac output and accentuate murmur.

Timing	Relation of opening snap to A ₂ important. The higher the LA pressure, the earlier the opening snap. Presystolic accentuation before S ₁ if in sinus rhythm. Graham Steell begins with P ₂ (early diastole) if associated pulmonary hypertension.	Pansystolic: begins with S ₁ and ends at or after A ₂ . May be late systolic in mitral valve prolapse.	Begins after S ₁ , ends before A ₂ . The more severe the stenosis, the later the murmur peaks.	Begins immediately after aortic second sound and ends before first sound (blurring both); helps distinguish from MR.	Rumble often follows audible opening snap.	At times, hard to hear. Begins with S ₁ and fills systole. Increases with inspiration.
Character	Low-pitched, rumbling; presystolic murmur merges with loud S ₁ .	Blowing, high-pitched; occasionally harsh or musical.	Harsh, rough.	Blowing, often faint.	As for mitral stenosis.	Blowing, coarse, or musical.
Optimum auscultatory conditions	After exercise, left lateral recumbency. Bell chest piece lightly applied.	After exercise; use diaphragm chest piece. In prolapse, findings may be more evident while standing.	Use stethoscope diaphragm. Patient resting, leaning forward, breath held in full expiration.	Use stethoscope diaphragm. Patient leaning forward, breath held in expiration.	Use stethoscope bell. Murmur usually louder and at peak during inspiration. Patient recumbent.	Use stethoscope diaphragm. Murmur usually becomes louder during inspiration.
Radiography	Straight left heart border from enlarged LA appendage. Elevation of left mainstem bronchus. Large right ventricle and pulmonary artery if pulmonary hypertension is present. Calcification in mitral valve in rheumatic mitral stenosis or in annulus in calcific mitral stenosis.	Enlarged left ventricle and LA.	Concentric left ventricular hypertrophy. Prominent ascending aorta. Calcified aortic valve common.	Moderate to severe left ventricular enlargement. Aortic root often dilated.	Enlarged right atrium with prominent SVC and azygous shadow.	Enlarged right atrium and right ventricle.
ECG	Broad P waves in standard leads; broad negative phase of diphasic P in V ₁ . If pulmonary hypertension is present, tall peaked P waves, right axis deviation, or right ventricular hypertrophy appears.	Left axis deviation or frank left ventricular hypertrophy. P waves broad, tall, or notched in standard leads. Broad negative phase of diphasic P in V ₁ .	Left ventricular hypertrophy.	Left ventricular hypertrophy.	Tall, peaked P waves. Possible right ventricular hypertrophy.	Right axis usual.

Table 10–2. Differential diagnosis of valvular heart disease. (Continued)

	Mitral Stenosis	Mitral Regurgitation	Aortic Stenosis	Aortic Regurgitation	Tricuspid Stenosis	Tricuspid Regurgitation
Echocardiography						
Two-dimensional echocardiography	Thickened, immobile mitral valve with anterior and posterior leaflets moving together. “Hockey stick” shape to opened anterior leaflet in rheumatic mitral stenosis. Annular calcium with thin leaflets in calcific mitral stenosis. LA enlargement, normal to small left ventricle. Orifice can be traced to approximate mitral valve orifice area.	Thickened mitral valve in rheumatic disease; mitral valve prolapse; flail leaflet or vegetations may be seen. Dilated left ventricle in volume overload. Operate for left ventricular end-systolic dimension > 4.5 cm.	Dense persistent echoes from the aortic valve with poor leaflet excursion. Left ventricular hypertrophy late in the disease. Bicuspid valve in younger patients.	Abnormal aortic valve or dilated aortic root. Diastolic vibrations of the anterior leaflet of the mitral valve and septum. In acute aortic regurgitation, premature closure of the mitral valve before the QRS. When severe, dilated left ventricle with normal or decreased contractility. Operate when left ventricular end-systolic dimension > 5.0 cm.	In rheumatic disease, tricuspid valve thickening, decreased early diastolic filling slope of the tricuspid valve. In carcinoid, leaflets fixed, but no significant thickening.	Enlarged right ventricle with paradoxical septal motion. Tricuspid valve often pulled open by displaced chordae.
Continuous and color flow Doppler and TEE	Prolonged pressure half-time across mitral valve allows estimation of gradient. MVA estimated from pressure half-time. Indirect evidence of pulmonary hypertension by noting elevated right ventricular systolic pressure measured from the tricuspid regurgitation jet.	Regurgitant flow mapped into LA. Use of PISA helps assess MR severity. TEE important in prosthetic mitral valve regurgitation.	Increased transvalvular flow velocity; severe AS when peak jet > 4 m/sec (64 mm Hg). Valve area estimate using continuity equation is poorly reproducible.	Demonstrates regurgitation and qualitatively estimates severity based on percentage of left ventricular outflow filled with jet and distance jet penetrates into left ventricle. TEE important in aortic valve endocarditis to exclude abscess. Mitral inflow pattern describes diastolic dysfunction.	Prolonged pressure half-time across tricuspid valve can be used to estimate mean gradient. Severe tricuspid stenosis present when mean gradient > 5 mm Hg.	Regurgitant flow mapped into right atrium and venae cavae. Right ventricular systolic pressure estimated by tricuspid regurgitation jet velocity.

A₂, aortic second sound; AS, aortic stenosis; ICS, intercostal space; LA, left atrial; MCL, midclavicular line; MR, mitral regurgitation; MVA, measured valve area; P₂, pulmonary second sound; PISA, proximal isovelocity surface area; PMI, point of maximal impulse; S₁, first heart sound; S₂, second heart sound; S₄, fourth heart sound; SVC, superior vena cava; TEE, transesophageal echocardiography; V₁, chest ECG lead 1.

Table 10-3. Effect of various interventions on systolic murmurs.

Intervention	Hypertrophic Obstructive Cardiomyopathy	Aortic Stenosis	Mitral Regurgitation	Mitral Prolapse
Valsalva	↑	↓	↓ or ×	↑ or ↓
Standing	↑	↑ or ×	↓ or ×	↑
Handgrip or squatting	↓	↓ or ×	↑	↓
Supine position with legs elevated	↓	↑ or ×	×	↓
Exercise	↑	↑ or ×	↓	↑

Rheumatic mitral stenosis results in thickening of the leaflets, fusion of the mitral commissures, retraction, thickening and fusion of the chordae, and calcium deposition in the valve. Mitral stenosis can also occur due to congenital disease with chordal fusion or papillary muscle malposition. The papillary muscles may be abnormally close together, sometimes so close they merge into a single papillary muscle (the parachute mitral valve). In these patients, the chordae or valvular tissue (or both) may also be fused. In other patients, mitral annular calcification may build up enough to produce a mitral gradient, most often in the elderly or patients with end-stage renal disease. Calcium in the mitral annulus virtually invades the mitral leaflet from the annulus inward. Mitral valve obstruction may also develop in patients who have had mitral valve repair with a mitral annular ring that is too small, or in patients who have had a surgical valve replacement (prosthetic valve-patient mismatch).

MITRAL STENOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea when the stenosis becomes severe.
- ▶ Symptoms often precipitated by onset of atrial fibrillation or pregnancy.
- ▶ Two syndromes occur; one with moderate mitral stenosis and pulmonary edema, and one with severe mitral stenosis, pulmonary hypertension, and low cardiac output.
- ▶ Echocardiography/Doppler is diagnostic.
- ▶ Intervention indicated for symptoms or evidence of pulmonary hypertension. Most symptomatic patients have a valve area < 1.5 cm².

▶ General Considerations

Patients with mitral stenosis are usually presumed to have underlying rheumatic heart disease, though a history of rheumatic fever is usually noted in only about one-third.

▶ Clinical Findings

A. Symptoms and Signs

A characteristic finding of rheumatic mitral stenosis is an opening snap following A₂ due to the stiff mitral valve. The interval between the opening snap and aortic closure sound is long when the LA pressure is low but shortens as the LA pressure rises and approaches the aortic diastolic pressure. As mitral stenosis worsens, there is a localized diastolic murmur low in pitch whose duration increases with the severity of the stenosis. The heart murmur is best heard at the apex with the patient in the left lateral position (Table 10–2).

Two clinical syndromes occur with mitral stenosis. In **mild to moderate mitral stenosis**, LA pressure and cardiac output may be essentially normal, and the patient is either asymptomatic or symptomatic only with extreme exertion. The measured valve area is usually between 1.5 cm² and 1.0 cm². In **severe mitral stenosis** (valve area < 1.0 cm²), severe pulmonary hypertension develops due to a “secondary stenosis” of the pulmonary vasculature. In this condition, pulmonary edema is uncommon, but symptoms of low cardiac output and right heart failure predominate.

Paroxysmal or chronic atrial fibrillation develops in 50–80% of patients. Any increase in the heart rate reduces diastolic filling time and increases the mitral gradient. A sudden increase in heart rate may precipitate pulmonary edema. Therefore, heart rate control is important to maintain, with slow heart rates allowing for more diastolic filling of the LV.

B. Diagnostic Studies

Echocardiography is the most valuable technique for assessing mitral stenosis. A scoring system is used to help define which patients are eligible for percutaneous valvuloplasty. One to four points are assigned to each of four observed parameters, with one being the least involvement and four the greatest: mitral leaflet thickening, mitral leaflet mobility, submitral scarring, and commissural calcium. Patients with a total valve score of 8 or less respond best to balloon valvuloplasty. LA size can also be determined by echocardiography: increased size denotes an increased likelihood of atrial fibrillation and thrombus formation. The effective mitral valve area can be determined by planimetry of the smallest mitral orifice or by using the continuous-wave Doppler gradient. Some determination of the pulmonary pressure can also be quantitated by measuring the peak RV pressure from the tricuspid velocity jet signal.

Because echocardiography and careful symptom evaluation provide most of the needed information, cardiac catheterization is used primarily to detect associated valve, coronary, or myocardial disease—usually after the decision to intervene has been made.

► Treatment & Prognosis

In most cases, there is a long asymptomatic phase, followed by subtle limitation of activity. Pregnancy and its associated increase in cardiac output, which results in an increased transmitral pressure gradient, often precipitate symptoms. Toward the end of pregnancy, the cardiac output is also maintained by an increase in heart rate, further increasing the mitral gradient by shortening diastolic time. Patients with moderate to severe mitral stenosis should have the condition corrected prior to becoming pregnant if possible. Pregnant patients who become symptomatic can undergo successful surgery, preferably in the third trimester, although balloon valvuloplasty is the treatment of choice if the echo score is low enough.

The onset of atrial fibrillation often precipitates symptoms, which usually initially improve with control of the ventricular rate or restoration of sinus rhythm. Conversion to and subsequent maintenance of sinus rhythm are most commonly successful when the duration of atrial fibrillation is brief (< 6–12 months) and the LA is not severely dilated (diameter < 4.5 cm). Once atrial fibrillation occurs, the patient should receive warfarin anticoagulation therapy even if sinus rhythm is restored, since atrial fibrillation often recurs even with antiarrhythmic therapy and 20–30% of these patients will have systemic embolization if untreated. Systemic embolization in the presence of only mild to moderate disease is not an indication for surgery but should be treated with warfarin anticoagulation.

Newer novel anticoagulants, such as dabigatran and rivaroxaban, are currently not approved for the prevention of stroke and non-central nervous system embolism in patients with rheumatic valvular atrial fibrillation.

Indications for intervention focus on symptoms such as an episode of pulmonary edema, a decline in exercise capacity, or any evidence for pulmonary hypertension (peak systolic pulmonary pressure > 50 mm Hg). Some experts believe that the presence of atrial fibrillation should be a consideration for an intervention. Other groups use the findings from exercise echocardiography to help with decision making, but the results from these studies are not standardized. In some patients, symptoms develop with calculated mitral valve areas between 1.5 cm² and 1.0 cm². Symptoms should drive the decision to intervene in these patients, not the estimated valve area.

Open mitral commissurotomy is now rarely performed and has given way to percutaneous balloon valvuloplasty. Ten-year follow-up data comparing surgery to balloon valvuloplasty suggest no real difference in outcome between the two modalities. Replacement of the valve is indicated when combined stenosis and regurgitation are present or when the mitral valve echo score is > 8–10. Percutaneous mitral valvuloplasty has a very low mortality rate (< 0.5%) and low morbidity rate (3–5%). Operative mortality rates are also low: 1–3% in most institutions. Repeat valvuloplasty can be done if the morphology of the valve is suitable. A Maze procedure may be done at the same time to reduce recurrent atrial arrhythmias.

Mechanical mitral prosthetic valves are more prone to thrombosis than aortic valves. Bioprosthetic valves degenerate after about 10–12 years and percutaneous balloon valvuloplasty procedures cannot be done on bioprosthetic valves should stenosis occur. Younger patients and those with end-stage renal disease do least well with bioprosthetic heart valves, although recent data have questioned the role of chronic kidney disease as a major risk factor. Endocarditis prophylaxis is always indicated for prosthetic valves. Percutaneous balloon valvuloplasty can safely be done during pregnancy if symptoms warrant.

► When to Refer

- Patients with mitral stenosis should be monitored with yearly examinations and echocardiograms.
- All patients should initially be seen by a cardiologist, who can then decide how often the patient needs cardiology follow-up.

MITRAL REGURGITATION (Mitral Insufficiency)

ESSENTIALS OF DIAGNOSIS

- ▶ May be asymptomatic for many years (or for life) or may cause left-sided heart failure.
- ▶ Echocardiographic findings can help decide when to operate.
- ▶ For chronic primary mitral regurgitation, surgery is indicated for symptoms or when the LV ejection fraction is $< 60\%$ or the echocardiographic LV end-systolic diameter is > 4.0 cm.
- ▶ In patients with mitral prolapse and severe mitral regurgitation, earlier surgery is indicated if mitral repair can be performed.

▶ General Considerations

Mitral regurgitation places a volume load on the heart (increases preload) but reduces afterload. The result is an enlarged LV with an increased ejection fraction (EF). Over time, the stress of the volume overload reduces myocardial contractile function; when this occurs, there is a drop in EF and a rise in end-systolic volume.

▶ Clinical Findings

A. Symptoms and Signs

In acute mitral regurgitation, the LA size is not large, and LA pressure rises abruptly, leading to pulmonary edema if severe. When chronic, the LA enlarges progressively and the increased volume can be handled without a major rise in the LA pressure; the pressure in pulmonary veins and capillaries may rise only transiently during exertion. Exertional dyspnea and fatigue progress gradually over many years.

Mitral regurgitation leads to chronic LA and LV enlargement and may result in subsequent atrial fibrillation and LV dysfunction. Clinically, mitral regurgitation is characterized by a pansystolic murmur maximal at the apex, radiating to the axilla and occasionally to the base; a hyperdynamic LV impulse and a brisk carotid upstroke; and a prominent third heart sound due to the increased volume returning to the LV in early diastole (Tables 10–2 and 10–3). The mitral regurgitation murmur due to mitral valve prolapse tends to radiate anteriorly in the presence of posterior leaflet prolapse and posteriorly when the prolapse is primarily of the anterior leaflet.

B. Diagnostic Studies

Echocardiography is useful in demonstrating the underlying pathologic process (rheumatic, prolapse, flail leaflet, cardiomyopathy), and Doppler techniques provide qualitative and semiquantitative estimates of the severity of mitral regurgitation. Echocardiographic information concerning LV size and function, LA size, PA pressure, and RV

function can be invaluable in planning treatment as well as in recognizing associated lesions. TEE may help reveal the cause of regurgitation and is especially useful in patients who have had mitral valve replacement, in suspected endocarditis, and in identifying candidates for valvular repair. Echocardiographic dimensions and measures of systolic function are critical in deciding the timing of surgery. In the past, exercise radionuclide angiography for measurements of exercise EF or determination of myocardial stress–EF relationships was recommended, but this is now rarely done. There is a growing body of evidence of the usefulness of B-type natriuretic peptide (BNP) in the early identification of LV dysfunction in the presence of mitral regurgitation, and it is likely that future guidelines will use this test to help decide when to intervene.

Cardiac MRI is occasionally useful, if specific myocardial causes are being sought (such as amyloid or myocarditis) or if myocardial viability assessment is needed prior to deciding whether to add coronary artery bypass grafting to mitral repair in patients with chronic ischemic mitral regurgitation.

Cardiac catheterization provides a further assessment of regurgitation and its hemodynamic impact along with LV function, resting cardiac output, and PA pressure. Coronary angiography is often indicated to determine the presence of CAD prior to valve surgery in all men over age 35 years and women over age 35 with risk factors, according to the 2006 ACC/AHA valvular guidelines. In younger patients (< 50 years of age), cardiac multidetector CT may be adequate to screen patients with valvular heart disease for asymptomatic CAD.

▶ Treatment & Prognosis

A. Primary Mitral Regurgitation

LA enlargement is at times considerable in chronic mitral regurgitation; the degree of LV enlargement usually reflects the severity and chronicity of regurgitation. Calcification of the mitral valve is less common than in pure mitral stenosis. Hemodynamically, LV volume overload may ultimately lead to LV failure and reduced cardiac output. For many years, the LV end-diastolic pressure and the cardiac output will be normal at rest. Nonrheumatic mitral regurgitation may develop abruptly, such as with papillary muscle dysfunction following myocardial infarction, valve perforation in infective endocarditis, or ruptured chordae tendineae in mitral valve prolapse.

Acute mitral regurgitation due to endocarditis, myocardial infarction, and ruptured chordae tendineae often requires emergency surgery. Some patients can be stabilized with vasodilators or intra-aortic balloon counterpulsation, which reduce the amount of regurgitant flow by lowering systemic vascular resistance. Patients with chronic lesions may remain asymptomatic for many years. Surgery is necessary when symptoms develop. However, because progressive and irreversible deterioration of LV function may occur prior to the onset of symptoms, early operation is indicated even in asymptomatic patients with a reduced EF ($< 60\%$) or marked LV dilation (end-systolic dimension > 4.0 cm on echocardiography). In some institutions, the calculation of an effective regurgitant orifice area by

echocardiogram has proven useful in helping decide the severity of the mitral regurgitation. Regurgitant orifice areas $> 40 \text{ mm}^2$ are considered severe.

There is controversy regarding the role of afterload reduction in mitral regurgitation, since the lesion inherently results in a reduction in afterload, and there are no data that chronic afterload reduction is effective. A heightened sympathetic state has led some experts to suggest β -blockade instead. Cardiomyopathy and mitral regurgitation due to persistent tachycardia may also improve with treatment of the higher heart rate.

B. Myocardial Disease and Mitral Regurgitation

When mitral regurgitation is due to papillary dysfunction, it may subside as the infarction heals or LV dilation diminishes. The cause of the regurgitation in most situations is displacement of the papillary muscles and an enlarged mitral annulus rather than true papillary muscle ischemia. The fundamental problem is the lack of leaflet coaptation during systole. In acute infarction, rupture of the papillary muscle may occur with catastrophic results. Transient—but sometimes severe—mitral regurgitation may occur during episodes of myocardial ischemia and contribute to flash pulmonary edema. Patients with dilated cardiomyopathies of any origin may have **secondary mitral regurgitation** due to papillary muscle displacement or dilation of the mitral annulus. In patients with ischemic cardiomyopathy, ventricular reconstructive surgery to restore the mitral apparatus anatomy and reshape the ventricle (Dor procedure) has had limited success. If mitral valve replacement is performed, preservation of the chordae to the native valve helps prevent further ventricular dilation following surgery. Several groups have reported good results with mitral valve repair in patients with left ventricular ejection fraction (LV EF) $< 30\%$ and secondary mitral regurgitation. Recent guidelines consider it acceptable to attempt mitral valve repair in patients with an EF $< 30\%$ or an LV end-systolic dimension $> 5.5 \text{ cm}$, or both, as long as repair and preservation of the chordae are possible. There may also be a role for cardiac resynchronization therapy with biventricular pacemaker insertion in reducing mitral regurgitation due to cardiomyopathy.

Currently, there are several ongoing trials of percutaneous approaches to reducing mitral regurgitation. These approaches include the use of a mitral clip device to create a double orifice mitral valve, various coronary catheter devices to reduce the mitral annular area, and devices to reduce the septal-lateral ventricular size and consequent mitral orifice size. Some success has been noted with the mitral clip device. In addition, vascular plugging and occluder devices are being used in selected patients to occlude perivalvular leaks around prosthetic valves.

► When to Refer

All patients with more than mild mitral regurgitation should be referred to a cardiologist for an evaluation. Serial examinations and echocardiograms (usually yearly) should be obtained, and referral made if there is any increase in the LV end-systolic dimensions, a fall in the EF to $< 60\%$, or symptoms.

MITRAL VALVE PROLAPSE

ESSENTIALS OF DIAGNOSIS

- Single or multiple mid-systolic clicks often heard on auscultation.
- Murmur may be pansystolic or only late in systole.
- Often associated with skeletal changes (straight back, pectus excavatum, and scoliosis) or hyperflexibility of joints.
- Echocardiography is confirmatory with prolapse of mitral leaflets in systole into the LA.
- Chest pain and palpitations common symptoms in the young adult.

► General Considerations

The significance of **mitral valve prolapse** (“floppy” or **myxomatous mitral valve**) is in dispute because of the frequency with which it is diagnosed by echocardiography even in healthy young women (up to 10%). A controversial hyperadrenergic syndrome has also been described (especially in young females) that may be responsible for some of the noncardiac symptoms observed. Fortunately, this hyperadrenergic component attenuates with age. Some patients with mitral prolapse have findings of a systemic collagen abnormality (Marfan or Ehlers-Danlos syndrome). In these conditions, a dilated aortic root and aortic regurgitation may coexist.

Patients who have only a mid-systolic click usually have no sequelae, but significant mitral regurgitation may develop, occasionally due to rupture of chordae tendineae (flail leaflet) or progressive annular dilation. The need for

valve repair or replacement increases with age, so that approximately 2% per year of patients with clinically significant regurgitation over age 60 years will eventually require surgery.

► Clinical Findings

A. Symptoms and Signs

Mitral valve prolapse is usually asymptomatic but may be associated with nonspecific chest pain, dyspnea, fatigue, or palpitations. Most patients are female, many are thin, and some have skeletal deformities such as pectus excavatum or scoliosis. On auscultation, there are characteristic mid-systolic clicks that may be multiple and emanate from the chordae or redundant valve tissue. If leaflets fail to come together properly, the clicks will be followed by a late systolic murmur. As the mitral regurgitation worsens, the murmur is heard more and more throughout systole. The smaller the LV chamber, the greater the degree of prolapse, and thus auscultatory findings are often accentuated in the standing position or during the Valsalva maneuver.

B. Diagnostic Studies

The diagnosis is primarily clinical and confirmed echocardiographically. Mitral prolapse is often associated with aortic root disease, and any evidence for a dilated aorta by chest radiography should prompt either CT or MRI angiography. If palpitations are an issue, an ambulatory monitor is often helpful to distinguish atrial from ventricular tachyarrhythmias.

► Treatment

β-Blockers in low doses are used to treat the hyperadrenergic state when present and are usually satisfactory for treatment of arrhythmias. Selective serotonin reuptake inhibitors have also been used, especially if orthostatic hypotension or anxiety is associated with mitral valve prolapse; results have been mixed. Afterload reduction has not been shown to be effective when mitral regurgitation is present.

Mitral valve repair is strongly favored over valve replacement, and its efficacy has led many to recommend intervention earlier and earlier in the course of the disease process. Mitral repair may include shortening of chordae, chordae transfers, wedge resection of redundant valve tissue, or the insertion of a mitral annular ring to reduce the annular size, or some combination of these techniques. Stitching of the leaflets together to create a double orifice mitral valve is also used at times (Alfieri procedure) and can be performed percutaneously. Mitral repair or replacement can be achieved through a right minithoracotomy with or without the use of a robotic device. Endocarditis prophylaxis is no longer recommended for most patients with mitral valve prolapse regardless of the degree of mitral regurgitation. A variety of percutaneous techniques and devices have been tried with some success (notably in the mitral clip trials). The

use of a ventricular remodeling device that pulls the mitral annulus in an anteroposterior direction and can be placed without cardiopulmonary bypass (the Coapsys system) reported favorable results, but it is unclear if it will ever be marketed.

► When to Refer

- All patients with mitral valve prolapse and audible mitral regurgitation should be seen at least once and then periodically by a cardiologist. If only mitral clicks are audible, then serial echocardiography is not warranted.
- Periodic echocardiography is warranted to assess LV size (especially end-systolic dimensions) and EF when mitral regurgitation is present.

AORTIC STENOSIS

ESSENTIALS OF DIAGNOSIS

- Congenital bicuspid aortic valve, usually asymptomatic until middle or old age.
- “Degenerative” or calcific aortic stenosis; same risk factors as atherosclerosis.
- Symptoms likely once the mean gradient is > 40 mm Hg.
- Echocardiography/Doppler is diagnostic.
- Surgery indicated for symptoms.
- Surgery considered for asymptomatic patients with severe aortic stenosis.
- Emerging role for BNP as marker of early LV myocardial failure.

► General Considerations

There are two common clinical scenarios in which aortic stenosis is prevalent. The first is due to a congenitally abnormal **unicuspid** or **bicuspid valve**, rather than tricuspid. Symptoms occur in young or adolescent individuals if

the stenosis is severe, but more often emerge at age 50–65 years when calcification and degeneration of the valve becomes manifest. A dilated ascending aorta, primarily due to an intrinsic defect in the aortic root media, may accompany the bicuspid valve in half of these patients. Coarctation of the aorta is also seen in a number of patients with congenital aortic stenosis. Offspring of patients with a bicuspid valve have a much higher incidence of the disease as well (up to 30% in some series).

A second group develops what has traditionally been called **degenerative** or **calcific** aortic stenosis, which is thought to be related to calcium deposition due to processes similar to what occurs in atherosclerotic vascular disease. Approximately 25% of patients over age 65 years and 35% of those over age 70 years have echocardiographic evidence of aortic sclerosis. About 10–20% of these will progress to hemodynamically significant aortic stenosis over a period of 10–15 years. Certain genetic markers are now being discovered that are associated with aortic stenosis (most notably Notch 1), so a genetic component appears a likely contributor, at least in some patients. Other associated genetic markers have also been described.

Aortic stenosis has become the most common surgical valve lesion in developed countries, and many patients are elderly. The risk factors include hypertension, hypercholesterolemia, and smoking. Hypertrophic obstructive cardiomyopathy may also coexist with valvular aortic stenosis.

► Clinical Findings

A. Symptoms and Signs

Slightly narrowed, thickened, or roughened valves (aortic sclerosis) or aortic dilation may produce the typical ejection murmur of aortic stenosis. In mild or moderate cases where the valve is still pliable, an ejection click may precede the murmur. The characteristic systolic ejection murmur is heard at the aortic area and is usually transmitted to the neck and apex. In some cases, only the high-pitched components of the murmur are heard at the apex, and the murmur may sound like mitral regurgitation (so-called Gallavardin phenomenon). In severe aortic stenosis, a palpable LV heave or thrill, a weak to absent aortic second sound, or reversed splitting of the second sound is present (see Table 10–2). When the valve area is < 0.8 – 1.0 cm² (normal, 3–4 cm²), ventricular systole becomes prolonged and the typical carotid pulse pattern of delayed upstroke and low amplitude is present. This may be an unreliable finding in older patients with extensive arteriosclerotic vascular disease and a stiff aorta. LVH increases progressively due to the pressure overload, eventually resulting in elevation in ventricular end-diastolic pressure. Cardiac output is maintained until the stenosis is severe (with a valve area < 0.8 cm²). LV failure, angina pectoris, or syncope may be presenting symptoms and signs of significant aortic stenosis; importantly, all symptoms tend to occur with exertion. In a few patients, there appears to be a mismatch among the typical aortic stenosis assessments: the aortic valve gradient severity (low), the aortic valve area (severe), the degree of

the LVH (severe), and the EF (normal). These low flow aortic stenosis patients may have significant LV afterload due to increased aortic vascular impedance as well as the valvular stenosis resistance. Some experts have suggested these lower aortic gradient patients might benefit from aortic valve replacement (AVR) if the calculated total resistance (Z score) is elevated. The Z score is calculated by dividing the sum of the aortic gradient and systolic BP by the stroke volume index.

Symptoms of LV failure may be sudden in onset or may progress gradually. Angina pectoris frequently occurs in aortic stenosis due to underperfusion of the endocardium. Of patients with calcific aortic stenosis and angina, 50% have significant associated CAD. Syncope is typically exertional and a late finding. Syncope occurs with exertion as the LV pressures rises, stimulating the LV baroreceptors to cause peripheral vasodilation. This vasodilation results in the need for an increase in stroke volume, which increases the LV systolic pressure again, creating a cycle of vasodilation and stimulation of the baroreceptors that eventually results in a drop in BP, as the stenotic valve prevents further increase in stroke volume. Less commonly, syncope may be due to arrhythmias (usually ventricular tachycardia but sometimes AV block as calcific invasion of the conduction system from the aortic valve may occur).

B. Diagnostic Studies

The clinical assessment of the severity of aortic stenosis may be difficult, especially when there is reduced cardiac output or significant associated aortic regurgitation. The ECG reveals LVH or secondary repolarization changes in most patients but can be normal in up to 10%. The chest radiograph may show a normal or enlarged cardiac silhouette, calcification of the aortic valve, and dilation and calcification of the ascending aorta. The echocardiogram provides useful data about aortic valve calcification and opening and the severity of LV wall thickness and overall ventricular function, while Doppler can provide an excellent estimate of the aortic valve gradient. Valve area estimation by echocardiography is less reliable. Cardiac catheterization mostly provides an assessment of the hemodynamic consequence of the aortic stenosis, and the anatomy of the coronary arteries. In younger patients, and in patients with high aortic gradients the aortic valve need not be crossed at catheterization. If the valve is crossed, the valve gradient can be measured at catheterization and an estimated valve area calculated; a valve area below 1.0 cm² indicates significant stenosis. Aortic regurgitation can be semiquantified by aortic root angiography.

In patients with a low EF and both low output and a low valve gradient, it may be unclear if an increased afterload is responsible for the low EF or if there is an associated cardiomyopathy. To sort this out, the patient should be studied at baseline and then during an intervention that increases cardiac output (eg, dobutamine or nitroprusside infusion). If the valve area increases and there is poor contractile reserve ($< 20\%$ increase in the stroke volume), the flow-limiting problem is not the valve, but rather the cardiomyopathy, and surgery is not warranted. If the valve area remains unchanged at the higher outputs and there remains

contractile reserve, then the valve is considered flow limiting and surgery is indicated. Recent data have suggested the use of BNP may provide prognostic data in the setting of poor LV function and aortic stenosis. A BNP > 550 pg/mL has been associated with a poor outcome in these patients regardless of the results of dobutamine testing.

► Prognosis & Treatment

Following the onset of heart failure, angina, or syncope, the prognosis without surgery is poor (50% 3-year mortality rate). Medical treatment may stabilize patients in heart failure, but surgery is indicated for all symptomatic patients with evidence of significant aortic stenosis. Valve replacement is usually not indicated in asymptomatic individuals, though a class II indication is to operate once the peak valve gradient by Doppler exceeds 64 mm Hg or the mean exceeds 40 mm Hg. Stress testing and perhaps the use of BNP may help identify patients who deny symptoms but are actually compromised from a ventricular function standpoint.

The surgical mortality rate for valve replacement is low, even in the elderly, and ranges from 2% to 5%. This low risk is due to the dramatic hemodynamic improvement that occurs with relief of the increased afterload. Mortality rates are substantially higher when there is an associated ischemic cardiomyopathy. Severe coronary lesions are usually bypassed at the same time, although there are little data to suggest this practice affects outcome.

All patients should have normal lipid levels, usually with goal of an LDL of ≤ 100 mg/dL, since progression of aortic stenosis theoretically may be slowed by control of cholesterol levels. Most studies have been negative or equivocal in this regard, but longer-term studies in patients with early disease are still pending. Many experts argue that for lipid lowering therapy to have any effect on the stenotic process, it needs to be initiated at an early stage in the disease. If patients with aortic stenosis have concomitant CAD, the LDL goal should be ≤ 70 mg/dL. Control of systemic hypertension is also an important adjunct, and inadequate systemic BP control is common due to unreasonable concerns about providing too much afterload reduction in patients with aortic stenosis.

The interventional options in patients with aortic stenosis are variable and dependent on the patient's lifestyle and age. In the young and adolescent patient, percutaneous valvuloplasty still has a role. Balloon valvuloplasty is less effective and is associated with early restenosis in the elderly, and thus is rarely used except as a temporizing measure in calcific aortic stenosis. Data suggest aortic balloon valvuloplasty in the elderly has an advantage only in those with preserved LV function, and such patients are usually excellent candidates for surgical AVR. The Ross procedure is generally still considered a viable option in younger patients, and it is performed by moving the patient's own pulmonary valve to the aortic position and replacing the pulmonary valve with a homograft (or rarely a bioprosthetic valve). However, dilation of the pulmonary valve autograft and consequent aortic regurgitation, plus early stenosis of the pulmonary homograft in the pulmonary position, has reduced the enthusiasm for this approach

in most institutions. Middle-aged adults generally can tolerate the anticoagulation therapy necessary for the use of mechanical AVR, so most undergo AVR with a bileaflet mechanical valve. If the aortic root is severely dilated as well (>4.5 cm), then the valve may be housed in a Dacron sheath (Bentall procedure) and the root replaced. Alternatively, a human homograft root and valve replacement can be used. In the elderly, bioprosthetic (either porcine or bovine pericardial) valves with a life expectancy of about 10–15 years are routinely used instead of mechanical valves to avoid need for anticoagulation. Recent data favor the bovine pericardial valve over the porcine aortic valve. If the aortic annulus is small, a bioprosthetic valve with a short sheath can be sewn to the aortic wall (the stentless AVR) rather than sewing the prosthetic annulus to the aortic annulus. (Annulus is a relative term when speaking of the aortic valve, since there is no true annulus.) Another surgical option becoming popular is the Wheat procedure; it involves aortic root replacement above the coronary arteries and AVR. The coronary arteries thus remain attached to the native aorta between the new graft and prosthetic valve rather than being reimplemented onto an artificial sheath or homograft.

In patients with a bicuspid aortic valve, there is often an associated ascending aortic aneurysm. If the maximal dimension of the aortic root exceeds 5.0 cm, it is recommended to proceed with root replacement regardless of the severity of the aortic valve disease. The aortic valve may be replaced at the same time or may be left alone (valve sparing operation).

Anticoagulation is required with the use of mechanical valves, and the international normalized ratio (INR) should be maintained between 2.0 and 3.0 or between 2.5 and 3.5, depending on type and position of valve and patient risk factors. In general, mechanical aortic valves are less subject to thrombosis than mechanical mitral valves. Some newer bileaflet mechanical valves (On-X) that require either no or a reduced dose of warfarin therapy are being evaluated, although the final data regarding the safety of this particular design are not available. The Prospective Randomized On-X valve AntiCoagulation Trial (PROACT) was begun in 2006 and is ongoing. Preliminary results have been reported and are very promising. Transcatheter aortic valve implantation (TAVI) is being used in Europe. In the United States, the Food and Drug Administration (FDA) has granted limited approval for one device (Edwards SAPIEN), and trials of a second device (CoreValve) are being completed. The devices use either a stent with a trileaflet bovine pericardial valve constructed in it or a stent with a large valve from a cow's jugular vein mounted inside. Both a retrograde approach (from the aorta or from the subclavian artery) and an antegrade approach (from the ventricles by way of a transeptal catheter across the atrial septum) are being investigated. The Edwards SAPIEN valve is a balloon-expandable valvular stent, while the CoreValve is a self-expanding valvular stent. The PARTNER TAVI trial randomized 358 high-risk patients who were not considered to be candidates for surgical AVR to either the TAVI or the medical therapy group. Confirming historical data, the medically treated patients had 50% mortality at 1 year,

compared with a 30% mortality in patients who underwent TAVI, a highly significant improved survival. An alternative approach using a minithoracotomy and LV puncture allows the aortic valve to be replaced from the LV apical area without opening the aortic root (transapical AVR)—a real advantage in some patients with severe calcification of the ascending aorta. Current TAVI is reserved for very high-risk surgical patients. Further data regarding outcomes will define whether this approach is appropriate for lower-risk patients.

▶ When to Refer

- All patients with an aortic murmur and echocardiographic evidence for mild-to-moderate aortic stenosis (estimated peak valve gradient > 30 mm Hg by echocardiography/Doppler) should be referred to a cardiologist for evaluation and to determine the frequency of follow-up.
- Any patients with symptoms suggestive of aortic stenosis should be seen by a cardiologist for further testing.
- Indications for AVR include symptoms and a mean gradient by echocardiography/Doppler of > 40 mm Hg or peak instantaneous gradient of > 64 mm Hg. When symptoms do not match the aortic stenosis severity by echocardiography/Doppler (either symptoms in those with minor gradients or no symptoms in those with severe gradients), then the use of serum BNP or N-terminal pro-B type natriuretic peptide (pro-NT BNP) is useful. Serial BNP levels may also be used to monitor patients; a progressive rise suggests early LV dysfunction even in the patients who deny symptoms.
- For newer interventional approaches, including mechanical valves that require little or no warfarin and percutaneous AVR.

AORTIC REGURGITATION

ESSENTIALS OF DIAGNOSIS

- ▶ Usually asymptomatic until middle age; presents with left-sided failure or chest pain.
- ▶ Wide pulse pressure.
- ▶ Diastolic murmur along left sternal border.
- ▶ Echocardiography/Doppler is diagnostic.
- ▶ Afterload reduction may be beneficial if there is evidence for systolic BP elevation.
- ▶ Surgery indicated for symptoms, EF < 55%, or LV end-systolic dimension > 5.0–5.5 cm.

▶ General Considerations

Rheumatic aortic regurgitation has become much less common than in the preantibiotic era, and nonrheumatic causes now predominate. These include congenitally bicuspid valves, infective endocarditis, and hypertension. Many patients have aortic regurgitation secondary to aortic root diseases such as that associated with Marfan syndrome or to aortic dissection. Rarely, inflammatory diseases, such as ankylosing spondylitis or reactive arthritis, may be causative.

▶ Clinical Findings

A. Symptoms and Signs

The clinical presentation is determined by the rapidity with which regurgitation develops. In chronic aortic regurgitation, the only sign for many years may be a soft aortic diastolic murmur. As the severity of the aortic regurgitation increases, diastolic BP falls, and the LV progressively enlarges. Most patients remain asymptomatic even at this point. LV failure is a late event and may be sudden in onset. Exertional dyspnea and fatigue are the most frequent symptoms, but paroxysmal nocturnal dyspnea and pulmonary edema may also occur. Angina pectoris or atypical chest pain may occasionally be present. Associated CAD and presyncope or syncope are less common than in aortic stenosis.

Hemodynamically, because of compensatory LV dilation, patients eject a large stroke volume, which is adequate to maintain forward cardiac output until late in the course of the disease. LV diastolic pressure may rise when heart failure occurs. Abnormal LV systolic function, as manifested by reduced EF (< 55%) and increasing end-systolic LV volume (>5.0 cm), is a sign that surgical intervention is warranted.

The major physical findings in **chronic aortic regurgitation** relate to the high stroke volume being ejected into the systemic vascular system with rapid runoff as the regurgitation takes place (see Table 10–2). This results in a wide arterial pulse pressure. The pulse has a rapid rise and fall (water-hammer pulse or Corrigan pulse), with an elevated systolic and low diastolic pressure. The large stroke volume is also responsible for characteristic findings such

as Quincke pulses (nailbed capillary pulsations), Duroziez sign (to and fro murmur over a partially compressed peripheral artery, commonly the femoral), and Musset sign (head bob with each pulse). In younger patients, the increased stroke volume may summate with the pressure wave reflected from the periphery and create an even higher systolic pressure in the extremity compared with the central aorta. Since the peripheral bed is much larger in the leg than the arm, the BP in the leg may be over 40 mm Hg higher than in the arm (Hill sign). The apical impulse is prominent, laterally displaced, usually hyperdynamic, and may be sustained. A systolic murmur is usually present and may be quite soft and localized; the aortic diastolic murmur is usually high-pitched and decrescendo. A mid or late diastolic low-pitched mitral murmur (Austin Flint murmur) may be heard in advanced aortic regurgitation, owing to relative obstruction of mitral inflow produced by partial closure of the mitral valve by the rapidly rising LV diastolic pressure due to the aortic regurgitation.

In **acute aortic regurgitation** (usually from aortic dissection or infective endocarditis), LV failure is manifested primarily as pulmonary edema and may develop rapidly; surgery is urgently required in such cases. Patients with acute aortic regurgitation do not have the dilated LV of chronic aortic regurgitation and the extra volume is handled poorly. For the same reason, the diastolic murmur is shorter and may be minimal in intensity, and the pulse pressure may not be widened, making clinical diagnosis difficult. The mitral valve may close prematurely even before LV systole has been initiated (pre-closure) due to the rapid rise in the LV diastolic pressure, and the first heart sound is thus diminished or inaudible. Pre-closure of the mitral valve can be readily detected on echocardiography.

B. Diagnostic Studies

The ECG usually shows moderate to severe LVH. Radiographs show cardiomegaly with LV prominence and sometimes a dilated aorta.

Echocardiography demonstrates the major diagnostic features, including whether the lesion involves the proximal aortic root and what valvular pathology is present. Serial assessments of LV size and function are critical in determining the timing for valve replacement. Color Doppler techniques can qualitatively estimate the severity of regurgitation, though some "mild" regurgitation due to aortic valve closure is not uncommon and should not be overinterpreted. Cardiac MRI and CT can estimate aortic root size, particularly when there is concern for an ascending aneurysm. MRI can provide a regurgitant fraction to help confirm severity. Scintigraphic studies are infrequently used but can quantify LV function and functional reserve during exercise. Exercise increases the heart rate and reduces the diastolic time, resulting in less aortic regurgitation per beat; this complicates interpretation of the exercise EF, and this test has therefore proved less helpful in deciding surgical timing than anticipated. Cardiac catheterization may be unnecessary in younger patients, particularly those with acute aortic regurgitation, but can

help define hemodynamics, aortic root abnormalities, and associated CAD preoperatively in older patients. Increasing data are emerging that serum BNP or pro-NT BNP may be an early sign of LV dysfunction, and it is possible that these data will be added to recommendations for surgical intervention in the future.

► Treatment & Prognosis

Aortic regurgitation that appears or worsens during or after an episode of infective endocarditis or aortic dissection may lead to acute severe LV failure or subacute progression over weeks or months. The former usually presents as pulmonary edema; surgical replacement of the valve is indicated even during active infection. These patients may be transiently improved or stabilized by vasodilators.

Chronic aortic regurgitation may be tolerated for many years, but the prognosis without surgery becomes poor when symptoms occur. Since aortic regurgitation places both a volume and afterload increase on the LV, medications that decrease afterload can reduce regurgitation severity. Current recommendations continue to advocate afterload reduction in aortic regurgitation when there is associated systolic hypertension (systolic BP > 140 mm Hg). Afterload reduction in normotensive patients remains controversial. While β -blocker therapy has been traditionally used in patients with Marfan disease to slow the rate of aortic dilation by reducing the dP/dt , angiotensin receptor blockers (ARBs) are becoming preferred additions to the medical therapy in these patients because of their ability to reduce aortic stiffness (likely by blocking TGF- β). The role of β -blockers continues to be explored in aortic regurgitation in an attempt to reduce adverse neuroendocrine activation.

Patients with aortic regurgitation should be monitored serially by echocardiography. Surgery is indicated once symptoms emerge or for any evidence of LV dysfunction. LV dysfunction in this situation can be defined by echocardiography if the EF is < 55% or if the LV end-systolic dimension is > 5.0 cm (class 2b indication), even in the asymptomatic patient. In addition, aortic root diameters of > 4.5 cm in Marfan or > 5.0 cm in non-Marfan patients are indications for surgery to avoid rapid expansion. Although the operative mortality rate is higher when LV function is severely impaired, valve replacement or repair is still likely indicated, since LV function often improves and the long-term prognosis is thereby enhanced even in this situation. The issues with AVR covered in the above section concerning aortic stenosis pertain here. Currently, however, there are no percutaneous approaches to aortic regurgitation. The choice of prosthetic valve for AVR depends on the patient's age and compatibility with warfarin anticoagulation.

The operative mortality rate is usually in the 3–5% range. Aortic regurgitation due to aortic root disease requires repair or replacement of the root. Though valve-sparing operations have improved recently, most patients with root replacement undergo valve replacement at the same time. Root replacement procedures

include the Ross procedure (moving the pulmonary valve to the aortic position and replacing the pulmonary valve with a homograft or, less commonly, bioprosthetic valve), the direct homograft for the aortic root and valve, and the Bentall procedure (the use of a Dacron sheath with a mechanical or bioprosthetic valve sewn in place). Root replacement in association with valve replacement may require reanastomosis of the coronary arteries, and thus the procedure is more complex than valve replacement alone. The Wheat procedure replaces the aortic root but spares the area where the coronaries attach to avoid the necessity for their reimplantation. Following surgery, LV size usually decreases and LV function generally improves even when the baseline EF is depressed.

▶ When to Refer

- Patients with audible aortic regurgitation should be seen, at least initially, by a cardiologist and a decision made as to how often the patient needs follow-up.
- Patients with a dilated aortic root should be monitored by a cardiologist, since imaging studies other than the chest radiograph or echocardiogram may be required to decide surgical timing.

TRICUSPID STENOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Female predominance.
- ▶ History of rheumatic heart disease. Carcinoid disease or prosthetic valve degeneration are the most common etiologies in the United States.
- ▶ Echocardiography/Doppler is key to diagnosis.
- ▶ Mean valve gradient > 5 mm Hg by echocardiography indicates severe tricuspid stenosis.

▶ General Considerations

Tricuspid stenosis is usually rheumatic in origin, although in the United States, tricuspid stenosis is more commonly due to tricuspid valve repair or replacement or to the carcinoid syndrome than to rheumatic fever. Tricuspid regurgitation frequently accompanies the lesion. It should be suspected when “right heart failure” appears in the course of mitral valve disease or in the postoperative period after tricuspid valve repair or replacement. Congenital forms of tricuspid stenosis may also be rarely observed, as have case reports of multiple pacemaker leads creating RV inflow obstruction at the tricuspid valve.

▶ Clinical Findings

A. Symptoms and Signs

Tricuspid stenosis is characterized by right heart failure with hepatomegaly, ascites, and dependent edema. In sinus rhythm, giant **a** wave is seen in the JVP, which is elevated (see Table 10–2). The typical diastolic rumble along the lower left sternal border mimics mitral stenosis, though the rumble increases with inspiration. In sinus rhythm, a presystolic liver pulsation also may be found.

B. Diagnostic Studies

In the absence of atrial fibrillation, the ECG reveals RA enlargement. The chest radiograph may show marked cardiomegaly with a normal PA size. A dilated SVC and azygous vein may be evident.

The normal valve area of the tricuspid valve is 10 cm², so significant stenosis must be present to produce a gradient. Hemodynamically, a mean diastolic pressure gradient of > 5 mm Hg is considered significant, although even a 2 mm Hg gradient can be considered abnormal. This can be demonstrated by echocardiography or cardiac catheterization.

▶ Treatment & Prognosis

Tricuspid stenosis may be progressive, eventually causing severe right-sided heart failure. Initial therapy is directed at reducing the fluid congestion, with diuretics the mainstay. When there is considerable bowel edema, torsemide may have an advantage over other loop diuretics, such as furosemide, because it is better absorbed from the gut. Aldosterone inhibitors also help, particularly if there is liver engorgement or ascites. Neither surgical nor percutaneous valvuloplasty is particularly effective for relief of tricuspid stenosis, as residual tricuspid regurgitation is common. Tricuspid valve replacement is clearly the preferred surgical approach. Mechanical tricuspid valve replacement is rarely done because the low flow predisposes to thrombosis and because the mechanical valve cannot be crossed should the need arise for right heart catheterization or pacemaker implantation. Therefore, bioprosthetic valves are almost always used. Often tricuspid valve replacement is done in conjunction with mitral valve replacement for mitral stenosis.

TRICUSPID REGURGITATION

ESSENTIALS OF DIAGNOSIS

- ▶ Frequently occurs in patients with pulmonary or cardiac disease with pressure or volume overload on the right ventricle.
- ▶ Tricuspid valve regurgitation from pacemaker lead placement is becoming more common.
- ▶ Systolic c-v wave in jugular venous pulsations.
- ▶ Holosystolic murmur along left sternal border, which increases with inspiration.
- ▶ Echocardiography useful in determining cause (low- or high-pressure tricuspid regurgitation).

▶ General Considerations

Tricuspid valvular regurgitation often occurs whenever there is RV dilation from any cause. As tricuspid regurgitation increases, the RV size increases further, and this in turn worsens the severity of the tricuspid regurgitation. The causes of tricuspid regurgitation thus relate to anatomic issues with either the valve itself or to the RV geometry. In most cases, the cause is the RV and not primary tricuspid valve disease. An enlarged, dilated RV may be present if there is pulmonary hypertension for any reason, in severe pulmonic regurgitation, or in cardiomyopathy. The RV may be injured from myocardial infarction or may be inherently dilated due to infiltrative diseases (RV dysplasia or sarcoidosis). RV dilation is often secondary to left heart failure. Inherent abnormalities of the tricuspid valve include Ebstein anomaly (displacement of the septal and posterior, but never the anterior, leaflets into the RV), tricuspid valve prolapse, carcinoid plaque formation, collagen disease inflammation, valvular tumors, or tricuspid endocarditis. In addition, pacemaker lead valvular injury is becoming an increasingly recognized iatrogenic cause.

▶ Clinical Findings

A. Symptoms and Signs

The symptoms and signs of tricuspid regurgitation are identical to those resulting from RV failure due to any cause. As a generality, the diagnosis can be made by careful inspection of the JVP (see Table 10–2). The JVP waveform should decline during ventricular systole (the x descent). The timing of this decline can be observed by palpating the opposite carotid artery. As tricuspid regurgitation worsens, more and more of this valley in the JVP is filled with the

regurgitant wave until all of the x descent is obliterated and a positive systolic waveform will be noted in the JVP. An associated tricuspid regurgitation murmur may or may not be audible and can be distinguished from mitral regurgitation by the left parasternal location and increase with inspiration. An S₃ may accompany the murmur and is related to the high flow returning from the RA. Cyanosis may be present if the increased RA pressure stretches the atrial septum and opens a PFO or there is a true ASD (eg, in about 50% of patients with Ebstein anomaly).

B. Diagnostic Studies

The ECG is usually nonspecific, though atrial fibrillation is not uncommon. The chest radiograph may reveal evidence of an enlarged RA or dilated azygous vein and pleural effusion. The echocardiogram helps assess severity of tricuspid regurgitation, RV systolic pressure, and RV size and function. A paradoxically moving interventricular septum may be present due to the volume overload on the RV. Catheterization confirms the presence of the regurgitant wave in the RA and elevated RA pressures. If the PA or RV systolic pressure is < 40 mm Hg, primary valvular tricuspid regurgitation should be suspected.

▶ Treatment & Prognosis

Mild tricuspid regurgitation is common and generally can be well managed with diuretics. When present, bowel edema may reduce the effectiveness of diuretics such as furosemide, and intravenous diuretics should initially be used. Torsemide is better absorbed in this situation when oral diuretics are added. Aldosterone antagonists have a role as well, particularly if ascites is present. At times, the efficacy of loop diuretics can be enhanced by adding a thiazide diuretic. Aquapheresis has also been proven helpful to reduce the edema in marked right heart failure.

Definitive treatment usually requires elimination of the cause of the tricuspid regurgitation. If the problem is left heart disease, then treatment of the left heart issues may lower pulmonary pressures, reduce RV size, and resolve the tricuspid regurgitation. Treatment for primary and secondary causes of pulmonary hypertension will generally reduce the tricuspid regurgitation. It is a class I recommendation that tricuspid annuloplasty be performed when tricuspid regurgitation is present and mitral valve replacement or repair is being performed for mitral regurgitation. Annuloplasty without insertion of a prosthetic ring (DeVega annuloplasty) may also be effective in reducing the tricuspid annular dilation. The valve leaflet itself can occasionally be repaired in tricuspid valve endocarditis. In years past, tricuspid regurgitation due to endocarditis in substance abuse patients was treated temporarily with removal of the valve, although it had to be replaced eventually (usually by 3–6 months); this practice is rarely done now. If there is an inherent defect in the tricuspid valve apparatus that cannot be repaired, then replacement of the tricuspid valve is warranted. Almost always, a bioprosthetic valve, and not a mechanical valve, is used. Anticoagulation is not required for bioprosthetic valves unless there is associated atrial fibrillation.

▶ When to Refer

- Anyone with moderate or severe tricuspid regurgitation should be seen at least once by a cardiologist to determine whether further studies are needed to elucidate cause and whether any other intervention is needed.
- Severe tricuspid regurgitation requires regular follow-up by a cardiologist.

PULMONARY VALVE REGURGITATION

ESSENTIALS OF DIAGNOSIS

- ▶ Most cases are due to pulmonary hypertension.
- ▶ Echocardiogram is definitive in high-pressure, but may be less definitive in low-pressure, pulmonic regurgitation.
- ▶ Low-pressure pulmonic regurgitation is well tolerated.

▶ General Considerations

Pulmonary valve regurgitation can be divided into **high-pressure causes** (due to pulmonary hypertension) and **low-pressure causes** (usually due to a dilated pulmonary annulus, to a congenitally abnormal [bicuspid or dysplastic] pulmonary valve, or to plaque from carcinoid disease). It may also follow surgical repair, eg, frequently occurring after repair of tetralogy of Fallot with a transannular patch. Because the RV tolerates a volume load better than a pressure load, it tends to tolerate low pressure pulmonic regurgitation for long periods of time without dysfunction.

▶ Clinical Findings

On examination, a hyperdynamic RV can usually be palpated (RV lift). If the PA is enlarged, it may be palpated along the left sternal border. P₂ will be palpable in pulmonary hypertension and both systolic and diastolic thrills are occasionally noted. On auscultation, the second heart sound may be widely split due to prolonged RV systole. Systolic clicks may be noted as well as a right-sided gallop. If pulmonic stenosis is also present, the ejection click may decline with inspiration while any associated systolic

murmur will increase. In high-pressure pulmonic regurgitation, the pulmonary diastolic (Graham Steell) murmur is readily audible. It is often due to a dilated pulmonary annulus. The murmur increases with inspiration and diminishes with the Valsalva maneuver. In low-pressure pulmonic regurgitation, the PA diastolic pressure may be only a few mm Hg higher than the RV diastolic pressure, and there is little diastolic gradient to produce a murmur or characteristic echocardiography/Doppler findings. At times, only contrast angiography or MRI of the main PA will show the free flowing pulmonic regurgitation in low-pressure pulmonic regurgitation. This situation is common in following patients with repair of tetralogy of Fallot where, despite little murmur, there may be free flowing pulmonic regurgitation. This can be suspected by noting an enlarging right ventricle.

The ECG is generally of little value, although right bundle branch block is common, and there may be ECG criteria for RVH. The chest radiograph may show only the enlarged RV and PA. Echocardiography may demonstrate evidence of RV volume overload (paradoxical septal motion and an enlarged RV), and Doppler can determine peak systolic RV pressure and reveal any associated tricuspid regurgitation. The interventricular septum may appear flattened if there is pulmonary hypertension. The size of the main PA can be determined and color flow Doppler can demonstrate the pulmonic regurgitation, particularly in the high-pressure situation. Cardiac MRI and CT can be useful for assessing the size of the PA, for imaging the jet lesion, for excluding other causes of pulmonary hypertension (eg, thromboembolic disease, peripheral PA stenosis), and for evaluating RV function. MRI provides a regurgitant fraction to help quantitate the degree of pulmonic regurgitation. Cardiac catheterization is confirmatory.

▶ Treatment & Prognosis

Pulmonary valve regurgitation rarely needs specific therapy other than treatment of the primary cause. In low-pressure pulmonic regurgitation due to surgical patch repair of tetralogy of Fallot, pulmonary valve replacement may be indicated if RV enlargement or dysfunction is present. In tetralogy of Fallot, the QRS will widen as RV function declines and the ECG is helpful here (a QRS > 180 msec suggests a higher risk for sudden death) and increasing RV volumes should trigger an evaluation for potential pulmonary valve regurgitation. In carcinoid heart disease, pulmonary valve replacement with a porcine bioprosthesis may be undertaken, though the plaque from this disorder eventually covers the prosthetic pulmonary valve, and this tends to limit the lifespan of these valves. In high-pressure pulmonic regurgitation, treatment to control the cause of the pulmonary hypertension is key. Low-pressure pulmonic regurgitation is well tolerated over many years; exercise and pregnancy are not interdicted. High-pressure pulmonic regurgitation is poorly tolerated and is a serious condition that needs a thorough evaluation for cause and therapy. High pulmonary pressures require a thorough evaluation to distinguish a primary pulmonary cause versus one due to left-sided heart disease.

▶ When to Refer

- Patients with pulmonary valve regurgitation that results in RV enlargement should be referred to a cardiologist regardless of the estimated pulmonary pressures.

CHOICE & MANAGEMENT OF SURGICAL VALVE REPLACEMENT OR REPAIR

Less invasive surgical procedures for valve replacement have increased in prevalence over the past few decades. There are now mini-incisional approaches to aortic, mitral, and tricuspid valve replacement and repair. Percutaneous valvuloplasty has replaced surgical commissurotomy for mitral stenosis in most cases. However, percutaneous aortic valvuloplasty is moderately effective only in children and adolescents and has a very limited role in adults. Neither surgical nor percutaneous tricuspid valvuloplasty for tricuspid stenosis is very effective. Percutaneous valve replacement is discussed above (see Aortic Stenosis).

Repair of the mitral valve is remarkably successful in appropriate patients and has lowered the threshold for intervention in mitral regurgitation to the point that some experts recommend that all mitral prolapse patients with mitral regurgitation undergo mitral valve repair even when other indications are not present. When tricuspid regurgitation is present and mitral valve repair or replacement is planned, tricuspid repair is a class I recommendation. Aortic valve sparing procedures are also improving and may obviate the need for AVR, especially in patients undergoing root replacement. Although early experience with aortic valve repair was mixed, recent studies reveal this as a more attractive option for some patients. Direct valvular repair and removal of vegetations are also viable options in some patients with endocarditis.

The choice of prosthetic valve depends on a variety of considerations, such as assessing the expected survival of the patient versus the durability of the valve and the safety of warfarin for the patient. Bioprosthetic valves usually have a life expectancy of 10–15 years, but less in young patients, those on dialysis, or those with hypercalcemia. High lipid levels may accelerate the degenerative process as much as in native heart valves. The lifespan of bovine pericardial valves is somewhat longer than porcine valves, and these are becoming the favorite bioprostheses. Bioprosthetic valves, homografts, and the Ross procedure (replacement of the aortic valve with the patient's own pulmonary valve, then replacement of the removed pulmonary valve usually with a homograft) do not require anticoagulation with warfarin, though current guidelines suggest warfarin be

used for 3 months after valve implantation to allow for endothelial growth over the sewing ring. This latter recommendation is controversial. Mechanical valves have a much longer lifespan, but all currently available ones require use of warfarin (and frequently aspirin as an adjunct, especially when used in the mitral position). The long-term risk of warfarin depends on patient compliance and whether there is coexisting disease that may predispose to bleeding. A newer mechanical valve, the On-X, may allow for either a reduced dose of warfarin or no warfarin at all (especially when used in the aortic position); trials are currently being completed but preliminary data are promising.

Mechanical mitral valve prostheses pose a greater risk for thrombosis than mechanical aortic valves. For that reason, the INR should be kept between 2.5 and 3.5 for mechanical mitral prosthetic valves but can be kept between 2.0 and 2.5 for mechanical aortic prosthetic valves. Enteric-coated aspirin (81 mg once daily) is given to patients with both types of mechanical valves but appears to be more important for mitral valve prostheses and for both types of valves when other risk factors are present, such as atrial fibrillation, a reduced EF, a hypercoagulable state, associated CAD, peripheral vascular disease, or a history of CVA.

Warfarin causes fetal skeletal abnormalities in about 2% of women who become pregnant while taking it, so every effort is made to defer valve replacement in women until after childbearing age. However, if a woman with a mechanical valve becomes pregnant while taking warfarin, the risk of stopping warfarin may be higher for the mother than the risk of continuing warfarin for the fetus. The risk of warfarin to the fetal skeleton is greatest during the first trimester, so if pregnancy is planned in a woman with a mechanical valve, unfractionated heparin is often used temporarily during the first trimester. After the first trimester, warfarin use is safe again until 2 weeks before planned delivery, when the patient should be switched back to unfractionated heparin. Low-molecular-weight heparin has not been shown to be effective and should not be substituted for unfractionated heparin in the pregnant patient with a mechanical heart valve.

When patients with mechanical valves must undergo noncardiac surgery, the risk of thrombosis from stopping warfarin versus the risk of excessive bleeding from continuing warfarin must be weighed. In general, for bileaflet aortic mechanical valves, warfarin can be stopped 5 days ahead of the surgical procedure and resumed the night of the procedure with no preprocedural “bridging”. After the procedure, unfractionated heparin or low-molecular-weight heparin can be used until the INR is 2.0. In patients with a bileaflet mitral valve, warfarin may be stopped 5 days ahead of time and bridging with either unfractionated heparin or low-molecular-weight heparin is recommended preoperatively once the INR falls below 2.0. The last dose of low-molecular-weight heparin should be half the therapeutic dose and be given 24 hours before any procedure. If unfractionated heparin is used, it should be stopped 4 hours before the procedure. As with AVR patients, warfarin is generally started within 24 hours after surgery, but heparin should not be started for 48–72 hours or until hemostasis is secured. Heparin therapy should be continued until the INR is > 2.0.

There is great interest in the use of direct antithrombin inhibitors, such as dabigatran, in place of warfarin. Ongoing trials are addressing whether these agents provide safe and effective anticoagulation in patients with mechanical prosthetic valves. Finally, there are an increasing number of isolated reports of the use of percutaneous methods to address both perivalvular regurgitation associated with prosthetic valve replacement by use of vascular plugs similar to those used to close a ductus arteriosus. The Melody percutaneous pulmonary valve has been approved for pulmonary valve replacement in patients with pulmonary valve regurgitation or stenosis in either a conduit or homograft. The use of percutaneously implanted valves in patients with dysfunctional aortic valves and even dysfunctional mitral and tricuspid valves has also been reported, although the long-term follow-up of these procedures is still lacking.

CORONARY HEART DISEASE (ATHEROSCLEROTIC CAD, ISCHEMIC HEART DISEASE)

Coronary heart disease, or atherosclerotic CAD, is the number one killer in the United States and worldwide. Every minute, an American dies of coronary heart disease. About 37% of people who experience an acute coronary event, either angina or myocardial infarction, will die of it in the same year. Death rates of coronary heart disease have declined every year since 1968, with about half of the decline from 1980 to 2000 due to treatments and half due to improved risk factors. Coronary heart disease is still responsible for approximately one of five deaths and over 600,000 deaths per year in the United States. Coronary heart disease afflicts nearly 16 million Americans and the prevalence rises steadily with age; thus, the aging of the US population promises to increase the overall burden of coronary heart disease.

Risk Factors for CAD

Most patients with coronary heart disease have some identifiable risk factor. These include a positive family history (the younger the onset in a first-degree relative, the greater the risk), male sex, blood lipid abnormalities, diabetes mellitus, hypertension, physical inactivity, abdominal obesity, and cigarette smoking, psychosocial factors, consumption of too few fruits and vegetables and too much alcohol. Smoking remains the number one preventable cause of death and illness in the United States. Although smoking rates have declined in the United States in recent decades, 18% of women and 21% of men still smoke. According to the World Health Organization, 1 year after quitting, the risk of coronary heart disease decreases by 50%. Various interventions have been shown to increase the likelihood of successful smoking cessation (see Chapter 1).

Hypercholesterolemia and other lipid abnormalities provide an important modifiable risk factor for coronary heart disease. Risk increases progressively with higher levels of low-density lipoprotein (LDL) cholesterol and declines with higher levels of high-density lipoprotein (HDL) cholesterol. Composite risk scores, such as the Framingham score (see Table 28–2), provide estimates of 10-year probability of development of coronary heart disease that can guide primary prevention strategies.

The metabolic syndrome is defined as a constellation of three or more of the following: abdominal obesity, triglycerides ≥ 150 mg/dL, HDL cholesterol < 40 mg/dL for men and < 50 mg/dL for women, fasting glucose ≥ 110 mg/dL, and hypertension. This syndrome is increasing in prevalence at an alarming rate. Related to the metabolic syndrome, the epidemic of obesity in the United States is likewise a major factor contributing to coronary heart disease risk. Data from National Health and Nutrition Examination Survey (NHANES) show that 34% of the US adult population was obese (body mass index [BMI] ≥ 30 kg/m²) in the 2007–2008 survey. Particularly alarming is the rapidly increasing incidence of obesity in adolescents in the United States, such that for children aged 12–19 years, prevalence of obesity increased from 5% (in 1976–1980) to 18%. Increasing physical activity is an important goal to help combat obesity and its consequences. Although the AHA continues to promote a diet based largely on low saturated fat, more information is needed on the health consequences of all diets, especially given the lack of protection from a low-fat diet in the largest randomized study ever done, the Women's Health Initiative trial. Low carbohydrate diets, even when high in saturated fat, may improve the cholesterol profile in overweight men and are as effective at achieving weight loss. Fish, rich in omega-3 fatty acids, may help protect against vascular disease, and it is recommended that it be eaten three times a week by patients at risk.

Markers of inflammation are strong risk factors for CAD. High-sensitivity CRP (hsCRP) is the best-characterized inflammatory marker, but others include interleukin-6, CD-40 ligand, myeloperoxidase, and placental growth factor. Although hsCRP levels > 10 mg/dL (>100 mg/L) are often

found in systemic inflammation, levels < 1 , $1-3$, and > 3 mg/dL (< 10 , $10-30$, and > 30 mg/L), respectively, identify patients at low, intermediate, and high risk for future cardiovascular events. The prognostic value of CRP levels is independent and additive to lipid levels. Use of CRP may be helpful in determining which patients at intermediate risk according to the Framingham 10-year risk of coronary heart disease calculation (score of $10-20\%$) are at high enough risk to warrant more intensive primary prevention, including use of statins to lower LDL cholesterol. CRP is included as a factor in the Reynolds Risk Score, as is family history; the Reynolds Risk Score aims to enhance the prognostic ability of the Framingham score (www.reynolds-riskscore.org). HsCRP ≥ 2 mg/L identifies older people without vascular disease and with normal cholesterol who benefit from statin therapy, specifically rosuvastatin. HsCRP levels are often elevated in patients who have other conditions associated with accelerated atherosclerosis, such as diabetes, the metabolic syndrome, and obesity. In patients presenting with acute coronary syndromes, the hsCRP elevation identifies a group that is at high risk for early recurrent events.

► Myocardial Hibernation & Stunning

Areas of myocardium that are persistently underperfused but still viable may develop sustained contractile dysfunction. This phenomenon, which is termed “myocardial hibernation,” appears to represent an adaptive response that maybe associated with depressed LV function. It is important to recognize this phenomenon, since this form of dysfunction is reversible following coronary revascularization. Hibernating myocardium can be identified by radionuclide testing, positron emission tomography (PET), contrast-enhanced MRI, or its retained response to inotropic stimulation with dobutamine. A related phenomenon, termed “myocardial stunning,” is the occurrence of persistent contractile dysfunction following prolonged or repetitive episodes of myocardial ischemia. Clinically, myocardial stunning is often seen after reperfusion of acute myocardial infarction and is defined with improvement following revascularization.

CHRONIC STABLE ANGINA PECTORIS

ESSENTIALS OF DIAGNOSIS

- Precordial chest pain, usually precipitated by stress or exertion, relieved rapidly by rest or nitrates.
- ECG or scintigraphic evidence of ischemia during pain or stress testing.
- Angiographic demonstration of significant obstruction of major coronary vessels.

► General Considerations

Angina pectoris is usually due to atherosclerotic heart disease. Coronary vasospasm may occur at the site of a lesion or, less frequently, in apparently normal vessels. Other unusual causes of coronary artery obstruction such as congenital anomalies, emboli, arteritis, or dissection may cause ischemia or infarction. Angina may also occur in the absence of coronary artery obstruction as a result of severe myocardial hypertrophy, severe aortic stenosis or regurgitation, or in response to increased metabolic demands, as in hyperthyroidism, marked anemia, or paroxysmal tachycardias with rapid ventricular rates. Rarely, angina occurs with angiographically normal coronary arteries and without other identifiable causes. This presentation has been labeled **syndrome X** and is most likely due to inadequate flow reserve in the resistance vessels (microvasculature). Syndrome X remains difficult to diagnose. Although treatment is often not very successful in relieving symptoms, the prognosis of syndrome X is good.

► Clinical Findings

A. Symptoms

The diagnosis of angina pectoris depends principally upon the history, which should specifically include the following information: circumstances that precipitate and relieve angina, characteristics of the discomfort, location and radiation, duration of attacks, and effect of nitroglycerin.

1. Circumstances that precipitate and relieve angina—

Angina occurs most commonly during activity and is relieved by resting. Patients may prefer to remain upright rather than lie down, as increased preload in recumbency increases myocardial work. The amount of activity required to produce angina may be relatively consistent under comparable physical and emotional circumstances or may vary from day to day. The threshold for angina is usually less after meals, during excitement, or on exposure to cold. It is often lower in the morning or after strong emotion; the latter can provoke attacks in the absence of exertion. In addition, discomfort may occur during sexual activity, at rest, or at night as a result of coronary spasm.

2. Characteristics of the discomfort—Patients often do not refer to angina as “pain” but as a sensation of tightness, squeezing, burning, pressing, choking, aching, bursting,

“gas,” indigestion, or an ill-characterized discomfort. It is often characterized by clenching a fist over the mid chest. The distress of angina is rarely sharply localized and is not spasmodic.

3. Location and radiation—The distribution of the distress may vary widely in different patients but is usually the same for each patient unless unstable angina or myocardial infarction supervenes. In most cases, the discomfort is felt behind or slightly to the left of the mid sternum. When it begins farther to the left or, uncommonly, on the right, it characteristically moves centrally substernally. Although angina may radiate to any dermatome from C8 to T4, it radiates most often to the left shoulder and upper arm, frequently moving down the inner volar aspect of the arm to the elbow, forearm, wrist, or fourth and fifth fingers. It may also radiate to the right shoulder or arm, the lower jaw, the neck, or even the back.

4. Duration of attacks—Angina is generally of short duration and subsides completely without residual discomfort. If the attack is precipitated by exertion and the patient promptly stops to rest, it usually lasts < 3 minutes. Attacks following a heavy meal or brought on by anger often last 15–20 minutes. Attacks lasting more than 30 minutes are unusual and suggest the development of unstable angina, myocardial infarction, or an alternative diagnosis.

5. Effect of nitroglycerin—The diagnosis of angina pectoris is supported if sublingual nitroglycerin promptly and invariably shortens an attack and if prophylactic nitrates permit greater exertion or prevent angina entirely.

B. Signs

Examination during angina frequently reveals a significant elevation in systolic and diastolic BP, although hypotension may also occur, and may reflect more severe ischemia or inferior ischemia (especially with bradycardia) due to a Bezold–Jarisch reflex. Occasionally, a gallop rhythm and an apical systolic murmur due to transient mitral regurgitation from papillary muscle dysfunction are present during pain only. Supraventricular or ventricular arrhythmias may be present, either as the precipitating factor or as a result of ischemia.

It is important to detect signs of diseases that may contribute to or accompany atherosclerotic heart disease, eg, diabetes mellitus (retinopathy or neuropathy), xanthelasma, tendinous xanthomas, hypertension, thyrotoxicosis, myxedema, or peripheral artery disease. Aortic stenosis or regurgitation, hypertrophic cardiomyopathy, and mitral valve prolapse should be sought, since they may produce angina or other forms of chest pain.

C. Laboratory Findings

Other than standard laboratory tests to evaluate for acute coronary syndrome (troponin and CK-MB), factors contributing to ischemia (such as anemia), and to screen for risk factors that may increase the probability of true coronary heart disease (such as hyperlipidemia), blood tests are not helpful to diagnose chronic angina.

D. ECG

The resting ECG is often normal in patients with angina. In the remainder, abnormalities include old myocardial infarction, nonspecific ST–T changes, and changes of LVH. During anginal episodes, as well as during asymptomatic ischemia, the characteristic ECG change is horizontal or downsloping ST-segment depression that reverses after the ischemia disappears. T wave flattening or inversion may also occur. Less frequently, transient ST-segment elevation is observed; this finding suggests severe (transmural) ischemia from coronary occlusion, and it can occur with coronary spasm.

E. Pretest Probability

The history as detailed above, the physical examination findings, and laboratory and ECG findings are used to develop a pretest probability of CAD as the cause of the clinical symptoms. Other important factors to include in calculating the pretest probability of CAD are patient age, sex, and clinical symptoms. Patients with low to intermediate pretest probability for CAD should undergo noninvasive stress testing whereas patients with high pretest probability are generally referred for cardiac catheterization. Of note, a recent large review of diagnostic cardiac catheterization findings in patients without known CAD undergoing invasive angiography, found that 38% had significant obstruction in one or more coronary arteries. These findings have highlighted the importance of careful pretest probability assessment.

F. Exercise ECG

Exercise testing is the most commonly used noninvasive procedure for evaluating for inducible ischemia in the patient with angina. Exercise testing is often combined with imaging studies (nuclear, echocardiography, or MRI [see below]), but in low-risk patients without baseline ST segment abnormalities or in whom anatomic localization is not necessary, the exercise ECG remains the recommended initial procedure because of considerations of cost and convenience.

Exercise testing can be done on a motorized treadmill or with a bicycle ergometer. A variety of exercise protocols are utilized, the most common being the Bruce protocol, which increases the treadmill speed and elevation every 3 minutes until limited by symptoms. At least two ECG leads should be monitored continuously.

1. Precautions and risks—The risk of exercise testing is about one infarction or death per 1000 tests, but individuals who have pain at rest or minimal activity are at higher risk and should not be tested. Many of the traditional exclusions, such as recent myocardial infarction or CHF, are no longer used *if the patient is stable and ambulatory*, but symptomatic aortic stenosis remains a contraindication.

2. Indications—Exercise testing is used (1) to confirm the diagnosis of angina; (2) to determine the severity of limitation of activity due to angina; (3) to assess prognosis in patients with known coronary disease, including those

recovering from myocardial infarction, by detecting groups at high or low risk; (4) to evaluate responses to therapy; and (5) less successfully, to screen asymptomatic populations for silent coronary disease. The latter application is controversial. Because false-positive tests often exceed true positives, leading to much patient anxiety and self-imposed or mandated disability, exercise testing of asymptomatic individuals should be done only for those whose occupations place them or others at special risk (eg, airline pilots), and older individuals commencing strenuous activity.

3. Interpretation—The usual ECG criterion for a positive test is 1 mm (0.1 mV) horizontal or downsloping ST-segment depression (beyond baseline) measured 80 milliseconds after the J point. By this criterion, 60–80% of patients with anatomically significant coronary disease will have a positive test, but 10–30% of those without significant disease will also be positive. False positives are uncommon when a 2-mm depression is present. Additional information is inferred from the time of onset and duration of the ECG changes, their magnitude and configuration, BP and heart rate changes, the duration of exercise, and the presence of associated symptoms. In general, patients exhibiting more severe ST-segment depression (>2 mm) at low workloads (< 6 minutes on the Bruce protocol) or heart rates (< 70% of age-predicted maximum)—especially when the duration of exercise and rise in BP are limited or when hypotension occurs during the test—have more severe disease and a poorer prognosis. Depending on symptom status, age, and other factors, such patients should be referred for coronary arteriography and possible revascularization. On the other hand, less impressive positive tests in asymptomatic patients are often “false positives.” Therefore, exercise testing results that do not conform to the clinical picture should be confirmed by stress imaging.

G. Myocardial Stress Imaging

Myocardial stress imaging (scintigraphy, echocardiography, or MRI) is indicated (1) when the resting ECG makes an exercise ECG difficult to interpret (eg, left bundle branch block, baseline ST–T changes, low voltage); (2) for confirmation of the results of the exercise ECG when they are contrary to the clinical impression (eg, a positive test in an asymptomatic patient); (3) to localize the region of ischemia; (4) to distinguish ischemic from infarcted myocardium; (5) to assess the completeness of vascularization following bypass surgery or coronary angioplasty; or (6) as a prognostic indicator in patients with known coronary disease. Recently, criteria have been published that summarize these indications for stress testing.

1. Myocardial perfusion scintigraphy—This test provides images in which radionuclide uptake is proportionate to blood flow at the time of injection. Thallium-201, technetium-99m sestamibi, and tetrafosmin are most frequently used. If the radiotracer is injected during exercise or dipyridamole- or adenosine-induced coronary vasodilation, scintigraphic defects indicate a zone of hypoperfusion that may represent either ischemia or scar. If the

myocardium is viable, as relative blood flow equalizes over time or during a scintigram performed under resting conditions, these defects tend to “fill in” or reverse, indicating reversible ischemia. Defects observed when the radiotracer is injected at rest or still present 3–4 hours after an injection during exercise or pharmacologic vasodilation (intravenous adenosine or dipyridamole) usually indicate myocardial infarction (old or recent) but may be present with severe ischemia. Occasionally, other conditions, including infiltrative diseases (sarcoidosis, amyloidosis), left bundle branch block, and dilated cardiomyopathy, may produce resting or persistent perfusion defects.

Stress imaging is positive in about 75–90% of patients with anatomically significant coronary disease and in 20–30% of those without it. False-positive radionuclide tests may occur as a result of diaphragmatic attenuation or, in women, attenuation through breast tissue. Tomographic imaging (single-photon emission computed tomography, SPECT) can reduce the severity of artifacts. Gated imaging allows for analysis of ventricular size, EF, and regional wall motion.

2. Radionuclide angiography—This procedure images the LV and measures its EF and wall motion. In coronary disease, resting abnormalities usually represent infarction, and those that occur only with exercise usually indicate stress-induced ischemia. Exercise radionuclide angiography has approximately the same sensitivity as thallium-201 scintigraphy, but it is less specific in older individuals and those with other forms of heart disease. The indications are similar to those for thallium-201 scintigraphy.

3. Stress echocardiography—Echocardiograms performed during supine exercise or immediately following upright exercise may demonstrate exercise-induced segmental wall motion abnormalities as an indicator of ischemia. This technique requires considerable expertise; however, in experienced laboratories, the test accuracy is comparable to that obtained with scintigraphy—though a higher proportion of tests is technically inadequate. While exercise is the preferred stress because of other information derived, pharmacologic stress with high-dose dobutamine (20–40 mcg/kg/min) can be used as an alternative to exercise. Echocardiography contrast agents allow for perfusion imaging and may improve the diagnostic accuracy of this form of testing, although these are not commonly used.

H. Other Imaging

1. Positron emission tomography—PET scanning uses positron-emitting agents to demonstrate either perfusion or metabolism of myocardium. PET scanning can accurately distinguish transiently dysfunctional (“stunned”) myocardium from scar by showing persistent glycolytic metabolism with the tracer fluorodeoxyglucose (FDG) in regions with reduced blood flow. The newer SPECT camera can provide acceptable images without the more expensive PET technology.

2. CT and MRI scanning—CT scanning can image the heart and, with contrast medium and multislice technology,

the coronary arteries, with increasing resolution. Coronary artery images can be obtained by 64- and higher slice technology, and, if the images are normal, this technology has high sensitivity for excluding significant CAD.

Thus, multislice CT angiography may be useful in evaluating patients with low likelihood of significant CAD who would otherwise have undergone coronary angiography. CT angiography may also be useful for evaluating chest pain and suspected acute coronary syndrome. However, the role of CT angiography in routine practice is yet to be established, since it currently requires both radiation exposure and contrast load. It should also be noted that radionuclide SPECT imaging also has similar radiation exposure.

Electron beam CT (EBCT) can quantify coronary artery calcification, which is highly correlated with atherosclerotic plaque and has high sensitivity, but low specificity, for obstructive coronary disease. Thus, although this test can stratify patients into lower and higher risk groups, the appropriate management of individual patients with asymptomatic coronary artery calcification—beyond aggressive risk factors modification—is unclear. This test has not traditionally been used in symptomatic patients. According to the American Heart Association, persons who are at low risk (< 10% 10-year risk) or at high risk (>20% 10-year risk) do not benefit from coronary calcium assessment (class III, level of evidence: B) (see Tables 28–2 and 28–3). However, in clinically selected, intermediate-risk patients, it may be reasonable to determine the atherosclerosis burden using EBCT in order to refine clinical risk prediction and to select patients for more aggressive target values for lipid-lowering therapies (class IIb, level of evidence: B).

Cardiac MRI provides high-resolution images of the heart and great vessels without radiation exposure or use of iodinated contrast media. Gadolinium, the contrast agent used for cardiac MRI, has been associated with a rare but fatal complication in patients with severe renal dysfunction, called necrotizing systemic fibrosis. Cardiac MRI provides excellent assessment of pericardial disease, neoplastic disease of the heart, myocardial thickness, chamber size, and many congenital heart defects. It is an excellent noninvasive test for nonemergently evaluating dissection of the aorta. Rapid acquisition sequences are a useful alternative when the echocardiogram is suboptimal. Perfusion imaging can be done with gadolinium first pass perfusion using dobutamine or adenosine to produce pharmacologic stress. Advances have been made in imaging the proximal coronary arteries, but this application remains investigational. Perhaps the most clinically used indication of cardiac MRI is for identification of myocardial fibrosis, either from myocardial infarction or infiltration. This allows high resolution imaging of myocardial viability.

I. Ambulatory ECG Monitoring

Ambulatory ECG recorders can monitor for ischemic ST-segment depression. In patients with CAD, these episodes usually signify ischemia, even when asymptomatic (“silent”). In many patients, silent episodes are more

frequent than symptomatic ones. In most cases, they occur in patients with other evidence of ischemia, so the role of ambulatory monitoring is limited.

J. Coronary Angiography

Selective coronary arteriography is the definitive diagnostic procedure for CAD. It can be performed with low mortality (about 0.1%) and morbidity (1–5%), but the cost is high, and with currently available noninvasive techniques it is usually not indicated solely for diagnosis.

Coronary arteriography should be performed in the following circumstances if percutaneous transluminal coronary angioplasty or bypass surgery is a consideration:

1. Limited stable angina despite an adequate medical regimen.
2. Clinical presentation (unstable angina, postinfarction angina, etc) or noninvasive testing suggests high-risk disease (see Indications for Revascularization).
3. Concomitant aortic valve disease and angina pectoris, to determine whether the angina is due to accompanying coronary disease.
4. Asymptomatic older patients undergoing valve surgery so that concomitant bypass may be done if the anatomy is propitious.
5. Recurrence of symptoms after coronary revascularization to determine whether bypass grafts or native vessels are occluded.
6. Cardiac failure where a surgically correctable lesion, such as LV aneurysm, mitral regurgitation, or reversible ischemic dysfunction, is suspected.
7. Survivors of sudden death or symptomatic or life-threatening arrhythmias when CAD may be a correctable cause.
8. Chest pain of uncertain cause or cardiomyopathy of unknown cause.
9. Emergently performed cardiac catheterization with intention to perform primary PCI in patients with suspected acute myocardial infarction.

A narrowing > 50% of the luminal diameter is considered hemodynamically (and clinically) significant, although most lesions producing ischemia are associated with narrowing in excess of 70%. In those with strongly positive exercise ECGs or scintigraphic studies, three-vessel or left main disease may be present in 75–95% depending on the criteria used. **Intravascular ultrasound (IVUS)** can be positioned within the artery and image beneath the endothelial surface. This technique is useful when the angiogram is equivocal as well as for assessing the results of angioplasty or stenting. In addition, IVUS is the invasive diagnostic method of choice for ostial left main lesions and coronary dissections. Fractional flow reserve is an important invasive method for evaluation of equivocal coronary stenosis. In this method, a pressure wire is used to measure the relative change in pressure across a coronary lesion after the administration of adenosine (usual dosing is 140 mcg/kg/min). Recent studies have demonstrated that

revascularization based on abnormal fractional flow reserve improves clinical outcomes compared to revascularization of all angiographically stenotic lesions.

LV angiography is usually performed at the same time as coronary arteriography. Global and regional LV function are visualized, as well as mitral regurgitation if present. LV function is a major determinant of prognosis in coronary heart disease.

► Differential Diagnosis

When atypical features are present—such as prolonged duration (hours or days) or darting, knifelike pains at the apex or over the precordium—ischemia is less likely.

Anterior chest wall syndrome is characterized by sharply localized tenderness of intercostal muscles. Inflammation of the chondrocostal junctions, which may be warm, swollen, and red, may result in diffuse chest pain that is also reproduced by local pressure (Tietze syndrome). Intercostal neuritis (due to herpes zoster, diabetes mellitus, for example) also mimics angina.

Cervical or thoracic spine disease involving the dorsal roots produces sudden sharp, severe chest pain suggesting angina in location and “radiation” but related to specific movements of the neck or spine, recumbency, and straining or lifting. Pain due to cervical or thoracic disk disease involves the outer or dorsal aspect of the arm and the thumb and index fingers rather than the ring and little fingers.

Reflux esophagitis, peptic ulcer, chronic cholecystitis, esophageal spasm, and functional gastrointestinal disease may produce pain suggestive of angina pectoris. The picture may be especially confusing because ischemic pain may also be associated with upper gastrointestinal symptoms, and esophageal motility disorders may be improved by nitrates and calcium channel blockers. Assessment of esophageal motility may be helpful.

Degenerative and inflammatory lesions of the left shoulder and thoracic outlet syndromes may cause chest pain due to nerve irritation or muscular compression; the symptoms are usually precipitated by movement of the arm and shoulder and are associated with paresthesias.

Pneumonia, pulmonary embolism, and spontaneous pneumothorax may cause chest pain as well as dyspnea. Dissection of the thoracic aorta can cause severe chest pain that is commonly felt in the back; it is sudden in onset, reaches maximum intensity immediately, and may be associated with changes in pulses. Other cardiac disorders such as mitral valve prolapse, hypertrophic cardiomyopathy, myocarditis, pericarditis, aortic valve disease, or RVH may cause atypical chest pain or even myocardial ischemia.

► Treatment

Sublingual nitroglycerin is the drug of choice for acute management; it acts in about 1–2 minutes. Nitrates decrease arteriolar and venous tone, reduce preload and afterload, and lower the oxygen demand of the heart. As soon as the attack begins, one fresh tablet is placed under the tongue. This may be repeated at 3- to 5-minute intervals, but current

recommendations are that if pain is not relieved or improving after 5 minutes, that the patient call 9-1-1. The dosage (0.3, 0.4, or 0.6 mg) and the number of tablets to be used before seeking further medical attention must be individualized. Nitroglycerin buccal spray is also available as a metered (0.4 mg) delivery system. It has the advantage of being more convenient for patients who have difficulty handling the pills and of being more stable. Nitroglycerin can also be used prophylactically before activities likely to precipitate angina. Pain not responding to three tablets or lasting more than 20 minutes may represent evolving infarction, and the patient should be instructed to seek immediate medical attention.

► Prevention of Further Attacks

A. Aggravating Factors

Angina may be aggravated by hypertension, LV failure, arrhythmia (usually tachycardias), strenuous activity, cold temperatures, and emotional states. These factors should be identified and treated when possible.

B. Nitroglycerin

Nitroglycerin, 0.3–0.6 mg sublingually or 0.4–0.8 mg translingually by spray, should be taken 5 minutes before any activity likely to precipitate angina. Sublingual isosorbide dinitrate (2.5–10 mg) is only slightly longer-acting than sublingual nitroglycerin.

C. Long-Acting Nitrates

Longer-acting nitrate preparations include isosorbide dinitrate, 10–40 mg orally three times daily; isosorbide mononitrate, 10–40 mg orally twice daily or 60–120 mg once daily in a sustained-release preparation; oral sustained-release nitroglycerin preparations, 6.25–12.5 mg two to four times daily; nitroglycerin ointment, 6.25–25 mg applied two to four times daily; and transdermal nitroglycerin patches that deliver nitroglycerin at a predetermined rate (usually 5–20 mg/24 h). The main limitation to long-term nitrate therapy is tolerance, which can be limited by using a regimen that includes a minimum 8- to 10-hour period per day without nitrates. Isosorbide dinitrate can be given three times daily, with the last dose after dinner, or longer-acting isosorbide mononitrate once daily. Transdermal nitrate preparations should be removed overnight in most patients.

Nitrate therapy is often limited by headache. Other side effects include nausea, light-headedness, and hypotension.

D. β -Blockers

β -Blockers are the only antianginal agents that have been demonstrated to prolong life in patients with coronary disease (post-myocardial infarction). They are at least as effective at relieving angina as alternative agents in studies employing exercise testing, ambulatory monitoring, and symptom assessment. β -Blockers should be considered for first-line therapy in most patients with chronic angina.

β -Blockers with intrinsic sympathomimetic activity, such as pindolol, are less desirable because they may exacerbate angina in some individuals and have not been

effective in secondary prevention trials. The pharmacology and side effects of the β -blockers are discussed in Chapter 11 (see Table 11–7). The dosages of all these drugs when given for angina are similar. The major contraindications are severe bronchospastic disease, bradyarrhythmias, and decompensated heart failure.

E. Calcium Channel Blocking Agents

Unlike the β -blockers, calcium channel blockers have not been shown to reduce mortality postinfarction and in some cases have increased ischemia and mortality rates. This appears to be the case with some dihydropyridines and with diltiazem and verapamil in patients with clinical heart failure or moderate to severe LV dysfunction. Meta-analyses have suggested that short-acting nifedipine in moderate to high doses causes an increase in mortality. It is uncertain whether these findings are relevant to longer-acting dihydropyridines. Nevertheless, considering the uncertainties and the lack of demonstrated favorable effect on outcomes, calcium channel blockers should be considered third-line anti-ischemic drugs in the postinfarction patient. Similarly, with the exception of amlodipine, which in the still-unpublished PRAISE trial proved safe in patients with heart failure, these agents should be avoided in patients with CHF or low EFs.

The pharmacologic effects and side effects of the calcium channel blockers are discussed in Chapter 11 and summarized in Table 11–9. Diltiazem and verapamil are preferable because they produce less reflex tachycardia and because the former, at least, may cause fewer side effects. Nifedipine, nicardipine, and amlodipine are also approved agents for angina. Isradipine, felodipine, and nisoldipine are not approved for angina but probably are as effective as the other dihydropyridines.

F. Ranolazine

Ranolazine is the first new antianginal drug to be approved by the FDA in many years, and it is approved as first-line use for chronic angina. It decreases the late sodium current and thereby decreases intracellular calcium overload. Ranolazine has no effect on heart rate and BP, and it has been shown in clinical trials to prolong exercise duration and time to angina, both as monotherapy and when administered with conventional antianginal therapy. It is safe to use with erectile dysfunction drugs. The usual dose is 500 mg orally twice a day. Because it can cause QT prolongation, it is contraindicated in patients with existing QT prolongation; in patients taking QT prolonging drugs, such as class I or III antiarrhythmics (eg, quinidine, dofetilide, sotalol); and in those taking potent and moderate CYP450 3A inhibitors. Of interest, in spite of the QT prolongation, there is a significantly lower rate of ventricular arrhythmias with its use following acute coronary syndromes, shown in the MERLIN trial. It also decreases occurrence of atrial fibrillation and results in a small decrease in Hgb_{A1C}. It is contraindicated in patients with significant liver and kidney disease. Ranolazine is not to be used for treatment of acute anginal episodes.

G. Alternative and Combination Therapies

Patients who do not respond to one class of antianginal medication often respond to another. It may, therefore, be worthwhile to use an alternative agent before progressing to combinations. If the patient remains symptomatic, a β -blocker and a long-acting nitrate or a β -blocker and a calcium channel blocker (other than verapamil, where the risk of AV block or heart failure is higher) are the most appropriate combinations. A few patients will have a further response to a regimen including all three agents.

H. Platelet-Inhibiting Agents

Several studies have demonstrated the benefit of antiplatelet drugs for patients with stable and unstable vascular disease. Therefore, unless contraindicated, aspirin (81–325 mg daily) should be prescribed for all patients with angina. Clopidogrel, 75 mg daily, reduces vascular events in patients with stable vascular disease (as an alternative to aspirin) and in patients with acute coronary syndromes (in addition to aspirin). Thus, it is also a good alternative in aspirin-intolerant patients. Clopidogrel may rarely induce thrombotic thrombocytopenic purpura.

I. Risk Reduction

Patients with coronary disease should undergo aggressive risk factor modification. This approach, with a particular focus on statin treatment, treating hypertension, stopping smoking, and exercise and weight control (especially for patients with metabolic syndrome or at risk for diabetes), may markedly improve outcome. For patients with diabetes and cardiovascular disease, there is uncertainty about the optimal target blood sugar control. The ADVANCE trial suggested some benefit for tight blood sugar control with target Hgb A_{1C} \leq 6.5%. The ACCORD trial found that routine aggressive targeting for blood sugar control to Hgb A_{1C} to $<$ 6.0% in patients with diabetes and coronary disease was associated with increased mortality. Therefore, tight blood sugar control should be avoided particularly in patients with history of severe hypoglycemia, long-standing diabetes, and advanced vascular disease. Aggressive BP control (target systolic BP $<$ 120 mm Hg) in the ACCORD trial was not associated with reduction in coronary heart disease events, although stroke was reduced.

J. Revascularization

1. Indications—There is general agreement that otherwise healthy patients in the following groups should undergo revascularization: (1) Patients with unacceptable symptoms despite medical therapy to its tolerable limits. (2) Patients with left main coronary artery stenosis $>$ 50% with or without symptoms. (3) Patients with three-vessel disease with LV dysfunction (EF $<$ 50% or previous transmural infarction). (4) Patients with unstable angina who after symptom control by medical therapy continue to exhibit ischemia on exercise testing or monitoring. (5) Post-myocardial infarction patients with continuing angina or severe ischemia on noninvasive testing. The use of revascularization for patients with acute coronary

syndromes and acute ST elevation myocardial infarction is discussed below.

In addition, many cardiologists have believed that patients with less severe symptoms should be revascularized if they have two-vessel disease associated with underlying LV dysfunction, anatomically critical lesions (>90% proximal stenoses, especially of the proximal left anterior descending artery), or physiologic evidence of severe ischemia (early positive exercise tests, large exercise-induced thallium scintigraphic defects, or frequent episodes of ischemia on ambulatory monitoring). Two sources of data have tempered some of the enthusiasm for coronary intervention for stable angina. Drug-eluting stents, widely used because of their benefits in preventing restenosis, have been associated with higher rates of late stent thrombosis. Moreover, data from the COURAGE trial have shown that for patients with chronic angina and disease suitable for percutaneous coronary intervention (PCI), PCI offers no mortality benefit beyond excellent medical therapy, and relatively moderate long-term symptomatic improvement. The ACC/AHA have recently developed criteria for appropriateness of coronary revascularization that highlight these conclusions.

2. Type of procedure

A. CORONARY ARTERY BYPASS GRAFTING—Coronary artery bypass grafting (CABG) can be accomplished with a very low mortality rate (1–3%) in otherwise healthy patients with preserved cardiac function. However, the mortality rate of this procedure rises to 4–8% in older individuals and in patients who have had a prior CABG.

Grafts using one or both internal mammary arteries (usually to the left anterior descending artery or its branches) provide the best long-term results in terms of patency and flow. Segments of the saphenous vein (or, less optimally, other veins) or the radial artery interposed between the aorta and the coronary arteries distal to the obstructions are also used. One to five distal anastomoses are commonly performed.

Minimally invasive surgical techniques utilize different approaches to the heart than standard sternotomy and cardiopulmonary bypass. The surgical approach may involve a limited sternotomy, lateral thoracotomy (MIDCAB), or thoracoscopy (port-access). These techniques allow earlier postoperative mobilization and discharge. They are more technically demanding, usually not suitable for more than two grafts, and do not have established durability. Bypass surgery can be performed both on circulatory support (on pump) and without direct circulatory support (off-pump). Recent randomized trial data have not shown a benefit with off-pump bypass surgery.

The operative mortality rate is increased in patients with poor LV function (LV EF < 35%) or those requiring additional procedures (valve replacement or ventricular aneurysmectomy). Patients over 70 years of age, patients undergoing repeat procedures, or those with important noncardiac disease (especially chronic kidney disease and diabetes) or poor general health also have higher operative mortality and morbidity rates, and full recovery is slow. Thus, CABG should be reserved for more severely

symptomatic patients in this group. Early (1–6 months) graft patency rates average 85–90% (higher for internal mammary grafts), and subsequent graft closure rates are about 4% annually. Early graft failure is common in vessels with poor distal flow, while late closure is more frequent in patients who continue smoking and those with untreated hyperlipidemia. Antiplatelet therapy with aspirin improves graft patency rates. Smoking cessation and vigorous treatment of blood lipid abnormalities (particularly with statins) are necessary. While the most important principle is to use proven doses of statins shown to improve outcomes in large trials, many advocate a goal for LDL cholesterol of 70–100 mg/dL (8.2–26 mmol/L) and for HDL cholesterol of \geq 45 mg/dL (11.1 mmol/L). Repeat revascularization (see below) may be necessitated because of recurrent symptoms due to progressive native vessel disease and graft occlusions. Reoperation is technically demanding and less often fully successful than the initial operation.

B. PERCUTANEOUS CORONARY INTERVENTION INCLUDING STENTING—PCI, including balloon angioplasty and coronary stenting, can effectively open stenotic coronary arteries. Coronary stenting, with either bare metal stents or drug-eluting stents, has substantially reduced restenosis. Stenting can also be used selectively for left main coronary stenosis, particularly when CABG is contraindicated.

PCI is possible but often less successful in bypass graft stenoses. Experienced operators are able to successfully dilate > 90% of lesions attempted. The major early complication is intimal dissection with vessel occlusion, although this is rare with coronary stenting. The use of intravenous platelet glycoprotein IIb/IIIa inhibitors (abciximab, eptifibatid, tirofiban) has substantially reduced the rate of periprocedural myocardial infarction, and placement of intracoronary stents has markedly improved initial and long-term angiographic results, especially with complex and long lesions. After percutaneous coronary intervention, all patients should have CK-MB and troponin measured, and a new rise of greater than three times the upper limit of normal constitutes a significant periprocedural myocardial infarction. Acute thrombosis after stent placement can largely be prevented by aggressive antithrombotic therapy (long-term aspirin, 81–325 mg, plus clopidogrel, 300–600 mg loading dose followed by 75 mg daily, for between 30 days and 1 year, and with acute use of platelet glycoprotein IIb/IIIa inhibitors).

A major limitation with PCI has been **restenosis**, which occurs in the first 6 months in < 10% of vessels treated with drug-eluting stents, 15–30% of vessels treated with bare metal stents, and 30–40% of vessels without stenting. Factors associated with higher restenosis rates include diabetes, small luminal diameter, longer and more complex lesions, and lesions at coronary ostia or in the left anterior descending coronary artery. Drug-eluting stents that elute antiproliferative agents such as sirolimus, everolimus, zotarolimus, or paclitaxel have substantially reduced restenosis. In-stent restenosis is often treated with restenting with drug-eluting stents, and rarely with brachytherapy. The nearly 2 million PCIs performed worldwide per year far exceeds the number of CABG operations, but the rationale for many of the procedures performed in patients with stable

angina should be for angina symptom reduction. The COURAGE trial has confirmed earlier studies in showing that even for patients with moderate anginal symptoms and positive stress tests, PCI provides no benefit over medical therapy with respect to death or with respect to death or myocardial infarction. PCI was more effective at relieving angina, although most patients in the medical group had improvement in symptoms. Thus, in patients with mild or moderate stable symptoms, aggressive lipid-lowering and antianginal therapy may be a preferable initial strategy, reserving PCI for patients with significant and refractory symptoms or for those who are unable to take the prescribed medicines.

Several studies of PCI, including with drug-eluting stents, versus CABG in patients with multivessel disease have been reported. The most recent trial with drug-eluting stent use in PCI patients, SYNTAX, reported similar findings to prior studies. The consistent finding has been comparable mortality and infarction rates over follow-up periods of 1–3 years but a high rate (approximately 40%) of repeat procedures following PCI. Stroke rates are higher with CABG. As a result, the choice of revascularization procedure may depend on details of coronary anatomy and is often a matter of patient preference. However, it should be noted that < 20% of patients with multivessel disease meet the entry criteria for the clinical trials, so these results cannot be generalized to all multivessel disease patients. Outcomes with percutaneous revascularization in diabetics have generally been inferior to those with CABG. However, most of these trials preceded the widespread use of stenting.

K. Mechanical Extracorporeal Counterpulsation

Extracorporeal counterpulsation (ECP) entails repetitive inflation of a high-pressure chamber surrounding the lower half of the body during the diastolic phase of the cardiac cycle for daily 1-hour sessions over a period of 7 weeks. Randomized trials have shown that ECP reduces angina, improves exercise tolerance, and can reduce symptoms of heart failure.

L. Neuromodulation

Spinal cord stimulation can be used to relieve chronic refractory angina. Spinal cord stimulators are subcutaneously implantable via a minimally invasive procedure under local anesthesia.

► Prognosis

The prognosis of angina pectoris has improved with development of therapies aimed at secondary prevention. Mortality rates vary depending on the number of vessels diseased, the severity of obstruction, the status of LV function, and the presence of complex arrhythmias. Mortality rates are progressively higher in patients with one-, two-, and three-vessel disease and those with left main coronary artery obstruction (ranging from 1% per year to 25% per year). The outlook in individual patients is unpredictable, and nearly half of the deaths are sudden. Therefore, risk stratification is often attempted. Patients with accelerating symptoms have a poorer outlook. Among stable patients,

Table 10–4. Duke treadmill score: Calculation and interpretation.

Time in minutes on Bruce protocol	=	_____
–5 × amount of depression (in mm)	=	_____
–4 × angina index	=	_____
0 = no angina on test		
1 = angina, not limiting		
2 = limiting angina		
Total Score	Risk Group	Annual Mortality
≥ 5	Low	0.25%
–10 to +4	Intermediate	1.25%
≤ –11	High	5.25%

those whose exercise tolerance is severely limited by ischemia (< 6 minutes on the Bruce treadmill protocol) and those with extensive ischemia by exercise ECG or scintigraphy have more severe anatomic disease and a poorer prognosis. The Duke Treadmill Score, based on a standard Bruce protocol exercise treadmill test, provides an estimate of risk of death at 1 year. The score uses time on the treadmill, amount of ST-segment depression, and presence of angina (Table 10–4).

► Trial Results

Several randomized trials have shown that over follow-up periods of several years, the mortality and infarction rates with percutaneous revascularization and CABG are generally comparable. Exceptions are patients with left main or three-vessel disease with reduced ventricular function, and perhaps diabetic patients, who have had better outcomes with CABG. The increasing popularity of PCI and stenting primarily reflects the lower cost and shorter hospitalization, the perception that CABG is best done only once and can be reserved for later, and the preference of patients for less invasive treatment. These arguments make PCI the procedure of choice for revascularization of single-vessel disease. The situation is less clear with multivessel disease. It should also be noted that the excellent outcome of patients treated medically has made it difficult to show an advantage with either revascularization approach except in patients who remain symptom limited or have left main lesions or three-vessel disease and LV dysfunction. The issue of late stent thrombosis may shift the balance toward bare metal stents, especially for patients who cannot tolerate or take long-term clopidogrel.

► When to Refer

All patients with new or worsening symptoms believed to represent angina or a positive stress test for myocardial ischemia (or both) should be referred to a cardiologist.

► When to Admit

- Patients with elevated cardiac biomarkers, ischemic ECG findings, or hemodynamic instability.

- Patients with new or worsened symptoms possibly thought to be ischemic but who lack high-risk features can be observed with serial ECGs and biomarkers, and discharged if stress testing shows low-risk findings.

CORONARY VASOSPASM & ANGINA WITH NORMAL CORONARY ARTERIOGRAMS

ESSENTIALS OF DIAGNOSIS

- ▶ Precordial chest pain, often occurring at rest during stress or without known precipitant, relieved rapidly by nitrates.
- ▶ ECG evidence of ischemia during pain, sometime with ST-segment elevation, including by Holter monitor.
- ▶ Angiographic demonstration of no significant obstruction of major coronary vessels.
- ▶ Angiographic demonstration of coronary spasm that responds to intra-coronary nitroglycerin or calcium channel blockers.

▶ General Considerations

Although most symptoms of myocardial ischemia result from fixed stenosis of the coronary arteries or intraplaque

hemorrhage or thrombosis at the site of lesions, some ischemic events may be precipitated or exacerbated by coronary vasoconstriction.

Spasm of the large coronary arteries with resulting decreased coronary blood flow may occur spontaneously or may be induced by exposure to cold, emotional stress, or vasoconstricting medications, such as ergot derivative drugs. Spasm may occur both in normal and in stenosed coronary arteries. Even myocardial infarction may occur as a result of spasm in the absence of visible obstructive coronary heart disease, although most instances of such coronary spasm occur in the presence of coronary stenosis.

Cocaine can induce myocardial ischemia and infarction by causing coronary artery vasoconstriction or by increasing myocardial energy requirements. It also may contribute to accelerated atherosclerosis and thrombosis. The ischemia in **Prinzmetal (variant) angina** usually results from coronary vasoconstriction. It tends to involve the right coronary artery and there may be no fixed stenoses. Myocardial ischemia may also occur in patients with normal coronary arteries as a result of disease of the coronary microcirculation or abnormal vascular reactivity. This has been termed “syndrome X.”

► Clinical Findings

Ischemia may be silent or result in angina pectoris.

Prinzmetal (variant) angina is a clinical syndrome in which chest pain occurs without the usual precipitating factors and is associated with ST-segment elevation rather than depression. It often affects women under 50 years of age. It characteristically occurs in the early morning, awakening patients from sleep, and is apt to be associated with arrhythmias or conduction defects. It may be diagnosed by challenge with ergonovine (a vasoconstrictor), although the results of such provocation are not specific and it entails risk.

► Treatment

Patients with chest pain associated with ST-segment elevation should undergo coronary arteriography to determine whether fixed stenotic lesions are present. If they are, aggressive medical therapy or revascularization is indicated, since this may represent an unstable phase of the disease. If significant lesions are not seen and spasm is suspected, avoidance of precipitants such as cigarette smoking and cocaine is the top priority. Episodes of coronary spasm generally respond well to nitrates, and both nitrates and calcium channel blockers (including long-acting nifedipine, diltiazem, or amlodipine) are effective prophylactically. By allowing unopposed α_1 -mediated vasoconstriction, β -blockers have exacerbated coronary vasospasm, but they may have a role in management of patients in whom spasm is associated with fixed stenoses.

► When to Refer

All patients with persistent symptoms of chest pain that may represent spasm should be referred to a cardiologist.

ACUTE CORONARY SYNDROMES WITHOUT ST SEGMENT ELEVATION

► General Considerations

Acute coronary syndromes comprise the spectrum of unstable cardiac ischemia from unstable angina to acute myocardial infarction. Acute coronary syndromes are classified based on the presenting ECG as either “ST segment elevation” (STEMI) or “non-ST segment elevation.” This allows for immediate classification and guides determination of whether patients should be considered for acute reperfusion therapy. The evolution of cardiac biomarkers then allows determination of whether myocardial infarction has occurred. The universal definition of myocardial infarction is a rise of cardiac biomarkers with at least one value above the 99th percentile of the upper reference limit together with evidence of myocardial ischemia with at least one of the following: symptoms of ischemia, ECG changes of new ischemia, new Q waves, or imaging evidence of new loss of viable myocardium or new wall motion abnormality.

Acute coronary syndromes represent a dynamic state in which patients frequently shift from one category to another, as new ST elevation can develop after presentation and cardiac biomarkers can become abnormal with recurrent ischemic episodes.

Chest pain is one of the most frequent reasons for emergency department visits. Algorithms have been developed to aid in determining the likelihood that a patient has an acute coronary syndrome, and for those patients who do have an acute coronary syndrome, the risk of ischemic events and death.

► Clinical Findings

A. Symptoms and Signs

Patients with acute coronary syndromes generally have symptoms and signs of myocardial ischemia either at rest or with minimal exertion. These symptoms and signs are similar to chronic angina symptoms described above, consisting of substernal chest pain or discomfort that may radiate to the jaw, left shoulder or arm. Dyspnea, nausea, diaphoresis or syncope may either accompany the chest discomfort or may be the only symptom of acute coronary syndrome. About one-third of patients with myocardial infarction have no chest pain per se—these patients tend to be older, female, have diabetes, and be at higher risk for subsequent mortality. Patients with acute coronary syndromes have signs of heart failure in about 10% of cases, and this is also associated with higher risk of death.

Many hospitals have developed **chest pain observation units** to provide a systematic approach toward serial risk stratification to improve the triage process. In many cases, those who have not experienced new chest pain and have insignificant ECG changes and no cardiac biomarker elevation undergo treadmill exercise tests or imaging procedures to exclude ischemia at the end of an 8- to 24-hour period and are discharged directly from the emergency department if these tests are negative.

B. Laboratory Findings

Depending on the time from symptom onset to presentation, initial laboratory findings may be normal. The markers of cardiac myocyte necrosis, myoglobin, CK, CK-MB, and troponin I and T may all be used to identify acute myocardial infarction. These markers have a well-described pattern of release over time in patients with myocardial infarction. In patients with STEMI, these initial markers are often within normal limits as the patient is being rushed to immediate reperfusion. In patients without ST-segment elevation, it is the presence of abnormal CK-MB or troponin values that are associated with myocyte necrosis and the diagnosis of myocardial infarction. Serum creatinine is an important determinant of risk, and estimated creatinine clearance is important to guide dosing of certain antithrombotics, including eptifibatid and enoxaparin.

C. ECG

Many patients with acute coronary syndromes will exhibit ECG changes during pain—either ST-segment elevation, ST-segment depression, or T wave flattening or inversion. Dynamic ST segment shift is the most specific for acute coronary syndrome. Patients may exhibit signs of LV dysfunction during pain and for a time thereafter.

► Treatment

A. General Measures

Treatment of acute coronary syndromes without ST elevation should be multifaceted. Patients who are at medium or high risk should be hospitalized, maintained at bed rest or at very limited activity for the first 24 hours, monitored, and given supplemental oxygen. Sedation with a benzodiazepine agent may help if anxiety is present.

B. Specific Measures

Table 10–5 provides a summary of the ACC/AHA Guideline recommendations for selected medical treatments.

C. Anticoagulation and Antiplatelet Therapy

Patients should receive a combination of antiplatelet and anticoagulant agents. **Aspirin**, 81–325 mg daily, and an **anticoagulant** (unfractionated heparin, enoxaparin, fondaparinux, or bivalirudin) should be commenced on presentation. The large CURRENT trial comparing 81 mg versus 325 mg of aspirin (in addition to **clopidogrel**) for the first month following diagnosis of ACS found little difference

in thrombotic events or in major bleeding. Thus, either dose is reasonable, at least for the first month. The longer-term optimal aspirin dose may be 81 mg/d (versus 160 mg/d or 325 mg/d) based on similar thrombotic event rates and lower rates of bleeding, and the 2011 ACC/AHA guidelines recommend the 81 mg/d as preferable to higher doses following coronary stenting. Several trials have shown that **low-molecular-weight heparin** (enoxaparin 1 mg/kg subcutaneously every 12 hours) is somewhat more effective than **unfractionated heparin** in preventing recurrent ischemic events in the setting of acute coronary syndromes. However, the SYNERGY trial showed that unfractionated heparin and enoxaparin had similar rates of death or (re)infarction in the setting of frequent early coronary intervention. **Fondaparinux**, a specific factor Xa inhibitor given in a dose of 2.5 mg subcutaneously once a day, was found in the OASIS-5 trial to be equally effective as enoxaparin among 20,000 patients at preventing early death, myocardial infarction, and refractory ischemia, and resulted in a 50% reduction in major bleeding. This reduction in major bleeding translated into a significant reduction in mortality (and in death and/or myocardial infarction) at 30 days. While catheter-related thrombosis was more common during coronary intervention procedures with fondaparinux, the FUTURA trial found that it can be controlled by adding unfractionated heparin (in a dose of 85 units/kg without glycoprotein IIb/IIIa inhibitors, and 60 units/kg with glycoprotein IIb/IIIa inhibitors) during the procedure. Guidelines recommend fondaparinux, describing it as especially favorable for patients who are initially treated medically and who are at high risk for bleeding, such as the elderly.

The ACUTY trial showed that the direct thrombin inhibitor **bivalirudin** appears to be a reasonable alternative to heparin (unfractionated heparin or enoxaparin) plus a glycoprotein IIb/IIIa antagonist for many patients with acute coronary syndromes who are undergoing early coronary intervention. Bivalirudin (without routine glycoprotein IIb/IIIa inhibitor) is associated with substantially less bleeding than heparin plus glycoprotein IIb/IIIa inhibitor. The ISAR REACT-4 trial showed that bivalirudin has similar efficacy compared to abciximab but better bleeding outcomes in NSTEMI patients.

The Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial demonstrated a 20% reduction in the composite end point of cardiovascular death, myocardial infarction, and stroke with the addition of **clopidogrel** (300 mg loading dose, 75 mg/d for 9–12 months) in patients with non-ST-segment elevation acute coronary syndromes.

ACC/AHA guidelines call for either a P2Y₁₂ inhibitor (clopidogrel, prasugrel [at the time of PCI], or ticagrelor) or a glycoprotein IIb/IIIa inhibitor “up-front” (prior to coronary angiography) as a class I recommendation. The European Society of Cardiology guidelines provide a stronger recommendation for a P2Y₁₂ inhibitor up-front, as a class IA recommendation for all patients.

The large CURRENT trial showed that “double-dose” **clopidogrel** (600 mg initial oral loading dose, followed by 150 mg orally daily) for 7 days reduced stent thrombosis

Table 10-5. Summary of the current ACC/AHA guideline recommendations for medical management of acute coronary syndromes (ACS) and acute myocardial infarction (AMI).¹

Medication	Acute Therapies ACS	Acute Therapies AMI	Discharge Therapies
Aspirin (ASA)	IA	IA	IA
Clopidogrel in ASA-allergic patients	IA	IC	IA
Clopidogrel, intended medical management	IA	—	IA
Clopidogrel, early catheterization/percutaneous coronary intervention (catheterization/percutaneous coronary intervention [cath/PCI])	IA (prior to or at time of PCI)	IB	IA
Prasugrel (as an alternative to clopidogrel), for unstable angina/non-STEMI patients undergoing PCI and for primary PCI	IB ²	IB ²	
Ticagrelor (as an alternative to clopidogrel)	IB	IB	IB
Clopidogrel and IIb/IIIa inhibitor, up front (prior to catheterization)	IIa, B		
Heparin (unfractionated or low-molecular-weight)	IA	IC ³	—
Fondaparinux	IB	IC	
Bivalirudin	IB	IB ⁴	
Bivalirudin for early invasive strategy (without IIb/IIIa inhibitor), if clopidogrel at least 300 mg was administered 6 hours before planned catheterization or PCI	IIa, B		
β-Blockers (oral)	IB	IA	IB
β-Blockers (intravenous) ⁵	IIaB ⁵	IIaB ⁵	
Angiotensin-converting enzyme (ACE) inhibitors	IB ⁵	IA/IIaB ⁶	IA/IIaB ⁷
GP IIb/IIIa inhibitors for intended early cath/PCI:			
Eptifibatide/tirofiban	IA	IIa, B	—
Abciximab	IA	IIaA	—
Adding GP IIb/IIIa inhibitors to clopidogrel for high-risk patients without intended early cath/PCI:			
Eptifibatide/tirofiban	IIbB	—	—
Abciximab	IIIa	—	—
Lipid-lowering agent ⁸	—	—	IA
Smoking cessation counseling	—	—	IB
Nonsteroidal anti-inflammatory agents (other than aspirin)	IIIC	IIIC	—

¹Class I indicates treatment is useful and effective, class IIa indicates weight of evidence is in favor of usefulness/efficacy, class IIb indicates weight of evidence is less well established, and class III indicates intervention is not useful/effective and may be harmful. Type A recommendations are based on data derived from multiple randomized clinical trials or meta-analyses; Type B recommendations are based on data derived from single randomized clinical trial or large nonrandomized studies; Type C recommendations are based on consensus of opinion of the experts or on data derived from small studies, retrospective studies, or registries. ACC/AHA = American College of Cardiology/American Heart Association.

²In STEMI patients with a prior history of stroke and transient ischemic attack for whom primary PCI is planned, prasugrel is not recommended as part of a dual-antiplatelet therapy regimen. (Class III, Level of Evidence: C).

³Unfractionated heparin, enoxaparin, or fondaparinux have established efficacy and should be used (IC) for a minimum of 48 hours and preferably for the duration of the hospitalization, up to 8 days. Enoxaparin or fondaparinux are preferred if therapy is given for more than 48 hours because of risk of heparin-induced thrombocytopenia (IA). Because of risk of catheter thrombosis, fondaparinux should not be used as the sole anticoagulant to support PCI.

⁴With primary PCI, with or without prior heparin bolus.

⁵For patients with hypertension and no heart failure, low output state, increased risk of shock, or other contraindications to β-blockers.

⁶For patients with persistent hypertension despite treatment, diabetes mellitus, congestive heart failure, or any left ventricular dysfunction.

⁷IA for patients with congestive heart failure or ejection fraction < 0.40, IIa for others, in absence of hypotension (systolic blood pressure < 100 mm Hg); angiotensin receptor blocker (valsartan or candesartan) for patients with ACE inhibitor intolerance.

⁸For patients with a low-density lipoprotein cholesterol level > 70 mg/dL.

STEMI, ST elevation myocardial infarction.

with a modest increase in major (but not fatal) bleeding and, therefore, it is an option for patients with ACS undergoing PCI.

Prasugrel is a P2Y₁₂ inhibitor that is both more potent and has a faster onset of action than clopidogrel. The TRITON trial compared prasugrel with clopidogrel in patients with STEMI or non-ST elevation MI in whom PCI was planned; prasugrel resulted in a 19% relative reduction in death from cardiovascular causes, myocardial infarction, or stroke, at the expense of a small increase in serious bleeding (including fatal bleeding). Stent thrombosis was reduced by half. Because patients with prior stroke or transient ischemic attack had higher risk of intracranial hemorrhage, prasugrel is contraindicated in such patients. Bleeding was also higher in patients with low body weight (< 60 kg) and older age (≥ 75 years), and caution should be used in these populations. For patients with STEMI treated with PCI, prasugrel appears to be especially effective without a substantial increase in bleeding.

Ticagrelor is a P2Y₁₂ inhibitor that has a faster onset of action than clopidogrel and a more consistent and potent effect. The PLATO trial showed that when ticagrelor was started at the time of presentation in ACS patients (UA/NSTEMI and STEMI), it reduced cardiovascular death, myocardial infarction, and stroke by 16% when compared with clopidogrel. In addition, there was a 22% relative risk reduction in mortality with ticagrelor. The overall rates of bleeding were similar between ticagrelor and clopidogrel, although non-CABG related bleeding was modestly higher. The finding of a lesser treatment effect in the United States may have been related to use of higher-dose aspirin, and thus when using ticagrelor, low-dose aspirin (81 mg/d) is recommended. The European College of Cardiology guidelines recommend (at a class I level) ticagrelor for all patients at moderate to high risk for ACS; prasugrel for patients who have not yet received another P2Y₁₂ inhibitor, who have planned PCI, and who are not at high risk for life-threatening bleeding; and clopidogrel only for patients who cannot receive either ticagrelor or prasugrel.

Small molecule inhibitors of the platelet glycoprotein IIb/IIIa receptor are useful adjuncts in high-risk patients (usually defined by fluctuating ST-segment depression or positive biomarkers) with acute coronary syndromes, particularly when they are undergoing PCI. **Tirofiban**, 0.4 mcg/kg/min for 30 minutes, followed by 0.1 mcg/kg/min, and **eptifibatide**, 180 mcg/kg bolus followed by a continuous infusion of 2 mcg/kg/min, have both been shown to be effective. Downward dose adjustments (1 mcg/kg/min) are required in patients with reduced kidney function. For example, if the estimated creatinine clearance is below 50 mL/min, the eptifibatide infusion should be cut in half to 1 mcg/kg/min. The ISAR-REACT 2 trial showed that for patients undergoing PCI with high-risk acute coronary syndrome, especially with elevated troponin, intravenous **abciximab** (added to clopidogrel 600 mg loading dose) reduces ischemic events by about 25%. The EARLY-ACS trial in over 10,000 patients with high-risk ACS found no benefit from eptifibatide started on admission compared with eptifibatide

treatment at the time of invasive coronary angiography, and higher rates of bleeding.

Fibrinolytic therapy should be avoided in patients without ST-segment elevation since they generally have a patent culprit artery, and since the risk of such therapy appears to outweigh the benefit.

D. Temporary Discontinuation of Antiplatelet Therapy for Procedures

Patients who have had recent coronary stents are at risk for thrombotic events, including **stent thrombosis**, if P2Y₁₂ inhibitors are discontinued for procedures (eg, dental procedures or colonoscopy). If possible, these procedures should be delayed until the end of the necessary treatment period with P2Y₁₂ inhibitors, which generally is at least 1 month with bare metal stents and 6 months with drug-eluting stents. Before that time, if a procedure is necessary, risk and benefit of continuing the antiplatelet therapy through the time of the procedure should be assessed. Aspirin should generally be continued.

E. Nitroglycerin

Nitrates are first-line therapy for patients with acute coronary syndromes presenting with chest pain. Nonparenteral therapy with sublingual or oral agents or nitroglycerin ointment is usually sufficient. If pain persists or recurs, intravenous nitroglycerin should be started. The usual initial dosage is 10 mcg/min. The dosage should be titrated upward by 10–20 mcg/min (to a maximum of 200 mcg/min) until angina disappears or mean arterial pressure drops by 10%. Careful—usually continuous—BP monitoring is required when intravenous nitroglycerin is used. Avoid hypotension (systolic BP < 100 mm Hg). Tolerance to continuous nitrate infusion is common.

F. β-Blockers

β-Blockers are an important part of the initial treatment of unstable angina unless otherwise contraindicated. The pharmacology of these agents is discussed in Chapter 11 and summarized in Table 11–7. Use of agents with intrinsic sympathomimetic activity should be avoided in this setting. Oral medication is adequate in most patients, but intravenous treatment with metoprolol, given as three 5-mg doses 5 minutes apart as tolerated and in the absence of heart failure, achieves a more rapid effect. Oral therapy should be titrated upward as BP permits.

G. Calcium Channel Blockers

Calcium channel blockers have not been shown to favorably affect outcome in unstable angina, and they should be used primarily as third-line therapy in patients with continuing symptoms on nitrates and β-blockers or those who are not candidates for these drugs. In the presence of nitrates and without accompanying β-blockers, diltiazem or verapamil is preferred, since nifedipine and the other dihydropyridines are more likely to cause reflex tachycardia or hypotension. The initial dosage should be low, but upward titration should proceed steadily (see Table 11–9).

H. Statins

The PROVE-IT trial provides evidence for starting a statin in the days immediately following an acute coronary syndrome. In this trial, more intensive therapy with atorvastatin 80 mg a day, regardless of total or LDL cholesterol level, improved outcome compared to pravastatin 40 mg a day, with the curves of death or major cardiovascular event separating as early as 3 months after starting therapy.

► Indications for Coronary Angiography

For patients with acute coronary syndrome, including non-ST-segment elevation myocardial infarction, risk stratification is important for determining intensity of care. Several therapies, including glycoprotein IIb/IIIa receptor antagonists, low-molecular-weight heparin, and early invasive catheterization, have been shown to have the greatest benefit in higher-risk patients with acute coronary syndrome. As outlined in the ACC/AHA guidelines, patients with any high-risk feature (Table 10–6) generally warrant an early invasive strategy with catheterization and revascularization. For patients without these high-risk features, either an invasive or noninvasive approach, using exercise (or pharmacologic stress for patients unable to exercise) stress testing to identify patients who have residual ischemia and/or high risk, can be used. Moreover, based on the ICTUS trial, a strategy based on selective coronary angiography and revascularization for instability or inducible ischemia, or both, even for patients with positive troponin, is acceptable (ACC/AHA class IIB recommendation).

Two risk-stratification tools are available that can be used at the bedside, the TIMI Risk Score and the GRACE Risk Score. The TIMI Risk Score includes nine variables: age ≥ 65 , three or more cardiac risk factors, prior coronary stenosis $\geq 50\%$, ST-segment deviation, two anginal events in prior 24 hours, acetylsalicylic acid in prior 7 days, and elevated cardiac markers. The GRACE risk score, which applies to patients with or without ST elevation, includes Killip class, BP, ST-segment deviation, cardiac arrest at presentation, serum creatinine, elevated creatine kinase (CK)-MB or troponin, and heart rate. The TIMI Risk Score is available for PDA download at http://www.outcomes-umassmed.org/grace/acs_risk_content.html.

► When to Refer

All patients with acute myocardial infarction should be referred to a cardiologist.

Patients who are taking a P2Y₁₂ inhibitor following coronary stenting should consult a cardiologist before discontinuing treatment for nonemergency procedures.

FUTURA/OASIS-8 Trial Group; Steg PG et al. Low-dose vs standard-dose unfractionated heparin for percutaneous coronary intervention in acute coronary syndromes treated with fondaparinux: the FUTURA/OASIS-8 randomized trial. *JAMA*. 2010 Sep 22;304(12):1339–49. [PMID: 20805623]

Table 10–6. Indications for catheterization and percutaneous coronary intervention.¹

Acute coronary syndromes (unstable angina and non-ST elevation MI)	
Class I	Early invasive strategy for any of the following high-risk indicators:
	Recurrent angina/ischemia at rest or with low-level activity
	Elevated troponin
	ST-segment depression
	Recurrent ischemia with evidence of CHF
	High-risk stress test result
	EF < 40%
	Hemodynamic instability
	Sustained ventricular tachycardia
	PCI within 6 months
	Prior CABG
	In the absence of these findings, either an early conservative or early invasive strategy
Class IIa	Early invasive strategy for patients with repeated presentations for ACS despite therapy
Class III	Extensive comorbidities in patients in whom benefits of revascularization are not likely to outweigh the risks
	Acute chest pain with low likelihood of ACS
Acute MI after fibrinolytic therapy (2009 ACC/AHA AMI Guideline Update)	
Class I	Recurrent ischemia (spontaneous or provoked)
	Recurrent MI
	Cardiogenic shock or hemodynamic instability
Class IIa	Reasonable to transfer high-risk patients treated with fibrinolytic therapy at a non-PCI center as soon as possible to a PCI facility for early diagnostic angiography and revascularization. (Level of evidence: B)
Class IIb	Consider transfer of non-high risk patients treated with fibrinolytic therapy at a non-PCI center to a PCI facility, especially if ischemic symptoms persist and failure to reperfuse is suspected.

¹Class I indicates treatment is useful and effective, IIa indicates weight of evidence is in favor of usefulness/efficacy, class IIb indicates weight of evidence is less well established, and class III indicates intervention is not useful/effective and may be harmful. Level of evidence A recommendations are derived from large-scale randomized trials, and B recommendations are derived from smaller randomized trials or carefully conducted observational analyses.

ACUTE MYOCARDIAL INFARCTION WITH ST SEGMENT ELEVATION

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden but not instantaneous development of prolonged (> 30 minutes) anterior chest discomfort (sometimes felt as “gas” or pressure).
- ▶ Sometimes painless, masquerading as acute CHF, syncope, stroke, or shock.
- ▶ ECG: ST-segment elevation or left bundle branch block.
- ▶ Immediate reperfusion treatment is warranted.
- ▶ Primary PCI within 90 minutes of first medical contact is the goal and is superior to thrombolysis.
- ▶ Thrombolysis within 30 minutes of hospital presentation and 6–12 hours of onset of symptoms reduces mortality.

▶ General Considerations

STEMI results, in most cases, from an occlusive coronary thrombus at the site of a preexisting (though not necessarily severe) atherosclerotic plaque. More rarely, infarction may result from prolonged vasospasm, inadequate myocardial blood flow (eg, hypotension), or excessive metabolic demand. Very rarely, myocardial infarction may be caused by embolic occlusion, vasculitis, aortic root or coronary artery dissection, or aortitis. Cocaine is a cause of infarction, which should be considered in young individuals without risk factors. A condition that may mimic STEMI is stress cardiomyopathy (also referred to as Tako-Tsubo or apical ballooning syndrome) (see below).

ST elevation connotes an acute coronary occlusion and thus warrants immediate reperfusion therapy.

▶ Clinical Findings

A. Symptoms

1. Premonitory pain—There is usually a worsening in the pattern of angina preceding the onset of symptoms of myocardial infarction; classically the onset of angina occurs with minimal exertion or at rest.

2. Pain of infarction—Unlike anginal episodes, most infarctions occur at rest, and more commonly in the early morning. The pain is similar to angina in location and radiation but it may be more severe, and it builds up rapidly or in waves to maximum intensity over a few minutes or longer. Nitroglycerin has little effect; even opioids may not relieve the pain.

3. Associated symptoms—Patients may break out in a cold sweat, feel weak and apprehensive, and move about, seeking a position of comfort. They prefer not to lie quietly. Light-headedness, syncope, dyspnea, orthopnea, cough, wheezing, nausea and vomiting, or abdominal bloating may be present singly or in any combination.

4. Painless infarction—One-third of patients with acute myocardial infarction present without chest pain, and these patients tend to be undertreated and have poor outcomes. Older patients, women, and patients with diabetes mellitus are more likely to present without classic chest pain. As many as 25% of infarctions are detected on routine ECG without any recallable acute episode.

5. Sudden death and early arrhythmias—Of all deaths from myocardial infarction, about 50% occur before the patients arrive at the hospital, with death presumably caused by ventricular fibrillation.

B. Signs

1. General—Patients may appear anxious and sometimes are sweating profusely. The heart rate may range from marked bradycardia (most commonly in inferior infarction) to tachycardia, low cardiac output, or arrhythmia. The BP may be high, especially in former hypertensive patients, or low in patients with shock. Respiratory distress usually indicates heart failure. Fever, usually low grade, may appear after 12 hours and persist for several days.

2. Chest—The **Killip classification** is the standard way to classify heart failure in patients with acute myocardial infarction and has powerful prognostic value. Killip class I is absence of rales and S_3 , class II is rales that do not clear with coughing over one-third or less of the lung fields or presence of an S_3 , class III is rales that do not clear with coughing over more than one-third of the lung fields, and class IV is cardiogenic shock (rales, hypotension, and signs of hypoperfusion).

3. Heart—The cardiac examination may be unimpressive or very abnormal. Jugular venous distention reflects RA hypertension, and a Kussmaul sign (failure of decrease of jugular venous pressure with inspiration) is suggestive of RV infarction. Soft heart sounds may indicate LV dysfunction. Atrial gallops (S_4) are the rule, whereas ventricular gallops (S_3) are less common and indicate significant LV dysfunction. Mitral regurgitation murmurs are not uncommon and may indicate papillary muscle dysfunction or, rarely, rupture. Pericardial friction rubs are uncommon in the first 24 hours but may appear later.

4. Extremities—Edema is usually not present. Cyanosis and cold temperature indicate low output. The peripheral pulses should be noted, since later shock or emboli may alter the examination.

C. Laboratory Findings

Cardiac-specific markers of myocardial damage include quantitative determinations of CK-MB, troponin I, and troponin T. Normal cut-off levels for troponins depend on the assay used and reference ranges for the laboratory performing the test. Troponins are more sensitive and specific than CK-MB. Each of these tests may become positive as early as 4–6 hours after the onset of a myocardial infarction and should be abnormal by 8–12 hours. Circulating levels of troponins may remain elevated for 5–7 days or longer and therefore are generally not useful for evaluating suspected early reinfarction. Elevated CK-MB generally normalizes within 24 hours, thus being more helpful for evaluation of reinfarction. High-sensitivity troponin assays are becoming available that have a 10- to 100-fold lower limit of detection with high analytic precision, enabling myocardial infarction to be detected earlier. While many conditions including chronic heart failure are associated with elevated levels of the high-sensitivity troponin assays, these assays may be especially useful when negative to exclude myocardial infarction in patients complaining of chest pain.

D. ECG

The extent of the ECG abnormalities, especially the sum of the total amount of ST-segment deviation, is a good indicator of extent of acute infarction and risk of subsequent adverse events. The classic evolution of changes is from peaked (“hyperacute”) T waves, to ST-segment elevation, to Q wave development, to T wave inversion. This may occur over a few hours to several days. The evolution of new Q waves (>30 milliseconds in duration and 25% of the R wave amplitude) is diagnostic, but Q waves do not occur

in 30–50% of acute infarctions (non-Q wave infarctions). Left bundle branch block, especially when new (or not known to be old), in a patient with symptoms of an acute myocardial infarction, is considered to be a “STEMI equivalent”; reperfusion therapy is indicated for the affected patient. Concordant ST elevation (ie, ST elevation in leads with an overall positive QRS complex) with left bundle branch block is a specific finding indicating STEMI.

E. Chest Radiography

The chest radiograph may demonstrate signs of CHF, but these changes often lag behind the clinical findings. Signs of aortic dissection, including mediastinal widening, should be sought as a possible alternative diagnosis.

F. Echocardiography

Echocardiography provides convenient bedside assessment of LV global and regional function. This can help with the diagnosis and management of infarction; echocardiography has been used successfully to make judgments about admission and management of patients with suspected infarction, including in patients with ST-segment elevation or left bundle branch block of uncertain significance, since normal wall motion makes an infarction unlikely. Doppler echocardiography is generally the most convenient procedure for diagnosing postinfarction mitral regurgitation or VSD.

G. Other Noninvasive Studies

Diagnosis of myocardial infarction and extent of myocardial infarction can be assessed by various imaging studies in addition to echocardiography. **MRI** with gadolinium contrast enhancement is now the most sensitive test to detect and quantitate extent of infarction, with the ability to detect as little as 2 g of myocardial infarction. **Technetium-99m pyrophosphate scintigraphy**, when injected at least 18 hours postinfarction, complexes with calcium in necrotic myocardium to provide a “hot spot” image of the infarction. This test is insensitive to small infarctions, and false-positive studies occur, so its use is limited to patients in whom the diagnosis by ECG and enzymes is not possible—principally those who present several days after the event or have intraoperative infarctions. **Scintigraphy with thallium-201** or technetium-based perfusion tracers will demonstrate “cold spots” in regions of diminished perfusion, which usually represent infarction when the radiotracer is administered at rest, but abnormalities do not distinguish recent from old damage. All of these tests may be considered after the patient has had revascularization.

H. Hemodynamic Measurements

These can be helpful in managing the patient with suspected cardiogenic shock. Use of PA catheters, however, has generally not been associated with better outcomes and should be limited to patients with severe hemodynamic compromise (Table 10–7).

Table 10-7. Hemodynamic subsets in acute myocardial infarction.

Category	CI or SWI	PCWP	Treatment	Comment
Normal	> 2.2, < 30	< 15	None	Mortality rate < 5%.
Hyperdynamic	> 3.0, > 40	< 15	β-Blockers	Characterized by tachycardia; mortality rate < 5%.
Hypovolemic	< 2.5, < 30	< 10	Volume expansion	Hypotension, tachycardia, but preserved left ventricular function by echocardiography; mortality rate 4–8%.
Left ventricular failure	< 2.2, < 30	> 15	Diuretics	Mild dyspnea, rales, normal blood pressure; mortality rate 10–20%.
Severe failure	< 2.0, < 20	> 18	Diuretics, vasodilators	Pulmonary edema, mild hypotension; inotropic agents, IABC may be required; mortality rate 20–40%.
Shock	< 1.8, < 30	> 20	Inotropic agents, IABC	IABC early unless rapid reversal occurs; mortality rate > 60%.

CI, cardiac index (L/min/m²); SWI, stroke work index (g-m/m², calculated as [mean arterial pressure – PCWP] × stroke volume index × 0.0136); PCWP, pulmonary capillary wedge pressure (in mm Hg; pulmonary artery diastolic pressure may be used instead); IABC, intra-aortic balloon counterpulsation.

► Treatment

Table 10-5 provides a summary of the ACC/AHA Guideline recommendations for selected medical treatments.

A. Aspirin, Clopidogrel, Prasugrel, and Ticagrelor

All patients with definite or suspected myocardial infarction should receive aspirin at a dose of 162 mg or 325 mg at once regardless of whether thrombolytic therapy is being considered or the patient has been taking aspirin. Chewable aspirin provides more rapid blood levels. Patients with a definite aspirin allergy should be treated with a P2Y₁₂ inhibitor (clopidogrel, prasugrel, or ticagrelor). Clopidogrel at a loading dose of 600 mg (or 300 mg) will result in faster onset of action than the standard 75 mg maintenance dose.

Clopidogrel, in combination with aspirin, has also been shown to provide important benefits in patients with acute ST elevation myocardial infarction. In the CLARITY trial, a loading dose of 300 mg of clopidogrel given with thrombolytic therapy, followed by 75 mg a day, led to substantial improvement in coronary patency on catheterization 3.5 days following thrombolysis. Moreover, there was no increase in serious bleeding in this population of patients up to 75 years of age. The COMMIT/CCS-2 trial randomized over 45,000 patients in China with acute myocardial infarction to clopidogrel 75 mg a day or placebo, and found a small but statistically significant reduction in early death, myocardial reinfarction, and stroke, with no excess in

major bleeding. Thus, guidelines now call for clopidogrel to be added to aspirin to all patients with STEMI, regardless of whether or not reperfusion is given, and continued for at least 14 days, and generally for 1 year. For patients who have received thrombolytic therapy but will undergo angiography in the first day or two, the early benefits of clopidogrel need to be weighed against the necessary delay in bypass surgery for approximately 5 days for those patients found to require surgical revascularization.

Compared with standard dose clopidogrel, “double dose” clopidogrel (600 mg oral loading dose followed by 150 mg orally daily) for 1 week reduces stent thrombosis at the cost of a modest increase in bleeding. In the TRITON study, prasugrel was shown to be of greater benefit than clopidogrel in reducing thrombotic events in the subgroup of patients with STEMI, including a 50% reduction in stent thrombosis. Prasugrel is contraindicated in patients with history of stroke. In the PLATO trial, ticagrelor was shown to be of greater benefit than clopidogrel in reducing cardiovascular death, myocardial infarction, and stroke as well as in reducing stent thrombosis.

B. Reperfusion Therapy

The current recommendation is to treat patients with STEMI who seek medical attention within 12 hours of the onset of symptoms with reperfusion therapy, either primary PCI or thrombolytic therapy. Patients without ST-segment elevation (previously labeled “non-Q wave” infarctions) do not benefit, and may derive harm, from thrombolysis.

1. Primary percutaneous coronary intervention—Immediate coronary angiography and primary PCI (including stenting) of the infarct-related artery have been shown to be superior to thrombolysis when done by experienced operators in high-volume centers with rapid time from first medical contact to intervention (“door-to-balloon”). US and European guidelines call for first medical contact or “door-to-balloon” times of < 90 minutes.

Several trials have shown that if efficient transfer systems are in place, transfer of patients with acute myocardial infarction from hospitals without primary PCI capability to hospitals with primary PCI capability with first door-to-device times of < 120 minutes can improve outcome compared with thrombolytic therapy at the presenting hospital, although this requires sophisticated systems to ensure rapid identification, transfer, and PCI. Primary PCI is the approach of choice in patients with absolute and many relative contraindications to thrombolytic therapy. The results of this approach in specialized centers are excellent, exceeding those obtainable by thrombolytic therapy even in good candidates, but this experience may not be generalizable to centers and operators with less experience or expertise. Stenting—generally in conjunction with either bivalirudin preferred over the platelet glycoprotein IIb/IIIa antagonist abciximab (based on the HORIZONS trial)—is standard for patients with acute myocardial infarction. Although randomized trials have shown a benefit with regards to fewer repeat interventions for restenosis with use of drug-eluting stents in STEMI patients, bare metal stents are used more commonly since the patient's ability to obtain and comply with P2Y₁₂ inhibitor therapy is often not known at the time of PCI. In the subgroup of patients with cardiogenic shock, early catheterization and percutaneous or surgical revascularization are the preferred management and have been shown to reduce mortality. Because an acute interventional approach carries a lower risk of hemorrhagic complications including intracranial hemorrhage, it may also be the preferred strategy in many older patients (see Tables 10–5 and 10–6 for factors to consider in choosing thrombolytic therapy or primary PCI).

Glycoprotein IIb/IIIa inhibitors, and specifically abciximab, have been shown to reduce major thrombotic events, and possibly mortality, when added to heparin for patients undergoing primary PCI. The HORIZONS trial showed that compared with unfractionated heparin plus abciximab, bivalirudin (with provisional use of “bail-out” IIb/IIIa inhibitors) results in similar rates of thrombotic events and 40% less bleeding. This appeared to be accompanied by lower mortality at 30 days and 1 year, providing further support for the safety and efficacy of bivalirudin in this setting.

In part because patients in the United States who are transferred for primary PCI tend to have long delays from first hospital arrival to balloon inflation, there has been interest in developing “facilitated” PCI whereby a combination of medications (full or reduced dose fibrinolytic agents with or without glycoprotein IIb/IIIa inhibitors) is given followed by immediate PCI. However, recent trials (and overviews of completed trials) have shown either no benefit or harm with this approach. Thus, patients should be treated either with fibrinolytic agents (and immediate rescue PCI for reperfusion failure) or with primary PCI, if it can be done promptly as outlined in the ACC/AHA and European guidelines. Timely access to most appropriate reperfusion, including primary PCI, can be expanded with development of regional systems of care, including emergency medical systems and networks of hospitals. Patients treated with fibrinolytic therapy appear to have improved

outcomes if transferred for routine coronary angiography and PCI within 24 hours. The American Heart Association has a program called Mission: Lifeline to support systems development (see <http://www.heart.org/missionlifeline>).

2. Thrombolytic therapy

A. BENEFIT—Thrombolytic therapy reduces mortality and limits infarct size in patients with acute myocardial infarction associated with ST-segment elevation (defined as ≥ 0.1 mV in two inferior or lateral leads or two contiguous precordial leads), or with left bundle branch block (not known to be old). The greatest benefit occurs if treatment is initiated within the first 3 hours, when up to a 50% reduction in mortality rate can be achieved. The magnitude of benefit declines rapidly thereafter, but a 10% relative mortality reduction can be achieved up to 12 hours after the onset of chest pain. The survival benefit is greatest in patients with large—usually anterior—infarctions.

B. CONTRAINDICATIONS—Major bleeding complications occur in 0.5–5% of patients, the most serious of which is intracranial hemorrhage. The major risk factors for intracranial bleeding are older age (> 65 years), hypertension at presentation (especially over 180/110 mm Hg), low body weight (< 70 kg), and the use of clot-specific thrombolytic agents (alteplase, reteplase, tenecteplase). Although patients over age 75 years have a much higher mortality rate with acute myocardial infarction and therefore may derive greater benefit, the risk of severe bleeding is also higher, particularly among patients with risk factors for intracranial hemorrhage, such as severe hypertension or recent stroke. Patients presenting more than 12 hours after the onset of chest pain may also derive a small benefit, particularly if pain and ST-segment elevation persist, but rarely does this benefit outweigh the attendant risk.

Contraindications to thrombolytic therapy include previous hemorrhagic stroke, other strokes or cerebrovascular events within 1 year, known intracranial neoplasm, recent head trauma (including minor trauma), active internal bleeding (excluding menstruation), or suspected aortic dissection. Relative contraindications are BP > 180/110 mm Hg at presentation, other intracerebral pathology not listed above as a contraindication, known bleeding diathesis, trauma (including minor head trauma) within 2–4 weeks, major surgery within 3 weeks, prolonged (> 10 minutes) or traumatic cardiopulmonary resuscitation, recent (within 2–4 weeks) internal bleeding, noncompressible vascular punctures, active diabetic retinopathy, pregnancy, active peptic ulcer disease, a history of severe hypertension, current use of anticoagulants (INR > 2.0–3.0), and (for streptokinase) prior allergic reaction or exposure to streptokinase or anistreplase within 2 years.

C. THROMBOLYTIC AGENTS—The following thrombolytic agents are available for acute myocardial infarction and are characterized in Table 10–8.

Alteplase (recombinant tissue plasminogen activator; t-PA) is a naturally occurring plasminogen activator that is modestly fibrin specific, resulting in about a 50% reduction in circulating fibrinogen. In the first GUSTO trial, which compared a 90-minute dosing of t-PA (with unfractionated

Table 10-8. Thrombolytic therapy for acute myocardial infarction.

	Alteplase; Tissue Plasminogen Activator (t-PA)	Retepase	Tenecteplase (TNK-t-PA)	Streptokinase
Source	Recombinant DNA	Recombinant DNA	Recombinant DNA	Group C streptococcus
Half-life	5 minutes	15 minutes	20 minutes	20 minutes
Usual dose	100 mg	20 units	40 mg	1.5 million units
Administration	Initial bolus of 15 mg, followed by 50 mg infused over the next 30 minutes and 35 mg over the following 60 minutes	10 units as a bolus over 2 minutes, repeated after 30 minutes	Single weight-adjusted bolus, 0.5 mg/kg	750,000 units over 20 minutes followed by 750,000 units over 40 minutes
Anticoagulation after infusion	Aspirin, 325 mg daily; heparin, 5000 units as bolus, followed by 1000 units per hour infusion, subsequently adjusted to maintain PTT 1.5-2 times control	Aspirin, 325 mg; heparin as with t-PA	Aspirin, 325 mg daily	Aspirin, 325 mg daily; there is no evidence that adjunctive heparin improves outcome following streptokinase
Clot selectivity	High	High	High	Low
Fibrinogenolysis	+	+	+	+++
Bleeding	+	+	+	+
Hypotension	+	+	+	+++
Allergic reactions	0	0	+	++
Reocclusion	10-30%	—	5-20%	5-20%
Approximate cost ¹	\$4779.71	\$5211.86	\$3238.76	Not available in the United States

PTT, partial thromboplastin time.

heparin) with streptokinase, the 30-day mortality rate with t-PA was one absolute percentage point lower (one additional life saved per 100 patients treated), though there was also a small *increase* in the rate of intracranial hemorrhage. An angiographic substudy confirmed a higher 90-minute patency rate and a higher rate of normal (TIMI grade 3) flow in patients.

Retepase is a recombinant deletion mutant of t-PA that is slightly less fibrin specific. In comparative trials, it appears to have efficacy similar to that of alteplase, but it has a longer duration of action and can be administered as two boluses 30 minutes apart.

Tenecteplase (TNK-t-PA) is a genetically engineered substitution mutant of native t-PA that has reduced plasma clearance, increased fibrin sensitivity, and increased resistance to plasminogen activator inhibitor-1. It can be given as a single weight-adjusted bolus. In a large comparative trial, this agent was equivalent to t-PA with regard to efficacy and resulted in significantly less noncerebral bleeding.

Streptokinase is commonly used elsewhere in the world, but not commonly used in the United States since it is somewhat less effective at opening occluded arteries and less effective at reducing mortality. It is non-fibrin-specific, causes depletion of circulating fibrinogen, and has a tendency to induce hypotension, particularly if infused rapidly.

This can be managed by slowing or interrupting the infusion and administering fluids. There is controversy as to whether adjunctive heparin is beneficial in patients given streptokinase, unlike its administration with the more clot-specific agents. Allergic reactions, including anaphylaxis, occur in 1-2% of patients, and this agent should generally not be administered to patients with prior exposure.

(1) Selection of a thrombolytic agent—In the United States, most patients are treated with alteplase, reteplase, or tenecteplase. The differences in efficacy between them are small compared with the potential benefit of treating a greater proportion of appropriate candidates in a more prompt manner. The principal objective should be to administer a thrombolytic agent within 30 minutes of presentation—or even during transport. The ability to administer tenecteplase as a single bolus is an attractive feature that may facilitate earlier treatment. The combination of a reduced-dose thrombolytic given with a platelet glycoprotein IIb/IIIa antagonist has been investigated in several trials, with no evidence of reduction in mortality but a modest increase in bleeding complications.

(2) Postthrombolytic management—After completion of the thrombolytic infusion, aspirin (81-325 mg/d) and heparin should be continued. The 2008 ACC/AHA guidelines recommend continued anticoagulation for the duration of

the hospital stay (or up to 8 days) with some anticoagulant, with advantages favoring either enoxaparin or fondaparinux.

(A) UNFRACTIONATED HEPARIN—Anticoagulation with intravenous heparin (initial dose of 60 units/kg bolus to a maximum of 4000 units, followed by an infusion of 12 units/kg/min to a maximum of 1000 units, then adjusted to maintain an activated partial thromboplastin time [aPTT] of 50–75 seconds beginning with an aPTT drawn 3 hours after thrombolytic) is continued for at least 48 hours after alteplase, reteplase, or tenecteplase, and with continuation of some anticoagulant until revascularization (if performed) or until hospital discharge (or day 8).

(B) LOW-MOLECULAR-WEIGHT HEPARIN—In the EXTRACT trial, enoxaparin significantly reduced death and myocardial infarction at day 30 (compared with unfractionated heparin), at the expense of a modest increase in bleeding. In patients younger than age 75, enoxaparin was given as a 30 mg intravenous bolus and 1 mg/kg every 12 hours; in patients age 75 years and older, it was given with no bolus and 0.75 mg/kg intravenously every 12 hours. This appeared to attenuate the risk of intracranial hemorrhage in the elderly that had been seen with full-dose enoxaparin. Another antithrombotic option is fondaparinux, given at a dose of 2.5 mg subcutaneously once a day. In the OASIS-6 trial, it resulted in significant reductions in death and reinfarction when compared with control (unfractionated heparin when indicated, otherwise placebo). Similar to the findings of the OASIS-5 trial, fondaparinux tended to result in less bleeding, despite its longer duration compared with heparin and despite its comparison to placebo in about half of the enrolled patients. There was no benefit of fondaparinux among patients undergoing primary PCI, and fondaparinux is not recommended as a sole anticoagulant during PCI due to risk of catheter thrombosis.

For all patients with acute myocardial infarction treated with intensive antithrombotic therapy, prophylactic treatment with proton pump inhibitors or antacids and an H₂-blocker is advisable, although certain proton pump inhibitors, such as omeprazole and esomeprazole, decrease the effect of clopidogrel.

3. Assessment of myocardial reperfusion, recurrent ischemic pain, reinfarction—Myocardial reperfusion can be recognized clinically by the early cessation of pain and the resolution of ST-segment elevation. Although at least 50% resolution of ST-segment elevation by 90 minutes may occur without coronary reperfusion, ST resolution is a strong predictor of better outcome. Even with anticoagulation, 10–20% of reperfused vessels will reocclude during hospitalization, although reocclusion and reinfarction appear to be reduced following intervention. Reinfarction, indicated by recurrence of pain and ST-segment elevation, can be treated by readministration of a thrombolytic agent or immediate angiography and PCI.

C. General Measures

Cardiac care unit monitoring should be instituted as soon as possible. Patients without complications can be transferred

to a telemetry unit after 24 hours. Activity should initially be limited to bed rest but can be advanced within 24 hours. Progressive ambulation should be started after 24–72 hours if tolerated. For patients without complications, discharge by day 4 appears to be appropriate. Low-flow oxygen therapy (2–4 L/min) should be given if oxygen saturation is reduced.

D. Analgesia

An initial attempt should be made to relieve pain with sublingual nitroglycerin. However, if no response occurs after two or three tablets, intravenous opioids provide the most rapid and effective analgesia and may also reduce pulmonary congestion. Morphine sulfate, 4–8 mg, or meperidine, 50–75 mg, should be given. Subsequent small doses can be given every 15 minutes until pain abates.

Nonsteroidal anti-inflammatory agents, other than aspirin, should be avoided during hospitalization for STEMI due to increased risk of mortality, myocardial rupture, hypertension, heart failure, and kidney injury with their use.

E. β -Adrenergic Blocking Agents

Although trials have shown modest short-term benefit from β -blockers given immediately after acute myocardial infarction, it has not been clear that intravenous β -blockers provide an advantage over simply beginning an oral β -blocker, which should be started during the first 24 hours if there are no contraindications. The Chinese COMMIT/CCS-2 trial involving 45,000 patients found no overall benefit to intravenous followed by oral metoprolol; the aggressive dosing (three 5 mg intravenous boluses followed by 200 mg/d orally) appeared to prevent reinfarction at the cost of increasing shock, with overall harm in patients presenting with heart failure. Thus, early β -blockade should be avoided in patients with any degree of heart failure, evidence of low output state, increased risk of cardiogenic shock, or other relative contraindications to β -blockade. The CAPRICORN trial showed the benefits of carvedilol (beginning at 6.25 mg twice a day, titrated to 25 mg twice a day) following the acute phase of large myocardial infarction with contemporary care.

F. Nitrates

Nitroglycerin is the agent of choice for continued or recurrent ischemic pain and is useful in lowering BP or relieving pulmonary congestion. However, routine nitrate administration is not recommended, since no improvement in outcome has been observed in the ISIS-4 or GISSI-3 trials, in which a total of over 70,000 patients were randomized to nitrate treatment or placebo. Nitrates should be avoided in patients who received phosphodiesterase inhibitors (sildenafil, vardenafil, and tadalafil) in the prior 24 hours.

G. Angiotensin-Converting Enzyme (ACE) Inhibitors

A series of trials (SAVE, AIRE, SMILE, TRACE, GISSI-III, and ISIS-4) have shown both short- and long-term

improvement in survival with ACE inhibitor therapy. The benefits are greatest in patients with EF \leq 40%, large infarctions, or clinical evidence of heart failure. Because substantial amounts of the survival benefit occur on the first day, ACE inhibitor treatment should be commenced early in patients without hypotension, especially patients with large or anterior myocardial infarction. Given the benefits of ACE-inhibitors for patients with vascular disease, it is reasonable to use ACE-inhibitors for all patients following STEMI who do not have contraindications.

H. Angiotensin Receptor Blockers

Although there has been inconsistency in the effects of different ARBs on mortality for patients post-myocardial infarction with heart failure and/or LV dysfunction, the VALIANT trial showed that valsartan 160 mg twice a day is equivalent to captopril in reducing mortality. Thus, valsartan should be used for all patients with ACE inhibitor intolerance, and is a reasonable, albeit more expensive, alternative to captopril. The combination of captopril and valsartan (at reduced dose) was no better than either agent alone and resulted in more side effects.

I. Aldosterone Antagonists

The RALES trial showed that spironolactone can reduce the mortality rate of patients with advanced heart failure, and the EPHESUS trial showed a 15% relative risk reduction in mortality with eplerenone for patients post-myocardial infarction with LV dysfunction and either heart failure or diabetes. Kidney dysfunction or hyperkalemia are contraindications, and patients must be monitored carefully for development of hyperkalemia.

J. Antiarrhythmic Prophylaxis

The incidence of ventricular fibrillation in hospitalized patients is approximately 5%, with 80% of episodes occurring in the first 12–24 hours. Prophylactic lidocaine infusions (1–2 mg/min) prevent most episodes, but this therapy has not reduced the mortality rate and it increases the risk of asystole, so this approach is no longer recommended except in patients with sustained ventricular tachycardia.

K. Calcium Channel Blockers

There are no studies to support the routine use of calcium channel blockers in most patients with acute myocardial infarction—and indeed, they have the potential to exacerbate ischemia and cause death from reflex tachycardia or myocardial depression. Long-acting calcium channel blockers should generally be reserved for management of hypertension or ischemia as second- or third-line drugs after β -blockers and nitrates.

L. Long-Term Antithrombotic Therapy

Discharge on aspirin, 81–325 mg/d, since it is highly effective, inexpensive, and well tolerated, is a key quality indicator

of myocardial infarction care. In the WARIS-II trial, long-term anticoagulation with warfarin post-myocardial infarction was associated with a reduction in the composite of death, reinfarction, and stroke. However, whether the results of this trial are transferable to the United States where anticoagulation services may be less organized and effective than in Norwegian hospitals is unknown. In the CURE trial, clopidogrel, 75 mg/d, (in addition to aspirin) for 3–12 months for non-ST elevation acute coronary syndromes resulted in a similar 20% relative risk reduction in cardiovascular death, myocardial infarction, and stroke, and continuing clopidogrel for 1 year for patients with STEMI is reasonable, regardless of whether they underwent reperfusion therapy. The TRITON trial showed that prasugrel was more beneficial than clopidogrel in reducing ischemic events in patients undergoing PCI, but it resulted in more bleeding. The PLATO trial showed that long-term therapy with ticagrelor and low-dose aspirin was superior to clopidogrel and aspirin.

Patients who have received a coronary stent and who require warfarin anticoagulation present a particular challenge, since “triple therapy” with aspirin, clopidogrel, and warfarin has a high risk of bleeding. Triple therapy should be (1) limited to patients with a clear indication for warfarin (such as CHADS2 score of 2 to 3 or more), (2) used for the shortest period of time (such as 1 month after placement of bare metal stent; drug-eluting stents that would require longer clopidogrel duration should be avoided), (3) used with low-dose aspirin and with strategies to reduce risk of bleeding (eg, proton pump inhibitors for patients with history of gastrointestinal bleeding).

M. Coronary Angiography

For patients who do not reperfuse based on lack of at least 50% resolution of ST elevation, rescue angioplasty should be performed and has been shown to reduce the composite of death, reinfarction, stroke, or severe heart failure. According to the evidence in the European Guidelines and the updated recommendations of the AHA/ACC for high-risk patients, patients treated with coronary angiography and PCI 3–24 hours after fibrinolytic therapy showed improved outcomes. Patients with recurrent ischemic pain prior to discharge should undergo catheterization and, if indicated, revascularization. Asymptomatic, clinically stable patients should undergo predischARGE stress testing to determine whether residual jeopardized myocardium is present. This can be accomplished by submaximal exercise or pharmacologic stress scintigraphy. Those with significantly positive tests or a low threshold for symptomatic ischemia should undergo angiography and revascularization where feasible. PCI of a totally occluded infarct-related artery > 24 hours after STEMI should generally not be performed in asymptomatic patients with one or two vessel disease without evidence of severe ischemia.

► When to Refer

All patients with acute myocardial infarction should be referred to a cardiologist.

► Complications

A variety of complications can occur after myocardial infarction even when treatment is initiated promptly.

A. Postinfarction Ischemia

In clinical trials of thrombolysis, recurrent ischemia occurred in about one-third of patients, was more common following non-ST elevation myocardial infarction than after STEMI, and had important short- and long-term prognostic implications. Vigorous medical therapy should be instituted, including nitrates and β -blockers as well as aspirin 81–325 mg/d, anticoagulant therapy (unfractionated heparin, enoxaparin, or fondaparinux) and clopidogrel. Most patients with postinfarction angina—and all who are refractory to medical therapy—should undergo early catheterization and revascularization by PCI or CABG.

B. Arrhythmias

Abnormalities of rhythm and conduction are common.

1. Sinus bradycardia—This is most common in inferior infarctions or may be precipitated by medications. Observation or withdrawal of the offending agent is usually sufficient. If accompanied by signs of low cardiac output, atropine, 0.5–1 mg intravenously, is usually effective. Temporary pacing is rarely required.

2. Supraventricular tachyarrhythmias—Sinus tachycardia is common and may reflect either increased adrenergic stimulation or hemodynamic compromise due to hypovolemia or pump failure. In the latter, β -blockade is contraindicated. Supraventricular premature beats are common and may be premonitory for atrial fibrillation. Electrolyte abnormalities and hypoxia should be corrected and causative agents (especially aminophylline) stopped. Atrial fibrillation should be rapidly controlled or converted to sinus rhythm. Intravenous β -blockers such as metoprolol (2.5–5 mg/h) or short-acting esmolol (50–200 mcg/kg/min) are the agents of choice if cardiac function is adequate. Intravenous diltiazem (5–15 mg/h) may be used if β -blockers are contraindicated or ineffective. Digoxin (0.5 mg as initial dose, then 0.25 mg every 90–120 minutes [up to 1–1.25 mg] for a loading dose, followed by 0.25 mg daily if kidney function is normal) is preferable if heart failure is present with atrial fibrillation, but the onset of action is delayed. Electrical cardioversion (commencing with 100 J) may be necessary if atrial fibrillation is complicated by hypotension, heart failure, or ischemia, but the arrhythmia often recurs. Amiodarone (150 mg intravenous bolus and then 15–30 mg/h intravenously, or rapid oral loading with 400 mg three times daily) may be helpful to restore or maintain sinus rhythm.

3. Ventricular arrhythmias—Ventricular arrhythmias are most common in the first few hours after infarction and are a marker of high risk. Ventricular premature beats may be premonitory for ventricular tachycardia or fibrillation but generally should not be treated in the absence of frequent or sustained ventricular tachycardia. Lidocaine is *not* recommended as a prophylactic measure. Toxicity (tremor, anxiety, confusion, seizures) is common, especially in older patients and those with hypotension, heart failure, or liver disease.

Sustained ventricular tachycardia should be treated with a 1 mg/kg bolus of lidocaine if the patient is stable or by electrical cardioversion (100–200 J) if not. If the arrhythmia cannot be suppressed with lidocaine, procainamide (100 mg boluses over 1–2 minutes every 5 minutes to a cumulative dose of 750–1000 mg) or intravenous amiodarone (150 mg over 10 minutes, which may be repeated as needed, followed by 360 mg over 6 hours and then 540 mg over 18 hours) should be initiated, followed by an infusion of 20–80 mg/kg/min. Ventricular fibrillation is treated electrically (300–400 J). Unresponsive ventricular fibrillation should be treated with additional amiodarone and repeat cardioversion while cardiopulmonary resuscitation (CPR) is administered.

Accelerated idioventricular rhythm is a regular, wide-complex rhythm at a rate of 70–100/min. It may occur with or without reperfusion and should not be treated with antiarrhythmics, which could cause asystole.

4. Conduction disturbances—All degrees of AV block may occur in the course of acute myocardial infarction. Block at the level of the AV node is more common than infranodal block and occurs in approximately 20% of inferior myocardial infarctions. First-degree block is the most common and requires no treatment. Second-degree block is usually of the Mobitz type I form (Wenckebach), is often transient, and requires treatment only if associated with a heart rate slow enough to cause symptoms. Complete AV block occurs in up to 5% of acute inferior infarctions, usually is preceded by Mobitz I second-degree block, and generally resolves spontaneously, though it may persist for hours to several weeks. The escape rhythm originates in the distal AV node or AV junction and hence has a narrow QRS complex and is reliable, albeit often slow (30–50 beats/min). Treatment is often necessary because of resulting hypotension and low cardiac output. Intravenous atropine (1 mg) usually restores AV conduction temporarily, but if the escape complex is wide or if repeated atropine treatments are needed, temporary ventricular pacing is indicated. The prognosis for these patients is only slightly worse than for patients in whom AV block did not develop.

In anterior infarctions, the site of block is distal, below the AV node, and usually a result of extensive damage of the His-Purkinje system and bundle branches. New first-degree block (prolongation of the PR interval) is unusual in anterior infarction; Mobitz type II AV block or complete heart block may be preceded by intraventricular conduction defects or may occur abruptly. The escape rhythm, if present, is an unreliable wide-complex idioventricular rhythm. Urgent ventricular pacing is mandatory, but even with successful pacing, morbidity and mortality are high because of the extensive myocardial damage. New conduction abnormalities such as right or left bundle branch block or fascicular blocks may presage progression, often sudden, to second- or third-degree AV block. Temporary ventricular pacing is recommended for new-onset alternating bilateral bundle branch block, bifascicular block, or bundle branch block with worsening first-degree AV block. Patients with anterior infarction who progress to second- or third-degree block even transiently should be considered for insertion of a prophylactic permanent ventricular pacemaker before discharge.

C. Myocardial Dysfunction

The severity of cardiac dysfunction is proportionate to the extent of myocardial necrosis but is exacerbated by preexisting dysfunction and ongoing ischemia. Persons with hypotension not responsive to fluid resuscitation or refractory heart failure or cardiogenic shock should be considered for urgent echocardiography to assess left and right ventricular function and for mechanical complications, right heart catheterization, and continuous measurements of arterial pressure. These measurements permit the accurate assessment of volume status and may facilitate decisions about volume resuscitation, selective use of pressors and inotropes, and mechanical support. Table 10–7 categorizes patients based on these hemodynamic findings.

1. Acute LV failure—Dyspnea, diffuse rales, and arterial hypoxemia usually indicate LV failure. General measures include supplemental oxygen to increase arterial saturation to above 95% and elevation of the trunk. Diuretics are usually the initial therapy unless RV infarction is present. Intravenous furosemide (10–40 mg) or bumetanide (0.5–1 mg) is preferred because of the reliably rapid onset and short duration of action of these drugs. Higher dosages can be given if an inadequate response occurs. Morphine sulfate (4 mg intravenously followed by increments of 2 mg) is valuable in acute pulmonary edema.

Diuretics are usually effective; however, because most patients with acute infarction are not volume overloaded, the hemodynamic response may be limited and may be associated with hypotension. Vasodilators will reduce PCWP and improve cardiac output by a combination of venodilation (increasing venous capacitance) and arteriolar dilation (reducing afterload and LV wall stress). In mild heart failure, sublingual isosorbide dinitrate (2.5–10 mg every 2 hours) or nitroglycerin ointment (6.25–25 mg every 4 hours) may be adequate to lower PCWP. In more severe failure, especially if cardiac output is reduced and BP is normal or high, sodium nitroprusside may be the preferred agent. It should be initiated only with arterial pressure monitoring; the initial dosage should be low (0.25 mcg/kg/min) to avoid excessive hypotension, but the dosage can be increased by increments of 0.5 mcg/kg/min every 5–10 minutes up to 5–10 mcg/kg/min until the desired hemodynamic response is obtained. Excessive hypotension (mean BP < 65–75 mm Hg) or tachycardia (>10/min increase) should be avoided.

Intravenous nitroglycerin (starting at 10 mcg/min) also may be effective but may lower PCWP with less hypotension. Oral or transdermal vasodilator therapy with nitrates or ACE inhibitors is often necessary after the initial 24–48 hours (see below).

Inotropic agents should be avoided if possible, because they often increase heart rate and myocardial oxygen requirements and worsen clinical outcomes. Dobutamine has the best hemodynamic profile, increasing cardiac output and modestly lowering PCWP, usually without excessive tachycardia, hypotension, or arrhythmias. The initial dosage is 2.5 mcg/kg/min, and it may be increased by similar increments up to 15–20 mcg/kg/min at intervals of

5–10 minutes. Dopamine is more useful in the presence of hypotension (see below), since it produces peripheral vasoconstriction, but it has a less beneficial effect on PCWP. Digoxin has not been helpful in acute infarction except to control the ventricular response in atrial fibrillation, but it may be beneficial if chronic heart failure persists.

2. Hypotension and shock—Patients with hypotension (systolic BP < 90 mm Hg, individualized depending on prior BP) and signs of diminished perfusion (low urinary output, confusion, cold extremities) that does not respond to fluid resuscitation should be presumed to have cardiogenic shock and should be considered for urgent catheterization and revascularization, intra-aortic balloon pump (IABP) support, and hemodynamic monitoring with a PA catheter. Up to 20% will have findings indicative of intravascular hypovolemia (due to diaphoresis, vomiting, decreased venous tone, medications—such as diuretics, nitrates, morphine, β -blockers, calcium channel blockers, and thrombolytic agents—and lack of oral intake). These should be treated with successive boluses of 100 mL of normal saline until PCWP reaches 15–18 mm Hg to determine whether cardiac output and BP respond. Pericardial tamponade due to hemorrhagic pericarditis (especially after thrombolytic therapy or cardiopulmonary resuscitation) or ventricular rupture should be considered and excluded by echocardiography if clinically indicated. RV infarction, characterized by a normal PCWP but elevated RA pressure, can produce hypotension. This is discussed below.

Most patients with cardiogenic shock will have moderate to severe LV systolic dysfunction, with a mean EF of 30% in the SHOCK trial. If hypotension is only modest (systolic pressure > 90 mm Hg) and the PCWP is elevated, diuretics and an initial trial of nitroprusside (see above for dosing) are indicated. If the BP falls, inotropic support will need to be added or substituted. Such patients should generally also be treated with IABP counterpulsation, which can both reduce myocardial energy requirements (systolic unloading) and improve diastolic coronary blood flow.

Dopamine is generally considered to be the most appropriate pressor for cardiogenic hypotension. It should be initiated at a rate of 2–4 mcg/kg/min and increased at 5-minute intervals to the appropriate hemodynamic end point. At low dosages (< 5 mcg/kg/min), it improves renal blood flow; at intermediate dosages (2.5–10 mcg/kg/min), it stimulates myocardial contractility; at higher dosages (> 8 mcg/kg/min), it is a potent α_1 -adrenergic agonist. In general, BP and cardiac index rise, but PCWP does not fall. Dopamine may be combined with nitroprusside or dobutamine (see above for dosing), or the latter may be used in its place if hypotension is not severe. Norepinephrine (0.1–0.5 mcg/kg/min) is generally reserved for failure of other vasopressors, since epinephrine produces less vasoconstriction and does not increase coronary perfusion pressure (aortic diastolic pressure), but it does tend to worsen the balance between myocardial oxygen delivery and utilization.

Patients with cardiogenic shock not due to hypovolemia have a poor prognosis, with 30-day mortality rates of

40–80%. If they do not respond rapidly, IABP should be instituted to both reduce myocardial energy requirements (systolic unloading) and improve diastolic coronary blood flow. Surgically implanted (or percutaneous) ventricular assist devices may be used in refractory cases. Emergent cardiac catheterization and coronary angiography followed by percutaneous or surgical revascularization offer the best chance of survival.

D. RV Infarction

RV infarction is present in one-third of patients with inferior wall infarction but is clinically significant in < 50% of these. It presents as hypotension with relatively preserved LV function and should be considered whenever patients with inferior infarction exhibit low BP, raised venous pressure, and clear lungs. Hypotension is often exacerbated by medications that decrease intravascular volume or produce venodilation, such as diuretics, nitrates, and narcotics. RA pressure and jugular venous pulsations are high, while PCWP is normal or low and the lungs are clear. The diagnosis is suggested by ST-segment elevation in right-sided anterior chest leads, particularly RV_4 . The diagnosis can be confirmed by echocardiography or hemodynamic measurements. Treatment consists of fluid loading to improve LV filling, and inotropic agents if necessary.

E. Mechanical Defects

Partial or complete rupture of a papillary muscle or of the interventricular septum occurs in < 1% of acute myocardial infarctions and carries a poor prognosis. These complications occur in both anterior and inferior infarctions, usually 3–7 days after the acute event. They are detected by the appearance of a new systolic murmur and clinical deterioration, often with pulmonary edema. The two lesions are distinguished by the location of the murmur (apical versus parasternal) and by Doppler echocardiography. Hemodynamic monitoring is essential for appropriate management and demonstrates an increase in oxygen saturation between the RA and PA in VSD and, often, a large v wave with mitral regurgitation. Treatment by nitroprusside and, preferably, IABC reduces the regurgitation or shunt, but surgical correction is mandatory. In patients remaining hemodynamically unstable or requiring continuous parenteral pharmacologic treatment or counterpulsation, early surgery is recommended, though mortality rates are high (15% to nearly 100%, depending on residual ventricular function and clinical status). Patients who are stabilized medically can have delayed surgery with lower risks (10–25%), although this may be due to the death of sicker patients, some of whom may have been saved by earlier surgery.

F. Myocardial Rupture

Complete rupture of the LV free wall occurs in < 1% of patients and usually results in immediate death. It occurs 2–7 days postinfarction, usually involves the anterior wall, and is more frequent in older women. Incomplete or gradual rupture may be sealed off by the pericardium, creating a **pseudoaneurysm**. This may be

recognized by echocardiography, radionuclide angiography, or LV angiography, often as an incidental finding. It demonstrates a narrow-neck connection to the LV. Early surgical repair is indicated, since delayed rupture is common.

G. LV Aneurysm

An LV aneurysm, a sharply delineated area of scar that bulges paradoxically during systole, develops in 10–20% of patients surviving an acute infarction. This usually follows anterior Q wave infarctions. Aneurysms are recognized by persistent ST-segment elevation (beyond 4–8 weeks), and a wide neck from the LV can be demonstrated by echocardiography, scintigraphy, or contrast angiography. They rarely rupture but may be associated with arterial emboli, ventricular arrhythmias, and CHF. Surgical resection may be performed for these indications if other measures fail. The best results (mortality rates of 10–20%) are obtained when the residual myocardium contracts well and when significant coronary lesions supplying adjacent regions are bypassed.

H. Pericarditis

The pericardium is involved in approximately 50% of infarctions, but pericarditis is often not clinically significant. Twenty percent of patients with Q wave infarctions will have an audible friction rub if examined repetitively. Pericardial pain occurs in approximately the same proportion after 2–7 days and is recognized by its variation with respiration and position (improved by sitting). Often, no treatment is required, but aspirin (650 mg every 4–6 hours) will usually relieve the pain. Indomethacin and corticosteroids can cause impaired infarct healing and predispose to myocardial rupture, and therefore should generally be avoided in the early post-myocardial infarction period. Likewise, anticoagulation should be used cautiously, since hemorrhagic pericarditis may result.

One week to 12 weeks after infarction, Dressler syndrome (post-myocardial infarction syndrome) occurs in < 5% of patients. This is an autoimmune phenomenon and presents as pericarditis with associated fever, leukocytosis and, occasionally, pericardial or pleural effusion. It may recur over months. Treatment is the same as for other forms of pericarditis. A short course of nonsteroidal agents or corticosteroids may help relieve symptoms.

I. Mural Thrombus

Mural thrombi are common in large anterior infarctions but not in infarctions at other locations. Arterial emboli occur in approximately 2% of patients with known infarction, usually within 6 weeks. Anticoagulation with heparin followed by short-term (3-month) warfarin therapy prevents most emboli and should be considered in all patients with large anterior infarctions. Mural thrombi can be detected by echocardiography or cardiac MRI, but these procedures should not be relied upon for determining the need for anticoagulation.

▶ Postinfarction Management

After the first 24 hours, the focus of patient management is to prevent recurrent ischemia, improve infarct healing and prevent remodeling, and prevent recurrent vascular events. Patients with hemodynamic compromise, who are at high risk for death, need careful monitoring and management of volume status.

A. Risk Stratification

Risk stratification is important for management of STEMI. GRACE and TIMI risk scores can be helpful tools. The TIMI Risk Score is available for PDA download at <http://www.timi.org>, and the GRACE risk score at <http://www.outcomes-umassmed.org/grace>. Patients with recurrent ischemia (spontaneous or provoked), hemodynamic instability, impaired LV function, heart failure, or serious ventricular arrhythmias should undergo cardiac catheterization (Table 10–6). ACE inhibitor (or ARB) therapy is indicated in patients with clinical heart failure or LV EF \leq 40%. Aldosterone blockade is indicated for patients with an LV EF \leq 40% and either heart failure or diabetes mellitus.

For patients not undergoing cardiac catheterization, submaximal exercise (or pharmacologic stress testing for patients unable to exercise) before discharge or a maximal test after 3–6 weeks (the latter being more sensitive for ischemia) helps patients and clinicians plan the return to normal activity. Imaging in conjunction with stress testing adds additional sensitivity for ischemia and provides localizing information. Both exercise and pharmacologic stress imaging have successfully predicted subsequent outcome. One of these tests should be used prior to discharge in patients who have received thrombolytic therapy as a means of selecting appropriate candidates for coronary angiography.

B. Secondary Prevention

Postinfarction management should begin with identification and modification of risk factors. Treatment of hyperlipidemia and smoking cessation both prevent recurrent infarction and death. Statin therapy should be started before the patient is discharged from the hospital to reduce recurrent atherothrombotic events. BP control and cardiac rehabilitation or exercise are also recommended.

β -Blockers improve survival rates, primarily by reducing the incidence of sudden death in high-risk subsets of patients, though their value may be less in patients without complications with small infarctions and normal exercise

tests. While a variety of β -blockers have been shown to be beneficial, for patients with LV dysfunction managed with contemporary treatment, carvedilol titrated to 25 mg twice a day has been shown to reduce mortality. β -Blockers with intrinsic sympathomimetic activity have not proved beneficial in postinfarction patients.

Antiplatelet agents are beneficial; aspirin (81–325 mg daily) is recommended, and adding clopidogrel (75 mg daily) has been shown to provide additional benefit short term after STEMI and for up to 1 year after non-ST elevation acute coronary syndromes. Prasugrel provides further reduction in thrombotic outcomes compared with clopidogrel, at the cost of more bleeding. Likewise, ticagrelor provides benefit over clopidogrel but should be used with low-dose aspirin (81 mg/d). Warfarin anticoagulation for 3 months reduces the incidence of arterial emboli after large anterior infarctions, and according to the results of at least one study it improves long-term prognosis, but these studies were before routine use of aspirin and clopidogrel. An advantage to combining low-dose aspirin and warfarin has not been demonstrated, except perhaps in patients with atrial fibrillation.

Calcium channel blockers have not been shown to improve prognoses overall and should not be prescribed purely for secondary prevention. Antiarrhythmic therapy other than with β -blockers has not been shown to be effective except in patients with symptomatic arrhythmias. Amiodarone has been studied in several trials of postinfarction patients with either LV dysfunction or frequent ventricular ectopy. Although survival was not improved, amiodarone was not harmful—unlike other agents in this setting. Therefore, it is the agent of choice for individuals with symptomatic postinfarction supraventricular arrhythmias. While implantable defibrillators improve survival for patients with postinfarction LV dysfunction and heart failure, the DINAMIT trial found no benefit to implantable defibrillators implanted in the 40 days following acute myocardial infarction.

Cardiac rehabilitation programs and exercise training can be of considerable psychological benefit and appear to improve prognosis.

C. ACE Inhibitors and ARBs in Patients with LV Dysfunction

Patients who sustain substantial myocardial damage often experience subsequent progressive LV dilation and dysfunction, leading to clinical heart failure and reduced long-term survival. In patients with EFs < 40%, long-term ACE inhibitor (or ARB) therapy prevents LV dilation and the onset of heart failure and prolongs survival. The HOPE trial, as well as an overview of trials of ACE-inhibitors for secondary prevention, also demonstrated a reduction of approximately 20% in mortality rates and the occurrence of nonfatal myocardial infarction and stroke with ramipril treatment of patients with vascular disease and without confirmed LV systolic dysfunction. Therefore, ACE inhibitor therapy should be strongly considered in this broader group of patients—and especially in diabetics and patients with even mild systolic hypertension, in whom the greatest benefit was observed.

D. Revascularization

Postinfarction patients not treated with primary PCI who appear likely to benefit from early revascularization if the anatomy is appropriate are (1) those who have undergone thrombolytic therapy and have high-risk features (including systolic BP of < 100 mm Hg, heart rate of > 100 bpm, Killip class II or III, ST segment depression of 2 mm or more in the anterior leads); (2) patients with LV dysfunction (EF < 30–40%); (3) patients with non-ST elevation MI and high-risk features; and (4) patients with markedly positive exercise tests and multi-vessel disease. The value of revascularization in the following groups is less clear: (1) patients without high-risk features treated with thrombolytic agents, with little evidence of reperfusion or residual ischemia; and (2) patients with preserved LV function who have mild ischemia and are not symptom limited. In general, patients without high-risk features who survive infarctions without complications, have preserved LV function (EF > 50%), and have no exercise-induced ischemia have an excellent prognosis and do not require invasive evaluation.

DISORDERS OF RATE & RHYTHM

Abnormalities of cardiac rhythm and conduction can be symptomatic (syncope, near syncope, dizziness, fatigue, or palpitations), or asymptomatic. In addition, they can be lethal (sudden cardiac death) or dangerous to the extent that they reduce cardiac output, so that perfusion of the brain and myocardium is impaired. Stable supraventricular tachycardia is generally well tolerated in patients without underlying heart disease but may lead to myocardial ischemia or CHF in patients with coronary disease, valvular abnormalities, and systolic or diastolic myocardial dysfunction. Ventricular tachycardia, if prolonged (lasting more than 10–30 seconds), often results in hemodynamic compromise and may deteriorate into ventricular fibrillation if left untreated.

Whether slow heart rates produce symptoms at rest or with exertion depends on whether cerebral and peripheral perfusion can be maintained, which is generally a function of

whether the patient is upright or supine and whether LV function is adequate to maintain stroke volume. If the heart rate abruptly slows, as with the onset of complete heart block or sinus arrest, syncope or convulsions (or both) may result.

Arrhythmias are detected either because they produce symptoms or because they are detected during the course of monitoring. Arrhythmias causing sudden death, syncope, or near syncope require further evaluation and treatment unless they are related to conditions that are reversible or immediately treatable (eg, electrolyte abnormalities or acute myocardial infarction). In contrast, there is controversy over when and how to evaluate and treat rhythm disturbances that are not symptomatic but are possible markers for more serious abnormalities (eg, nonsustained ventricular tachycardia [NSVT]). This uncertainty reflects two issues: (1) the difficulty of reliably stratifying patients into high-risk and low-risk groups; and (2) the lack of treatments that are both effective and safe. Thus, screening patients for these so-called “premonitory” abnormalities is often not productive.

A number of procedures are used to evaluate patients with symptoms who are believed to be at risk for life-threatening arrhythmias, including in-hospital and ambulatory ECG monitoring, event recorders (instruments that can be used for prolonged periods to record or transmit rhythm tracings when infrequent episodes occur), exercise testing, catheter-based electrophysiologic studies (to assess sinus node function, AV conduction, and inducibility of arrhythmias), and tests of autonomic nervous system function (tilt-table testing).

Treatment of arrhythmias varies and can include modalities such as antiarrhythmic drugs (see Table 10–9) and more invasive techniques such as catheter ablation.

► Antiarrhythmic Drugs (Table 10–9)

Antiarrhythmic drugs are frequently used to treat arrhythmias, but have variable efficacy and produce frequent side effects. They are often divided into classes based on their electropharmacologic actions and many of these drugs have multiple actions. The most frequently used classification scheme is the Vaughan-Williams classification, which consists of four classes.

Class I agents block membrane sodium channels. Three subclasses are further defined by the effect of the agents on the Purkinje fiber action potential. Class Ia drugs (ie, quinidine, procainamide, disopyramide) slow the rate of rise of the action potential (V_{max}) and prolong its duration, thus slowing conduction and increasing refractoriness (moderate depression of phase 0 upstroke of the action potential). Class Ib agents (ie, lidocaine, mexiletine, phenytoin) shorten action potential duration; they do not affect conduction or refractoriness (minimal depression of phase 0 upstroke of the action potential). Class Ic agents (ie, flecainide, propafenone) prolong V_{max} and slow repolarization, thus slowing conduction and prolonging refractoriness, but more so than class Ia drugs (maximal depression of phase 0 upstroke of the action potential).

Class II agents are the β -blockers, which decrease automaticity, prolong AV conduction, and prolong refractoriness.

Class III agents (ie, amiodarone, dronedarone, sotalol, dofetilide, ibutilide) block potassium channels and prolong repolarization, widening the QRS and prolonging the QT interval. They decrease automaticity and conduction and prolong refractoriness. Dronedarone has been shown to reduce cardiovascular hospitalizations when used in patients with paroxysmal atrial fibrillation in the absence of heart failure; however, the PALLAS trial found an *increase* in cardiovascular events when dronedarone was used in patients with permanent atrial fibrillation.

Class IV agents are the calcium channel blockers, which decrease automaticity and AV conduction.

There are some antiarrhythmic agents that do not fall into one of these categories. The most frequently used are digoxin and adenosine. Digoxin inhibits the Na^+ , K^+ -ATPase pump. Digoxin prolongs AV nodal conduction and the AV nodal refractory period, but it shortens the action potential and decreases the refractoriness of the ventricular myocardium and Purkinje fibers. Adenosine can block AV nodal conduction and shortens atrial refractoriness.

Although the *in vitro* electrophysiologic effects of most of these agents have been defined, their use remains largely empiric. All can exacerbate arrhythmias (proarrhythmic effect), and many depress LV function.

The risk of antiarrhythmic agents has been highlighted by many studies, most notably the Coronary Arrhythmia Suppression Trial (CAST), in which two class Ic agents (flecainide, encainide) and a class Ia agent (moricizine) increased mortality rates in patients with asymptomatic ventricular ectopy after myocardial infarction. A similar result has been reported in the Mortality in the Survival With Oral D-sotalol (SWORD) study with d-sotalol, a class III agent without the β -blocking activity of the currently marketed formulation d,l-sotalol. Therefore, these agents (and perhaps any antiarrhythmic drug) should not be used except for life-threatening ventricular arrhythmias and symptomatic supraventricular tachyarrhythmias and patients receiving these agents should be monitored regularly.

The use of antiarrhythmic agents for specific arrhythmias is discussed below.

Table 10-9. Antiarrhythmic drugs.

Agent	Intravenous Dosage	Oral Dosage	Therapeutic Plasma Level	Route of Elimination	Side Effects
Class Ia: Action: Sodium channel blockers: Depress phase 0 depolarization; slow conduction; prolong repolarization.					
Indications: Supraventricular tachycardia, ventricular tachycardia, prevention of ventricular fibrillation, symptomatic ventricular premature beats.					
Quinidine	6-10 mg/kg (intramuscularly or intravenously) over 20 min (rarely used parenterally)	200-400 mg every 4-6 h or every 8 h (long-acting)	2-5 mg/mL	Hepatic	GI, ↓LVEF, ↑Dig
Procainamide	100 mg/1-3 min to 500-1000 mg; maintain at 2-6 mg/min	50 mg/kg/d in divided doses every 3-4 h or every 6 h (long-acting)	4-10 mg/mL; NAPA (active metabolite), 10-20 mcg/mL	Renal	SLE, hypersensitivity, ↓LVEF
Disopyramide		100-200 mg every 6-8 h	2-8 mg/mL	Renal	Urinary retention, dry mouth, markedly ↓LVEF
Class Ib: Action: Shorten repolarization.					
Indications: Ventricular tachycardia, prevention of ventricular fibrillation, symptomatic ventricular beats.					
Lidocaine	1-2 mg/kg at 50 mg/min; maintain at 1-4 mg/min		1-5 mg/mL	Hepatic	CNS, GI
Mexiletine		100-300 mg every 6-12 h; maximum: 1200 mg/d	0.5-2 mg/mL	Hepatic	CNS, GI, leukopenia
Class Ic: Action: Depress phase 0 repolarization; slow conduction. <i>Propafenone</i> is a weak calcium channel blocker and α-blocker and prolongs action potential and refractoriness.					
Indications: Life-threatening ventricular tachycardia or fibrillation, refractory supraventricular tachycardia.					
Flecainide		100-200 mg twice daily	0.2-1 mg/mL	Hepatic	CNS, GI, ↓↓LVEF, incessant VT, sudden death
Propafenone		150-300 mg every 8-12 h	<i>Note:</i> Active metabolites	Hepatic	CNS, GI, ↓↓LVEF, ↑Dig
Class II: Action: β-blocker, slows AV conduction. <i>Note:</i> Other β-blockers may also have antiarrhythmic effects but are not yet approved for this indication in the United States.					
Indications: Supraventricular tachycardia; may prevent ventricular fibrillation.					
Esmolol	500 mcg/kg over 1-2 min; maintain at 25-200 mcg/kg/min	Other β -blockers may be used concomitantly	Not established	Hepatic	↓LVEF, bronchospasm
Propranolol	1-5 mg at 1 mg/min	40-320 mg in 1-4 doses daily (depending on preparation)	Not established	Hepatic	↓LVEF, bradycardia, AV block, bronchospasm
Metoprolol	2.5-5 mg	50-200 mg daily	Not established	Hepatic	↓LVEF, bradycardia, AV block
Class III: Action: Prolong action potential.					
Indications: <i>Amiodarone:</i> refractory ventricular tachycardia, supraventricular tachycardia, prevention of ventricular tachycardia, atrial fibrillation, ventricular fibrillation; <i>dofetilide:</i> atrial fibrillation and flutter; <i>sotalol:</i> ventricular tachycardia, atrial fibrillation; <i>ibutilide:</i> conversion of atrial fibrillation and flutter.					
Amiodarone	150-300 mg infused rapidly, followed by 1-mg/min infusion for 6 h (360 mg) and then 0.5 mg/min	800-1600 mg/d for 7-21 days; maintain at 100-400 mg/d (higher doses may be needed)	1-5 mg/mL	Hepatic	Pulmonary fibrosis, hypothyroidism, hyperthyroidism, photosensitivity, corneal and skin deposits, hepatitis, ↑Dig, neurotoxicity, GI

(continued)

Table 10-9. Antiarrhythmic drugs. (Continued)

Agent	Intravenous Dosage	Oral Dosage	Therapeutic Plasma Level	Route of Elimination	Side Effects
Dronedaron		400 mg twice daily		Hepatic (contraindicated in severe impairment)	QTc prolongation, CHF. Contraindicated in CHF (NYHA class IV and class II and III if recent decompensation)
Sotalol		80-160 mg every 12 h (higher doses may be used for life-threatening arrhythmias)		Renal (dosing interval should be extended if creatinine clearance is < 60 mL/min)	Early incidence of torsades de pointes, ↓LVEF, bradycardia, fatigue (and other side effects associated with β-blockers)
Dofetilide		500 mcg every 12 h		Renal (dose must be reduced with kidney dysfunction)	Torsades de pointes in 3%; interaction with cytochrome P-450 inhibitors
Ibutilide	1 mg over 10 min, followed by a second infusion of 0.5-1 mg over 10 min			Hepatic and renal	Torsades de pointes in up to 5% of patients within 3 h after administration; patients must be monitored with defibrillator nearby
Class IV: Action: Slow calcium channel blockers.					
Indications: Supraventricular tachycardia.					
Verapamil	10-20 mg over 2-20 min; maintain at 5 mg/kg/min	80-120 mg every 6-8 h; 240-360 mg once daily with sustained-release preparation	0.1-0.15 mg/mL	Hepatic	↓LVEF, constipation, ↑Dig, hypotension
Diltiazem	0.25 mg/kg over 2 min; second 0.35-mg/kg bolus after 15 min if response is inadequate; infusion rate, 5-15 mg/h	180-360 mg daily in 1-3 doses depending on preparation (oral forms not approved for arrhythmias)		Hepatic metabolism, renal excretion	Hypotension, ↓LVEF
Miscellaneous: Indications: Supraventricular tachycardia.					
Adenosine	6 mg rapidly followed by 12 mg after 1-2 min if needed; use half these doses if administered via central line			Adenosine receptor stimulation, metabolized in blood	Transient flushing, dyspnea, chest pain, AV block, sinus bradycardia; effect ↓ by theophylline, ↑ by dipyridamole
Digoxin	0.5 mg over 20 min followed by increment of 0.25 or 0.125 mg to 1-1.5 mg over 24 h	1-1.5 mg over 24-36 h in 3 or 4 doses; maintenance, 0.125-0.5 mg/d	0.7-2 mg/mL	Renal	AV block, arrhythmias, GI, visual changes

AV, atrioventricular; CHF, congestive heart failure; CNS, central nervous system; ↑Dig, elevation of serum digoxin level; GI, gastrointestinal (nausea, vomiting, diarrhea); ↓LVEF, reduced left ventricular function; NAPA, *N*-acetylprocainamide; NYHA, New York Heart Association; SLE, systemic lupus erythematosus; VT, ventricular tachycardia.

► Catheter Ablation for Cardiac Arrhythmias

Catheter ablation has become first-line therapy for the treatment of many arrhythmias. This growing trend reflects the increasing ability to localize the origin or conduction circuit of many arrhythmias and safely deliver lesions to eliminate the arrhythmia focus. Catheter ablation has become the primary modality of therapy for many symptomatic supraventricular arrhythmias, including AV nodal reentrant tachycardia, tachycardias involving accessory pathways, paroxysmal atrial tachycardia, and atrial flutter. Catheter ablation of atrial fibrillation is more complex and usually involves complete electrical isolation of the pulmonary veins (which are often the sites of initiation of atrial fibrillation) or placing linear lesions within the atria to prevent propagation throughout the atrial chamber. This technique is considered a reasonable second-line therapy for certain patients with symptomatic drug-refractory atrial fibrillation. Catheter ablation of ventricular arrhythmias has proved more difficult, but experienced centers have had reasonable success with all types of ventricular tachycardias including: bundle-branch reentry, tachycardia originating in the ventricular outflow tract or papillary muscles, tachycardias originating in the left side of the interventricular septum (also called fascicular ventricular tachycardia), and even ventricular tachycardias occurring in patients with ischemic or dilated cardiomyopathy.

Catheter ablation has also been successfully performed for the treatment of ventricular fibrillation when an inciting uniform premature ventricular contraction can be identified. In addition, patients with symptomatic premature ventricular contractions (PVCs) or PVCs occurring at a high enough burden to result in a cardiomyopathy (usually > 10,000/day) are often referred for catheter ablation as well.

There is also increasing data to suggest effectiveness of ablation of many of these arrhythmias from the epicardial surface of the heart via a percutaneous subxiphoid approach.

These procedures are generally reasonably safe, with an overall major complication rate ranging from 2% to 8%. There is a low incidence of perforation of the myocardial wall that results in pericardial tamponade. Sufficient damage to the AV node to require permanent cardiac pacing occurs in < 5% of patients. In addition, some procedures involve transeptal access through the interatrial septum or retrograde LV catheterization, with the attendant potential complications of aortic perforation, damage to the heart valves, damage to a coronary artery, or systemic emboli. A potentially fatal complication during the ablation of atrial fibrillation is the development of an atrio-esophageal fistula resulting from ablation lesions of the posterior wall of the LA just overlying the esophagus, but this is extremely rare.

SINUS ARRHYTHMIA, BRADYCARDIA, & TACHYCARDIA

Sinus arrhythmia is a cyclic increase in normal heart rate with inspiration and decrease with expiration. It results from reflex changes in vagal influence on the normal pacemaker and disappears with breath holding or increase of heart rate. It has no clinical significance. It is common in both the young and the elderly.

Sinus bradycardia is a heart rate slower than 60 beats/min due to increased vagal influence on the normal pacemaker or organic disease of the sinus node. The rate usually increases during exercise or administration of atropine. In healthy individuals, and especially in patients who are in excellent physical condition, sinus bradycardia to rates of 50 beats/min or even lower is a normal finding. However, severe sinus bradycardia (< 45 beats/min) may be an indication of sinus node pathology (see below), especially in elderly patients and individuals with heart disease. It may cause weakness, confusion, or syncope if cerebral perfusion is impaired. Atrial, junctional and ventricular ectopic rhythms are more apt to occur with slow sinus rates. Pacing may be required if symptoms correlate with the bradycardia.

Sinus tachycardia is defined as a heart rate faster than 100 beats/min that is caused by rapid impulse formation from the sinoatrial node; it occurs with fever, exercise, emotion, pain, anemia, heart failure, shock, thyrotoxicosis,

or in response to many drugs. Alcohol and alcohol withdrawal are common causes of sinus tachycardia and other supraventricular arrhythmias. The onset and termination are usually gradual, in contrast to paroxysmal supraventricular tachycardia due to reentry. The rate infrequently exceeds 160 beats/min but may reach 180 beats/min in young persons. The rhythm is generally regular, but serial 1-minute counts of the heart rate indicate that it varies five or more beats per minute with changes in position, with breath holding, or with sedation. In rare instances, individuals have persistent or episodic “inappropriate” sinus tachycardia that may be very symptomatic or may lead to LV contractile dysfunction. Pharmacologic agents, such as β -blockers and in some cases flecainide, or catheter-based radiofrequency modification of the sinus node have shown to have varying success in treating this problem.

► When to Refer

Patients with symptoms related to bradycardia or tachycardia when reversible etiologies have been excluded.

► When to Admit

Patients with bradycardia and recent or recurrent syncope.

ATRIAL PREMATURE BEATS (Atrial Extrasystoles)

ESSENTIALS OF DIAGNOSIS

- Usually asymptomatic.
- Isolated interruption in regular rhythm.
- Can be harbingers of future development of atrial fibrillation.
- P-wave morphology on ECG usually differs from sinus P-wave morphology.

Atrial premature beats occur when an ectopic focus in the atria fires before the next sinus node impulse or a reentry circuit is established. The contour of the P wave usually differs from the patient's normal complex, unless the ectopic focus is near the sinus node. Such premature beats occur frequently in normal hearts. Acceleration of the heart rate by any means usually abolishes most premature beats. Early atrial premature beats may cause aberrant QRS complexes (wide and bizarre) or may not be conducted to

the ventricles because the AV node or ventricles are still refractory.

Differentiation of Aberrantly Conducted Supraventricular Beats from Ventricular Beats

This distinction can be very difficult in patients with a wide QRS complex; it is important because of the differing prognostic and therapeutic implications of each type. Findings favoring a ventricular origin include (1) AV dissociation; (2) a QRS duration exceeding 0.14 second; (3) capture or fusion beats (infrequent); (4) left axis deviation with right bundle branch block morphology; (5) monophasic (R) or biphasic (qR, QR, or RS) complexes in V_1 ; and (6) a qR or QS complex in V_6 . Supraventricular origin is favored by (1) a triphasic QRS complex, especially with initial negativity in leads I and V_6 ; (2) ventricular rates exceeding 170 beats/min; (3) QRS duration longer than 0.12 second but not longer than 0.14 second; and (4) the presence of preexcitation syndrome.

The relationship of the P waves to the tachycardia complex is helpful. A 1:1 relationship usually means a supraventricular origin, except in the case of ventricular tachycardia with retrograde P waves.

PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA

ESSENTIALS OF DIAGNOSIS

- Frequently associated with palpitations.
- Abrupt onset/offset.
- Rapid, regular rhythm.
- Most commonly seen in young adults.
- Rarely causes syncope.
- Usually have a narrow QRS complex on ECG.
- Often responsive to vagal maneuvers, AV nodal blockers, or adenosine.

► General Considerations

This is a common paroxysmal tachycardia and often occurs in patients without structural heart disease. The most common mechanism for paroxysmal supraventricular tachycardia is reentry, which may be initiated or terminated by a fortuitously timed atrial or ventricular premature beat. The reentrant circuit most commonly involves dual pathways (a slow and a fast pathway) within the AV node. This is referred to as AV nodal reentrant tachycardia (AVNRT). Less commonly, reentry is due to an accessory pathway between the atria and ventricles, referred to as AV reentrant tachycardia (AVRT). Approximately one-third of patients with supraventricular tachycardia have accessory pathways to the ventricles. The pathophysiology and management of arrhythmias due to accessory pathways differ in important ways and are discussed separately below.

► Clinical Findings

A. Symptoms and Signs

Patients may be asymptomatic except for awareness of rapid heart action, but some experience mild chest pain or shortness of breath, especially when episodes are prolonged, even in the absence of associated cardiac abnormalities. Episodes begin and end abruptly and may last a few seconds to several hours or longer.

B. ECG

The heart rate may be 140–240 beats/min (usually 160–220 beats/min) and is regular (despite exercise or change in position). The P wave usually differs in contour from sinus beats and is often buried in the QRS complex.

► Treatment

In the absence of structural heart disease, serious effects are rare, and most episodes resolve spontaneously. Particular effort should be made to terminate the episode quickly if cardiac failure, syncope, or anginal pain develops or if there is underlying cardiac or (particularly) coronary disease. Because reentry is the most common mechanism for paroxysmal supraventricular tachycardia, effective therapy requires that conduction be interrupted at some point in the reentry circuit and the vast majority of these circuits involve the AV node.

A. Mechanical Measures

A variety of maneuvers have been used to interrupt episodes, and patients may learn to perform these themselves. These maneuvers result in an acute increase in vagal tone and include the Valsalva maneuver, stretching the arms and body, lowering the head between the knees, coughing, splashing cold water on the face, and breath holding. Carotid sinus massage is often performed by physicians but should be avoided if the patient has carotid bruits or a history of transient cerebral ischemic attacks. Firm but gentle pressure and massage are applied first over the right carotid sinus for 10–20 seconds and, if unsuccessful, then over the left carotid sinus. **Pressure should not be exerted on both sides at the same time!** Continuous ECG or auscultatory monitoring of the heart rate is essential so that pressure can be relieved as soon as the rhythm is broken or if excessive bradycardia occurs. Carotid sinus pressure will interrupt up to half of the attacks, especially if the patient has received a digitalis glycoside or other agent (such as adenosine or a calcium channel blocker) that delays AV conduction. These maneuvers stimulate a vagal outpouring, delay AV conduction, and block the reentry mechanism at the level of the AV node, terminating the arrhythmia.

B. Drug Therapy

If mechanical measures fail, two rapidly acting intravenous agents will terminate more than 90% of episodes. Intravenous **adenosine** has a very brief duration of action and minimal negative inotropic activity (Table 10–9).

Initially, a 6 mg bolus is administered. If no response is observed after 1–2 minutes, a 12 mg bolus should be given, followed by another 12 mg bolus if necessary. Because the half-life of adenosine is < 10 seconds, the drug must be given rapidly (in 1–2 seconds from a peripheral intravenous line); use half the dose if given through a central line. Adenosine causes block of electrical conduction through the AV node. Adenosine is very well tolerated, but nearly 20% of patients will experience transient flushing, and some patients experience severe chest discomfort. Caution must be taken when adenosine is given to elderly patients because the resulting pause can be prolonged. Adenosine must also be used with caution in patients with reactive airways disease because it can promote bronchospasm.

Calcium channel blockers also rapidly induce AV block and break many episodes of reentrant supraventricular tachycardia. These agents should be used with caution in patients with heart failure due to their negative inotropic effects. Intravenous **verapamil** may be given as a 2.5 mg bolus, followed by additional doses of 2.5–5 mg every 1–3 minutes up to a total of 20 mg if BP and rhythm are stable. If the rhythm recurs, further doses can be given. Oral verapamil, 80–120 mg every 4–6 hours, can be used as well in stable patients who are tolerating the rhythm without difficulty, but avoid it if there is any concern that the arrhythmia may be ventricular in origin. Intravenous **diltiazem** (0.25 mg/kg over 2 minutes, followed by a second bolus of 0.35 mg/kg if necessary and then an infusion of 5–15 mg/h) may cause less hypotension and myocardial depression.

Esmolol, a very short-acting β -blocker, may also be effective; the initial dose is 500 mcg/kg intravenously over 1 minute followed by an infusion of 25–200 mcg/min. **Metoprolol** is also effective and can be given in 5 mg boluses every 5 minutes and repeated up to two times. If the tachycardia is believed to be mediated by an accessory pathway, intravenous **procainamide** may terminate the tachycardia by prolonging refractoriness in the accessory pathway; however, because it facilitates AV conduction and an initial increase in rate may occur, it is usually not given until after a calcium channel blocker or a β -blocker has been administered. Although intravenous amiodarone is safe, it is usually not required and often ineffective for treatment of these arrhythmias.

C. Cardioversion

If the patient is hemodynamically unstable or if adenosine, β -blockers, and verapamil are contraindicated or ineffective, synchronized electrical cardioversion (beginning at 100 J) is almost universally successful. If digitalis toxicity is present or strongly suspected, as in the case of paroxysmal tachycardia with block, electrical cardioversion should be avoided.

► Prevention

A. Catheter Ablation

Because of concerns about the safety and the intolerability of antiarrhythmic medications, radiofrequency ablation is the preferred approach to patients with recurrent symptomatic reentrant supraventricular tachycardia, whether it is

due to dual pathways within the AV node or to accessory pathways.

B. Drugs

AV nodal blocking agents are the drugs of choice as first-line medical therapy (Table 10–9). β -Blockers or non-dihydropyridine calcium channel blockers, such as diltiazem and verapamil, are typically used first. Patients who do not respond to agents that increase refractoriness of the AV node may be treated with antiarrhythmics. The class Ic agents (flecainide, propafenone) can be used in patients without underlying structural heart disease. In patients with evidence of structural heart disease, class III agents, such as sotalol or amiodarone, are probably a better choice because of the lower incidence of ventricular proarrhythmia during long-term therapy.

SUPRAVENTRICULAR TACHYCARDIAS DUE TO ACCESSORY AV PATHWAYS (Preexcitation Syndromes)

ESSENTIALS OF DIAGNOSIS

- ▶ Frequently associated with palpitations.
- ▶ Can be associated with syncope.
- ▶ Rapid, regular rhythm.
- ▶ May have narrow or wide QRS complex on ECG.
- ▶ Often have preexcitation (delta wave) on baseline ECG.

▶ General Considerations

Accessory pathways or bypass tracts between the atrium and the ventricle bypass the compact AV node and can predispose to reentrant arrhythmias, such as AVRT and atrial fibrillation. These may be wholly or partly within the node (eg, Mahaim fibers), yielding a short PR interval and normal QRS morphology. More commonly, they make direct connections between the atrium and ventricle through Kent bundles (**Wolff-Parkinson-White syndrome**). This often produces a short PR interval with a delta wave (preexcitation) at the onset of the wide, slurred QRS complex owing to early ventricular depolarization of the region adjacent to the pathway. Although the morphology and polarity of the delta wave can suggest the location of the pathway, mapping by intracardiac recordings is required for precise anatomic localization.

Accessory pathways occur in 0.1–0.3% of the population and facilitate reentrant arrhythmias owing to the disparity in refractory periods of the AV node and accessory pathway. Whether the tachycardia is associated with a narrow or wide QRS complex is frequently determined by whether antegrade conduction is through the node (narrow) or the bypass tract (wide). Some bypass tracts only conduct in a retrograde direction. In these cases, the bypass tract is termed “concealed.” Orthodromic reentrant tachycardia is a reentrant rhythm that conducts antegrade down the AV node and retrograde up the accessory pathway, resulting in a narrow QRS complex unless an underlying bundle branch block or interventricular conduction delay is present. Antidromic reentrant tachycardia conducts antegrade down the accessory pathway and retrograde through the AV node, resulting in a wide QRS complex. Accessory pathways are often less refractory than specialized conduction tissue and thus tachycardias involving accessory pathways have the potential to be more rapid. Up to 30% of patients with Wolff-Parkinson-White syndrome will develop atrial fibrillation or flutter with antegrade conduction down the accessory pathway and a rapid ventricular response. If this conduction is very rapid, it can potentially degenerate to ventricular fibrillation.

▶ Treatment

Some patients have a delta wave found incidentally on ECG. In the absence of palpitations, light-headedness, or syncope, these patients do not require specific therapy. They should be advised to report the onset of any of these symptoms. Occasionally, these patients are referred for exercise treadmill testing to determine if preexcitation is lost at rapid rates. Patients found incidentally to have delta waves who have jobs that could potentially put others at risk (ie, pilot, bus driver, etc) may need to undergo electrophysiologic testing with possible catheter ablation to ensure that they are not at an increased risk for syncope or sudden death.

A. Catheter Ablation

As with AVNRT, radiofrequency ablation has become the procedure of choice in patients with accessory pathways and

recurrent symptoms. Patients with preexcitation syndromes who have episodes of atrial fibrillation or flutter should be tested by induction of atrial fibrillation in the electrophysiology laboratory, noting duration of the RR cycle length; if it is < 220 ms, a short refractory period is present. These individuals are at highest risk for sudden death, and prophylactic ablation is indicated. Success rates for ablation of accessory pathways with radiofrequency catheters exceed 90% in appropriate patients.

B. Pharmacologic Therapy

Narrow-complex reentrant rhythms involving a bypass tract can be managed as discussed for AVNRT. Atrial fibrillation and flutter with a concomitant antegrade conducting bypass tract must be managed differently, since agents such as digoxin, calcium channel blockers, and even β -blockers may decrease the refractoriness of the accessory pathway or increase that of the AV node, often leading to faster ventricular rates. Therefore, these agents should be avoided. The class Ia, class Ic, and class III antiarrhythmic agents will increase the refractoriness of the bypass tract and are the drugs of choice for wide-complex tachycardias involving accessory pathways. If hemodynamic compromise is present, electrical cardioversion is warranted.

Long-term therapy often involves a combination of agents that increase refractoriness in the bypass tract (class Ia or Ic agents) and in the AV node (verapamil and β -blockers), provided that atrial fibrillation or flutter with short RR cycle lengths is not present (see above). The class III agent, amiodarone, can be effective in refractory cases. Patients who are difficult to manage should undergo electrophysiological evaluation.

▶ When to Refer

- Patients with an incidental finding of preexcitation and a high-risk job.
- Patients with recurrent symptoms or episodes despite treatment with AV nodal blocking agents.
- Patients with preexcitation and a history of atrial fibrillation.

▶ When to Admit

- Patients with paroxysmal supraventricular tachycardia and syncope.
- Patients with a history of syncope and preexcitation identified on an ECG.

ATRIAL FIBRILLATION

ESSENTIALS OF DIAGNOSIS

- ▶ Irregularly irregular heart rhythm.
- ▶ Usually tachycardic.
- ▶ Often associated with palpitations (acute onset) or fatigue (chronic).
- ▶ ECG shows erratic atrial activity with irregular ventricular response.
- ▶ High incidence and prevalence in the elderly population.

▶ General Considerations

Atrial fibrillation is the most common chronic arrhythmia, with an incidence and prevalence that rise with age, so that it affects approximately 9% of individuals over age 80 years. It occurs in rheumatic and other forms of valvular heart disease, dilated cardiomyopathy, ASD, hypertension, and coronary heart disease as well as in patients with no apparent cardiac disease; it may be the initial presenting sign in thyrotoxicosis, and this condition should be excluded with the initial episode. The heart rate may range from quite slow to extremely rapid, but is uniformly irregular unless underlying complete heart block and a permanent ventricular pacemaker is in place. The surface ECG typically demonstrates erratic, disorganized atrial activity between discrete QRS complexes occurring in an irregular pattern. The atrial activity may be very fine and difficult to detect on the ECG, or quite coarse and often mistaken for atrial flutter. Atrial fibrillation often appears in a paroxysmal fashion before becoming the established rhythm. Pericarditis, chest trauma, thoracic or cardiac surgery, thyroid disorders, obstructive sleep apnea, or pulmonary disease (as well as medications such as theophylline and β -adrenergic agonists) may cause attacks in patients with normal hearts. Acute alcohol excess and alcohol withdrawal—and, in predisposed individuals, even consumption of small amounts of alcohol—may precipitate atrial fibrillation. This latter presentation, which is often termed “holiday heart,” is usually transient and self-limited. Short-term rate control usually suffices as treatment. Perhaps the most serious consequence of atrial fibrillation is the propensity for thrombus formation due to stasis in the atria (particularly the left atrial appendage) and

Table 10–10. CHADS₂ Risk Score for assessing risk of stroke and for selecting antithrombotic therapy for patients with atrial fibrillation.

	Condition	Points
C	Congestive heart failure	1
H	Hypertension (current or treated)	1
A	Age ≥ 75 years	1
D	Diabetes mellitus	1
S ₂	Stroke or transient ischemic attack	2
CHADS ₂ Score	Adjusted Stroke Rate, %/year (95% Confidence Interval)	Patients ¹ (n = 1733)
0	1.9 (1.2 to 3.0)	120
1	2.8 (2.0 to 3.8)	463
2	4.0 (3.1 to 5.1)	523
3	5.9 (4.6 to 7.3)	337
4	8.5 (6.3 to 11)	220
5	12.5 (8.2 to 17.5)	65

¹Validation performed in a population of Medicare beneficiaries age 65 to 95 years who were not prescribed warfarin at hospital discharge.

consequent embolization, most devastatingly to the cerebral circulation. Overall, the rate of stroke is approximately 5 events per 100 patient-years of follow-up. However, patients with significant obstructive valvular disease, chronic heart failure or LV dysfunction, diabetes mellitus, hypertension, or age over 75 years and those with a history of prior stroke or other embolic events are at substantially higher risk (up to nearly 20 events per 100 patient-years in patients with multiple risk factors) (Table 10–10).

► Clinical Findings

A. Symptoms and Signs

Atrial fibrillation itself is rarely life-threatening; however, it can have serious consequences if the ventricular rate is sufficiently rapid to precipitate hypotension, myocardial ischemia, or tachycardia-induced myocardial dysfunction. Moreover, particularly in patients with risk factors, atrial fibrillation is a major preventable cause of stroke. Although many patients—particularly older or inactive individuals—have relatively few symptoms if the rate is controlled, some patients are aware of the irregular rhythm and may find it very uncomfortable. Most patients will complain of fatigue whether they experience other symptoms or not. The heart rate may range from quite slow to extremely rapid, but is uniformly irregular unless underlying complete heart block and a permanent ventricular pacemaker is in place. Atrial fibrillation is the only common arrhythmia in which the ventricular rate is rapid and the rhythm very irregular.

Because of the varying stroke volumes resulting from varying periods of diastolic filling, not all ventricular beats produce a palpable peripheral pulse. The difference between the apical rate and the pulse rate is the “pulse deficit”; this deficit is greater when the ventricular rate is high.

B. ECG

The surface ECG typically demonstrates erratic, disorganized atrial activity between discrete QRS complexes occurring in an irregular pattern. The atrial activity may be very fine and difficult to detect on the ECG, or quite coarse and often mistaken for atrial flutter.

► Treatment

A. Newly Diagnosed Atrial Fibrillation

1. Initial management

A. HEMODYNAMICALLY STABLE PATIENT—If, as is often the case—particularly in older individuals—the patient has no symptoms, hemodynamic instability, or evidence of important precipitating conditions (such as silent myocardial infarction or ischemia, decompensated heart failure, pulmonary embolism, or hemodynamically significant valvular disease), hospitalization is usually not necessary. In most of these cases, atrial fibrillation is an unrecognized chronic or paroxysmal condition and should be managed accordingly (see below). For new onset atrial fibrillation, thyroid function tests and assessment for occult valvular or myocardial disease should be performed.

B. HEMODYNAMICALLY UNSTABLE PATIENT—If the patient is hemodynamically unstable—usually as a result of a rapid ventricular rate or associated cardiac or noncardiac conditions—hospitalization and immediate treatment of atrial fibrillation are required. Urgent cardioversion is usually indicated in patients with shock or severe hypotension, pulmonary edema, or ongoing myocardial infarction or ischemia. There is a potential risk of thromboembolism in patients undergoing cardioversion who have not received anticoagulation therapy if atrial fibrillation has been present for > 48 hours; however, in hemodynamically unstable patients the need for immediate rate control outweighs that risk. Electrical cardioversion is usually preferred in unstable patients. An initial shock with 100–200 J is administered in synchrony with the R wave. If sinus rhythm is not restored, an additional attempt with 360 J is indicated. If this fails, cardioversion may be successful after loading with intravenous **ibutilide** (1 mg over 10 minutes, repeated in 10 minutes if necessary).

In more stable patients or those at particularly high risk for embolism (ie, underlying mitral stenosis, a history of prior embolism, or severe heart failure), a strategy of rate control and anticoagulation is appropriate. This is also true when the conditions that precipitated atrial fibrillation are likely to persist (such as following cardiac or noncardiac surgery, with respiratory failure, or with pericarditis). Rate control and anticoagulation is also appropriate even when the conditions causing the atrial fibrillation might resolve spontaneously over a period of hours to days (such as alcohol-induced atrial fibrillation, electrolyte or fluid
